APPLIED CHEMISTRY.

L

L-ACID. 1-Naphthol-5-sulphonic acid.

LABDANUM or **LADANUM** *v.* OLEO-RESINS.

LABEL VARNISH *v.* VARNISH.

LABRADORITE *v.* FELSPAR.

LACCASE *v. Japanese Lacquer*, art. RESINS.

LAC DYE. Lac dye is produced by an insect, the *Coccus lacca* or *ficus*, living on the twigs of various kinds of trees, particularly the *Ficus religiosa* (Linn.), the *Zizyphus jujuba* (Lam.), and the *Butea frondosa* (Roxb.). These insects appear usually in November, and subsequently fasten themselves to the fleshy portions of the young branches. Gradually the abdomen of the insects becomes covered by a viscous fluid, which slowly forms a cellule surrounding the animal. The substance composing this cellule is the *stick lac*. The cellule attains its full size in March, and the insect then exhibits the appearance of a red oval-shaped, smoothly polished lifeless sac entirely filled with a beautiful red liquid; its size is then the same as that of the fully grown cochineal (Crookes, Dyeing and Calico Printing, 354). Commercial stick lac is chiefly gathered on the hilly banks of the Ganges in India, that for dyeing purposes possessing a deep red colour, whereas the pale perforated kind in which no insects exist is employed for varnish-making, and constitutes the material for *shellac*.

Of *lac*, the following varieties occur: *stick lac*, the crude product together with the twigs upon which it is formed; *grained lac*, the material removed from the twigs; and *caked lac*, the latter variety fused and cast into moulds.

Such a resinous material is not suitable for dyeing purposes, and a simple process is adopted to remove the colouring matter from the resin, or at least to obtain it in a more concentrated form. This consists in extracting the stick lac with hot dilute sodium carbonate solution, evaporating the extract, and moulding the residue into square cakes. According to Crookes the product, which is *lac dye*, contains on an average about 50 p.c. of colouring matter, 25 p.c. of resin, and 22 p.c. of earthy impurities.

Lac dye is an extremely ancient dyestuff, and was employed in the East for many centuries before it was known in Europe. It appears to have been introduced into this country about 1790. Early in the last century, lac dye was a very important article of commerce, so much so that at one time shellac was practically a bye-product of its manufacture. The position of these products has now been reversed, for whereas the dyestuff is almost no longer used, the shellac industry is of considerable importance.

According to the older writers, the colouring matter of lac dye was considered to be identical with that of cochineal, but that this is not the case has been clearly established by Schmidt (Ber. 20, 1285).

Laccaic acid.—Finely powdered lac dye, after treatment with dilute hydrochloric acid to remove mineral matter, is extracted with boiling water, and the colouring matter is precipitated from the resulting solution by means of lead acetate. The lead precipitate, suspended in water, is decomposed with sulphuretted hydrogen, and the filtrate which contains the free colouring matter is evaporated to dryness. The residue thus obtained is extracted with alcohol and ether and is then added to the solution until a precipitate no longer forms. The filtered liquid on gradual evaporation deposits crystals of laccaic acid. According to Schmidt, the amount of pure colouring matter which can be isolated by this method from a kilogram of lac dye is 20 grams.

A simpler process has been described by Dimroth and Goldschmidt (Annalen, 1913, 399, 62), in which the stick lac is digested in water at 50°, the clear red solution, after cooling, acidified with acetic acid, separated from the resinous matter that is precipitated, and, after evaporation to small bulk, acidified with hydrochloric acid. When the crude product thus obtained is crystallised from hot 85 p.c. formic

acid, washed, dried (at 60°–70°C.), and recrystallised from hot dilute hydrochloric acid, laccaic acid separates in the form of dark red microscopic rhombohedra. The acid is soluble in water yielding blood-red solutions, but is insoluble in ether; when heated it decomposes at about 180°, yielding a small quantity of a red sublimate. Only the sodium hydrogen salt has been prepared in crystalline condition, and to this Dimroth ascribes the formula

$$C_{20}H_{12}O_{10}Na_2.C_{20}H_{13}O_{10}Na$$

whilst he concludes that the acid has the composition $C_{20}H_{14}O_{10}$, and not $C_{16}H_{12}O_8$, as previously supposed.

Although no distinction is to be observed in the absorption spectra of the aqueous and alkaline solutions of laccaic and carminic acids, it is possible when the colouring matters are dissolved in sulphuric acid to discriminate between them in this way. When fused with potassium hydroxide, laccaic acid gives, in addition to a substance (*a*) volatile in steam, colourless needles, m.p. 142°–143°; a compound (*b*) $C_{10}H_6O_6$, or $C_{10}H_8O_6$, m.p. 285°, readily soluble in water; a compound (*c*) $C_8H_8O_3$, m.p. 169°, possibly a hydroxytoluic acid; and (*d*) an easily soluble substance, the aqueous solution of which gives a black coloration with ferric chloride (Schmidt).

Reduction of laccaic acid with tin and hydrochloric acid, or with zinc-dust and aqueous ammonia, yields a compound $C_{20}H_{16}O_9$, which crystallises in brown-yellow rhombohedra, and which on oxidation by means of cupric chloride and hydrochloric acid, yields a substance of the composition $C_{20}H_{14}O_9$, which Dimroth considers is related to the former substance as quinone to hydroquinone.

Although laccaic acid does not yield crystalline bromination products similar to α- and β-bromocarmine, compounds of this nature have been obtained by Dimroth from its oxidation product, calaic acid.

Calaic acid is produced when laccaic acid is oxidised by means of hydrogen peroxide (2½–3 molecular proportions) in the presence of a catalyst (cobalt, manganous, cerous, or ferrous salts; manganous chloride is best). This acid, $C_{18}H_{14}O_{11}$, crystallises from ether in small yellow prisms, and from water in needles having the composition $C_{18}H_{14}O_{11}$, $2\frac{1}{2}H_2O$. It does not possess dyeing properties, contains one carbonyl and three carboxyl groups, and may be purified by means of its crystalline barium salt. A silver salt, $C_{18}H_{12}O_{11}Ag_2$, has also been prepared.

When calaic acid is brominated in glacial acetic acid, two products are formed: (i) an α-ketonic acid $C_{12}H_{10}O_6Br_2$, and (ii) β-bromolaccain $C_{12}H_5O_8Br$, these products being separated by taking advantage of the solubility of the latter in cold acetone.

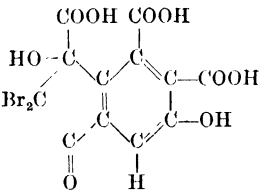
The α-ketonic acid forms brown-yellow crystals, m.p. 208°–209°; it gives an impure red-violet colour reaction with ferric chloride, and when heated to 80°–90° with concentrated sulphuric acid, it loses carbon monoxide, yielding a monobasic acid $C_{11}H_{10}O_5Br_2$, which has m.p. 245°–246° (decomposition), and gives an intense violet colour reaction with ferric chloride. The keto-acid forms a phenylhydrazone and semicarbazone, and, by treatment with methyl alcoholic hydrobromic acid, yields the hydrobromic acid compound of its methyl ester $C_{13}H_{12}O_6Br_2.HBr$, colourless needles, m.p. 133°–134° (decomposition).

β-Bromolaccain separates from water in crystals of the composition

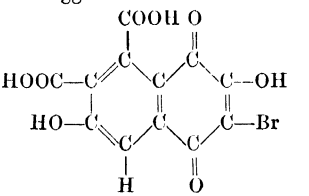
$$C_{12}H_5O_8Br,\ 2H_2O$$

it has m.p. 234°–235° (decomposition). It dyes wool orange from an acid bath, and gives a strong red colour with ferric chloride. The potassium salt $C_{12}HO_8BrK_4$, H_2O, crystallises in hexagonal plates. Concentrated sulphuric acid and acetic anhydride produce *diacetyl-β-bromolaccain anhydride* $C_{16}H_7O_9Br$, indicating that two hydroxy groups are present in the molecule, and that it also contains two carboxyl groups in the ortho position.

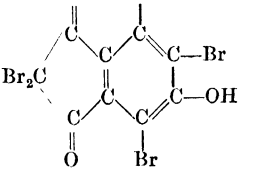
Oxidation of β-bromolaccain by means of hydrogen peroxide in warm glacial acetic acid yields two products, viz. (i) *hydroxy-tricarboxyphenyl-glyoxylic acid*, and (ii) a compound $C_{12}H_6O_9Br_2$. The former, which is the chief product, crystallises in plates, m.p. 229·5°–230° (decomposition), and on treatment with concentrated sulphuric acid at 130°–140° yields a phenol-tetracarboxylic acid which melts at 212°–214° (decomposition). The second oxidation product of β-bromolaccain has m.p. 188°–190° (decomposition), and readily loses bromine; for it Dimroth tentatively proposes the formula—



For β-bromolaccain itself Dimroth and Goldschmidt suggest the structure—



and for this they find support in the fact that it resembles 2 : 6-dihydroxy-α-naphthoquinone in its colour reactions. Moreover, it behaves very similarly to β-bromocarmine in that it yields an indone derivative, *α-bromolaccain* (*cf.* α-bromocarmine), when its boiling solution in water is treated with bromine :—



This compound crystallises in colourless needles, and yields 2 : 6-dibromophenol-3 : 4 : 5-tricarboxylic acid, m.p. 257°–258°, and bromoform when treated with sodium hypobromite.

Dyeing properties.—The dyeing properties of lac dye are practically identical with those of cochineal, but the shades obtained are somewhat faster. Owing to the resinous and mineral impurities accompanying the colouring matter, it is not readily soluble in water, and before use it is therefore ground to a paste with the requisite quantity of tin spirit together with a little hydrochloric acid, and allowed to stand overnight. Cochineal and lac dye can be used together with advantage, or after the wool is dyed with lac it may be entered into a fresh bath with cochineal. Its employment at the present time is, however, extremely limited.

Fowler (Indian Textile Jour. 1917, 244) has made attempts to standardise various Indian colouring matters so that they may be marketed in uniform strengths. It would appear that 'Lac dye' is one of those with which he has been concerned. A. G. P.

LACMOID $C_{12}H_9NO_4$ (?)

Preparation.—(1) A mixture of resorcinol (20 parts), sodium nitrite (1 part), and water (1 part) is slowly heated to 110°, when a vigorous reaction sets in; the mass is then kept at 115°–120° until it has become quite blue and no more ammonia is evolved. The product is dissolved in water and the lacmoid precipitated with hydrochloric acid (Traub and Hock, Ber. 1884, 17, 2615). (2) By fusing resorcinol (5 parts) with potassium nitrite (6 parts) (Benedict and Julius, Monatsh. 1884, 5, 534). (3) By the action of H_2O_2 on ammoniacal resorcinol solution (Wurster, Ber. 1887, 20, 2938).

To purify the substance, extract it almost completely with boiling water, cool, filter, and acidify the blue solution with hydrochloric acid. Filter off the precipitated lacmoid, wash with cold water and dry it below 100°. An alternative method is to warm gently powdered lacmoid (8 parts) with 20 p.c. alcohol (100 parts) for 15 minutes, cool and filter (Foerster, Zeitsch. angew. Chem. 1890, 3, 163).

Properties.—A glistening brown powder, easily soluble in methyl, ethyl, or amyl alcohol, acetone, acetic acid, or phenol, less easily in ether or water, insoluble in benzene or petroleum spirit. It dissolves in concentrated HCl or H_2SO_4, yielding a blue solution. Heated below 200° it decomposes.

Lacmoid differs from the colouring matter of litmus in being soluble in strong alcohol. Its absorption spectrum resembles that of azolitmin (Hartley, Proc. Roy. Dublin Soc. 5, 159).

For the use of lacmoid as an indicator, *v.* Thomson (Chem. News, 1885, 52, 18, 29) and ACIDIMETRY AND ALKALIMETRY.

LACQUER (*Urushi*, *Ki-urushi*). A varnish usually obtained from the juice of *Rhus vernicifera* (DC.), a tree indigenous to China, whence in early times it was introduced into Japan (Bull. Imp. Inst. 1910, 8, 32; J. Soc. Chem. Ind. 1910, 639).

Burmese lacquer, or 'thitsi,' is obtained from the stems of *Melanorrhoea usitata* (Wall) as a grey viscous liquid of sp.gr. 1·0016 at 20°, which, on exposure to air, becomes first brown, and then, very rapidly, deep black. The drying of the lacquer is not accelerated by siccatives, and is retarded by dry heat, the presence of moisture being essential. The constituent of the lacquer soluble in alcohol is not identical with the urushinic acid (urushiol) of Japan lacquer. It is known as *thitsiol* $C_{23}H_{36}O_2$, and is a homologue of *iso*hydrourushiol. The ether extract consists of a gummy substance soluble in water, and a nitrogenous, coagulable substance which acts as an oxygen carrier in the drying of the lacquer, but loses its activity when heated above 60° (Rosenthal, Farbenzeit., 1914, 19, 1573; Majima, Ber. 1922, 55, 191).

Chinese lacquer. The tree is abundant in Central China, growing wild or under cultivation at altitudes of 3000 to 7500 feet. It is tapped in June or early July; shallow incisions are made in the bark of the stem and the greyish-white, milky juice collected in shells, bamboos, &c., and covered with oiled paper to prevent oxidation. The tapping is repeated seven times at intervals of 7 days, and the tree is then left for 5–7 years to recover. Much of the varnish is sent to Japan. The lacquer is frequently adulterated with tung oil.

Japanese lacquer. The lacquer tree grows abundantly all over Japan, and is cultivated largely in the district north of Tokyo. Tapping takes place when the tree is 10 years old and is continued from June to October, each tree yielding from 27 to 54 grams of lacquer. Usually the tree is left to recover, but sometimes it is cut down. In the latter case, a further yield of lacquer is obtained from the branches by steeping them in water for 10–20 days, and then making incisions and heating the water to cause the sap to exude. The varnish thus obtained, called *seshine-urushi*, is harder and of poorer quality, and is used only for groundwork and for cheap articles. The best quality is obtained from between the inner and outer bark of trees from 14 to 15 years old. It is called *ki-urushi* (Pudor, Zeitsch. öffentl. Chem. 1910, 16, 315). A very inferior quality, known as *Moku-yshi*, is used mixed with the better kinds in varying proportions. Both Chinese and Japanese lacquer contain urushiol (*q.v.*).

Yunan lacquer is derived from *R. succedanea* (L. fils), Formosan lacquer from *Semeocarpus vernicifera*, and ivy lacquer from *R. toxicodendron*. These contain *laccol* $C_{23}H_{36}O_2$, a homologue of urushiol. Siam lacquer is probably a mixture of Yunan and Burmese lacquers. Korean lacquer is probably identical with Japanese lacquer (Riko Majima, J. Tokyo Chem. Soc. 1919, 40, 91).

The raw varnish is packed in wooden tubs and covered with oiled paper to prevent oxidation. It is prepared for use by various processes, the quality and value of the varnish and of the lacquered ware produced depending upon the time and care spent upon the purification.

The juice is strained from particles of bark, &c., and is allowed to stand in wooden vessels until it separates into various layers, when the lighter and finer qualities are decanted from the heavier and inferior varnish. The product is finally filtered through hempen or cotton cloth and exposed in shallow wooden pans to the heat of the sun or to artificial warmth. It thus becomes syrupy and of a dark brown colour, the change being due principally to loss of water. It is thinned with camphor or oil of turpentine or other suitable solvent.

Coloured lacquers are prepared from *ki-urushi* during the exposure to the sun (*v.s.*) by

mixing in appropriate pigments, those most commonly employed being as follows (Miyama, J. Coll. Engineering, Imp. Univ. Tokyo, 1908, 4, 201; J. Soc. Chem. Ind. 1909, 318):—

White.—Barium sulphate; bismuth oxychloride.

Red.—Cinnabar; rouge.

Blue.—Prussian blue; ultramarine.

Yellow.—Cadmium sulphide; lead chromate; orpiment.

Green.—Chromic oxide (or by the addition of indigo from *Polygonum tinctorum* (Ait.) to the yellow lacquer).

Black.—Lampblack; iron powder or compounds of iron.

Brown.—Mixture of red and black.

The so-called 'pear-ground' lacquer, used with gold-dust, is prepared with gamboge.

Use of the lacquer.—The prepared surface of the article to be lacquered first receives several coats of the poorer quality mixed with a special clay called *ching-chu*, or in some cases with an inferior clay or with pottery dust. After each coat, the article is kept for several days in a moist atmosphere until the lacquer has set, and it is then rubbed down with pumice to a dull, smooth surface before another coat is given. The final coat is of the better quality lacquer, and the article may be further decorated with a pattern in coloured lacquer. Any joint in the wood is scraped down below the general level of the surface and then filled up with alternate layers of silk and lacquer.

Lacquering is applied to small articles, *e.g.* card-cases, vases, images, &c., either for ornamental purposes or for practical use. Hollow articles of lacquer are made by building up a layer of lacquer and silk on a clay model which is afterwards washed out with water through a hole left for that purpose. (For full details of the manufacture of lacquered ware, *see* Nightingale, J. Indust. and Engineering Chem. 1911, 3, 59; also Workshop Receipts, 3rd series, 306.)

The drying of lacquer at ordinary temperatures is caused by an enzyme (an oxydase) called *laccase*, contained in the sap (Tschirch and Stevens, Arch. Pharm. 1905, 243, 504; J. Soc. Chem. Ind. 1906, 81). During the drying it absorbs 5·75 p.c. of oxygen.

It may also be dried by heat, this process being specially applicable to lacquered articles of glass, porcelain, and papier-mache (Miyama, J. Soc. Chem. Ind. 1909, 318). At 100° it dries in 4–5 hours, at 150° in 30 minutes, and at 180° in 10 minutes. The drying by heat is attended by absorption of oxygen and some decomposition, giving a dark-coloured coating which is harder and more durable than the cold-dried lacquer. Coloured lacquers cannot usually be dried by heat because of the darkening of the lacquer. For a similar reason it is not the practice to use 'driers' in lacquers.

Composition of lacquer.—The main constituent of most lacquers to which their peculiar properties are due, is an unsaturated polyhydric phenol, *urushiol*, having the formula $C_{20}H_{30}O_2$ (Majima, Ber. 1909, 42, 3664; 1912, 45, 2727).

Miyama gives the following analyses of typical specimens of the juice (J. Coll. Eng. Tokyo, 1908, 4, 89; J. Soc. Chem. Ind. 1908, 456):—

	Japanese	Chinese	Indian
Moisture	17·81–26·72 p.c.	—	—
Urushiol	64·14–77·63 „	36·88 p.c.	26·39 p.c
Gum	2·62–7·57 „	23·5 „	37·78 „
Nitrogenous matter	1·78–2·47 „	—	—

Sun-dried Japanese lacquer contains 94·5 p.c. urushiol.

Urushiol forms a compound with barium hydroxide and is estimated by titrating with a solution of that base, using phenolphthalein as indicator.

Urushiol may be obtained from lacquer by repeated extraction with alcohol, and is purified by treatment with petroleum spirit. It is a light brown, viscous fluid, sp.gr. 0·9687 at 21·5°/4°, and is readily soluble in most organic solvents. It forms a dimethyl ether and an easily hydrolysable acetyl derivative. On dry distillation it yields various hydrocarbons and polyhydric phenols, but no simple alicyclic hydrocarbon or ordinary terpene (Majima and Cho, Ber. 1907, 40, 4390; Majima, *ibid.* 1909, 42, 1418, 3664; 1912, 45, 2727; Majima and Nakamura, *ibid.* 1913, 46, 4080; *ibid.* 1915, 48, 1597; Majima and Tahara, *ibid.* 1915, 48, 1606). Tschirch and Stevens (*l.c.*) found in the lac an irritant poison, named by them *verniciferol.* This substance may be identical with the compound $C_{15}H_{27}\cdot C_6H_3(OH)_2$ found in lacquer, which, according to Toyama and Kayaba (Chem. Soc. Abst. 1918, 114, ii, 143), is poisonous. Lacquer also contains a hydrated and a methylated urushiol which are toxic, and a dimethylated and a hydro-dimethylated urushiol which are non-toxic.

Lacquer poisoning may be produced in susceptible individuals by passing near a lacquer tree or through a store containing lacquered articles.

LAC RESIN *v.* RESINS.

LACTANIN *v.* SYNTHETIC DRUGS.

LACTARIC ACID $C_{14}H_{29}COOH$ is obtained by extracting the fungus *Agaricus integer* with alcohol (Chuit, Bull. Soc. chim. [iii.] 2, 153); m.p. 69·5°–70°.

LACTASE is the enzyme decomposing lactose (milk sugar) to dextrose and galactose. The distribution in animals is limited, being confined entirely to the intestine and generally of young animals only. Lactase has not been found in the mammary gland or milk of animals; this fact is regarded as opposed to the theory that it plays any part in the synthesis of lactose in these tissues (Bradley, J. Biol. Chem. 1913, 13, 431). Plimmer (J. physiol. 1906, 35, 20) found lactase in the cat and the pig during the whole of their lives, but only in the young guinea pig. The gastro-intestinal sac of snails contains a lactase (Bierry, Compt. rend. 1909, 148, 949). It is present in a few torula (*S. fragilis, S. kayser, S. adametz,* &c.) and in kephir. Lactose is also hydrolysed by the emulsin derived from almonds, which accordingly contains a lactase. There is apparently a difference between kephir and almond lactase, since the hydrolytic activity of the former is restricted mainly by galactose, that of the latter mainly by glucose (Armstrong, Proc. Roy. Soc. 1908, B, 80, 321). According to Stephenson (Bio-Chem. J. 1912, 6, 250), the lactase in the intestines of animals is inhibited only by glucose,

and is therefore similar to almond lactase. Lactase also hydrolyses β-methylgalactoside and melibiose. The optimum activity is about 37°. Lactase is precipitated by alcohol, and behaves very similarly to emulsin; its rate of action is governed by the same laws. It has not been fully investigated. E. F. A.

LACTIC ACID or **α-HYDROXYPROPIONIC ACID** (Ger. *Milchsäure*), $CH_3CH(OH)COOH$, was first obtained by Scheele in 1780 from sour milk. Its exact constitution was, however, first ascertained by Liebig and Mitscherlich (Annalen, 7, 47) and by Gay-Lussac and Pelouze (*ibid.* 7, 40). It is widely distributed in nature, occurring in the lesser centaury (*Erythræa Centaurium* [Pers.]) (Habermann, Chem. Zeit. 30, 40); in the sap of the vine; and in most fermented liquids of vegetable origin, especially in sour milk; it is not, however, present in fresh milk. It is found in beet molasses, and owes its origin to the boiling of the sucrose solution with lime in the process of defecation (Schöne and Tollens, J. Soc. Chem. Ind. 1901, 54; Weisberg, *ibid.* 375; Beythien, Parcus and Tollens, Annalen, 255, 228). It has also been found in small quantities in saliva; in the brain and under certain conditions in the gastric juice; in the blood and in urine. The acid obtained by Braconnot, and termed *nancéic acid*, as well as the *thebolactic* acid obtained from opium, have been proved to be identical with common lactic acid. On the other hand, the acid obtained by Berzelius from flesh, and further investigated by Liebig, differs from the ordinary lactic acid in certain of its properties, and is therefore distinguished as *paralactic acid*. This will be described later on.

Lactic acid is formed in the fermentation of various sugars, of mannitol, and of dextrin (*v.* FERMENTATION), and also by the action of caustic alkalis on the sugars. It has also been obtained synthetically in a number of ways, the three most important of which are the following:—

(1) Aldehyde unites with hydrogen cyanide, forming the nitrile

$$CH_3{\cdot}CHO + HCN = CH_3{\cdot}CH(OH)CN$$

and this on treatment with acids is converted into lactic acid (Wislicenus, Annalen, 128, 13, 22).

(2) By the action of alkalis on α-chloropropionic acid (Friedel and Machuca, Annalen, 120, 285)

$$CH_3{\cdot}CHCl{\cdot}COOH + 2KOH = CH_3{\cdot}CH(OH)COOH + KCl + H_2O$$

(3) By the reduction of pyruvic acid with sodium amalgam, hydriodic acid (Wislicenus, Annalen, 126, 227), zinc (Debus, *ibid.* 127, 332), or electrolytically (Tafel and Friedrichs, Ber. 1904, 3187)

$$CH_3{\cdot}CO{\cdot}COOH + H_2 = CH_3{\cdot}CH(OH)COOH$$

These syntheses clearly show that the acid is α-hydroxypropionic acid.

In order to distinguish lactic acid from the allied acids it is frequently called *ethylidene-lactic* or *fermentation lactic acid.*

Preparation.—Lactic acid is usually prepared by the fermentation of sugar. McLauchan (J. Soc. Chem. Ind. 1909, 734) recommends the following method: 400 grams of commercial glucose are dissolved in 1200 c.c. of hot water, and to this is added 170 grams of whitening or well-powdered calcium carbonate and 20 grams of malt, previously boiled for a few minutes with 100 c.c. of water. The solution is kept simmering for 30 minutes, then cooled to 60°–70°, and after stirring is poured into a narrow-necked bottle, of 2½ litres capacity. The calcium carbonate is rinsed out with water and the solution made up to 1800 c.c. The bottle is placed in an air-bath at 45°, a small quantity of sour milk or casein added to start fermentation, and a wad of cotton used to stopper the bottle. The bottle is shaken every few hours for 6 days and when the unfermented sugar is less than 0·4 p.c. the solution is filtered. The final filtrate after concentration should be one litre of 25 p.c. acid. Kassner (Chem. Zentr. 1897, ii. 20) dissolves 300 grams of cane sugar and 15 grams of tartaric acid in 1700 grams of boiling water and allows the solution to stand for several days, the temperature being maintained at 60°; 100 grams of old cheese and a little more than the calculated quantity of finely powdered chalk are then added and fermentation is allowed to proceed with daily stirring for about 3 weeks. Brensch (Annalen, 61, 177) proceeds in a similar manner, but during fermentation keeps the temperature at 30°–35°. Lautemann (*ibid.* 113, 142) replaces the chalk in the original mixture by 2 kilos. zinc white. After about 10 days a magma of zinc lactate together with some mannitol is formed, which may be recrystallised from water. The purified salt obtained by any of these methods is dissolved in boiling water, and precipitated with H_2S, the filtrate evaporated to a syrup, cooled, and separated from mannitol and any undecomposed salt by extraction with ether. The syrup which remains after evaporation of the ether is then warmed on the water-bath.

A large number of micro-organisms are capable of causing lactic fermentation of sugar; these are classified according to their morphological properties, their growth on media, and chiefly their fermentative power (*cf.* Lore and Brooke, U.S. Dept. Agric. Bull, 154, 1). *Bac. acidi lacti*, types i. and ii., and *Bac. lactis ærogenes* are those most commonly occurring, and of these the first named is by far the most plentiful. The solution must be kept neutral, and access of air must be allowed, as well as the necessary nitrogenous food. Its form in a highly nitrogenous saccharine solution, is a double truncated cone, and it has the tendency of all lactic bacteria to link itself together in pairs or short chains (Claflin, J. Soc. Chem. Ind. 1897, 516). Where potato or other starch saccharified by malt is used for the mash, *Bac. Delbreicki*, which ferments maltose, is used as the fermentating organism. (For further particulars of the micro-organisms, *v.* Andreasch, J. Soc. Chem. Ind. 1897, 53; Leichmann and Bazarewski, *ibid.* 1900, 698; Harden, Chem. Soc. Trans. 1901, 624; J. Soc. Chem. Ind. 1901, 921; Hashimoto, *ibid.* 1902, 506; Beijerinck, *ibid.* 1903, 106; Henneberg, *ibid.* 1904, 332; Buchner and Meisenheimer, Annalen, 349, 125; Wehmer, Chem. Zeit. 30, 1033; Heinemann, J. Biol. Chem. 1907, 2, 603.) Lactolase is an enzyme which causes the formation of lactic acid in plant cells (Stoklasa, Chem. Zentr. 1905, i. 265; 1907, i. 828). Malic, succinic, tartaric, and citric acids are all readily converted into lactic acid by certain moulds such as *Pencillium*

glaucum, *Aspergillus niger*, and *Botrytis cinera* (Bied. Zentr. 1908, 37, 215).

For the preparation of the acid from sugar by the action of caustic alkalis, Kiliani (Ber. 1882, 699) recommends the following method: 500 grams cane sugar are mixed with 250 c.c. water, and 10 c.c. of the sulphuric acid employed later on, and warmed in a flask of 2 litres capacity to 50° for 2 hours. To the well-cooled solution 400 c.c. of caustic soda solution (1 part of caustic to 1 part water) are gradually added, the mixture being constantly cooled. The exact quantity of sulphuric acid necessary is then allowed to flow in; the acid is prepared by adding 3 parts H_2SO_4 to 4 parts water, and previously directly compared with the caustic soda solution by titration. A crystal of Glauber's salt is added to facilitate crystallisation, the whole being cooled and well shaken, and allowed to stand 24 hours. The mass is then extracted with 93 p.c. alcohol, filtered on the pump, and half the filtrate neutralised with $ZnCO_3$ on the water-bath, then mixed with the other portion, and the whole allowed to stand 36 hours. The separated zinc salt is filtered off, well pressed, recrystallised from water, and converted into the acid as before.

Just as lactic acid may be obtained by boiling hexoses and hexobioses with caustic alkalis, so it may be obtained from pentoses such as arabinose and xylose (Katsuyama, Ber. 1902, 669; Araki, Zeitsch. physiol. Chem. 19, 463) and from cane sugar and raffinose (Beythien, Parcus, and Tollens, Annalen, 255, 222). Meisenheimer (Ber. 1908, 1009) states that lactic acid is formed in small quantities when glucose, fructose, or galactose are allowed to stand in dilute sodium hydroxide for many months in the dark.

Manufacture.—There are three stages in the manufacture of lactic acid, the preparation of the saccharine solution, the fermentation process, and the conversion of the fermented liquid into commercial lactic acid. The saccharine solution, which should have a sp.gr. of about 1·075, *i.e.* a saccharine content of 7½–11 p.c., and which should be faintly alkaline or neutral but not acid, is sterilised either by boiling for an hour, or by blowing live steam into the solution for one hour at 95°. It is advantageous to have about 10–15 p.c. of the saccharine matter in the form of cane sugar and the remainder as glucose. After sterilisation, the liquid is conveyed to the fermentation tank, cooled to between 45° and 55°, and impregnated. Where continuous manufacture of lactic acid is carried on, impregnation takes place from a previously fermented liquor where a lively fermentation is in progress; for an original fermentation, milk, which has been kept until it is slightly sour, is used. For efficient working, the lactic acid ferment must be well nourished with nitrogenous matter, the most convenient sources being vegetable matter, *e.g.* as extracted from bran by the action of boiling water and dilute acid. If mineral food is employed, ammonium salts should be in excess of nitrates. Pollak claims that the amount of lactic acid is increased by the repeated addition of ammonium salts in preparing the mashes for fermentation (Eng. Pat. 13193, 1913). As the fermentation proceeds, the temperature is allowed to decrease and the solution is neutralised with milk of lime or chalk in suspension, as the lactic acid bacteria are only healthy in solutions containing between 0·02 and 0·5 p.c. of acid; the fermentation is best completed in from 3 to 6 days. The fermented liquid, which contains calcium lactate with a layer of dead bacteria floating on it, is evaporated and filtered. For a commercial acid, decomposition of the syrupy solution of calcium lactate with sulphuric acid gives an acid of sufficient purity, which may be concentrated *in vacuó*. Iron may be removed by stirring the cooled liquor from the vacuum pans and leaving it to stand for some days, or the addition of a little potassium ferrocyanide has been used. It is important that the lactic acid used by the dyer should be iron-free. The concentrated acid for commercial purposes is about 80 p.c. If a pure acid is required, the solution of calcium lactate is set to crystallise; the solid crystals are pressed to remove mother liquor, and may be recrystallised if required (Claflin, J. Soc. Chem. Ind. 1897, 516; Dreher, *ibid.* 1898, 1070; McLauchan, *ibid.* 1907, 734; *cf.* Just, U.S Pat. 868444; J. Soc. Chem. Ind. 1907, 1211; D. R. P. 203306; Chem Zentr. 1908, ii. 1843). Various methods have been patented for the manufacture of lactic acid, differing mainly as to the source of the saccharine solution. Mislin and Lewin (Eng. Pat 10436; Fr. Pat. 355520; J. Soc. Chem. Ind. 1905, 1248) place alternate layers of malt and rye in a suitable apparatus until saccharification of the starch is complete. The must is removed by pressure and fermented as in above method (*cf.* Brookes, Eng. Pat. 5780; J. Soc. Chem. Ind. 1885, 116; Avery, Pharm. J. Aug. 5, 1882). Jean and Bougard obtain lactic acid from powdered grain or oil-free cake (Fr. Pats. 315325, 315326, 321374; J. Soc. Chem. Ind. 1903, 225), and Claflin uses as the starting material a wort containing about 10 p.c. of fermentable material (U.S. Pat 861163; J. Soc. Chem. Ind. 1907, 985). Boullanger acts on starch or sugar containing substances with a mould such as *Rumex acetosella*, and then proceeds as above (D. R. P. 118083; Chem. Zentr. 1901, i. 650).

Boehringer states that calcium lactate and sulphuric acid form a paste which is very difficult to work up. The method recommended is to take 300 litres of calcium lactate solution (10°Bé.), obtained from fermentation process, and evaporated to 50 litres; 50 kilos. of a 50 p.c. solution of lactic acid is added and then the calcium lactate is decomposed by sulphuric acid. The solution of lactic acid thus obtained is 50 p.c. (Eng. Pat. 7094; Fr. Pat. 401395; D. R. P. 221112; J. Soc. Chem. Ind. 1909, 674).

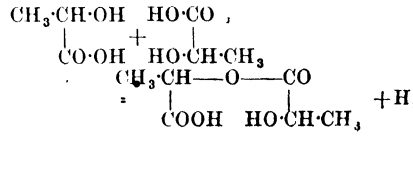
Patents have been granted for processes to recover lactic acid from brewers' and distillers' slop and from the waste water of jam factories. One such method consists in neutralising the liquid with milk of lime, partly evaporating and causing the albuminoid substances to coagulate, filtering and allowing the calcium lactate to separate out from the filtrate (Beckers, D. R. P. 104281, Chem. Zentr. 1899, ii. 926; *v.* also Beckers, D. R. P. 113383; Chem. Zentr. 1900, ii. 702; Roehr, U.S. Pat. 823366; J. Soc. Chem. Ind. 1906, 901).

Several processes have been patented for

the purification of the acid thus obtained. Waite (Eng. Pat. 13403; D. R. P. 140319; J. Soc. Chem. Ind. 1901, 931) washes the crude acid with amyl alcohol and distils off the solvent from the alcoholic solution of the acid, or washes this solution with water and concentrates the aqueous solution. Blumenthal and Chai (D. R. P. 169992; J. Soc. Chem. Ind. 1907, 279) mix the crude acid with aniline (150 parts 60 p.c. acid with 93 of aniline) and cool to −5°; the precipitate is recrystallised from a small quantity of water, decomposed with steam, and the acid concentrated *in vacuô*. Noerdlinger (Eng. Pat. 26415; Fr. Pat. 364468; D. R. P. 221786; U.S. Pat. 924494; J. Soc. Chem. Ind. 1908, 245) distils the crude acid in a current of inert gas. The water is first expelled and then pure lactic acid passes over. Laudau (Eng. Pat. 7998, 1915) boils the commercial acid with charcoal while a current of inert gas is passed through. It is concentrated *in vacuô* to 90–95 p.c., and the dextrins present precipitated by alcohol. After standing 24 hours, the liquid is filtered and the alcohol distilled off. Blaise recommends boiling the technical acid for 12 hours with an equal weight of water, and concentrating quickly *in vacuô* at a temperature not above 60° (Bull. Soc. chim. [4] 15, 666). In another process the mixture of calcium sulphate and lactic acid is dried at 130° when lactide and lactic anhydride are formed. After removal of the soluble impurities, pure lactic acid is obtained by hydrolysis in steam (U.S. Pat. 1240766, 1917). Erdmann (D. R. P. 217846; Chem. Zentr. 1910, i. 701) obtains pure lactic acid from copper lactate and water, heated at 150°–250°.

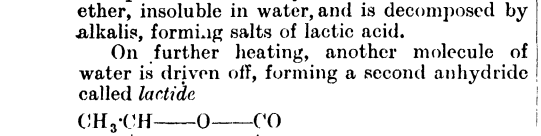
Properties.—The acid thus obtained forms a syrup of sp.gr. 1·21–1·24, and is soluble in all proportions in water and alcohol, less readily in ether. It is hygroscopic, colourless, and inodorous, but has a very sharp acid taste. The syrup is, however, not the pure acid, but a mixture of the latter with small quantities of water and the anhydride. The pure acid cannot be obtained by evaporation of the aqueous solution, as formation of the anhydride commences before all the water is driven off. Krafft and Dyës (Ber. 1895, 2589; Chem. Zentr. 1896, i. 742) have obtained lactic acid in the form of very hygroscopic white crystals, m.p. 18°, by the distillation of the commercial acid under reduced pressure. Lactic acid is slightly volatile at the ordinary temperatures, lactide is less volatile, and lactic anhydride practically non-volatile (Müller, Bull. Soc. chim. 1896, 15, 1206); lactic acid is volatile in steam, but not sufficiently volatile to be quantitatively separated from aqueous solutions by this means (Utz, Chem. Zeit. 1905, 29, 363). Lactic acid contains an asymmetric carbon atom, and hence can exist in two optically active modifications (*v. infra*). The fermentation lactic acid is optically inactive, but the acid obtained from the works is sometimes optically active. According to McKenzie (Chem. Soc. Trans. 1905, 1377), this is due to the fact that the action of the pure culture on sugar is to produce equal amounts of *d*- and *l*-isomerides. On converting these into the calcium salts and recrystallising, the crop of crystals which separate is mostly calcium *r*- salt, the active salt remaining in solution. If crystallisation takes place from a concentrated solution and the precipitate is not washed free from mother liquor, the acid obtained will be optically active. This would also be the case if the bacterial action had been such as to produce an excess of one isomeride (*cf.* Pottevin, J. Soc. Chem. Ind. 1899, 700). Wehmer recommends the use of *Oïdium lactis* and two mycoderma to decompose lactic acid in liquids where its presence is not desirable (Chem. Zentr. 1903, i. 891). An aqueous solution of lactic acid is stated to decompose in sunlight into acetaldehyde, pyruvic acid, carbon dioxide, and water (Ganassini, Boll. Chim. Farm. 48, 785; Giorn, Farm. Chim. 61, 540), but this is denied by Neuberg (Biochem. Zeitsch. 39, 158). Oxidation of lactic acid with hydrogen peroxide yields pyruvic acid (Fenton and Jones, Chem. Soc. Trans. 1900, 71); with bromine water, pyruvic acid (Ciusa and Piergallini, Atti R. Accad. Lincei, 1914, 821); oxidation by bacteria yields pyruvic acid and ketonic substances (Mazé, Compt. rend. 1918, 81, 1150); with potassium permanganate, pyruvic acid (Aristoff, J. Russ. Phys. Chem. Soc. 1884, 2, 249), acetaldehyde and malic acid (Schoorl, Zeitsch. angew. Chem. 1900, 15, 367); with dilute sulphuric acid at 130°, or by heating alone at 440°–460°, acetaldehyde and formic acid (Nef, Annalen, 335, 296); with chromic acid, acetic acid, and carbon dioxide (Dossios, Zeitsch. Chem. 1866, 451; Chapman and Smith, *ibid.* 1867, 477). Photochemical oxidation in the presence of uranyl or ferric salts yields acetaldehyde and carbon dioxide (Bolin, Zeitsch. physikal. Chem. 87, 490). Oxidation of the ammonium salt with hydrogen peroxide yields acetaldehyde, acetic acid, and carbon dioxide (Dakin, J. Biol. Chem. 4, 91). Reduction with hydriodic acid yields propionic acid. Electrolysis of the sodium salt results in the production of acetaldehyde and carbon dioxide (Walker, Chem. Soc. Trans. 1896, 1278; Ber. 1894, 467; Kolbe, Annalen, 113, 244). Phosphorus pentachloride converts lactic acid into α-chlorpropionic acid (Walden, Ber. 1895, 1293; Le Bel, *ibid.* 1895, 1923); bleaching powder converts it into chloroform and formic acid (Eberhard, Chem. Soc. Abstr. 1901, i. 357). Lactic acid reduces the nitrates of the heavy metals, *e.g.* bismuth, silver, mercury, cadmium, &c.; cobalt and nickel yield strongly magnetic powders (Vanino and Hauser, Zeitsch. anal. Chem. 1900, 29, 506). When the silver salt is treated with alkyl iodides, the hydrogen of the hydroxyl and carboxyl groups are both attacked (Purdie and Lander, Chem. Soc. Trans. 1898, 296, 300). For thermo-chemical data, *v.* Berthelot and Delépine, Compt. rend. 1899, 129, 920; dielectric constant, electrical conductivity, Drude, Zeitsch. physikal. Chem. 23, 349; Walden, *ibid.* 46, 103; 54, 129.

Lactic anhydride, which has been mentioned above, is formed by the elimination of a molecule of water from two molecules of the acid in the following manner, the one molecule acting as an alcohol and the other as an acid:—



This compound, *lactic anhydride* or *lacto-lactic acid*, is at the same time an alcohol, an acid, and an ethereal salt. It is a light yellow amorphous mass, easily soluble in alcohol and ether, insoluble in water, and is decomposed by alkalis, forming salts of lactic acid.

On further heating, another molecule of water is driven off, forming a second anhydride called *lactide*



This substance, which is a double ethereal salt, is very slightly soluble in water, and forms white needles melting at 124·5° (Bischoff and Walden, Annalen, 279, 71; Nef, *ibid.* 335, 296; Raper, J. Physiol. 32, 216).

Detection and estimation.—On heating lactic acid with potassium chromate and sulphuric acid it is decomposed into formic acid and acetaldehyde. The mixture is distilled and vapours collected in Nessler's solution, giving a yellow precipitate or opalescence (Lassar-Cohn, Annalen, 284, 226; Windisch, J. Soc. Chem. Ind. 1887, 262). Thoms (Apoth. Zeit. 1907, 22, 206) recommends treating a few c.c. of the liquid with 3 or 4 drops of 30 p.c. solution of chromic acid sufficient to impart a bright yellow tint. In the presence of free lactic acid a reddish-brown coloration is produced on warming the solution on the water-bath for 10 minutes. Denigès (Ann. Chim. 18, [viii.] 191) treats the solution with bromine water, and then after the addition of acetic acid a red-violet colour is produced on adding sodium nitro-prusside. Lactic acid gives a red coloration with alcoholic guaicol solution and may thus be distinguished from acetic, malic, benzoic and salicylic acids (Hartwig and Saar, Chem Ztg. 1921, 45, 322). Other methods, *v.* Denigès, Bull. Soc chim. 1909, 5, 647; Croner and Cronheim, J. Soc. Chem. Ind. 1905, 1258; Herzog, Annalen, 1907, 351, 263. The following process has been recommended by Jean (Ann. Chim. Anal. Appl. 1900, 5, 285) for estimating the commercial acid. (i.) Total acidity is determined as H_2SO_4; (ii.) free acids by evaporating three times to dryness on the water-bath; (iii.) lactic acid by evaporating 10 c.c. to dryness several times, and dissolving the residue in water. The solution is heated to boiling, neutralised with barium carbonate, and then filtered and evaporated to dryness in a platinum dish. The residue is incinerated to carbonate, extracted with boiling water, collected on a filter, well washed, and dissolved in a known volume of decinormal hydrochloric acid. The solution is heated to remove the carbon dioxide, titrated with decinormal alkali, and the volume of N/10-hydrochloric acid neutralised by the carbonate formed by subtraction. This number of c.c. × 0·009 gives weight of lactic acid originally present. To estimate the amount of lactic acid and lactic anhydride present in a sample of lactic acid, the following process is used: (i.) dilute sample with water and titrate with normal sodium hydroxide, using phenolphthalein as an indicator; (ii.) add a known excess of sodium hydroxide and titrate back with acid; (i.) gives actual amount of acid and (ii.) of anhydride (Philip, Collegium, 1906, 88; Kunz, Chem. Zentr. 1901, i. 791; Bellet, Bull. Soc. chim. 1913, 13, 565). Other methods, *v.* Ulzer and Seidel, Monatsh. 18, 138; Paessler, Collegium, 1907, 388, 396; Phelps and Palmer, J. Amer. Chem. Soc. 1917, 136. Estimation in wines, *v.* Kunz, Chem. Soc. Abstr. 1901, ii. 700; 1903, ii. 701; Sostegni and Prandi, Chem. Zentr. 1905, ii. 469; Müller, Bull. Soc. chim. 1896, 15, [iii.] 1203; Parthiel, Chem. Soc. Abstr. 1903, ii. 189; Arch. Pharm. 241, 401; Paris, Chem. Zentr. 1908, i. 773; Trummer, Chem. Zentr. 1908, ii. 101; Heiduschka and Quincke, Arch. Pharm. 245, 458. In milk, *v.* Thörner, Chem. Zeit. 16, 1469. 1519. In urine, *v.* Proc. Physiol. Soc. 1909, v.–vii.; J. Physiol. 39; Biochem. Zeitsch. 68, 175. In gastric juice, *v.* De Jong, Chem. Zentr. 1896, ii. 806. In the presence of pyruvic acid, Czapski, Biochem. Zeitsch. 71, 167. For the extraction of lactic acid from the tissues, amyl alcohol is recommended as the most suitable solvent, Ohlsson, Chem. Soc. Abstr. 1916, ii. 542.

Technical uses.—Lactic acid is used by the woollen dyer as an assistant in mordanting with potassium dichromate and its advantages over tartaric and oxalic acids are its greater reducing power, the greater solubility of itself and its salts, and the fact that it is less corrosive. It gives the wool a very fine, soft 'handle' and a beautiful lustre. *Lactolin*, which consists of equal parts of lactic acid and potassium lactate, is stated to be superior to lactic acid, which is in itself superior to tartar (Claflin, *l.c.*; Norton and Tuttle, J. Soc. Chem. Ind. 1891, 263; Hoffmann, *ibid.* 1896, 196, 540; Dreher, *ibid.* 1896, 448; 1898, 1070; 1899, 491; Kielmeyer, *ibid.* 1899, 368; Kapff, *ibid.* 1900, 659; Fuchs, Chem. Zentr. 1897, i. 1183; Archer, J. Soc. Chem. Ind. 1897, 140; Düring, Bull. Soc. Ind. Mulhouse, 1902, [v.] 3; Paessler and Appelius, Collegium, 1903, 152, 153, 164, 169). Aniline lactate is used in producing aniline black on cotton (Goldovsky, Bull. Soc. Ind. Mulhouse, Jan. 9, 1900; Schener and Schoellkopf, *ibid.* 1901, 102; Düring, Chem. Zentr. 1905, i. 1515; D. R. P. 96600; J. Soc Chem. Ind. 1899, 1119). The double lactate of calcium and antimony is used in mordanting cotton, and as a substitute for glycerin and tartaric acid in printing fabrics (Dreher, J. Soc. Chem. Ind. 1898, 919, 921). For methods of obtaining double lactates of antimony and calcium or of antimony and alkalis or alkaline earths, *v.* Moritz, Zeitsch. angew. Chem. 17, 1143; Akt. Ges. Reavler Chem. Fab. R. Mayer, D. R. P. 136135; Chem. Zentr. 1902, ii. 1286; Ch. Fab. von Heyden, D. R. P. 184202; Chem. Soc. Abstr. 1907, i. 888; Boehringer, D. R. P. 98939; Chem. Zentr. 1898, ii. 1231; Ch. Werke Schuster and Wilhelmj, D. R. PP. 216158, 217806; Chem. Zentr. 1909, ii. 1908; 1910, i. 701.

A solution containing the lactates of aluminium, calcium, and tin has been used instead of the above (Oswald, Bull. Soc. Ind. Mulhouse, 1900, 343), whilst Boehringer (D. R. P. 91230; Chem. Zentr. 1897, i. 1189) employs zinc lactate for the same purpose. Lactolin and sulphuric acid are used in hat dyeing (Düring, J. Soc. Chem. Ind. 1900, 660; 1901, 470) and lactic acid, free from traces of iron, is used as a discharge for

Turkey red (Düring, *ibid.* 1900, 1013). It has also been used as a solvent for dyestuffs insoluble in water (Dreher, *ibid.* 1897, 1014; 1898, 919, 921).

Lactic acid is used in tanning for colouring, bating, and plumping. In preparing the skins it completely removes the lime, ensures a fine even grain, and does not dissolve the hide substance. It is easier to control than the bran drench, which is also used for this purpose, and which owes its efficiency to the lactic acid produced during the fermentation of the bran (Claflin, J. Soc. Chem. Ind. 1901, 210, 596, 730, 913; Paessler and Appelius, *ibid.* 1902, 1461, 57; 1903, 1201). It is also used in the preparation of yeast (Büchler, *ibid.* 1901, 376) and in the distillery, *e.g.* to check the bacterial development in the 'Hefengut' mash (Moritz, *ibid.* 1899, 778).

Lactic acid is also used for medicinal purposes in cases of laryngeal tuberculosis and of infantile diarrhœa. It dissolves false membrane and a solution of 1 part of acid in 6 parts of water is employed in the local treatment of diphtheria and croup. Local applications are used in stopping the growth of venereal worts and in treatment of tuberculous ulcers, lupus, and epithelioma. Calcium lactate is used in the treatment of rheumatism. For pharmaceutical purposes, the acid must be colourless and inodorous, and have a sp.gr. of at least 1·21, and should leave scarcely any residue on ignition. It should be unaffected by NH_3 and $(NH_4)_2S$, should give, at most, only a faint opalescence with $BaCl_2$, $AgNO_3$, $(NH_4)_2C_2O_4$, and should give no precipitate on boiling with Barreswil's (Fehling's) solution. For its influence in human dietary, *v.* J. Soc. Chem. Ind. 1920, 236.

Esters. The esters of lactic acid may be prepared by treating a salt of lactic acid with sulphuric acid or gaseous hydrogen chloride and the corresponding alcohol; or the anhydride (lactide) may be treated with alcohol in the presence of aluminium sulphate or titanic acid anhydride as catalyst, D. R. P. 278,487. The product is distilled *in vacuô*, whereby the pure ester is obtained. By treating the pure ester with steam, distilling off the alcohol and concentrating, the pure acid is obtained (Ch. Fab. Güstrow, Hillringhaus and Heilmann, D. R. P. 171835; Chem. Zentr. 1906, ii. 470).

Methyl ester. Colourless liquid, b.p. 144·8°; sp.gr. 1·0898 at 19° (Schreiner, Annalen, 197, 12).

Ethyl ester. Colourless liquid, b.p. 154–5°; sp.gr. 1·0308 at 19° (Schreiner, *l.c.*; Friedel and Wurz, Ann. Chim. [iii.] 63, 102; Brüggen, Annalen, 148, 227).

Ethylidene ester. Prepared by heating acetaldehyde and lactic acid at 120°–170° for some hours: colourless liquid, b.p. 150°–151·5° (Leipen. Monatsh. 9, 45).

Glyceryl mono- and di-lactates (*v.* Kalle & Co. D. R. P. 216917; Chem. Zentr. 1910, i. 214).

Salts. The salts of lactic acid are all soluble in water, many so readily that they are very difficult to obtain crystalline. They are obtained by direct neutralisation of the free acid, or by double decomposition from the calcium salt.

The K, Na salts are very hygroscopic, and only the latter has been obtained crystalline (Wislicenus, Annalen, 125, 49; Engelhardt and Maddrell, *ibid.* 63, 88; Brüning, *ibid.* 104, 192).

Ammonium lactate is crystalline and very hygroscopic. On distilling it *in vacuô*, acid ammonium lactate, a syrup (b.p. 140° at 10 mm.) passes over (D. R. P. 247,240; J. pr. Chem. [2] 87, 258).

Calcium lactate $(C_3H_5O_3)_2Ca,5H_2O$ is usually obtained direct from sugar in the preparations of lactic acid (*v. supra*). In small quantities it is sometimes prepared by neutralising lactic acid with chalk. It forms cauliflower-like aggregates of microscopic rhombic needles, which are soluble in 9·5 parts of cold, much more readily in hot water, and also soluble in alcohol. It loses its water of crystallisation at 100°, and at 250°–275° loses another molecule of water, forming *calcium dilactate* $(CH_3{\cdot}CH)_2{\cdot}O((CO_2)_2Ca$. The product is a vesicular mass, from which alcohol extracts some unaltered calcium lactate, and leaves the new compound behind as a very slightly soluble substance (Friedel and Würtz Ann. Chim. Phys. [iii.] 63, 114).

Barium lactate $(C_3H_5O_3)_2Ba,4H_2O$ crystallises with great difficulty, forming cauliflower-like aggregates. It does not lose all its water of crystallisation at 100° (Meyer, Ber. 1886, 2454).

Magnesium lactate $(C_3H_5O_3)_2Mg,3H_2O$ is prepared by dissolving lactic acid syrup in 10 times its bulk of water, and neutralising with basic magnesium carbonate. The solution is evaporated until a skin forms, and then allowed to crystallise. It forms small light prismatic crystals, which frequently unite to form crusts. It dissolves in 28 parts of cold and 6 parts of hot water, forming a neutral very bitter solution. It loses its water of crystallisation at 100°.

Zinc lactate $(C_3H_5O_3)_2Zn,3H_2O$ is best obtained direct from sugar by neutralising the lactic acid produced with zinc carbonate or zinc white (Lautemann, Annalen, 113, 142, Kiliani, Ber. 1882, 659). It crystallises better than any other lactate, and forms colourless, well-developed, four-sided rhombic prisms. It loses its water of crystallisation *in vacuô* or at 100°. It dissolves in 53 parts of water at 15°, and in 6 parts at 100°, forming an acid, bitter-tasting solution. It is very slightly soluble in alcohol (Strecker, Annalen, 105, 316).

Ferrous lactate $(C_3H_5O_3)_2Fe,3H_2O$. This salt was introduced into pharmacy by Gélis and Conté in 1840, and was again recommended in 1847 by Engelhardt and Maddrell (*l.c.*). It is best prepared from crude calcium lactate in the following manner. The crude salt is recrystallised from water to which a little lime has been added, and if necessary the operation repeated. To the conc. aqueous solution of the purified salt the theoretical quantity of ferrous chloride is added, and the mixture allowed to stand for 3 days in a cool place. When no more crystals form the precipitated salt is filtered off, washed with a little alcohol, and dried at 50°.

Ferrous lactate forms greenish-white crusts of needles, or a similarly coloured crystalline powder. It dissolves at the ordinary temperature in 48 parts, and at 100° in 12 parts of water, forming an acid solution with a sweetish chalybeate taste. The solution becomes yellow, and then brown, in the air, ferric lactate being formed, and also undergoes alteration on evaporation in the air, leaving a hygroscopic residue

containing ferrous and ferric lactates and some free acid. The dry salt is unaltered in the air, and loses its water of crystallisation when heated at 100° in a current of hydrogen.

Silver lactate $C_3H_5O_3Ag,\frac{1}{2}H_2O$ is prepared by treating freshly prepared lactic acid, after cooling, with silver oxide, evaporating the solution in the dark *in vacuô* at the ordinary temperature. It forms colourless needles, soluble in 20 parts of cold water, insoluble in cold, but readily soluble in hot alcohol. On heating the salt in the dark for 3 hours at 80°, anhydrous silver lactate is obtained (Klimenko, J. Russ. Chem. Soc. 12, 97; Berthelot and Delépine, Compt. rend. 129, 920).

Bismuth lactate $BiC_6H_9O_6,7H_2O$ is prepared by the slow dissolution of freshly precipitated bismuth hydroxide in lactic acid slightly diluted with water. The solution gradually deposits needles of the hydrated salt; on heating to 105° this yields the anhydrous salt, which is very sparingly soluble in water. The latter may be obtained by digesting freshly precipitated bismuth hydroxide in lactic acid at 100°. It forms rhombic tablets which decompose slightly when boiled with water for some time (Telle, Arch. Pharm. 1908, 246, 484).

Mercury lactates. *Mercurous lactate*

$$(C_3H_5O_3)_2Hg,HgO$$

is prepared by dissolving freshly precipitated mercurous oxide in dilute lactic acid, which has previously been heated with water to destroy the anhydride which it contains. The solution is allowed to evaporate in a desiccator over sulphuric acid, when the salt separates in short white prismatic needles. It is not completely soluble in water, hydrolysis occurring with the formation of a basic lactate, which then decomposes into mercuric lactate and mercury. *Mercuric lactate* $(C_3H_5O_3)_2Hg$, prepared in a similar manner from lactic acid and mercuric oxide, forms colourless prismatic needles, readily soluble in water. On boiling the aqueous solution, mercurous lactate, acetaldehyde, lactic acid, and carbon dioxide are produced (Guerbet, Bull. Soc. chim. 1902, 27, [iii.] 803).

Glucinium lactate (*v.* Tanatar and Kurowski, J. Russ. Phys. Chem. Soc. 39, 936; Glassmann, Ber. 1908, 33).

Cerous lactate (*v.* Morgan and Cahen, Pharm. J. 1907, 78, 428).

Optically active acids. As has already been stated, lactic acid can be resolved into two optically active components. This resolution has been effected by the fractional crystallisation of zinc ammonium lactate (Purdie and Walker, Chem. Soc. Trans. 1893, 1143; 1895, 616); of the strychnine salts (Purdie and Walker, *ibid.* 1892, 754; morphine salts (Irvine, *ibid.* 1906, 935); and of the quinine salts (Jungfleisch, Compt. rend. 1904, 139, 56, 203; 1905, 140, 719; 1906, 142, 515). Asymmetric syntheses have been made by the reduction of the *l*-menthyl (McKenzie, Chem. Soc. Trans. 1905, 1373), *l*-bornyl (McKenzie and Wren, *ibid.* 1906, 688), and *d*-amyl (McKenzie and Müller, *ibid.* 1909, 544) salts of pyruvic acid.

Paralactic acid (Sarcolactic acid, *d*-lactic acid) is present in flesh, in the blood, in muscles, in the thymus and thyroid and other animal organs (Berlinbauer, Chem. Zentr. 1888, 757; Salomon, Chem. Soc. Abstr. 1889, 64; Asker and Jackson, Zeit. Biol. 41, 393; Moscatelli, Zeitsch. physiol. Chem. 12, 416; Griffiths, Chem. News, 91, 147; Werther, Chem. Soc. Abstr. 1890, 348; Inouye and Kondo, Zeitsch. physiol. Chem. 54, 481; Frew, *ibid.* 60, 15; Moriya, *ibid.* 43, 397). In muscle tissue, the amount increases with the degree of muscular activity. According to Embden (Zeitsch. physiol. Chem. 93, 1) a compound of phosphoric and lactic acids occurs as an intermediate metabolic product.

It is obtained from extract of meat by dissolving in 4 parts of warm water, adding 3 times the volume of 90 p.c. alcohol, and evaporating the filtrate to a syrup. This is again precipitated with alcohol, filtered, and evaporated, then acidified with H_2SO_4, and extracted with ether (Wislicenus, Annalen, 167, 302). The crude acid may be purified by conversion into the zinc salt. If *Penicillium glaucum* is allowed to grow in the solution of the inactive ammonium lactate, the *d*- modification alone will remain (Lewkowitsch, Ber. 1883, 2720; Linossier, Bull. Soc. chim. [iii.] 6, 10). *Micrococcus acidi paralacti*, an anaërobic micrococcus formed in the preparation of the *Rauschbrand bacillus*, is found to convert sugar into paralactic acid (Nencki and Sieber, Monatsh. 10, 532).

Paralactic acid is a syrup which can only be distinguished from lactic acid by the fact that it rotates the plane of polarisation to the right, whereas lactic acid is inactive. The salts strongly resemble the lactates, but are somewhat more soluble in water. The methyl ester boils at 143°–145° and has sp.gr. 1·1017 at 15°/16°; and the ethyl ester, b.p. 152°–154°, sp. gr. 1·0414 at 15°/16° (Frankland, Chem. Soc. Proc. 1895, 54). Further details as to rotatory power of acid and derivatives, *v.* Walker, Chem. Soc. Trans. 1895, 914; Purdie and Williamson, *ibid.* 1896, 827; Guye and Melikian, Compt. rend. 123, 1291; Henderson, and Prentice Chem. Soc. Trans. 1902, 658; 1903, 259; Wassmer and Guye, J. Phys. Chem. 1903, i. 257; Purdie and Irvine, Chem. Soc. Trans. 1899, 484; Walker, J. Phys. Chem. 13, 574.

***l*-Lactic acid** has not been found in nature. It is prepared by the resolution of the inactive acid (*q.v.*); by the fermentation of sugar with *Bacillus acidi lævolacti* (Schardinger, Monatsh. 11, 545) or with a lævolactic ferment obtained from pears (Tate, Chem. Soc. Trans. 1893, 1263). It is similar in properties to *d*-lactic acid, with the exception that it rotates the plane of polarisation to the left.

Besides these acids, another isomeric acid remains to be described. *Hydracrylic acid, ethylene-lactic acid* or *β-hydroxypropionic acid* $CH_2(OH)CH_2CO_2H$ is prepared by the action of moist silver oxide on *β*-iodopropionic acid (Sokolow, Annalen, 150, 167; Wislicenus, Annalen, 166, 10); by heating the sodium salt of acrylic acid with sodium hydroxide at 100° (Linnemann, Ber. 1875, 1095); and by the action of prussic acid on ethylene chlorhydrin and saponification of the resulting nitrile (Wislicenus, Annalen, 128, 1; 167, 346; Erlenmeyer, *ibid.* 191, 268). It forms a syrup which decomposes into water and acrylic acid on heating. Chromic acid oxidises it into oxalic acid and carbon dioxide, and silver oxide converts it into glycollic acid. Wislicenus also obtained from flesh, in addition to paralactic acid, an

acid which he believed to be identical with this ethylene-lactic acid, but it has been shown (Siegfried, Ber. 1889, 2713) that this is in reality *acetyllactic acid.*

Atrolactinic acid (*αα-phenylhydroxypropionic acid*) $CH_3{\cdot}C(C_6H_5)OH{\cdot}CO_2H$. Prepared by the action of fuming hydrochloric acid on acetophenone hydrocyanide (Spiegel, Ber. 1881, 14, 1353; Tiemann and Köhler, *ibid.* 1980); colourless needles, m.p. (anhydrous) 93°–94°.

LACTIC FERMENTATION GUM *v.* GUMS.

LACTOLIN. Trade name for potassium di-lactate used as a mordant.

LACTONES. Generally speaking a lactone is formed by the elimination of water from a hydroxyl group and a carboxyl group present in the same molecule. They may therefore be regarded as internal salts corresponding with the external salts which are known as the ethereal salts or esters:

$$R{\cdot}CH(OH){\cdot}\cdot\cdot\cdot\cdot CH_2{\cdot}COOH \rightarrow R{\cdot}CH\cdot\cdot\cdot\cdot CH_2 + H_2O$$
Hydroxy acid. | | | O — — CO
Lactone.

$$R{\cdot}CH_2OH + CH_3COOH \rightarrow R{\cdot}CH_2\ \ CH_3 + H_2O$$
| | | O · CO
Ethereal salt.

The lactones are therefore derived from that class of organic compounds known as the hydroxy acids. The hydroxy acids are divided into several series depending on the position of the hydroxyl group in respect to the carboxyl group and are named α-, β-, γ-, &c., hydroxy acids according as the hydroxyl group is in the α-, β,- γ-, &c., position in respect to the acid group, thus:

$R{\cdot}CH(OH){\cdot}COOH$ — (α) α-Hydroxy acid
$R{\cdot}CH(OH){\cdot}CH_2{\cdot}COOH$ — (β) (α) β-Hydroxy acid
$R{\cdot}CH(OH){\cdot}CH_2{\cdot}CH_2{\cdot}COOH$ — (γ) (β) (α) γ-Hydroxy acid
$R{\cdot}CH(OH){\cdot}CH_2{\cdot}CH_2{\cdot}CH_2{\cdot}COOH$ — (δ) (γ) (β) (α) δ-Hydroxy acid
$R{\cdot}CH(OH){\cdot}CH_2{\cdot}CH_2{\cdot}CH_2{\cdot}CH_2{\cdot}COOH$ — (ε) (δ) (γ) (β) (α) ε-Hydroxy acid
$R{\cdot}CH(OH){\cdot}CH_2{\cdot}CH_2{\cdot}CH_2{\cdot}CH_2{\cdot}CH_2COOH$ — (ζ) (ε) (δ) (γ) (β) (α) ζ-Hydroxy acid

The lactones derived from these acids are named accordingly α-, β-, γ-, &c., lactones and thus a γ-lactone would be constituted $R{\cdot}CH{\cdot}CH_2CH_2$ | | $O — — CO$ and a δ-lactone would have the structure $R{\cdot}CH{\cdot}CH_2{\cdot}CH_2{\cdot}CH_2$ | | $O \cdot\cdot\cdot\cdot CO$

Nomenclature.—The name of the lactone is usually taken from the trivial name of the acid from which the corresponding hydroxy acid is derived, as for example, butyrolactone from γ-hydroxybutyric acid, valerolactone from γ-hydroxyvaleric acid. In those cases where the formation of two isomeric lactones is possible the prefix γ- or δ- is added to indicate the order of the lactone, thus:

$CH_3{-}CH{-}CH_2CH_2$ | | $O — — — CO$
γ-Valerolactone.

$CH_2{-}CH_2{-}CH_2{-}CH_2$ | | $O — — — — CO$
δ-Valerolactone.

α-Lactones are not known, and in only a few exceptional cases has the formation of β-lactones been observed. Thus Baeyer and Villiger (Ber 1897, 30, 1954; compare also Fichter and Hirsch, *ibid.* 1900, 33, 3273) have shown that when α-bromo-α′α′-dimethylsuccinic acid is treated with moist silver oxide the β-lactone of dimethylmalic acid is formed:

$COOH{-}CH{-}C(CH_3)_2 \rightarrow COOH{-}CH{-}C(CH_3)_2$
| | | |
Br COOH OH COOH

$\rightarrow COOH{-}CH{-}C(CH_3)_2$
| |
O — — CO
β-Lactone.

This compound crystallises in rhombic plates containing 1 mol. of water, and melts at 54°–55°; it loses this water of crystallisation at 45° in a vacuum. When distilled under diminished pressure it passes by rearrangement into the anhydride of αα-dimethylmalic acid

$COOH{-}CH{-}C(CH_3)_2 \rightarrow OH{\cdot}CH\cdot\cdot C(CH_3)_2$
| | | |
O CO CO– O—CO

In the same way, trimethylbromosuccinic acid is converted into the β-lactone of trimethylmalic acid (Kömppa, Ber. 1902, 35, 534)

$COOH{\cdot}C(CH_3){-}C(CH_3)_2$
| |
Br COOH

$\rightarrow COOH{-}C(CH_3){-}C(CH_3)_2$
| |
O · · CO

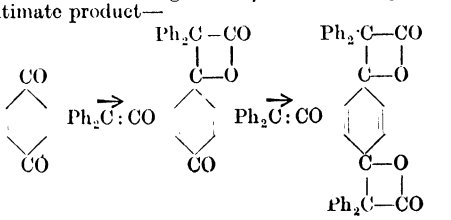
The formation of a similar compound has been recorded by Meldrum (Chem. Soc. Trans. 1908, 93, 598), who finds that when acetone is condensed with malonic acid in the presence of acetic anhydride containing a little sulphuric acid, the β-lactone of β-hydroxy*iso*propylmalonic acid $(CH_3)_2C{-}CH{\cdot}COOH$ is formed. This substance | | O—CO crystallises from acetone in transparent four-sided plates melting at 97°.

β-Lactone formation occurs in the aromatic series from β-hydroxy acids having a phenyl-group, in which strongly negative groups are present, attached to the β-carbon atom. Thus the lactones of *o*-, *m*-, and *p*-nitrophenyl-β-lactic acids are formed when the corresponding nitro phenyl-β-bromopropionic acids are treated with cold aqueous sodium carbonate

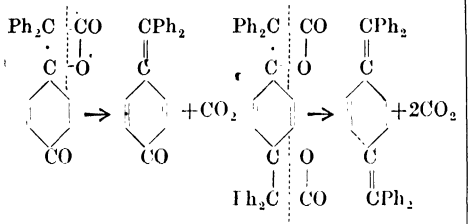
$NO_2{-}C_6H_4{-}CHBr \rightarrow NO_2{-}C_6H_4{\cdot}CH{-}O$
| | |
$CH_2{\cdot}COOH$ $CH_2{-}CO$

o-Nitrophenyllactic acid lactone readily passes into indigo when boiled with glacial acetic acid.

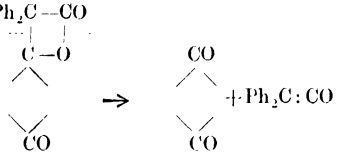
A remarkable series of aromatic β-lactones have been prepared by Staudinger by condensing diphenylketene with various quinones. When, for example, quinone itself is used the reaction proceeds in two stages, a di-β-lactone being the ultimate product—



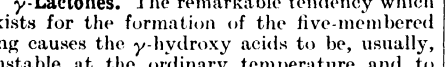
Both lactones eliminate carbon dioxide when heated—



but in the former case a certain amount of fission takes place in the other direction (Ber 1908, 41, 1355)—



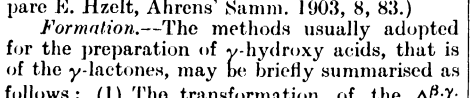
γ-Lactones. The remarkable tendency which exists for the formation of the five-membered ring causes the γ-hydroxy acids to be, usually, unstable at the ordinary temperature and to pass, with elimination of water, into the γ-lactone



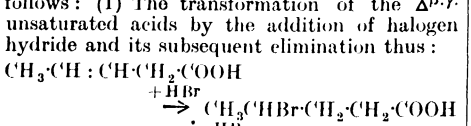
γ-Hydroxy acid. γ-Lactone.

The tendency for the formation of the inner anhydride is so great that the change from the hydroxy acid to the lactone is usually effected by merely raising the temperature of an aqueous solution of the acid and in many cases the lactone exists in aqueous solution at the ordinary temperature. The simplest member of the class, butyrolactone $CH_2 \cdot CH_2 \cdot CH_2$ / O —— CO, was discovered by Saithew in 1873, although certain naturally occurring lactones, such as coumarin and meconine (*q.v.*), were known before that time. (For a general description of the lactones, compare E. Hzelt, Ahrens' Samm. 1903, 8, 83.)

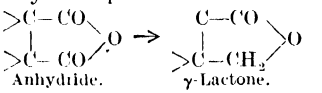
Formation.—The methods usually adopted for the preparation of γ-hydroxy acids, that is of the γ-lactones, may be briefly summarised as follows: (1) The transformation of the $\Delta^{\beta.\gamma.}$ unsaturated acids by the addition of halogen hydride and its subsequent elimination thus:



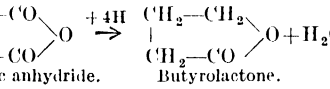
The $\Delta^{\beta.\gamma.}$ unsaturated acids are also transformed into the γ-lactones either by merely heating them alone or by warming them with a mixture of equal volumes of concentrated sulphuric acid and water at 140° (Fittig. Ber. 1894, 27, 2667; Annalen, 1894, 283, 51). In the latter instance, the same change is shown by those $\Delta^{\alpha.\beta.}$ unsaturated acids which have two alkyl groups on the β-carbon atom. Thus Fichter, Kiefer, and Bernoulli (Ber. 1909, 42, 4710) find that when ββ-diethylacrylic acid is warmed for a short time with 60 p.c. aqueous sulphuric acid, it is converted into β-ethyl-γ-valerolactone



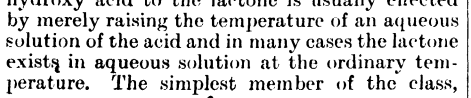
(2) The relation between the anhydrides of the dibasic acids and the γ-lactones, which is illustrated by the expression:



indicates that the last-named compounds can be derived from the anhydrides by reduction. Thus butyrolactone is formed when succinic anhydride is reduced by sodium amalgam (Fichter and Herbrand, Ber. 1896, 29, 1192):

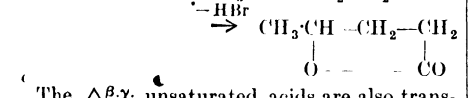


(3) The sodium salts of γ-hydroxy acids are also formed when γ-ketonic acids, such as lævulic acid, are reduced by sodium amalgam, thus:

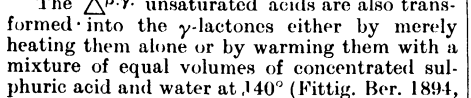


In a similar manner, β-aldehydo acids, for example, β-aldehydopropionic acid, yield γ-lactones when reduced.

(4) The alkyl salts of γ-hydroxy acids may be formed by the condensation of chlorhydrins of the type $CH_2Cl \cdot CH_2OH$ with the sodium compounds of ethyl acetoacetate and its homologues, thus:

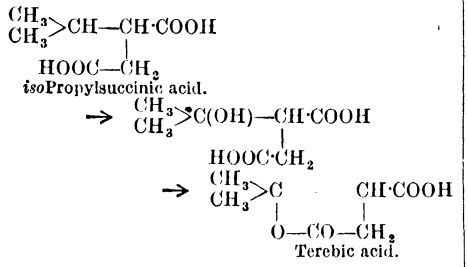


When this ethyl salt is hydrolysed with baryta, the acetyl group is eliminated and the barium salt of the hydroxy acid, which is then formed, is converted into the γ-lactone by the action of dilute mineral acids:



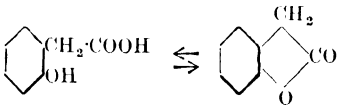
(5) The formation of certain γ-lactones may

also be effected by taking advantage of the fact that the tertiary hydrogen atom of the system $CH_3>\overset{*}{C}H-$ is readily oxidised to hydroxyl by alkaline permanganate. Thus *iso*propyl-succinic acid passes on oxidation into terebic acid (Lawrence, Chem. Soc. Trans. 1899, 75, 527).

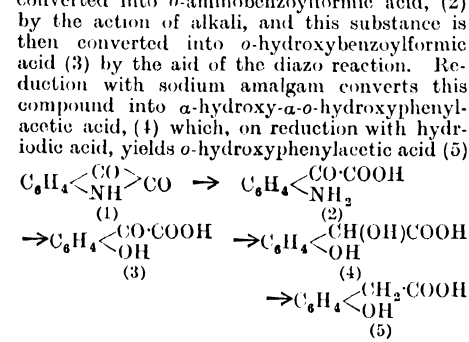


(6) The methods of formation of γ-lactones of the aromatic series are similar to those employed with aliphatic compounds, but for the sake of convenience the substances belonging to this class may be divided into three sections. (*a*) The γ-lactones which are derived from hydroxy acids having the hydroxyl group in the ortho- position in the benzene nucleus to a side chain bearing a carboxyl group. (*b*) The γ-lactones which are formed when both the hydroxyl and carboxyl groups are attached to the side chain. (*c*) The γ-lactones formed from compounds having the hydroxyl group in the side chain and the carboxyl group attached to the ortho- position in the benzene nucleus.

o-Hydroxyphenylacetic acid may be given as an illustration of compounds included under section (*a*). This acid, unlike the γ-hydroxy acids of the aliphatic series, can be isolated in the free state, but passes into the γ-lactone on distillation:



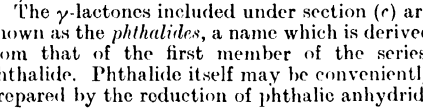
The lactone is again converted into the acid on shaking with water. The method employed for the preparation of *o*-hydroxyphenylacetic acid is as follows (Baeyer and Fritsch, Ber. 1884, 17, 973; compare also Stoermer, Annalen, 1900, 313, 83; Ber. 1901, 34, 1807). Isatin (1) is converted into *o*-aminobenzoylformic acid, (2) by the action of alkali, and this substance is then converted into *o*-hydroxybenzoylformic acid (3) by the aid of the diazo reaction. Reduction with sodium amalgam converts this compound into α-hydroxy-α-*o*-hydroxyphenylacetic acid, (4) which, on reduction with hydriodic acid, yields *o*-hydroxyphenylacetic acid (5)



Under section (*b*) may be given, as illustration, the example of γ-phenyl-γ-hydroxybutyric acid. $C_6H_5\cdot CH(OH)CH_2\cdot CH_2\cdot COOH$, which can be produced by the reduction of β-benzoyl-propionic acid

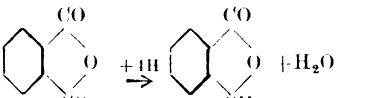
$$C_6H_5\cdot CO\cdot CH_2\cdot CH_2\cdot COOH$$

and by other methods. Although this substance is more stable than the corresponding γ-hydroxy-acids of the aliphatic series, and can be isolated in the free state, it nevertheless passes into the γ-lactone when heated above its melting-point (75°).



The hydroxy acid may be recrystallised from warm water, but at 80° lactone formation slowly occurs, and when the acid is treated with very dilute hydrochloric acid the transformation into the lactone (m.p. 37°) is complete even at low temperatures.

The γ-lactones included under section (*c*) are known as the *phthalides*, a name which is derived from that of the first member of the series, phthalide. Phthalide itself may be conveniently prepared by the reduction of phthalic anhydride



Other methods of preparation will be found under the head of *Meconine* (*q.v.*).

General properties of γ-lactones.—As already mentioned, the γ-hydroxy acids of the aliphatic series are, for the most part, unstable, and therefore cannot be isolated in the free state. The corresponding γ-lactone separates in almost every case when the aqueous solution of the salt of the acid is acidified even at low temperatures, and in only one or two instances has it been found possible to isolate the hydroxy acid in the free condition. Thus Fittig and Chanlarow (Annalen, 1884, 226, 325, 334) found that γ-hydroxybutyric acid as well as its ethyl derivatives are stable at very low temperatures. The lactones titrate as monobasic acids, and the salts of the corresponding hydroxy acids can usually be isolated in the crystalline condition; the silver salts, which are mostly well-defined crystalline substances, can be readily obtained by double decomposition from the potassium salt.

The γ-lactones derived from the monohydroxy-mono-carboxylic acids of the aliphatic series, and which therefore have the general formula $C_nH_{2n-2}O_2$, are neutral, colourless liquids or low-melting solids which are volatile with steam, and can be distilled without decomposition under ordinary atmospheric pressure. The lower members of the series are miscible with water in all proportions, but the solubility decreases with increase of molecular weight. The less soluble γ-lactones are frequently characterised by possessing the curious property of being varyingly soluble in water; thus when a concentrated solution of the lactone is warmed, the solution becomes cloudy owing to the partial separation of the dissolved substance; the emulsion again clears above 80°. When the γ-lactones are dissolved in water, a

partial conversion into the hydroxy acid takes place, and a state of equilibrium between the two compounds is attained. Thus it has been found by P. Henry (Zeitsch. physikal. Chem. 1892, 10, 96) that a boiling 1 p.c. solution of butyrolactone contains 80 p.c. of the lactone and 20 p.c. of the hydroxy acid. γ-Lactones frequently react with halogen hydrides, yielding the γ-halogen derivatives of the acid, thus:

$$\begin{array}{l}CH_2\cdot CH_2\cdot CH_2\\ |\quad\quad |\\ O\quad\quad CO\end{array} + HBr \rightarrow CH_2Br\cdot CH_2\cdot CH_2\cdot COOH$$

but the breaking of the lactone ring in this manner is usually more easily effected by heating the compound with an alcoholic solution of the halogen hydride, whereby the corresponding ester is formed (Henry, Compt. rend. 1886, 102, 368; Cloves, Annalen, 1901, 319, 362). When treated with aqueous ammonia in the cold, the γ-lactones yield the amide of the hydroxy acid, thus:

$$\begin{array}{l}CH_2—CH_2—CH_2\\ |\quad\quad |\\ O\quad\quad CO\end{array} + NH_3 \rightleftarrows CH_2OH\cdot CH_2\cdot CH_2\cdot CONH_2$$

These compounds readily split off ammonia and pass again into the lactone (Fittig and Rasch, Annalen, 1890, 256, 151; Fittig and Dubois, *ibid.* 1890, 256, 153). The γ-lactones react with hydrazine (Blanc and Luttringer, Bull. Soc. chim. 1905, [iii.] 33, 1095) also with potassium cyanide (Wislicenus, Annalen, 1886, 233, 113; Blanc, Bull. Soc. chim. 1905, [iii.] 33, 886, 904).

The more important γ-lactones of the formula $C_nH_{2n-2}O_2$ are:

Butyrolactone $\begin{array}{l}CH_2—CO\\ |\quad\quad\diagdown\\ CH_2—CH_2\quad\diagup O\end{array}$ Preparation method (3): boils at 204° and solidifies at −42°. It has sp.gr. 1·129 at 16°.

Valerolactones. γ - *Methylbutyrolactone* (*n-valerolactone*) $\begin{array}{l}CH_2—CO\\ |\quad\quad\diagdown\\ CH_2—CH\cdot CH_3\quad\diagup O\end{array}$ Preparation from lævulic acid method (3); occurs in pyroligneous acid (crude acetic acid from the distillation of wood). It boils at 206°–207°, solidifies at −31°, and has sp.gr. 1·072 at 0°. The reduction of lævulic acid to the lactone is very readily effected by hydrogen at 250° (method of Sabatier and Senderens).

α-Methylbutyrolactone $\begin{array}{l}CH_3\cdot CH—CO\\ |\quad\quad\diagdown\\ CH_2—CH_2\quad\diagup O\end{array}$ is a pungent-smelling oil, boiling at 200°–202°.

Caprolactones. γ-*Ethylbutyrolactone* (*n-caprolactone*) $\begin{array}{l}CH_2—CO\\ |\quad\quad\diagdown\\ CH_2—CH\cdot C_2H_5\quad\diagup O\end{array}$ boils at 220°.

α-Ethylbutyrolactone $\begin{array}{l}C_2H_5\cdot CH—CO\\ |\quad\quad\diagdown\\ CH_2—CH_2\quad\diagup O\end{array}$ boils at 215°. *αα-Dimethylbutyrolactone* $\begin{array}{l}(CH_3)_2C—CO\\ |\quad\quad\diagdown\\ CH_2CH_2\quad\diagup O\end{array}$ boils at 200°–201°. *αγ-Dimethylbutyrolactone* $\begin{array}{l}CH_3\cdot CH—CO\\ |\quad\quad\diagdown\\ CH_2—CH\cdot CH_3\quad\diagup O\end{array}$ boils at 206°. *βγ-Dimethylbutyrolactone* $\begin{array}{l}CH_2—CO\\ |\quad\quad\diagdown\\ CH(CH_3)—CH\quad\diagup O\end{array}$ boils at 213°, and *γγ-Dimethylbutyrolactone* (*isocaprolactone*) $\begin{array}{l}CH_2—CO\\ |\quad\quad\diagdown\\ CH_2—C(CH_3)_2\quad\diagup O\end{array}$ boils at 95° (20 mm.), and at 206°–207° under ordinary atmospheric pressure. It melts at +6° and dissolves in 20 parts of water at 0°.

Stearolactone (*γ-tetradecylbutyrolactone*)

$$\begin{array}{l}CH_2—CO\\ |\quad\quad\diagdown\\ CH_2—CH(CH_2)_{13}CH_3\quad\diagup O\end{array}$$

is formed, in yield of 30–40 p.c., when oleic acid, elaïdic acid, or *iso*-oleic acid is warmed with zinc chloride or concentrated sulphuric acid at 80°–85°. It crystallises from alcohol as leaflets melting at 47°–48°.

Behenolactone (*γ-octodecylbutyrolactone*)

$$\begin{array}{l}CH_2—CO\\ |\quad\quad\diagdown\\ CH_2—CH(CH_2)_{17}CH_3\quad\diagup O\end{array}$$

which is formed from erucic acid by the action of sulphuric acid, crystallises from alcohol or ether as plates melting at 63·5°.

The unsaturated monohydroxymonocarboxylic acids also yield γ-lactones, and the following are important members of this series:—

Crotonolactone $\begin{array}{l}CH_2—CH:CH\\ |\quad\quad\quad |\\ O—\quad\quad CO\end{array}$ is formed from vinylacetic acid by converting it into $\beta\gamma$-dichlorobutyric acid by the addition of chlorine and then eliminating hydrogen chloride by heating at 200°–215°. It melts at 4° and boils at 95°–96° (13 mm.):

$$\begin{array}{l}CH_2=CH—CH_2\\ |\quad\quad\quad\\ COOH\end{array} \rightarrow \begin{array}{l}CH_2—CHCl—CH_2\\ |\quad\quad\quad\\ Cl\quad\quad COOH\end{array} \rightarrow \begin{array}{l}CH_2—CH=CH\\ |\quad\quad\quad |\\ O—\quad\quad CO\end{array}$$

Crotonolactone.

$\triangle^{\beta\gamma}$-Angelicalactone $\begin{array}{l}CH_3\cdot C—CH—CH_2\\ |\quad\quad\quad |\\ O—\quad\quad CO\end{array}$ is formed, unaccompanied by the $\triangle^{\alpha\beta}$-lactone (*see* below), when acetyllævulic acid

$$\begin{array}{l}CH_3\cdot C(OCOCH_3)CH_2\cdot CH_2\\ |\quad\quad\quad\quad |\\ O—\quad\quad\quad CO\end{array}$$

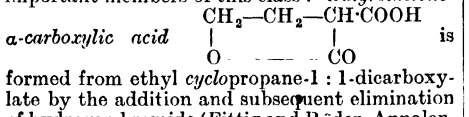
is distilled under 200–230 mm. pressure. It melts at 18°–18·5°, and distils at 55°–56° (12 mm.),

$\triangle^{\alpha\beta}$-Angelicalactone $\begin{array}{l}CH_3\cdot CH—CH=CH\\ |\quad\quad\quad |\\ O\quad\quad CO\end{array}$ is formed from the $\triangle^{\beta\gamma}$ compound by warming it with triethylamine. It does not solidify at −17°, and boils at 89° (15 mm.). The $\triangle^{\alpha\beta}$-lactone is partially converted into the $\triangle^{\beta\gamma}$-lactone on distillation under ordinary pressure (Thiele, Tischbein, and Lossow, Annalen, 1910, 319, 180).

The γ-lactones which are derived from the hydroxydicarboxylic acids are, of course, no longer neutral substances, but contain a free carboxyl group; the following compounds are

important members of this class : *Butyrolactone-α-carboxylic acid*

is formed from ethyl *cyclo*propane-1 : 1-dicarboxylate by the addition and subsequent elimination of hydrogen bromide (Fittig and Rieder, Annalen, 1885, 227, 19) :



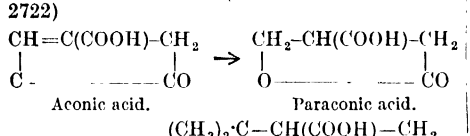
The lactonic acid forms a thick viscid liquid which is readily soluble in water, and when heated at 120° evolves carbon dioxide and passes into butyrolactone. *Butyrolactone-β-carboxylic acid, Paraconic acid*

is formed by the reduction of aconic acid by zinc-dust and acetic acid (Reitter, Ber. 1898, 31, 2722)

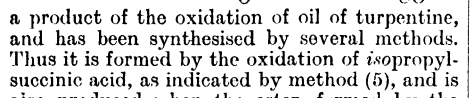
Aconic acid. Paraconic acid.

Terebic acid

is a product of the oxidation of oil of turpentine, and has been synthesised by several methods. Thus it is formed by the oxidation of *iso*propylsuccinic acid, as indicated by method (5), and is also produced when the ester, formed by the condensation of ethyl bromosuccinate with acetone in the presence of zinc (Reformatzky's method), is hydrolysed :



It is also obtained from teraconic acid by warming with sulphuric acid



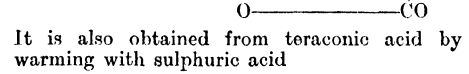
Terebic acid.

Terebic acid crystallises from water as needles which melt at 174°–175°.

Two other lactonic acids, which have played an important part in the elucidation of the chemistry of the terpenes, are terpenylic acid and homoterpenylic acid. *Terpenylic acid*

which occurs frequently as a product of the degradation of the terpenes, was discovered by Hempel and investigated by Fittig and his pupils; its structure was determined by Wallach. The acid has been synthetically prepared by Lawrence (Chem. Soc. Trans. 1899, 75, 529) by the oxidation of *β-iso*propylglutaric acid

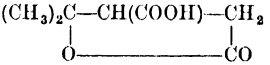
(compare method (5)), and by Simonsen (Chem. Soc. Trans. 1907, 91, 187) by the action of magnesium methyl iodide on ethyl β-acetoglutarate



Ethyl β-acetoglutarate.

Terpenylic acid crystallises with 1 molecule of water as colourless prisms which melt at 56°. The water of crystallisation is removed by sulphuric acid and the anhydrous substance then melts at 89°.

Homoterpenylic acid



was isolated by Baeyer during his researches on the constitution of pinene—the chief constituent of oil of turpentine : its relation to terpenylic acid and terebic acid is shown by the following formulæ :—

Homoterpenylic acid.

Terpenylic acid.

Terebic acid.

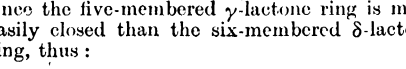
Homoterpenylic acid is, as a matter of fact, converted into terpenylic acid and some terebic acid by oxidation with nitric acid. Homoterpenylic acid has been synthesised by Simonsen (Chem. Soc. Trans. 1907, 91, 184) by treating ethyl β-acetoadipate with magnesium methyl iodide and hydrolysing the product.

The acid crystallises from water as glistening prisms which melt at 103°–102°.

The formation of γ-lactones from polyhydroxycarboxylic acids. Those polyhydroxy derivatives of the carboxylic acids which have a hydroxyl group in the γ-position yield γ-lactones (Fittig, Annalen, 1892, 268, 4, 34, 40, 62, 68).

When hydroxyl groups are present in both the γ- and δ- positions, the γ-lactone is formed, since the five-membered γ-lactone ring is more easily closed than the six-membered δ-lactone ring, thus :

$CH_2(OH)\cdot CH(OH)\cdot CH(OH)\cdot CH(OH)\cdot CH(OH)\cdot COOH$
Gluconic acid.



Gluconolactone.

The hydroxylactones, which are derived from the acids of the sugar group and which therefore contain several hydroxyl complexes, are characterised by showing a greater tendency to crystallise than the hydroxy acids themselves ; their formation has therefore been of considerable service in elucidating the structure of the sugars. The remarkable property possessed by the acids of the sugar group of passing into the aldehyde, that is, the sugar itself, when reduced by nascent hydrogen, thus :

$CH_2(OH)\cdot(CH\cdot OH)_4\cdot COOH \rightarrow CH_2(OH)(CH\cdot OH)_4CHO$
Gluconic acid. Glucose.

is entirely dependent on the formation of the lactone. That is to say, the acid itself is not reducible but only the lactone (E. Fischer, Ber. 1889, 22, 2204 ; 1890, 23, 930).

The following lactones are derived from the pentahydroxycarboxylic acids : *d-Mannonolactone* $C_6H_{10}O_6$ melts at 149°–153°, and has $[\alpha]_D = +53{\cdot}8°$; *l-Mannonolactone* melts at 140°–150°, and has $[\alpha]_D = -54{\cdot}8°$: *(d+l)-Mannonolactone* melts at 149°–155°. *d-Gluconolactone* $C_6H_{10}O_6$ melts at 130°–135° and yields grape sugar when reduced by sodium amalgam. *l-Gluconolactone* melts at 185° and gives *l*-xylose when oxidised by hydrogen peroxide. *d-Galactonolactone* melts at 91° in the anhydrous state, but with water yields a hydrate, containing one molecule of water of crystallisation, which melts at 64°. The *(d+l)-lactone* melts at 122°–125°. *α-Rhamnolactone* melts at 162°–168° ; *β-Rhamnolactone* melts at 134°–138°. The following lactones are derived from the hexahydroxycarboxylic acids : *d-Mannolactone* (m.p. 149°) ; *l-Mannolactone* (m.p. 154°); *α-d-Glucolactone* (m.p. 140°–145°); *β-d-Glucolactone* (m.p. 151°); *α-d-Galactolactone* (m.p. 150°); *d-Fructolactone* (m.p. 130°). These lactones are reduced by sodium amalgam to the corresponding heptoses.

The formation of γ-lactones from the acids of the sugar series has been used by Purdie and Irvine (Chem. Soc. Trans. 1903, 83, 1021) to supply direct evidence of the γ- linkage in glucosides. Thus α-methylglucoside when alkylated by the aid of silver oxide yields tetramethyl-α-methylglucoside which, on hydrolysis, is converted into tetramethylglucose (m.p. 81°–83°). When this substance is oxidised by bromine water it is converted into tetramethylgluconolactone.

$CH_2(OH)CH(OH)\cdot CH\cdot(CH\cdot OH)_2\cdot CH\cdot OCH_3$
α-Methylglucoside.

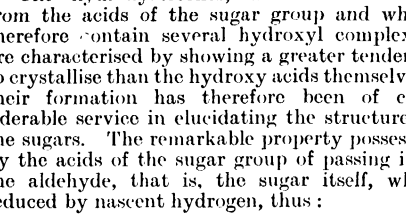
$\rightarrow CH_2(OCH_3)\cdot CH(OCH_3)\cdot CH\cdot(CH\cdot OCH_3)_2\cdot CH\cdot OCH_3$
Tetramethyl-α-methylglucoside

$\rightarrow CH_2(OCH_3)\cdot CH(OCH_3)\cdot CH(OH)\cdot(CH\cdot OCH_3)_2CHO$
Tetramethylglucose (m.p. 81°–83°).

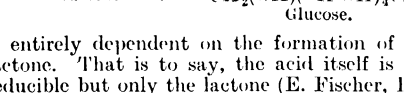
$CH_2(OCH_3)\cdot CH(OCH_3)\cdot CH(OH)\cdot(CH\cdot OCH_3)_2\cdot COOH$
Tetramethylgluconic acid.

$\rightarrow CH_2(OCH_3)\cdot CH(OCH_3)\cdot CH\cdot(CH\cdot OCH_3)_2\cdot CO$
Tetramethylgluconolactone.

Polyhydroxy derivatives of the dicarboxylic acids yield $\gamma\gamma$-dilactones, where possible. Thus $\alpha\alpha'$-dihydroxyglutaric acid yields in the first instance the hydroxylactonic acid melting at 167°–168°, and finally the dilactone (Fittig, Annalen, 1907, 353, 1)

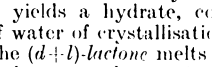


The formation of lactones from alicyclic compounds appears to proceed in much the same manner as with the open chain substances. In many cases, the formation of the lactone proceeds normally as, for example, when bromocamphoric anhydride is converted into camphanic acid by the action of boiling water (Wreden, Annalen, 1872, 163, 330) :



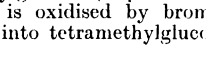
Bromocamphoric anhydride. Camphanic acid.

On the other hand, steric hindrance seems, in some cases, to prevent the formation of the lactone. Thus 1-1-dimethyl-4-hydroxy-*cyclo*-pentane-2-carboxylic acid



shows no tendency to pass into the inner anhydride (Perkin, Thorpe, and Walker, Trans. 1901, 79, 783). It is, however, possible that in this instance the hydroxy acid may represent the *trans*-configuration of this substance, in which case the formation of the lactone would be prevented (*see* orthocoumaric acid).

The γ-lactones of the aromatic series. The following lactones are important members of this series. (For methods of preparation see above.) *The lactone of o-hydroxyphenylacetic acid* $C_6H_4\begin{matrix}CH_2\\O\end{matrix}\!\!>\!CO$, exists in two modifications, a labile form, melting at 28°, and a stable form, melting at 49°. It boils at 248°–252° and is slowly converted into the hydroxy acid on shaking with water. *Phenylbutyrolactone*



melts at 37°. It is volatile with steam and has a pleasant aromatic odour. *Phenylpa. conic acid* $C_6H_5\cdot CH\cdot CH(COOH)\cdot CH_2$ is formed by the condensation of benzaldehyde with sodium

succinate in the presence of acetic anhydride. It crystallises with $\frac{1}{2}H_2O$ and melts at 99°. When dried at 90° it melts at 121° and after resolidifying melts at 106°. If the melted specimen is heated at 115° and seeded with a crystal melting at 121°, the modification of higher melting-point is produced (Fittig, Annalen, 1889, 255, 143). It is sparingly soluble in cold water. *Phthalide* $C_6H_4<^{CO}_{CH_2}>O$ is formed by the reduction of phthalic anhydride and was first obtained by Kolbe and Wischin in 1866 by the reduction of phthalyl chloride

$$C_6H_4<^{CCl_2}_{CO}>O$$

It can also be obtained by the action of bromine on *o*-toluic acid at 140°:

$$C_6H_4<^{CH_3}_{COOH} \rightarrow C_6H_4<^{CH_2Br}_{COOH} \rightarrow C_6H_4<^{CH_2}_{CO}>O$$

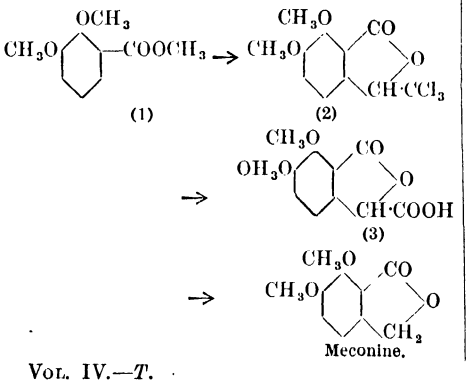
Phthalide.

Phthalide crystallises from hot water as rhombic plates which melt at 73°; it boils at 290° without decomposition and is sparingly soluble in alcohol, ether and in cold water. The lactone is converted by alkalis into the salt of the corresponding hydroxy acid

$$C_6H_4(CH_2{\cdot}OH)COOH$$

This acid is stable, but by long standing in aqueous solution, or by melting, is converted into phthalide.

Meconine  . This substance, which was formerly named *opianyl*, was discovered independently in 1830 by Couerbe and by Dublanc in opium. It also occurs in the root of the *Hydrastis canadensis* (Linn.), and is, moreover, one of the products which are formed when narcotine is oxidised by nitric acid. It has been prepared synthetically by Fritsch in the following way (Annalen, 1898, 301, 352): Methyl 2:3-dimethoxybenzoate (1) is condensed with chloral, under the influence of concentrated sulphuric acid, to form 5:6-dimethoxytrichloromethylphthalide. (2) This compound, when hydrolysed, is converted into the corresponding carboxylic acid, (3) which is transformed into carbon dioxide and meconine when heated:



(1) (2) (3)

Meconine.

Meconine forms white crystals which melt at 101°–102°. It sublimes unchanged and dissolves in 700 parts of water at 15·5° and in 22 parts at 100°.

δ-Lactones. The remarks which have already been made respecting the ease of formation of the γ-lactones from the γ-hydroxy acids apply also to the production of the δ-lactones from the corresponding δ-hydroxy acids, excepting that the six-membered δ-lactone ring is not so readily formed as the five-membered ring of the γ-lactones and is consequently more easily broken.

Aliphatic δ-lactones. δ-*Valerolactone*

$$CH_2<^{CH_2—CH_2}_{CH_2—CO}>O$$

is formed by the reduction of glutaric anhydride:

$$CH_2<^{CH_2{\cdot}CO}_{CH_2{\cdot}CO}>O + 4H$$

Glutaric anhydride.

$$\rightarrow CH_2<^{CH_2—CH_2}_{CH_2—CO}>O + H_2O$$

It boils at 113°–114° (13·14 mm.) and at 220° under ordinary atmospheric pressure, is sparingly soluble in water and is characterised by passing, on standing, into a crystalline polymeride melting at 47°–48°. When water is added to the lactone an acid reaction is at once obtained, showing that the lactone ring is readily broken.

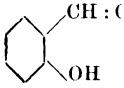
δ-*Caprolactone*, $CH_3CH{\cdot}CH_2{\cdot}CH_2{\cdot}CH_2$ (O———CO) was the first δ-lactone of the aliphatic series to be prepared, and was obtained by Fittig and Wolff (Annalen, 1883, 216, 127) by the reduction of γ-acetobutyric acid:

$$CH_3{\cdot}CO{\cdot}CH_2{\cdot}CH_2{\cdot}CH_2{\cdot}COOH \rightarrow CH_3{\cdot}CH(O)CH_2{\cdot}CH_2{\cdot}CH_2{\cdot}CO$$

It boils at 230°–231° and forms needles melting at 17°–19°. It is miscible with water and absorbs moisture from damp air, passing into the hydroxy acid.

Aromatic δ-lactones. Several δ-lactones of the aromatic series are of considerable importance because they either occur free in nature or are obtained as the products of fission of certain natural glucosides. They are largely used industrially for the preparation of perfumes.

Coumarin  which is the δ-lactone of *o*-hydroxycinnamic acid



may be regarded as the prototype of this group to which the general name of 'the Coumarins' is applied, chiefly because the other members of the series are derivatives of coumarin in which hydroxyl or methoxyl groups are present in the benzene nucleus,

The coumarins may be prepared either by applying the Perkin method for the synthesis of

coumarin (see below) to the necessary derivatives of salicylaldehyde, or by the v. Pechmann method, which is carried out by heating phenols with malic acid in the presence of concentrated sulphuric acid (v. Pechmann, Ber. 1884, 17, 929; v. Pechmann and Welsch, *ibid.* 1646). This reaction is explained by assuming that the strong sulphuric acid first decomposes malic acid into carbon monoxide, water, and hydroxyacrylic acid, thus:

$$COOH{\cdot}CH(OH)CH_2{\cdot}COOH$$

Malic acid.

$$\rightarrow CO+H_2O+CH(OH):CH{\cdot}COOH$$

and that the hydroxyacrylic acid then condenses with the phenol to form the coumarin, thus:

$$HO{\cdot}C_6H_4{\cdot}OH+HO{\cdot}CH:CH{\cdot}COOH$$

Resorcinol.

$$=H_2O+HO{\cdot}C_6H_3\langle{}^{OH}_{CH:CH{\cdot}COOH}$$

$$\rightarrow H_2O+HO{\cdot}C_6H_3\langle{}^{O\text{——}CO}_{CH=CH}$$

Umbelliferone.

This reaction yields the best results with the *m*-substitutes phenols. *Coumarin* was first isolated in 1820 from Tonka beans, the seed of the *Dipteryx odorata* (Willd.), and was subsequently characterised by Guibort. It was first prepared synthetically by Perkin from salicylaldehyde by heating with sodium acetate and acetic anhydride:

$$C_6H_4\langle{}^{OH}_{CHO}+(CH_3CO)_2O$$

$$\rightarrow C_6H_4\langle{}^{O{\cdot}CO{\cdot}CH_3}_{CH(OH)CH_2{\cdot}COOH}$$

$$\rightarrow C_6H_4\langle{}^{O\text{——}CO}_{CH:CH}+CH_3{\cdot}COOH+H_2O$$

This synthesis may, moreover, be applied to the formation of other coumarins since, by the method of Gattermann (Ber. 1899, 32, 278, 287), many hydroxyaromatic aldehydes can now be prepared from phenols by the action of hydrocyanic and hydrochloric acids in the presence of aluminium chloride.

Coumarin forms prismatic crystals which melt at 67° and boil at 290°–290·5°. It is sparingly soluble in cold water but readily dissolves on warming. The corresponding hydroxy acid, coumarinic acid, cannot be isolated in the free state, but when coumarin is boiled for some time with a solution of potassium hydroxide, an acid separates on acidification which decomposes above 200° with evolution of carbon dioxide but does not yield coumarin (Zwenger, Annalen Suppl. 1872, 8, 23). This acid, which is called orthocoumaric acid, is stereoisomeric with the unstable coumarinic acid (Clayton, Chem. Soc. Trans. 1910, 2102) the two acids being represented by the formulæ:

$$H\text{—}C\text{—}COOH \qquad H\text{—}C\text{—}COOH$$
$$\quad\| \qquad\qquad\quad\|$$
$$H\text{—}C\text{—}C_6H_4{\cdot}OH \qquad HO{\cdot}C_6H_4\text{—}C\text{—}H$$

Coumarinic acid (cis-form) *o*-Coumaric acid (trans-form).

The ease of formation of coumarin from coumarinic acid is explained by the proximity of the hydroxyl and carboxyl groups in the cis-configuration (*cf.* Borsche, Ber. 1904, 37, 346).

Umbelliferone, Hydroxycoumarin

$$HO\text{—}C_6H_3\langle{}^{CH:CH}_{O\text{——}CO}$$

This substance, which is the δ-lactone of 2 : 4-dihydroxycinnamic acid, is found in the bark of the *Daphne Mezereum* (Linn.) and is also obtained by distilling various resins such as galbanum and asafœtida. Its synthesis may be effected directly from resorcinol by v. Pechmann's malic acid method, or indirectly from resorcylaldehyde by the aid of Perkin's reaction, a method which establishes the position of the hydroxyl group in umbelliferone:

$$HO\text{—}C_6H_3(CHO)(OH) \rightarrow HO\text{—}C_6H_3\langle{}^{CH=CH}_{O\text{——}CO}$$

Resorcylaldehyde. Umbelliferone.

Umbelliferone crystallises from hot water in slender needles melting at 225°. It dissolves very sparingly in water, yielding a solution which shows a marked blue fluorescence.

Herniarin is the methoxyl derivative of umbelliferone $CH_3O{\cdot}C_6H_3\langle{}^{CH=CH}_{O\text{——}CO}$, and occurs in *Herniaria hirsuta* (Linn.) (Barth and Herzig, Monatsh, 1889, 10, 161). It melts at 117°–118°.

Daphnetin $HO_2{\cdot}C_6H_2\langle{}^{CH=CH}_{O\text{——}CO}$ is obtained by the fission of the glucoside daphnin, either by acids or by ferments. It can be prepared synthetically either from pyrogallol by the malic acid method or from pyrogallolaldehyde by Perkin's reaction; the second method of preparation determines the positions of the hydroxyl groups in daphnetin:

$$HO(HO)(OH)C_6H(CHO) \rightarrow OH(HO)(OH)C_6H\langle{}^{CH=CH}_{O\text{——}CO}$$

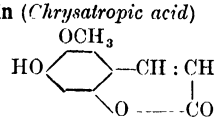
Pyrogallolaldehyde. Daphnetin.

Daphnetin crystallises as needles or prisms, melts at 256°, and develops a pleasant coumarin-like smell when heated. It dissolves in alkali, forming a reddish-yellow solution and gives in aqueous solution a green coloration with ferric chloride.

Æsculetin $(OH)_2C_6H_2\langle{}^{CH=CH}_{O\text{——}CO}$, is isomeric with daphnetin. It occurs in the bark of the horse chestnut, partly free and partly as the glucoside æsculin. It also occurs in the seed of the *Euphorbia Lathyris* (Linn.), and can be prepared synthetically from hydroxyhydroquinone by converting this substance into hydroxyhydroquinonealdehyde $HO_2(CHO)C_6H$, by means of hydrocyanic and hydrochloric acids in the presence of zinc chloride (Gattermann's reaction), and then by subjecting the aldehyde to the Perkin reaction. Æsculetin crystallises

from water as leaflets or needles, melts at 268° with decomposition, and is sparingly soluble in cold water, but readily dissolves in hot water and in alcohol. The aqueous solution, which has a faint blue fluorescence gives a green coloration with ferric chloride. The lactone dissolves in alkali, forming a yellowish-red solution.

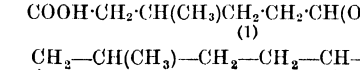
Scopoletin (*Chrysatropic acid*)



which is the methoxyl derivative of æsculetin, was isolated by Eykman (Rec. trav. chim. 1884, 3, 171) from the rhizome of *Scopolia japonica* (Maxim.). It also occurs in *Atropa belladonna* (Linn.), in *Gelsemium*, in the bark of the *Prunus serotina*, and in jalap. The lactone crystallises from ethyl acetate as needles which melt at 204°, and exhibits a fine blue fluorescence in aqueous solution, which is enhanced by the addition of alkali. The constitution of this substance as 4-hydroxy-5-methoxy-coumarin has been determined by Moore (Chem. Soc. Trans. 1911, 99, 1043).

ϵ-Lactones. The existence of ϵ-lactones has been shown to be possible by the researches of v. Baeyer and his collaborators. Thus when the hydroxy acid (1) is distilled, it is partially decomposed into water and the ϵ-lactone: β-methyl-ϵ-*iso*propyl-ϵ-caprolactone (2) (Baeyer and Öhler, Ber. 1896, 29, 29; Baeyer and Seuffert, *ibid.* 1899, 32, 3619):

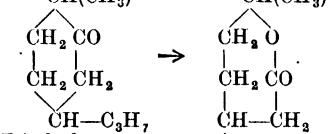
$$COOH\cdot CH_2\cdot CH(CH_3)CH_2\cdot CH_2\cdot CH(OH)CH(CH_3)_2$$
(1)



(2)

The hydroxy acid (1), which is derived from menthone by oxidation and subsequent reduction, exists in two forms, one of which is liquid, the other solid. There are, therefore, two lactones (both of which are feebly lævorotatory), one melting at 47° derived from the solid acid, and the other, a liquid boiling at 135° (12 mm.) derived from the liquid acid. Both modifications of the lactone are insoluble in cold alkali but dissolve on warming. The solid ϵ-lactone (m.p. 47°) is also formed when menthone is oxidised by Caro's acid (Baeyer and Villiger, Ber. 1899, 32, 3628; 1900, 33, 860).

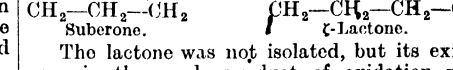
β-*iso*-Propyl-ϵ-methyl-ϵ-caprolactone is formed when tetrahydrocarvone is treated with Caro's acid (Baeyer and Villiger, Ber. 1899, 32, 3629; Wallach, Annalen, 1902, 323, 331):



Tetrahydrocarvone. ϵ-Lactone.

The lactone boils at 155·5° (21 mm.).

ζ-Lactones. An unstable lactone of this series is formed when suberone is treated with Caro's acid (Baeyer and Villiger, Ber. 1900, 33, 862; v. Braun, *ibid.* 1906, 39, 4362):



Suberone. ζ-Lactone.

The lactone was not isolated, but its existence in the crude product of oxidation was inferred from the fact that when treated with alcohol and sulphuric acid it was converted into the ethyl salt of ζ-hydroxyœnanthylic acid

$$OH(CH_2)_6COOR$$

LACTOPHENIN *v.* SYNTHETIC DRUGS.

LACTOSE *v.* CARBOHYDRATES.

LACTUCARIUM. *Lettuce opium.* The inspissated juice of *Lactuca virosa* (Linn.) (*Lactucarium*, U.S.P.), and other species of *Lactuca* (*v.* Woodville, Med. Bot. 1, 31; Bentl. a. Trim. 160, 161). Lactucarium is sometimes employed in medicine as a substitute for opium, and has often been examined chemically.

Half the weight of lactucarium, or more, consists of the tasteless inodorous compound *lactucerin* or *lactucon*, first obtained in a crystalline form by Lenoir (Annalen, 59, 83). It has been repeatedly investigated, with varying results, apparently last by Pomeranz and Sperling (Monatsh. 1904, 25, 785), who by extraction of *Lactucarium germanicum* (from *L. virosa*) with light petroleum obtained *lactucon* (=*lactucerin*) $C_{23}H_{36}O_2$, needles m.p. 183°, $[\alpha]_D^{18°}+50°$, readily soluble in most organic solvents and hot alcohol, but not in water. It is the acetate of *lacticol* $C_{21}H_{34}O$, m.p. 154·5°.

French lactucarium (from *L. virosa* or *L. altissima*) has been examined by Franchimont and Wigman (Ber. 1879, 12, 10), who obtained a lactucon which may or may not be identical with that above-mentioned. The bitter taste, and probably the medicinal properties of lactucarium, are, however, due to small quantities of *lactucin* $C_{11}H_{12}O_3,H_2O$, crystallising from hot water (Kromeyer, Arch. Pharm. 1861, 105, 3), and possibly to other substances. For the rest (German) lactucarium contains 8–10 p.c. of inorganic matter, 2 p.c. of mannitol, free oxalic acid (up to 1 p.c.), citric and malic acids, sugar, gum, asparagin, protein, caoutchouc, and resin (Kremel, Pharm. Zentralh, 1888, 512).

For *L. canadensis*, see Flowers (Pharm. J. [iii] 10, 44). G. B.

LACTUCERIN, LACTUCIN, LACTUCOL, and **LACTUCON** *v.* LACTUCARIUM.

LAC VARNISH *v.* VARNISH.

LADANUM, is a resinous exudation of Cistus *Spp.*, more particularly of *Cistus creticus*. It is dark brown in colour, softens readily when worked in the fingers, and has a peculiar pleasant odour with a balsamic, bitter, pungent taste. Partially soluble in ether, chloroform, and alcohol, practically insoluble in water or light petroleum. Consists of a brown resin, an essential oil, and a solid crystalline substance, *ladaniol* $C_{17}H_{30}O$, m.p. 89°, resembling champacol and guaiol. The portion of ladanum insoluble in ether and alcohol contains a bassorin-like gum, which gives mucic acid on oxidation with nitric acid; a greyish-white, pulverulent resin; and bitter substance (Emmanuel, Arch. Pharm. 1912, 250, 111).

LAKES. The origin of their manufacture, as well as of the term 'lake' itself, is seen from the following brief historical sketch :—

According to Pliny, the dried scum collected by the dyers of Tyrian purple from their dye-liquors furnished a costly purple-coloured pigment employed by painters. The *indicum* of the Roman artists was probably obtained in the same manner from a woad or indigo vat. Caneparius, a Venetian writer on dyeing, in 1619, states that it was the custom of dyers to evaporate the waste lac dye-liquors in order to obtain an artificial lac used by artists.

Similar pigments were afterwards prepared or collected from the waste dye-liquors of kermes, brazilwood, &c. Such pigments were called by the Italians *lacæ*, and these were distinguished from each other by adding the name of the substance whence the colour was derived—*e.g. lacca di verzino* (Brazilwood), *lacca di grana* (kermes), *lacca di cremise*, &c.

As to the word 'lake' itself, the Indian 'lac' or 'lakh' means a hundred thousand, and refers to the immense numbers in which the lac insects (*Coccus laccæ*) appear at certain seasons on the branches of the trees infested with them.

At the present time true lakes are like those of the early days—namely, insoluble pigments obtained by precipitating solutions of organic colouring matters with metallic salts, &c. They are, indeed, the same coloured precipitates which it is the object of the dyer to produce and fix directly on the fibre, but they are no longer the waste products of the dye-bath, but are specially prepared for the use of artists and others.

The precipitating agent employed in their preparation varies according to the nature of the colouring matter; if the latter is of an acid or phenolic character the active constituent of the former is of a basic character, and *vice versâ*. The essential part of all such lakes consists of colouring matter chemically combined with the active constituent of the precipitating agent. In some cases, no doubt, there may be colouring matter or precipitating agent mechanically mixed with the true lake, the amount varying according to the proportions and the method of preparation adopted; but these must be regarded as more or less adventitious and not essential to the composition of a lake

Most of the vegetable colouring matters are of a phenolic character, and the metallic compounds of some are so insoluble that, to produce lakes from them, it suffices to add to a filtered solution of the colouring matter the solution of the metallic salt, for example, alum. In most cases, however, the acid character of the colouring matter is not sufficiently pronounced to enable it to displace the acid of the metallic salt; hence the further addition of an alkali (*e.g.* sodium carbonate) is necessary, in order to neutralise the strong acid of the salt and to liberate the base, with which the colouring matter then combines to form the lake.

If it is possible to employ an alkaline solution of the colouring matter, a lake may be at once obtained on adding to it a metallic salt solution.

Freshly precipitated metallic hydroxides are also capable, in many cases, of attracting and combining with phenolic colouring matters when agitated or heated with their solutions.

It is well to bear in mind that not unfrequently the normal compounds of a colouring matter with a single metallic hydroxide are comparatively soluble, and in these cases the addition of a second metallic salt (*e.g.* calcium salts) may be found necessary to bring about the formation of the lake, which then bears the character of a double salt. All the older lakes, derived from vegetable or animal colouring matters, were produced by one or other of the foregoing methods; and these same methods may be employed with all phenolic colouring matters produced from coal tar. A variety of pigments are now obtained by precipitating certain basic and acid coal tar colours from their solutions by making suitable additions, and although they are not always veritable lakes, they usually bear the name 'aniline lakes,' and are, therefore, most conveniently considered here.

In some cases, no doubt, certain elements of the precipitant combine with the colouring matter, and produce an insoluble pigment to which the term 'lake' may be legitimately extended. In those instances, however, where their production depends upon the property, possessed by many insoluble bodies, of attracting the colouring matters from their aqueous solutions by mere absorption, or in virtue of molecular surface attraction, &c., they cannot be regarded as true lakes. The same remarks apply to the modern pigments from insoluble azo colours (pigment colouring matters) and the developed or ice colours.

Such insoluble substances as are here referred to act as a base or substratum for the colouring matter; they are termed 'carriers,' and consist of kaolin, aluminium hydroxide, barytes, &c.

It is quite usual, however, to find such insoluble bodies mixed with all lakes, not as precipitants, but for the purpose of increasing the body or covering power of the pigment, or as diluents in order to obtain pale shades.

Good lakes should never dissolve in the vehicles by means of which they are applied as pigments, otherwise all their covering power will be lost, and what should be a paint becomes in this case merely a coloured varnish.

LAKES DERIVED FROM PHENOLIC COLOURING MATTERS.

Reds.

Madder-lake. In the preparation of madder-lake extraction of the madder with *boiling* water is avoided, in order not to dissolve those impurities which would cause the production of a less brilliant lake. It is well, first of all, to decompose the glucoside of the madder, and thus increase the actual colouring matter, by steeping in slightly tepid water and allowing the mixture to ferment for 24 hours, then wash with cold water and extract with alum solution at 60°–70°, employing about equal weights of madder and alum. The hot filtered alum solution of the colouring matter is precipitated as an

alumina lake by adding sodium carbonate, and the precipitate is washed.

Another method is to precipitate impurities from a hot filtered decoction of madder by adding a small quantity of lead acetate, then filter, add a solution of alum, and precipitate with sodium carbonate.

Matters may be so arranged as to precipitate basic aluminium sulphate instead of aluminium hydroxide, namely, by adding an insufficiency of sodium carbonate to the cooled solution of alum and colouring matter, and then boiling the mixture.

Garancine is preferable to madder for preparing madder-lake, since it does not contain any of the colouring matter in the form of glucoside (ruberythric acid), and the soluble impurities have also been for the most part removed. Extract 1 kilo. garancine repeatedly for several hours with 20 litres of boiling water containing 0·25–0·5 kilo. alum, and filter hot through flannel. On cooling, the colouring matter separates from the filtrate as a flocculent precipitate. This is collected and dissolved in ammonia, and the filtered solution is precipitated with alum, or stannous chloride, or a mixture of both. The colour intensity of the lake varies with the proportions of ammonia and precipitant employed. A method similar to that described for madder may also be employed in preparing madder-lake from garancine.

Bright carmine-red lakes are obtained if, in the preparation of madder-lake, an ammoniacal solution of cochineal-carmine is employed for precipitating the alum solution, instead of the sodium carbonate. This method can be adopted to render the lower qualities of madder-lakes more attractive. Cheap qualities of madder-lakes are also prepared sometimes by extracting mixtures of madder and Brazilwood with sodium carbonate, and precipitating with alum or a solution of tin.

So-called 'crystallised-madder-lakes' are such as contain a certain quantity of potassium or sodium sulphate, &c., and are not to be recommended.

'Madder-pink-lake' is simply madder-lake diluted with about 7 parts of 'blanc fixe' (precipitated barium sulphate).

Madder-lake is entirely, or for the most part, soluble in caustic potash and soda. If chalk or other diluent is present, this may remain undissolved. Boiled with dilute sulphuric or hydrochloric acid, the lake is decomposed, alizarin being liberated in the form of a flocculent or crystalline precipitate. In dilute ammonia pure well-made madder-lake is not soluble (distinguishing test from cochineal-carmine).

References.—Colomb, Bull. Mülh. 12, 307; Dingl. poly. J. 73, 47; Persoz, Traité de l'Impression des Tissus, 1, 507; Merimé, *ibid.* 1, 505; Robiquet and Colin, *ibid.* 1, 505; Khittel, Polyt. Centr. 1859, 81.

Alizarin-red lake is the modern representative of the old madder-lake. It is made either with alizarin (20 p.c.) only, or with mixtures of alizarin and purpurin. Generally the alizarin-red lake contains, in addition to alizarin and aluminium hydroxide, calcium salts, sulphated oil (Turkey-red oil), and sodium phosphate; the exact function of these latter in the formation of the lake is not properly understood, but they exercise great influence on the brightness of the final product as well as in rendering it less sensitive to the action of dilute acids and alkalis.

The Turkey-red oil may be assumed to influence the brilliancy of the shade as in the production of Turkey red by the dyer; the part played by the sodium phosphate is more obscure, but it is always present in the finished lake, and without it there is a loss in brightness.

The absence of calcium salts is also detrimental; in most cases no satisfactory lake can then be obtained.

The general procedure is to dissolve the alizarin in a cold solution of soda, adding in succession the sodium phosphate and Turkey-red oil with thorough stirring to ensure complete admixture. The solution of aluminium sulphate is then run in at such a rate that the evolution of carbon dioxide never becomes very vigorous. When no more gas is given off the requisite amount of lime-water is included and the whole mass stirred for many hours; heat is applied very gradually, so that the boiling-point is reached in 4 or 5 hours, always stirring. After boiling for several hours the lake is allowed to cool, well washed by decantation, filtered, and dried at the temperature of the air.

A method given by Meister, Lucius, and Brüning for their brands of alizarin RR and IB extra, is as follows:—

2 kilos. aluminium sulphate 18 p.c. are dissolved in 13 litres of water and precipitated hot by the addition of a solution of sodium carbonate (1 kilo. calcined soda in 7 litres of water), stirring continuously. The precipitated alumina is boiled for half an hour to remove the last traces of carbon dioxide, and after standing overnight, the supernatant liquor is decanted off.

To this cold substratum the solution of sodium phosphate (0·16 kilo. in 1·8 litres water) is next added, and subsequently calcium chloride (1·266 kilos. liquor, 24°Bé., diluted with 2 litres of water) in the same manner, stirring well during the additions, and taking care that the former has been thoroughly incorporated before proceeding with the latter.

2 kilos. of the colouring matter mixed with 2 litres of water and 0·6 kilo. of Turkey-red oil (50 p.c.) diluted with 0·8 litre of water are further run in with the same precautions and the whole heated gradually to boiling within 1 hour and boiled for 2½ hours, stirring throughout the whole time as before.

Modern improvements in the methods of manufacturing alizarin-red lakes have furnished results showing a much higher degree of intensity and brightness than was formerly possible. After-treatment of the lake by boiling (steaming) under pressure is said to yield brilliant shades and of great intensity.

Slight additions of tin salts are also added on occasion to brighten the shade.

In making alizarin-red lake it is very essential that the aluminium sulphate employed be free from iron if brilliant lakes are desired. Further, the solutions should be as dilute as possible, as this ensures fineness of structure and softness in the finished article.

Maroon and **claret-red lakes** are produced from alizarin with chromium salts, and **purple lakes** may be obtained by the aid of iron salts.

In connection with the production of

alizarin-red lake, the following observations of Liechti and Suida (Mittheil. Gewerb. Museum, Wien, May, 1885) are of interest.

Pure aluminium hydroxide is incapable of directly forming a lake with alizarin—*e.g.* when boiled with an aqueous solution of the latter. The addition, however, of calcium salts at once effects the formation of a lake.

Aluminium-alizarin lakes of definite composition are best prepared by mixing solutions of aluminium salts with an alkaline solution of alizarin. Lakes are also produced if a solution of aluminium acetate mixed with alizarin is heated; or if aluminium hydroxide is heated with alizarin and ammonia, and the mixture is carefully neutralised with acetic acid; or if a mixture of aluminium hydroxide, alizarin, and concentrated sodium acetate solution is heated.

Normal aluminium alizarate $Al_2(C_{14}H_6O_4)_3$, produced by the double decomposition of solutions of aluminium sulphate and ammoniacal alizarin (1 mol. Al_2O_3 to 3 mols. alizarin), forms a purplish-red precipitate, which changes to purplish-black on drying. It is soluble in distilled water and alcohol with a red colour, and in alkalis, especially ammonia, with a fine purplish-red tint. Basic aluminium alizarates of definite composition are prepared by proportionately decreasing the amount of alizarin employed in the above-mentioned decomposition.

$Al_4(C_{14}H_6O_4)_3(OH)_6$ is a bright-red precipitate changing to brownish-red on drying. It is soluble in ammonia with a bright-red colour. $Al_2(C_{14}H_6O_4)(OH)_4$ is also a bright-red precipitate, which gives a red powder on drying. In ammonia it is much less soluble than the foregoing. $Al_4(C_{14}H_6O_4)(OH)_6$ is a bright-red precipitate, which still remains a fiery-red powder on drying and is very sparingly soluble in ammonia. All the above basic aluminium alizarates are insoluble in water and in alcohol.

Alkaline solutions of normal aluminium alizarate and of the basic compound

$$Al_4(C_{14}H_6O_4)_3(OH)_6$$

may be mixed with solutions of sodium phosphate, sulphated oil, soap, &c., without undergoing decomposition, but, on neutralising these mixed solutions with acids, very brilliant red lakes are precipitated. Normal aluminium phosphate $Al_2(PO_4)_2$ obtained by precipitation and well washed, cannot be dyed with alizarin. The formation of a lake only occurs when a calcium salt, *e.g.* calcium acetate, is also added. Aluminium-calcium-alizarin lakes of varied composition may be prepared by boiling together definite proportions of pure aluminium hydroxide, calcium acetate solution, and alizarin. They form either dark or bright brownish-red precipitates. All are insoluble in water, and some are insoluble in ammonia. The amount of calcium entering into the composition of the lakes produced in this manner depends upon the amount of alizarin employed and *vice versâ*.

The probable formula of normal alizarin-red lake is given as $Al_2Ca(C_{14}H_6O_4)_3(OH)_2$ by the above-mentioned authors.

Cochineal-carmine. In the preparation of this brilliant scarlet-lake, cochineal is extracted in tin-lined vessels with a large quantity of boiling water. Certain additions are made to the filtered decoction, and it is then allowed to stand for several weeks, or even months, in shallow vessels of tin or porcelain, during which period the carmine gradually separates in the form of a fine red powder. The additions referred to vary with different makers, and include the following: potassium binoxalate, acid potassium tartrate (cream of tartar), alum with or without cream of tartar, hydrochloric acid, &c. In all cases the presence of iron must be strictly avoided. The necessary ingredients may also be added to the water with which the cochineal is boiled, in which case the decoction must be filtered hot, since it rapidly becomes turbid on cooling. The addition of gypsum, calcium carbonate, zinc oxide, &c., so usual in other cases, must be avoided, since these would produce violet-coloured lakes.

The manufacture of cochineal-carmine is now very restricted, and the methods employed for producing the finest product have always been kept secret.

According to Alyon and Langlois 500 grams cochineal are boiled for 1½ hours in 30 litres water containing 25 grams sodium carbonate. The decanted solution is well stirred up with 25–35 grams powdered alum, and then allowed to settle about 20 minutes; the clear liquid is poured off, a dilute solution of isinglass or albumen is added, and the whole is heated until the carmine collects together in the form of a coagulum. After cooling and allowing to settle, the supernatant liquid is decanted off, the carmine is collected on a filter, washed, and dried at a low temperature. The deeply coloured filtrate serves for the production of carmine-lake.

Even alum alone could apparently be used as the precipitating agent, according to an old recipe, but it seems likely that in this case water possessing an alkaline reaction must of necessity have been employed. Boil 16 parts ground cochineal for 10 minutes with about 600 parts of water, then add 1 part ground alum, boil a few minutes longer, filter the hot solution and allow the filtrate to stand in shallow porcelain basins. In the course of a few days the carmine is said to separate in the form of a red slimy precipitate, which is collected and dried. The decanted liquor on standing yields a further quantity of carmine of a lower quality; its precipitation is facilitated by the addition of a small quantity of stannous chloride.

The residual cochineal which has thus been only partially exhausted serves for the preparation of carmine-lake.

In other similar recipes a mixture of alum and cream of tartar is used instead of alum only, but in that of Madame Cenette, at one time a celebrated maker of carmine, the statement that the effective precipitating agents are potassium nitrate and potassium binoxalate is difficult to understand.

Chinese carmine is said to be prepared by extracting cochineal with a boiling solution of alum, heating the filtered decoction with the addition of a solution of tin in nitric and hydrochloric acid (*aqua regia*), and finally leaving the liquid to stand till the carmine separates.

Cochineal-carmine is insoluble in water but soluble in alcohol. In ammonia solution it dissolves readily with a purplish-crimson colour;

from this solution tartaric acid precipitates the original carmine, for although when dried the precipitate has a brownish-red colour it becomes bright red when powdered. The following analysis of cochineal-carmine is given by C. Liebermann (Ber. 18, 1969):

Moisture	17 p.c.
Nitrogenous matter	20 ,,
Ash	7 ,,
Colouring matter	56 ,,
Wax	traces

The ash consists of SnO_2 0·67 p.c., Al_2O_3 43·09, CaO 44·85, MgO 1·02, Na_2O 3·23, K_2O 3·56, P_2O_5 3·20. From these analyses Liebermann considers cochineal-carmine to be a peculiar aluminium-calcium-protein compound of the carmine colouring matter, somewhat analogous to the Turkey-red lake, in which alizarin is combined with aluminium and calcium. According to the experiments of the late J. Bedford of Leeds, cochineal-carmine can only be prepared if a calcareous water is employed, or if calcium salts are added during the reaction. Cochineal-carmine can, indeed, be readily produced by adding to a cold extract of the dye prepared with a hard water potassium carbonate, alum, and subsequently cream of tartar (or potassium binoxalate) in definite proportion. The carmine precipitate separates very gradually during some days, and has an extremely brilliant character. If a small quantity of stannic chloride is also added to the mixture the precipitation is hastened and the product possesses a more scarlet tint (private communication).

Carmine-lake is simply an ordinary aluminium or tin lake of the colouring matter of cochineal, produced by adding sodium carbonate to a cochineal decoction containing alum or stannous chloride, or both. The latter may also be added to an alkaline solution of the colouring matter.

Florentine-lake is merely a special quality of carmine-lake, containing usually an excess of alumina, and sold in the form of 'drops'; and the so-called Venetian-lake, Hamburg-, Chinese-, Roman-, and scarlet-lakes, are all varieties of Florentine-lake.

Brazil Indian-lake or **lac-lake** is a dark purplish-red lake analogous to carmine-lake, and prepared in a similar manner from the Indian product 'lac.'

Brazilwood-lake can be prepared by extracting Brazilwood or peachwood with boiling water, adding alum and tin solution to the filtered decoction, and finally precipitating with sodium carbonate, avoiding excess. Another method is to add precipitated and washed aluminium hydroxide to a filtered decoction of Brazilwood. Freshly prepared decoctions are never suitable for the manufacture of these lakes; they should always be oxidised, by exposure to air or otherwise, in order to change the principle brazilin into the necessary colouring matter brazilein.

Vienna-lake is a species of Brazilwood-lake, prepared in the following manner: A mixture of ground starch (30 kilos.), chalk (10 kilos.), and a little gypsum, is stirred up with a decoction of Brazilwood; then ground alum (1 kilo.) is added and the whole is well stirred for 12 hours and finally allowed to settle. After decanting the clear liquor, Brazilwood decoction is again added to the residual precipitate, together with a further quantity of alum (1 kilo.), and the stirring is continued as before. This process is repeated until the precipitate has taken up sufficient colouring matter and acquired the character of a lake. The decanted liquors are agitated with fresh starch, chalk, &c., in order to yield further quantities of lake.

In the foregoing process the alum is decomposed by the chalk, and the alumina precipitate thus produced combines with the colouring matter. At first the lakes appear violet through the presence of excess of chalk, but with the continued addition of alum they gradually acquire a crimson colour.

Fine dark carmine-red lakes are obtained by adding stannous chloride and cream-of-tartar to a concentrated old decoction of Brazilwood.

Yellows.

Persian-berry lake is prepared by extracting Persian-berries two or three times with boiling water, dissolving alum in the combined and filtered liquors, and then precipitating with sodium carbonate, taking care to avoid excess. The precipitate is collected on a filter, washed, and sold in the form of paste. This lake, containing much starch, and sold in the dry form, is said to be employed in the colouring of sweetmeats.

Persian-berry carmine is produced if stannous chloride is employed instead of alum in the above process. It is a bright orange lake employed by calico-printers.

Persian-berry lakes may also be made after the manner of Vienna-lake, *i.e.* with the use of chalk, alum, and starch.

It is essential to employ only freshly prepared decoctions if bright-coloured lakes are desired.

The following procedure is described by Zubelen (Bull. Soc. Ind. Mulhouse, 1919, 84, 511): The berries are extracted to form an infusion of 2°–3°Bé. (sp.gr. 1·013–1·020). Solutions of salts of tin and aluminium are then added, and the liquor is neutralised with 300 litres of caustic soda solution. The ingredients required are: 300 kilos. Persian berries, 90 kilos. of tin salt, 15 kilos. of potash alum, and 31 kilos. of caustic soda. If the neutralisation be performed at 50° immediately after the addition of the mordants, no rhamnetin is produced, and the canary-yellow lake corresponds to xanthorhamnin. By operating at 100° some rhamnetin is formed and the lake has an orange shade. By working between 50° and 100° and allowing the acid salts to react for a quarter of an hour before neutralising, shades ranging from canary-yellow at 50° to deep orange at 100° may be obtained, according to the proportion of rhamnetin produced (J. Soc. Chem. Ind. 1919, 712, A.).

Quercitron-yellow lake, Flavin-lake, or **Dutch-pink** is made according to the method adopted in the case of Venetian-lake, by precipitating a decoction of quercitron-bark containing alum with chalk. The methods employed in making yellow lakes from Persian-berries may also be used. To ensure bright colours the decoction of quercitron bark is clarified by adding a little gelatin solution, thereby removing the tannic

acid. Sometimes milk of lime is used instead, taking care to avoid excess.

It is said that these quercitron colours retain their intensity by gaslight better than all other vegetable yellows, and are hence useful for theatre decoration, &c.

The yellow natural colouring matters, especially flavine and Persian berries, are still in some demand for the production of green lakes by combination with basic green artificial colouring matters.

The yellow-lake is first prepared and a solution of the coal-tar colour precipitated upon it by tannin and tartar emetic. A partial precipitation of the basic colour is effected by the tannic acid in the vegetable colour, but must be completed by a further addition. These lakes are used for wall papers and for colouring toys.

Stil de grain is a low quality of Dutch-pink.

English- and **Italian-pinks** are other qualities of quercitron-bark yellow lakes.

The above lakes are sold in the dry condition in the form of pyramidal-shaped 'drops.' They never possess the brilliancy of those obtained from Persian-berries.

Lakes from vegetable colouring matters have no longer their former importance, and there can be little doubt that most of them will eventually become obsolete.

Lakes derived from Artificial Colouring matters.

The great increase in the number and variety of coal-tar colouring matters has given rise to a corresponding increase in the colour lakes made from them. Moreover, many of the lakes so formed are at least as fast as any obtainable from natural colouring matters. In consequence the latter have lost much of their former importance.

In the preparation of these lakes the 'base' or 'carrier' upon which the colouring matter is precipitated in a more or less insoluble form is a most important element, since it determines in great measure their brilliancy, covering power, and general qualities.

On the other hand, upon the character of the colouring principle depend other properties of the lake, *e.g.* fastness to light, to spirit, to alkalis and acids.

'Carriers' for lakes are usually very finely divided, insoluble, white (more rarely coloured) materials, such as starch, kaolin (China clay), gypsum, heavy spar (barytes), artificial barytes (blanc-fixe), lithopone, precipitated chalk, kieselguhr, zinc white, red lead, &c. They are intimately mixed with the colour solution, and attract the colouring matter either directly or when suitable precipitating agents are added to the mixture. More often, however, they are formed and precipitated along with the colouring matter, and may then consist of aluminium hydroxide, phosphate, or arsenate, or the first named along with barium sulphate.

The precipitating agent to be employed in any particular case varies according to the nature of the colouring matter—whether acid or basic, for example—and the purpose for which the lake is intended. For lakes employed in decorative painting finely ground barytes is considered to be the most serviceable 'carrier.' Gypsum and kaolin are also used. The chief base for lakes employed in printing wall-papers is blanc-fixe, since it excels all others in giving body and covering power; usually some quantity of alumina, starch, or China clay is admixed with it to render the resulting lake lighter and easier to work. Higher-class papers contain a proportionately greater amount of alumina. For paper-staining, lithographic, and printing inks the lakes must possess fineness and covering power to a very high degree, and for these aluminium hydroxide, precipitated apart from the colouring matter, is highly esteemed. It is particularly valuable in producing lakes of a transparent nature for use in the three-colour process; some blanc-fixe is often precipitated together with the alumina. Starch, China clay, zinc white, and lithopone are also employed where transparency in the pigment is not of primary importance.

China clay is most largely used with the basic coal tar colours, since for these its attractive power is very marked. Barium sulphate and aluminium hydroxide precipitated during the process of forming the lake, are chiefly used with the azo colours and the acid colouring matters generally. Lead sulphate and red lead are important bases for the eosin lakes.

The proportions of the various materials employed in making the lakes vary considerably according to the desired intensity of the final product.

All lakes should be washed with water, preferably by decantation, till neutral and free from soluble salts. They are sold as pastes or powders, the latter being sometimes in the form of light porous blocks or 'drops' of suitable size.

In all cases the 'extra' brands of all colouring matters should be purchased. They contain the dyestuff in a more highly concentrated form, for ordinary brands are standardised for the use of the dyer by the addition of starch, common salt, or sodium sulphate, and these are useless, or even harmful, from the point of view of the lake manufacturer.

A. *From Basic Colouring Matters.*

The chief methods of precipitating basic colouring matters are—

(*a*) With tannic acid; (*b*) with soap or sulphonated oil; (*c*) with sodium phosphate or arsenate; (*d*) with resin soap; (*e*) with casein or albumen.

(*a*) Tannic acid is the most generally used of all precipitating agents for basic colouring matters, combining with them to form tannates insoluble in water. It is but rarely used alone, since the resulting lakes are dull and extremely fugitive; an addition of half the equivalent quantity of tartar emetic causes the complete fixation of the lake, and improves its properties as regards brightness, fastness to light, spirit, &c. Sodium acetate, or occasionally sodium carbonate, is employed to reduce the acidity of the solution.

The 'carrier' is well mixed with water, the solution of the colour added together with sufficient sodium acetate to combine with the mineral acid liberated by the colour base. The solution of tannic acid is next poured in whilst

stirring well, and the precipitation completed with tartar emetic.

This method is most suitable for green and red colours, such as malachite green, brilliant green, magenta, rhodamine, and safranine.

(*b*) A method especially suitable for violet and blue basic colours is based on the precipitation of their colour bases as salts of oleic, palmitic, and stearic acids. A pure soap, containing no free alkali, or a sulphonated olive oil (*e.g.* Turkey-red oil) is employed. Aluminium sulphate, tannic acid, zinc or tin salts are also added on occasion.

(*c*) For basic colours of the methyl violet class a further method consists in the precipitation of aluminium phosphate, together with the added colour by means of aluminium sulphate and sodium phosphate to which sufficient sodium carbonate has been added to produce a perfectly neutral solution.

$$Al_2(SO_4)_3 + 2Na_2HPO_4 + Na_2CO_3 = Al_2(PO_4)_2 + 3Na_2(SO_4) + H_2O + CO_2$$

Similarly sodium arsenate, freshly prepared from white arsenic and sodium carbonate, is used in place of sodium phosphate—no addition of soda is then necessary, but care must be taken that the solution is neither strongly acid nor alkaline. As a rule, the precipitation is made in a very slightly acid solution obtained by using a slight excess of aluminium sulphate with addition of sodium acetate.

(*d*) All basic colouring matters form lakes of great brilliancy with resin soap, *i.e.* a solution of colophony in caustic or carbonated alkali. They are precipitated on the carrier along with a metallic salt of the resinate, usually zinc or aluminium.

Auramine, magenta, rhodamine, and patent blue furnish the most satisfactory lakes, and are much used for wall papers. They are of no value for oil or lithographic work, being very fugitive and readily soluble in alcohol and benzene.

It has been found possible to use the benzene solution of these 'resinate' colours for dyeing silk without injuring its finish, lustre, and general appearance. They are also used for preparing coloured varnishes employed in ornamenting metallic surfaces, wood, leather, glass, &c.

(*e*) According to Weber albumen can be employed as a precipitating agent for basic colouring matters with production of lakes of excellent brilliancy, notably fast to water and light. A cold aqueous solution of the dyestuff is mixed with the albumen (also in aqueous solution), stirred into the carrier, and the whole precipitated by raising the temperature to 90° with or without the final addition of a little acetic acid.

Casein may also be applied in a somewhat similar manner.

It is stated that this method is also applicable to the acid colouring matters, and is of special importance for producing non-poisonous eosin and rhodamine lakes.

Blue and violet lakes of great brilliancy may be obtained by mixing certain blue and red colour solutions with precipitated and washed Prussian-blue, which thus becomes dyed.

Potassium dichromate along with starch, &c., has been used as a precipitant with safranine, with which it produces a brownish-red lake changing to carmine-red on drying.

Basic colouring matters are especially remarkable for their ready absorption by inert materials, such as kaolin, starch, diatomaceous earth, green earth, &c., without the aid of any precipitating agent. A solution of the dyestuff is well mixed with the finely divided and well-washed base, and allowed to stand for some time with occasional stirring. A certain amount of colouring matter is attracted from the solution and the carrier becomes, as it were, dyed. Other carriers, *e.g.* gypsum, blanc-fixe, zinc oxide, &c., may be used, but their attractive power for the colouring matter is very small, and they serve chiefly as diluents. The lakes from the silicious earths are the more firmly fixed, and withstand the action even of strong alkalis. For this reason they find application in the manufacture of cheap lime washes.

Coloured powders, prepared according to these latter methods, can scarcely be regarded as true lakes, as they mostly give up their colouring matter on repeated washing.

B. *From Acid Colouring Matters.*

The great majority of the acid colouring matters referred to here are the sulphonic acid derivatives of certain colour bases and azo colouring matters derived from benzene, naphthalene, &c. With these barium chloride is almost exclusively employed as the precipitating agent; a further addition of aluminium sulphate is also often made, especially if the colouring matter exhibits mordant dyeing properties according to the law of Liebermann and v. Kostanecki.

More rarely, lead salts replace barium chloride.

Some of the phenolic colouring matters which possess special features may be included under this head, notably the eosins. Lead acetate or nitrate is especially suitable as a precipitating agent for colours of this class.

Other suitable materials are alum, aluminium acetate, calcium, magnesium, zinc, or stannic salts; as a rule, they are used in conjunction with caustic or carbonated alkali.

As in the case of the basic colour lakes, so here, the 'base' or 'carrier' upon which the lakes are precipitated is of great importance, and the reader is referred to what has been said already upon this point.

The standard method for the formation of lakes from acid colouring matters containing the sulphonic acid group is that with aluminium sulphate and barium chloride. The aluminium sulphate is precipitated as hydroxide in the first instance by soda, the colouring matter stirred in and then precipitated by the addition of barium chloride. In this way part of the 'carrier' is also produced, in the form of artificial barytes, at the moment of precipitation through the interaction of the barium chloride and the sodium sulphate resulting from the decomposition of the aluminium sulphate, and not only is the precipitation rendered more complete thereby, but also a very intimate admixture of the 'carrier' and precipitated colour is secured.

A proportion of inert 'carrier,' *e.g.* heavy spar, kaolin, lithopone, may also be added to the solution of aluminium sulphate before precipitation when lakes of greater opacity or less tinctorial power are desired; an extra addition of Glauber's salt before the final precipitation, will bring about the same result by increasing the amount of artificial barytes produced. Replacing the aluminium sulphate by alum yields lakes of a higher quality and valuable for printing purposes. They are, of course, more costly to manufacture.

A typical example of this method, published by the Farbwerke vormals Meister Lucius and Brüning, Hoechst am Main, is the following:—

30 parts	aluminium sulphate	1/100	solution
12 ,,	calcined soda .	1/100	,,
12 ,,	colouring matter .	1/50	,,
42 ,,	barium chloride .	1/100	,,

Precipitate at 50°–60°C. This method is stated to be suitable for the various brands of azo scarlets.

Reds. These are chiefly derived from the azo colouring matters. A great variety are now on the market, furnishing shades from a very bright scarlet to a dark bluish-red. Such are Ponceau 2G, G, GR, R, 2R, 3R, &c., Fast red, Bordeaux red, Crocein scarlet, &c.

Red lakes, in nearly all cases, are shaded by admixture with other colours, especially the various brands of oranges (*see* below under *Combined Lakes*). In such cases it is of considerable importance whether the colours are dissolved separately or together, the latter method often producing brighter lakes than the former.

Generally speaking, complete precipitation is obtained by the use of barium chloride upon a 'base' of alumina with or without the admixture of an inert diluent, blanc-fixe being produced simultaneously with the precipitation; certain colours are more difficult to throw down completely, but this may be obviated by suitable variations of quantities, temperature, dilution, &c. The addition of a little Turkey-red oil frequently has a favourable influence.

Another method in the case of some red azo colouring matters consists in treating a solution of aluminium sulphate with milk of lime, forming a 'base' of alumina and calcium sulphate. The colour is thrown down upon this by the addition of barium chloride, and at the same time the calcium sulphate is replaced more or less completely by blanc-fixe. The resulting lakes are said to be very soft and light.

The milk of lime may be replaced by levigated chalk with advantage.

Eosins. These colouring matters give scarlet and crimson lakes of great brilliancy, some of which (the so-called 'vermilionettes') are employed as substitutes for vermilion. They are mostly very fugitive. For yellowish-reds a yellow shade of eosin is employed; for reds, gradually increasing in blueness, erythrosine, phloxine, cyanosine, and rose bengal may be used. The usual precipitants are lead salts, 1 part pure eosin being precipitated by 1 part lead acetate, or 0·75 lead nitrate. Aluminium, tin, and zinc salts are also used.

The nature of the precipitating agent influences the shade of the resulting lake; thus lead acetate gives more yellowish products than lead nitrate from the same colouring matter. Lead salts give blue, tin and aluminium salts yellow shades.

For 'vermilionettes' red lead is a suitable base, with or without the addition of small quantities of lead sulphate or barytes. Better class varieties are made with chromate-of-lead-orange and alumina, in order to lessen their high specific gravity. Due allowance must be made for the variation in shade caused by the presence of a coloured 'carrier.' Their production is very simple; the solution of colouring matter is mixed with the base, complete precipitation being obtained on the addition of a lead salt.

Printing and lithographic colours (known as *geranium*-lakes) are largely produced from the eosin colouring matters. They may be transparent or opaque, according to the special use for which they are intended; they all possess great covering power. Alumina and blanc-fixe—either alone or in conjunction—and lead sulphate are chiefly used as the 'carriers'; or, occasionally, starch, kaolin, or red lead. The colour is precipitated upon them by a lead salt. Aluminium (as alum, &c.) does not produce so complete a precipitation.

If desired the lake may be shaded up by the addition of rhodamine B, which unites with, and is precipitated along with the eosin.

Combined lake pigments are also made with the various brands of azo scarlets and orange II.

Oranges. The methods applicable to the red colouring matters are also suitable for making orange lakes.

Orange II. furnishes a bright lake of good fastness to light, and is in considerable demand on account of its cheapness. Other brands are orange R, O, and fast orange O. For better-class lakes used in printing and lithography brilliant orange G and R are employed.

As stated above, orange colouring matters find frequent application in shading the scarlet azo colours.

Yellows. The number of yellow lakes is comparatively small owing to the superior properties of the various chrome yellows (*see* PIGMENTS). They are employed, however, to shade green lakes in a manner similar to that of the oranges for azo scarlets.

The most important colours used are naphthol yellow S, quinoline yellow S, Victoria yellow, &c.

Greens. The colouring matters mostly employed for these lakes are sulphonic acids of the triphenylmethane series, *e.g.* the various acid greens, but are among the most difficult of all the acid colouring matters to precipitate.

Naphthol green belongs to a different class.

They are only partially precipitated by barium chloride, employing the usual aluminium sulphate and soda method, and special modifications must be resorted to, such as after-precipitation with further quantities of aluminium sulphate or barium chloride, or both at once, reversing the order of precipitation and so on.

The lakes from acid greens (the so-called viridine greens) possess a bluish-green shade. Lakes from naphthol green are particularly fast to light. Better results and a greater range of

shades are obtained by admixture with naphthol yellow or quinoline yellow. Combination apparently takes place with the basic amino groups of the acid green with the formation of a less soluble combined colour.

Blues. With the exception of the red acid colouring matters the blues furnish the greatest number of colours for lake-making. A large number of shades are obtainable, but, unlike the scarlets, a separate brand is used for each particular shade, and mixtures are rarely found necessary. Alkali blues (opal blue, water blue, &c.), patent blue, and crioglaucine are chiefly in demand. They are readily precipitated by barium chloride upon a mixed alumina and blanc-fixe or other suitable base. The patent blues and crioglaucines are exceptions; for the former the addition of a little barium hydroxide has been found effective, for the latter some zinc sulphate is added, and this is precipitated by sodium carbonate as mixed hydroxide and carbonate.

For printing purposes alkali blue can be precipitated by Turkey-red oil or soap, and subsequent addition of a lead or aluminium salt, with a suitable carrier. The latter, again, may be dispensed with, and in such cases the lakes often exhibit a magnificent lustre.

Violets. Very few violet lakes are manufactured from acid violet dyestuffs, although they are very much faster than the corresponding lakes from basic colours. Fast acid violet is principally employed. They are all expensive to make, and only find application for special purposes.

A very blue violet is formyl violet S4B; it furnishes lakes suitable for the manufacture of printing inks.

All these colours are precipitated by barium chloride upon a suitable 'carrier.'

C. *From Mordant Colouring Matters.*

Besides the very important alizarin-red lakes already described, a certain number of other adjective colouring matters are used for lake making. They are mostly closely related to alizarin itself, *e.g.* alizarin orange, brown, bordeaux, yellow, green, black, blue; acid alizarin blue, and galloflavin, cœrulein, and gallein are also employed. They furnish lakes very fast to light, although they cannot compare in brilliancy of shade with other, but much more fugitive lakes from basic and acid colours.

Lake formation is brought about in the same manner as with alizarin red, the general principle involved being the precipitation of an alkaline solution of the colour by aluminium hydroxide.

Colours which do not dissolve in soda require a modification or reversal of the usual method; they are stirred up with the solution of aluminium sulphate (or alum), and combination is effected by addition of soda, sodium phosphate, and Turkey-red oil.

The Badische Anilin und Soda Fabrik publish a special method for cœrulein:

22 lbs. colouring matter in 27½ gallons of water with 44 lbs. sodium bisulphite (40°Bé.) are well mixed and allowed to stand for 12 hours; then heated to 70°C. with a further 27½ gallons of water, filtered, and the filtrate diluted with 110 gallons water. The whole is then raised to boiling, and 44 lbs. potassium alum added. After half an hour's boiling a final addition of 33 lbs. sodium bisulphite is made, the boiling again continued for half an hour, and the lake filtered, washed, and dried at the ordinary temperature.

D. *From Insoluble Colouring Matters.*

A series of azo colours insoluble in water are now made by the principal colour-works and sold in paste form for working up into lakes, according to specially adapted methods. The range of shades varies from yellow to bluish-red.

They are mixed with suitable 'carriers' such as heavy spar, lithopone, orange lead, magnesium oxide, and chalk. Frequently the mixture is simply ground together in the cold; another method is to heat to boiling and add barium chloride. Salts of magnesium, copper sulphate, and ferrous sulphate with Turkey-red oil are also used. The dry lakes are subjected to prolonged grinding with zinc white, orange lead, &c., this process greatly increasing their intensity. They are employed for lithographic and printing inks, as well as for oil and varnish colours and possess good brilliancy; many of them are exceptionally fast to light as well as to alkalis and spirit.

E. *From Developed Azo Colours.*

The application of the 'ice colours' to carriers for the production of lake pigments was a natural outcome of their successful use upon textile fibres.

At the present time the method is in very general use as the lakes made after this manner are distinguished by their fastness to light and other valuable properties. Practically all shades are obtainable except a green.

The pigments are all produced by the diazotisation of an amine followed by coupling with a phenol or another amine in a solution which contains the 'base' or 'carrier' in suspension.

The chief amines used in diazotising are: *m*- and *p*-nitraniline, the nitro-toluidines, anisidine, nitrophenetidine, benzidine, tolidine, α- and β-naphthylamines. Bluer shades, but less fast to light, are obtained from aminoazobenzene and -toluene.

The diazo compounds are coupled with various phenols and amines, especially β-naphthol which produces very bright lakes fast to water (the *insoluble azo-colours*). Other phenols used are phenol itself, resorcinol, α-naphthol, and its disulphonic acid, and β-naphtholdisulphonic acid.

The principal amines are diphenylamine and *m*-phenylenediamine.

Certain precautions are necessary to produce lakes of maximum brightness, *e.g.* care must be taken to regulate the proportions of acid and alkali so that a neutral liquor is present when the formation of the lake is complete. In practice a little sodium acetate is added, acetic acid having a less harmful action than free hydrochloric acid. An alkaline liquor renders the lake dull and dirty in shade.

The following recipes (published by Chem.

Fabrik Griesheim-Elektron) will best illustrate the manufacture o these lakes:

A base (A) is prepared from solutions of
1330 grams aluminium sulphate,
650 ,, calcined soda,
490 ,, barium chloride.

The precipitate is washed thoroughly and well mixed with the alkaline solution of β-naphthol (B) prepared from

300 grams β-naphthol dissolved in
300 c.c. caustic lye (34°Bé.) and 2 litres boiling water.

Add 300 grams calcined soda in 3 litres cold water,

180 grams Turkey-red oil,

300 grams sodium acetate, making the whole up to 10 litres.

Into this is run the diazo solution (C) from

280 grams *p*-nitraniline dissolved in
600 c.c. hydrochloric acid (21°Bé.) and 2 litres boiling water.

The temperature of this liquid is then reduced to 10°C. by addition of 2 litres cold water and ice and then diazotised with a solution of 144 grams of sodium nitrite.

The precipitated lake is washed thoroughly and dried. The above recipe is said to yield a deep-red shade.

The azophor reds of M.L.B. may be used in place of the diazotised bases.

F. *From Sulphide Colouring Matters and Indigo.*

Within recent years a number of processes have been patented for the manufacture of lake pigments from the vat dyestuffs, especially the sulphide colours. They are brought into solution as in dyeing cloth and precipitated upon a base by various means.

According to one such patent, taken out by Cassella & Co., the dyestuff (25 p.c. paste) is dissolved in 1 p.c. sodium sulphide and precipitated upon barytes or other suitable 'carrier' by the addition of sodium carbonate and barium chloride.

In another method, patented by the Berlin Aniline Co., the dyestuff is dissolved in sodium sulphide, a solution of barium chloride added, and oxidation brought about by blowing air through or adding manganese dioxide.

For instance, 20 parts sulphur black T extra are dissolved in a solution of 15 parts sodium sulphide, a solution of 25 parts barium chloride run in and air blown through the mixture.

Lakes may also be obtained from indigo. They are said to be exceptionally fast and especially suitable for producing very bright combined lakes.

Combined Lake Pigments.

As already mentioned a lake is frequently produced by the precipitation of more than one colouring matter, either separately or in conjunction, upon the 'carrier.' The colours may be of similar chemical nature, but varying shade, or they may differ absolutely in both these respects. To the first class belong, for example, the numerous scarlet lakes obtained by combining orange and scarlet colouring matters of various shades.

Lakes belonging to the second class differ materially both in shade and properties from any member of the combination used to produce the pigment, *e.g.* the maroon lakes made from scarlets combined with magenta or safranine.

For the latter lakes and others of the same class the initial colour is always either red, orange, or yellow, and from these all possible shades from bluish-red to yellowish-green are obtained by the addition of other colours such as magenta, safranine, methylene blue, malachite green, acid green, and even diamond black.

The methods available for manufacturing these combined lakes are obviously too numerous for detailing here, but a few general outlines and precautions may be indicated. Thus due consideration must always be given to the acid or basic character of the colours used and suitable means of precipitation arranged. Acid and basic colours should never be dissolved together, since combination takes place often with the production of a dark resinous precipitate. The same applies to colours such as the acid greens, which contain groups capable of combining with the acid or basic groups of the second colour.

The first colour may be made into a pigment (termed the 'initial lake'), upon which a second colour is then precipitated by suitable reagents. When, as most frequently happens, the initial lake is prepared from a soluble azo colour by means of barium chloride, and a basic colour is thrown down upon it, care must be taken that the precipitating agent used in the latter case does not affect the pigment first formed. For this reason materials such as Turkey-red oil and resin soap must be excluded, and the tannic acid and tartar emetic method is the only one really suitable for this purpose.

Analysis of Lake Pigments.

The analysis of the colouring matters in a lake is often a matter of great difficulty, and the subject remains largely in an empirical state. The composition of the 'base' or 'carrier,' on the other hand, presents no serious difficulties; a portion of the lake is incinerated and the residue examined by the usual processes of qualitative analysis. In this way the presence of mineral pigments to which coal-tar colours have been added may also be detected. Valuable indications may often be given by the presence of the precipitating agent in the mineral residue, *e.g.* a red lake which is found to contain lead is most likely to have been produced from a colouring matter of the eosin series, &c.

Other properties, chemical and physical, also furnish important evidence, the colour, fastness to light, to acids, alkalis, spirit, &c. Further, the selling price of a lake will often be a deciding factor where two colours are under consideration, of similar shade but different in price.

The class of colouring matter from which any given sample of a lake may have been derived can generally be settled with considerable precision by employing the schemes drawn up by various authors for the analysis of dyestuffs, both on the fibre and in the solid state, making allowance for the alterations in properties brought about by the presence of the carrier and precipitating agent. The identification may be carried further by noting the behaviour of the sample

towards such reagents as sulphuric acid, caustic soda, hydrochloric acid, alcohol, &c.; but where more than one colouring matter is present the only satisfactory method of determining the shading colours is by trials in the laboratory or by comparison with a series of standards. Modern pigments, as previously stated, are mostly examples of 'combined' lakes, and in such cases, though the principal constituent may be identified, it is frequently all but impossible to detect the small quantity of the secondary colours present by any process of direct analysis. In this case it is best to ascertain their nature indirectly by a comparison with lakes specially prepared for the purpose.

Dyers and Colourists (1890, 6, 32); Instructions issued by several Coal-tar Colour Manufacturers: Weber (J. Soc. Chem. Ind. 1891, 10, 896; 1893, 12, 650; 1894, 13, 1151).

For the analysis of lake pigments.—Tests for Coal-tar Colours in Aniline Lakes, Geo. Zerr, translated by Mayer. A. G. P.

LAMPBLACK is the soot or finely divided carbon produced by the imperfect combustion of various substances of a fatty or resinous nature, such as vegetable and animal oils, pinewood, and dead oil; and it may be taken that whatever the combustible material which, on full exposure to the oxygen of the air, produces the best illumination, that material will, if partially deprived of air, produce the greatest amount of sooty deposit. The German mode of manufacturing lampblack consists in collecting it on a woollen cloth exposed to the smoke emitted from resinous woods burning in a close furnace. The cloth being shaken from time to time, the particles are detached and collected. Lampblack is employed in the manufacture of printing-inks and pigments.

What is known in American trade as *carbon black* is a fluffy, velvety form of lampblack produced by the incomplete combustion of natural gas containing ethane, burning against a metal surface. It is made in various localities where supplies of natural gas are available, but mainly in West Virginia and Louisiana, which accounts for 90 per cent. of the total yield. One thousand cubic feet of gas yield from 1 lb. to 1¼ lb. of carbon black. Upwards of fifty-one million pounds were produced in 1920 from 39 plants. About 40 per cent. of the production is used as a colouring material in the rubber industry. 35 per cent. in manufacturing printer's ink, and 10 per cent. for various uses: *e.g.* stove and boot polish, gramophone records, black leather, electric insulators, drawing and marking inks, celluloid and carbon papers; about 15 per cent. is exported. Carbon black is used instead of zinc oxide as a filler for rubber tyres, as it increases their tensile strength and elasticity (U.S. Geol. Surv. 1921; Jour Soc. Chem. Ind., 1922, 60 R).

LANCASTER YELLOW

A colouring matter obtained by P. Greiss, in 1875, by the action of picramic (*iso*purpuric) acid on phenol. Sparingly soluble in water; soluble in sulphuric acid, with reddish-yellow colour. Dyes silk and wool in an acid bath brownish-yellow. No longer used.

LANGBEINITE. A double salt

$$K_2SO_4{\cdot}2MgSO_4$$

crystallised in the cubic system with tetartohedral symmetry,[1] and containing K_2O 22·7 p.c. Crystals are very rare, the mineral usually occurring in a granular massive form. This is colourless to grey with a glassy to greasy lustre and a conchoidal fracture; H. 3–4; sp.gr. 2·81–2·86; refractive index (Na) 1·5347. It is completely, though slowly, soluble in water. On exposure to the air it absorbs moisture, becoming cloudy, and finally falling to powder with a considerable increase in volume; the material then consists of a mixture of picromerite ($K_2SO_4{\cdot}MgSO_4{\cdot}6H_2O$) and epsomite ($MgSO_4{,}7H_2O$). The mineral is found in considerable quantities at several localities in the Prussian salt deposits, where it was first recognised in 1891. At Wilhelmshall north of Halberstadt and near Wolfenbüttel in Brunswick it occurs as a primary mineral in the older beds of rock-salt, taking the place of polyhalite in places where calcium is deficient. At Westeregeln and Neu-Stassfurt it is found in association with sylvite and rock-salt, and is partly of secondary formation; and at Solvayhall near Bernburg it overlies the carnallite stratum. It is found also at Hall in Tyrol and in the Mayo salt mines in Punjab, India. At the last-named locality it was found with rock-salt, sylvite, and kieserite, and partly described in 1873 (F. R. Mallet, Min. Mag. 1899, 12, 159). The salt is prepared artificially from a boiling concentrated solution of magnesium chloride and potassium sulphate with excess of magnesium sulphate; or by fusing together potassium and magnesium sulphates in the proper proportions.

L. J. S.

LANOLIN *v.* CHOLESTEROL.

LANORESIN *v.* RESINS.

LANTHANITE. Hydrated carbonate of lanthanum, didymium, and cerium

$$R_2(CO_3)_3{,}8H_2O$$

crystallised in the orthorhombic system. An analysis by G. Lindström (1910) of material from Bastnäs, Sweden, gave: $(La,Di)_2O_3$ 28·34, Ce_2O_3 25·52, Y_2O_3 0·79, CO_2 21·95, H_2O 23·40, insol. 0·13 = 100·13. Crystals have the form of thin plates or scales with very nearly square outlines, or sometimes they are of a thick-tabular habit resembling apophyllite. They have a perfect micaceous cleavage parallel to the basal plane, on which the lustre is pearly. The colour is usually a delicate pink. Sp.gr. 2·6–2·74; H. 2½–3. The mineral occurs sparingly as an alteration product on cerite (*q.v.*)

[1] The degree of symmetry is the same as that of crystals of sodium chlorate, but the crystals of langbeinite are optically inactive.

in gneiss at Bastnäs in Sweden; with zinc-ores in limestone at Bethlehem in Lehigh Co., Pennsylvania; with iron-ore at Moriah in Essex Co., New York; and at Canton mine in Cherokee Co., Georgia. L. J. S.

LANTHANUM. Sym. La. At.wt. 138·91 (Baxter, Pani and Chapin). Crude lanthana was obtained from the cerite earths in 1839 by Mosander, who afterwards separated this material by fractional crystallisation of the sulphates into lanthana and 'didymia' (neo- and praseo-dymia).

Sources.—The minerals containing the cerite metals, *e.g.* cerite, orthite, monazite, and lanthanite (native lanthanum carbonate containing didymium).

Separation. If the material employed as the source of lanthanum contains considerable quantities of yttrium earths a preliminary separation of the two main groups may be effected with sodium sulphate.

Methods of Isolation depending on Differences in Basic Strength.

The separation of lanthana from 'didymia' is quickly effected, although with some loss of material, by adding magnesia to a boiling solution of the mixed salts until the liquid ceases to give the characteristic absorption bands of neodymium and praseodymium, the less basic oxides of these elements being precipitated, whilst the more basic lanthana remains dissolved (Muthmann and Rölig, Ber. 1898, 31, 1718; R. J. Meyer and Marckwald, *ibid.* 1900, 33, 3009). Fractional precipitation with ammonia or caustic soda is hardly to be recommended for experiments on a large scale, because of the difficulty of collecting and washing the hydroxides. Moreover, ammonium salts are decomposed by lanthana and 'didymia,' so that these bases are not effectively removed from solution by ammonia.

An interesting modification of the basic method consists in utilising the ignited mixed oxides of the rare earth metals to precipitate fractionally an equivalent proportion of these metals from the neutral solution of their nitrates. A solution of the neutral nitrates is divided into two parts, one portion precipitated with oxalic acid, the oxalates ignited, and the resulting oxides added to the remaining portion of the nitrates in 12 p.c. aqueous solution. A vigorous action occurs, the mixture is diluted, heated on the water-bath, and the clear liquid decanted from the precipitate. The fractionation is repeated on both the soluble and insoluble portions. By this process the lanthanum accumulates in the solutions, whilst the praseodymium and neodymium are concentrated in the precipitates (Hermann, J. pr. Chem. 1861, 82, 385; Auer von Welsbach, Monatsh. 1883, 4, 630; *ibid.* 1884, 5, 508; Schottländer, Ber. 1892, 25, 378).

Boiling the rare earth oxides with ammonium salts leads to a fractionation, since the more basic constituents displace ammonia and pass into solution (Drossbach, Ber. 1902, 35, 2826).

The fractional decomposition of the nitrates is another method depending on differences in basic strength (Bettendorff, Annalen, 1890, 256, 159; Urbain, Ann. Chim. Phys. 1900, [vii.] 19, 184).

The mixed nitrates of lanthanum, praseodymium, neodymium, and samarium melt at about 400°–500° to a clear liquid, in which are gradually formed small crystals of basic nitrate. The solution obtained by boiling the product of fusion with 10 parts of water deposits the basic salt. The fusion is then repeated on the normal nitrates from both the insoluble and soluble portions. The lanthanum accumulates in the undecomposed nitrate, while praseodymium, neodymium, samarium, together with terbium and yttrium metals are found in the basic nitrate fractions.

Methods of Isolation by Crystallisation.

By a systematic fractional crystallisation of the double ammonium nitrates

$$R(NO_3)_3,2NH_4NO_3,4H_2O$$

in nitric acid solution, Auer von Welsbach succeeded in separating lanthanum from the other cerite metals, and also in dividing 'didymium' into its components, praseodymium, and neodymium. In this fractionation lanthanum accumulates in the least soluble portions, and is followed successively by praseodymium and neodymium, whilst the most soluble fractions contain samarium and the terbium and yttrium metals (Monatsh. 1885, 6, 477). In operating on large quantities of cerite earths it is more convenient to work in neutral solutions rather than in nitric acid, but in the absence of acid the number of fractions is considerably increased (Wien Sitzungsber. 1903, 11A, 112).

Other modifications of von Welsbach's method have been devised, having for their object the more rapid separation of praseodymium and neodymium (*cf.* Schéele, Ber. 1899, 32, 409; Dennis and Chamot, J. Amer. Chem. Soc. 1897, 19, 799; Demarçay, Compt. rend. 1900, 139, 1019, 1185; Drossbach, Ber. 1902, 38, 2826; Lacombe, Bull. Soc. chim. 1904, [iii.] 31, 570).

By each of these processes lanthanum can be readily separated in a highly purified condition, because it yields the least soluble double nitrates. Last traces of praseodymium are removed by fractional crystallisation of the double carbonates $K_2R_2(CO_3)_4$, $12H_2O$, where R=La, Ce, Pr or Nd, the metals being arranged in ascending order of solubility (R. J. Meyer, Zeitsch. anorg. Chem. 1904, 41, 94).

The classical 'sulphate' method may also be employed in separating lanthanum from the other cerite metals (Holtzmann, J. pr. Chem. 1858, 75, 321).

According to Dennis and Lemon (J. Amer. Chem. Soc. 1915, 37, 131) in the fractional electrolysis of a neutral solution of the nitrates of neodymium, praseodymium, lanthanum, and samarium, the lanthanum collects in the last fractions, and can thus be separated from the other earths of the didymium group. Lanthanum can be satisfactorily separated from praseodymium by this method.

Metallic lanthanum, m.p. 810°, sp.gr. 6·1545–6·193, sp. heat 0·04637, is best prepared by the electrolysis of the fused chloride, a current of 50 amperes and 10–15 volts being required; it is the most active of the rare earth metals, tarnishing in dry air, and in presence of moisture becoming coated with white hydroxide

(Muthmann, Kraft and Weiss, Annalen, 1903, 325, 261; 1904, 331, 1).

When heated in air lanthanum furnishes a mixture of oxide and nitride, and in hydrogen it yields the hydride. With aluminium, lanthanum forms the alloy $LaAl_4$, a crystalline white substance (sp.gr. 3·923), stable in air, and insoluble in nitric acid (*cf.* Muthmann and Beck, Annalen, 1904, 331, 46).

Lanthana (*Lanthanum oxide*) is a snow-white powder produced by heating the hydroxide or oxalate; its sp.gr. is 5·94, or 6·53 after raising to white heat. The amorphous oxide readily absorbs water or carbon dioxide, but the crystalline modification (sp.gr. 5·295) obtained in rhombic prisms by heating lanthanum carbonate in fused borax can no longer be directly hydrated.

The oxide has been reduced to the metal by magnesium but not by aluminium.

Lanthanum hydroxide $La(OH)_3$, a white amorphous precipitate produced by adding excess of ammonia or caustic alkali to the solution of a lanthanum salt, is the strongest base of the rare earth series; it turns red litmus blue, absorbs carbon dioxide from the atmosphere, and displaces ammonia from ammonium salts. In the presence of hydrogen peroxide, the hydroxide gives a hydrated lanthanum peroxide.

Lanthanum hydride LaH_3 or LaH_2 (Winkler, Ber. 1891, 24, 873; Muthmann and Kraft, Annalen, 1903, 325, 279), formed by direct union of its components at 240°, is a black substance more stable in air than the corresponding cerium compound.

Lanthanum carbide LaC_2, sp.gr. 5·02, is prepared by heating in a carbon tube, with an electric current of 350 amperes and 500 volts, 100 parts of lanthana and 80 parts of sugar carbon. When decomposed with water the carbon yields 70–71 p.c. of acetylene, 27–28 p.c. of methane, and 2·0 p.c. of ethylene (Moissan, Compt. rend. 1896, 123, 148).

Lanthanum nitride LaN, a black powder prepared from lanthanum and nitrogen at red heat, is decomposed by moisture yielding ammonia and lanthanum hydroxide (Annalen, 1903, 325, 261). A basic lanthanum azide $La(N_3)_3{\cdot}OH,1\frac{1}{2}H_2O$ having explosive properties, is obtained by dissolving lanthana in aqueous hydrazoic acid, and precipitating with ether alcohol (J. pr. Chem. 1900, [ii.] 61, 408).

Lanthanum sulphide La_2S_3. A yellow powder, sp.gr. 4·9108, obtained by heating the anhydrous sulphate in hydrogen sulphide, is stable in air but decomposed by boiling water. A higher sulphide La_2S_4 has been produced by the further action of hydrogen sulphide on the sesquisulphide at 600° (Biltz, Ber. 1908, 41, 3341).

Lanthanum nitrate $La(NO_3)_3,6H_2O$ crystallises from water in transparent colourless prisms; it loses $5H_2O$ over strong sulphuric acid, and is readily soluble in alcohol. A strong solution of the commercial nitrate is used as a stamping fluid for marking the maker's name or brand on incandescent mantles, so that when these are burnt the design appears in brown on the white thoria skeleton.

Lanthanum ammonium nitrate

$$La(NO_3)_3,2NH_4NO_3,4H_2O$$

monoclinic crystals, is isomorphous with the corresponding double salts of the other cerite metals (Kraus, Zeitsch. Krist. 1901, 34 307).

Lanthanum magnesium nitrate

$$2La(NO_3)_3,3Mg(NO_3)_2,24H_2O$$

separates in lustrous colourless rhombohedral prisms belonging to the hexagonal system. Lanthanum also forms well-defined double nitrates with pyridine, quinoline, and other organic bases.

Lanthanum sulphate $La_2(SO_4)_3,9H_2O$ is the most stable of three hydrates, and the least soluble sulphate of the rare earth series, its solubility diminishing with rise of temperature; it separates in hexagonal prisms, isomorphous with the cerous salt $Ce_2(SO_4)_3,9H_2O$. The anhydrous sulphate is produced by heating the hydrate with strong sulphuric acid, when the acid sulphate $La(SO_4H)_3$ first produced is afterwards decomposed above 280°. The double sulphates $La_2(SO_4)_3,3K_2SO_4$ and

$$La_2(SO_4)_3,Na_2SO_4,2H_2O$$

are sparingly soluble, particularly in the presence of excess of alkali sulphate.

Lanthanum fluoride LaF_3 prepared in the anhydrous state by burning lanthanum carbide in fluorine (*cf.* Moissan, *l.c.*) and as a gelatinous precipitate $2LaF_3,H_2O$ by the interaction of hydrofluoric acid and lanthanum acetate; the sulphate yields the acid fluoride $2LaF_3,3HF$.

Lanthanum chloride $LaCl_3$, m.p. 907°, sp.gr. 3·947, is prepared by the general methods for preparing anhydrous chlorides (*cf.* CERIUM; and Matignon and Bourrion, Compt. rend. 1904, 138, 627; 1905, 140, 1181; Ann. Chim. Phys. [viii.] 5, 127); it is a colourless compound dissolving in water or alcohol with considerable generation of heat. In aqueous solution this salt shows very little hydrolytic dissociation; its hydrate $2LaCl_3,15H_2O$ or $LaCl_3,7H_2O$ forms triclinic crystals, the alcoholate is $LaCl_3,2C_2H_5.OH$ (Zschiesche, J. pr. Chem. 1868, 104, 174; Cleve, Bull. Soc. chim. 1874, [ii.] 21, 196). The following double chlorides $2LaCl,3PtCl_4,24H_2O$; $LaCl_3,PtCl_4,13H_2O$; and $LaCl_3,AuCl_3,10H_2O$ have been described.

Lanthanum platinocyanide

$$2La(CN)_3,3Pt(CN)_2,18H_2O$$

forms yellow fluorescent prisms with a blue reflex.

Lanthanum-cobalticyanide

$$La_2(COC_6N_6)_2,9H_2O$$

one of the most soluble of the rare earth cobalticyanides in 10 p.c. hydrochloric acid: 1000 pts. saturated solution contain 10·41 pts. of the salt.

Lanthanum acetate $La(C_2H_3O_2)_3,1\frac{1}{2}H_2O$, thin prisms, furnishes in the cold with ammonia a gelatinous precipitate of basic acetate, which, when mixed with solid iodine, becomes blue like starch iodide. This reaction, which does not occur with the nitrate or with the precipitate from boiling solutions of the normal acetate, depends on the colloidal nature of the basic salt, the colour being due to an adsorption compound. Although this coloration is used as a test for lanthanum it is uncertain so long as other elements are present (Biltz, Ber. 1904, 37, 719).

Lanthanum oxalate $La_2(C_2O_4)_3$, 9, 10, or $11H_2O$, a white curdy precipitate becoming crystalline; is more soluble in acid or in aqueous ammonium oxalate than the oxalates of other

rare earth metals (*cf.* Cleve, Bull Soc. chim. 1874, [ii.] 21, 196; Power and Sheddon, J. Soc. Chem. Ind. 1900, 19, 636; Brauner and Pavliček, Chem. Soc. Trans. 1902, 81, 1243). Whittemore and James, J. Amer. Chem. Soc. 1912, 34, 1168.

Lanthanum acetylacetonate $La(C_5H_7O_2)_3$, colourless needles, m.p. 185°, crystallises from water with $3H_2O$ (Annalen, 1902, 323, 26; 1904, 331, 334).

Lanthanum dimethyl phosphate

$$La_2(Me_2PO_4)_6,4H_2O$$

white, hexagonal crystals, solubility in water 103·7 pts per 100 at 25° (Morgan and James, J. Amer. Chem. Soc. 1914, 36, 10).

For other organic salts of lanthanum, see Rimbach and Schubert, Zeitsch. physikal. Chem. 1909, 67, 183; Erdmann and Wirth, Annalen, 1908, 361, 190; Holmberg, Zeitsch. anorg. Chem. 1907, 53, 83; Jantsch and Grünkraut, *ibid.* 1913, 79, 305; Armstrong and Rodd, Proc. Roy. Soc. 1912, 87, 204; James and co-workers, J. Amer. Chem. Soc. 1911, 33, 1330; 1913, 35, 127; 1913, 35, 872; 1914, 36, 10; 1915, 37, 2652.

Spectra of lanthanum.—Spark and Arc Spectra, *v.* Exner and Haschek, Die Wellenlängen der Bogenspektra, I. and II. 1904; Rowland, A Preliminary Table of Solar Spectrum Wave Lengths, 1896.

Unless rendered impure by the presence of traces of other rare earths, lanthana and lanthanum salts do not become luminescent *in vacuô* under the influence of cathode rays.

G. T. M.

LANTHOPINE *v.* OPIUM.

LAPACHOL. This colouring matter has been obtained from the wood of the Lapacho tree, from Greenheart wood, and also from Bethaberra wood. It was from the first-named that Arnaudon (Compt. rend. 1858, 46, 1154) originally obtained it by extracting the wood with alcohol, and recrystallising the product from a mixture of alcohol and ether. Stein (J. pr. Chem. 99, 1) showed that the same colouring matter was present in Greenheart wood, whilst Green and Hooker (Amer. Chem. J. 11, 267) obtained it from Bethaberra wood.

According to Paternò (Gazz. chim. ital. 12, 337; 21, 374) the colouring matter is best extracted from the wood by means of soda solution (1 gram soda crystals in 16 grams water for 20 grams finely divided wood), the product being precipitated from the combined extracts by means of hydrochloric acid, purified by extraction with barium hydroxide solution and reprecipitation with acid. The product thus obtained when recrystallised from benzene is readily obtained in a pure condition.

Lapachol $C_{15}H_{14}O_3$. The m.p. of the crystalline product has been variously stated as 138°C. (Paternò) and 140·5°C. (Green). It is insoluble in water, but soluble in alkalis, yielding red solutions which contain its salts. It is not very soluble in ether, but easily soluble in chloroform, glacial acetic acid, and in hot alcohol or benzene.

Monoacetyl derivative $C_{15}H_{13}O_3Ac$, yellow prisms, m.p. 82°–83°C., is prepared by the action of acetic anhydride and sodium acetate on lapachol. It is insoluble in water, crystallises from alcohol and is very easily hydrolysed; cold nitration converts it into *nitro-acetyl-lapachol* $C_{15}H_{12}O_3(NO_2)Ac$, m.p. 166°–168°C., whilst further acetylation yields a *diacetyl-derivative* $C_{15}H_{12}O_3Ac_2$, colourless crystals, m.p. 131°–132°C.

Various salts of lapachol have been described, of which those of the metals are red in colour, those of organic bases yellow to orange. The sodium and potassium salts crystallise with $5H_2O$: $C_{15}H_{13}O_3Na(K),5H_2O$; the calcium, or strontium salt has only $1\frac{1}{2}H_2O$:

$$(C_{15}H_{13}O_3)_2Ca(Sr),1\tfrac{1}{2}H_2O$$

whilst the barium salt has $7H_2O$:

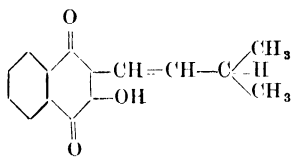
$$(C_{15}H_{13}O_3)_2Ba,7H_2O$$

Anhydrous lead, silver, and ammonium salts have also been described. Of the salts of organic bases, the aniline salt $C_{15}H_{14}O_3{\cdot}C_6H_7N$ consists of yellow needles, m.p. 121°–122°C., that of *p*-toluidine $C_{15}H_{14}O_3{\cdot}C_7H_9N$ of orange-yellow leaflets, m.p. 130°C., and that of *o*-toluidine $C_{15}H_{14}O_3{\cdot}C_7H_9N$ of yellow crystals, m.p. 135°C.

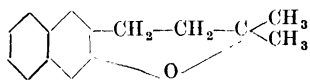
The elucidation of the constitution of this colouring matter is due to Paternò (Gazz. chim. ital. 1883, 12, 337, 622; 1890, 19, 601; 1891, 21, 374); and Hooker (J. Chem. Soc. 1892, 61, 611; 1896, 69, 1355).

It was Paternò who first put forward a structural formula for lapachol, which he based chiefly upon evidence obtained from examination of its oxidation and reduction products.

When oxidised by nitric acid (sp.gr. 1·38), lapachol gives rise to phthalic acid in good yield, whereas when the colouring matter is reduced by means of hydriodic acid and red phosphorus, a substance is obtained which Paternò considered to be β-isoamyl-naphthalene. As the result he suggested the following constitution for lapachol:—

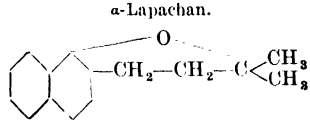


The position of the double bond has been disputed by Hooker. This author concludes that the product which Paternò considered to be β-isoamyl-naphthalene in reality consists of a mixture of two substances to which he gives the names α- and β-*lapachan*, and formulates thus:—



α-Lapachan.

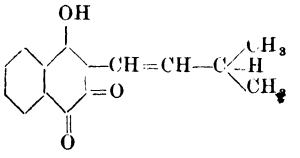
and



β-Lapachan.

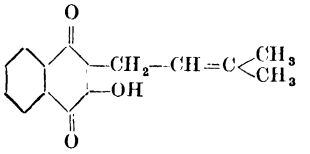
He was able to show that the product obtained by treating naphthalene with isoamyl-chloride, in the presence of aluminium chloride, was not identical with that obtained by Paternò by the reduction of lapachol. Moreover, by condensation of *β-hydroxy-α-naphthoquinone* and *isovaleric aldehyde*, in the presence of hydrochloric acid,

he obtained a compound that should have the structure applied to lapachol by Paternò, though to this, in view of its bright red colour, he assigned the formula—

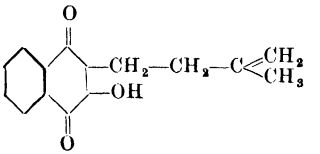


and the name *iso-β-lapachol.*

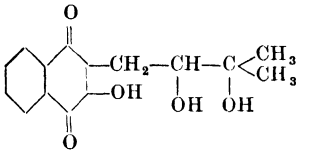
Although iso-β-lapachol is a derivative of β-naphthoquinone, whilst Paternò's formula for lapachol represents it as a derivative of α-naphthoquinone, both substances should yield the same reduction product, but as the reduction product given by *iso-β*-lapachol is not identical with that obtained by Paternò from lapachol, Hooker concluded that lapachol has in reality the structure—

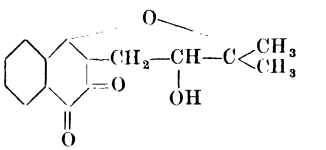


The alternative form—



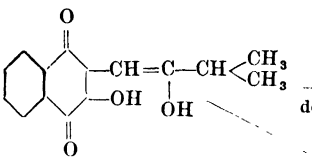
Then



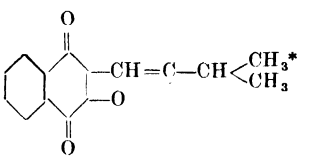


dehydration and rearrangement

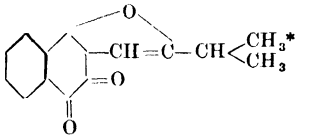
(I.)



(II.) Hydroxy-isolapachol.



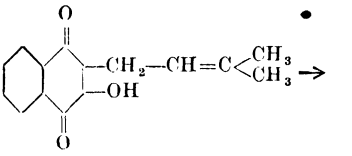
(III.) Isopropyl-furan-α-naphthoquinone.



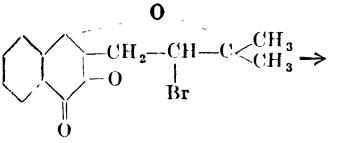
(IV.) Isopropyl-furan-β-naphthoquinone.

was rejected by Hooker, and a consideration of the following series of changes makes clear his ground for this rejection.

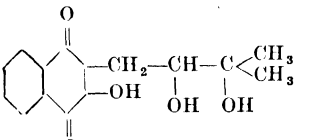
When lapachol is brominated, in chloroform, the product is *brom-β-lapachone*, orange-red crystals, m.p. 139°–140°C. This when boiled with caustic soda yields *dihydroxy-hydro-lapachol*, m.p. 181°–182°C., and, according to Hooker, on treatment of this product with concentrated sulphuric acid the products (1), (2), (3), and (4) are formed simultaneously, and the changes may be represented by the following scheme :—



Lapachol.



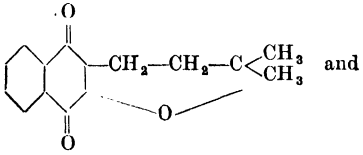
Brom-β-Lapachone.



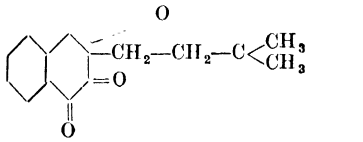
Dihydroxy-hydro-lapachol.

* Both of these substances can be reconverted by the action of caustic soda into dihydroxy-isolapachol though Hooker did not succeed in isolating this as an intermediate product in the initial reaction with sulphuric acid.

When lapachol is treated with mineral acids, Hooker obtained two substances which he termed α- and β-lapachone, and to which the following constitutions have been assigned :—



α-Lapachone.



β-Lapachone.

The former consists of pale yellow crystals, m.p. 117°C., and changes on solution in concentrated sulphuric acid into the latter, which forms orange-red crystals, m.p. 155°–156°C.

According to Crosa and Manuelli (Atti R. Accad. Lincei. 1895, ii. 250), Lapacho wood, on prolonged distillation with steam, yields a volatile crystalline product to which they gave the name *Lapachonone*, and composition $C_{16}H_{16}O_2$ colourless crystals, m.p. 61·5°C. It is optically active; its picrate

$$C_{16}H_{16}O_2 \cdot C_6H_2(NO_2)_3OH$$

m.p. 145°C.; on recrystallisation from alcohol forms products in which the proportion of picric acid is variable.

From lapachonone, by oxidation with dilute nitric acid, they obtained phthalic acid, whilst by the action of phosphorus pentachloride it was converted into *dichlor-lapachonone* $C_{16}H_{14}Cl_2O_2$ large colourless prisms, m.p. 108°C., volatile with steam.

Bromination of lapachonone, in cold acetic acid solution, yields *brom-lapachonone* $C_{16}H_{15}O_2Br$ colourless prisms, m.p. 126°C., together with small quantities of a *brom-dihydroxy-compound* $C_{15}H_{15}O_4Br$, yellow prisms, m.p. 140°C., which forms almost the whole product when lapachonone is brominated in aqueous suspension. It yields a *diacetyl-derivative*, yellow plates, m.p. 132°C., and a phenyl-hydrazone, red crystalline crusts, which has no definite melting-point (Manuelli, Atti R. Accad. Lincei. 1900 (v.), 9, ii. 314).

A. G. P.

LAPIS-LAZULI (Ger. *Lasurstein*; Fr. *Outremer*). An opaque precious stone valued for its rich deep blue colour. It takes a good polish, and is much used for small ornaments and for inlaying. Formerly it was the only source of the then valuable pigment ultramarine, which is now manufactured on a considerable scale.

Rather than being a simple mineral, it is a mixture of minerals, amongst which the members of the sodalite group predominate, together with calcite, pyroxene, amphibole, mica, scapolite, felspar, iron-pyrites, &c. The material is really an impregnation of various secondary minerals in a crystalline limestone, and has been formed by the contact-metamorphism of calcareous rocks at their junction with granite. The minerals of the sodalite group have been investigated by Brögger and Bäckström, and for the predominant blue constituent of lapis-lazuli they proposed the name *lazurite* (Zeitsch. Kryst. Min. 1890, 16, 231). This is a sodium aluminium silicate and sulphide, and is essentially the same in composition as artificial ultramarine. The formulæ they give for the members of the sodalite group are :

Sodalite $Na_4(AlCl)Al_2(SiO_4)_3$
Haüynite $(Na_2,Ca)_3(NaSO_4 \cdot Al)Al_2(SiO_4)_3$
Noselite $Na_4(NaSO_4 \cdot Al)Al_2(SiO_4)_3$
Lazurite $Na_4(NaS_3 \cdot Al)Al_2(SiO_4)_3$.

An analysis by Brögger and Bäckström of lapis-lazuli from Central Asia gave :

SiO_2	Al_2O_3	CaO	Na_2O	K_2O	SO_3	S	Cl	Total
32·52	27·61	6·47	19·45	0·28	10·46	2·71	0·47	99·97

Here, as in all other analyses, sulphate and chloride are present in addition to sulphide, and, in fact, the haüynite molecule actually predominates in this case.

Lazurite is decomposed and decolorised by hydrochloric acid, with the separation of gelatinous silica and evolution of hydrogen sulphide. It is occasionally found as deep-blue crystals with the form of the rhombic-dodecahedron; sp.gr. 2·38–2·42; hardness 5½.

The best quality of lapis-lazuli comes from Badakshan in Afghanistan; the mines here were visited by Marco Polo in the year 1271. Another occurrence of importance is at the western end of Lake Baikal in Siberia; here the material varies in colour from deep blue to light blue, violet, and green. Large blocks of pale blue lapis-lazuli are also found in the Chilean Andes, and small crystals in the ejected limestone blocks of Monte Somma, Vesuvius.

LARCH TURPENTINE *v.* OLEO-RESINS.

LARD. The term 'lard' was originally used to denote the fat rendered from the leaf of the pig, *i.e.* the fat from the kidneys and the bowels. The increased consumption of lard during the latter half of the last century (which has seen the rise of large American packing houses manufacturing lard on an enormous scale) has chiefly contributed to the extension of the above definition of lard, so that at present 'lard' denotes the fat from any and every part of the hog.

Leaf lard is still being sold on a small scale as 'butcher's lard' and 'home-rendered lard,' but the amount is insignificant in comparison with the enormous quantities produced in the slaughter-houses of the United States and Canada. The term 'bladder lard,' so named from the package, used to be leaf lard rendered in small establishments. At present this term is still used to denote the best quality of home rendered, as also of American lard of the quality (*c*) (*v. infra*). The commercial quality 'keg lard' contains, besides leaf lard, the fat taken from other parts of the animal. This extension of the term 'lard,' viz. that it denotes the fat taken from any and every part of the hog, has been implicitly acknowledged by the Adulteration Laws of the United States, according to which lard is defined as the 'rendered fat from slaughtered, healthy hogs, free from

rancidity and containing no more than 1 p.c. of substances other than hog fat.'

The production of, and trade in, lard at present may be considered as being completely dominated by the processes and trade usages in vogue in the United States, especially in the large packing houses of Chicago.

The rules of the Chicago Board of Trade define the following brands of edible lard: (*a*) Neutral lard No. 1; (*b*) Neutral lard No. 2 ('Imitation neutral lard'); (*c*) Leaf lard; (*d*) Choice lard, choice kettle-rendered lard; (*e*) Prime steam lard. These brands will be described here in the order in which they are produced in the factory, so as to give, at the same time, a concise account of the manufacturing processes involved in the production of edible lard.

(*a*) **Neutral lard** is prepared from the leaf, which is taken out of the animal immediately after it has been slaughtered, freed from the flesh and skin, and chopped up in a fat-cutting machine into small lumps, which are thoroughly washed with iced water. The comminuted mass is then delivered into jacketed rendering vessels, in which it is heated up to a temperature of 40°–50°. The lard so obtained is practically neutral, and is used almost exclusively in the manufacture of margarine (termed in America 'oleomargarine').

(*b*) **Neutral lard No. 2** ('Imitation neutral lard') is the fat taken from the back, and rendered in a similar manner.

As the Neutral lard No. 1 and Neutral lard No. 2 are not 'cooked' (*i.e.* not rendered at a higher temperature than 50°), these lards do not keep well, and cannot, therefore, be used, like 'leaf lard' and 'steam lard,' for domestic purposes.

(*c*) **Leaf lard** ('**Flare lard,**' '**Flair lard**'). When the residue from (*a*) is subjected to steam heat under pressure in a digester, the leaf lard of commerce is obtained. Formerly this was the only kind of lard recognised by the Chicago Board of Trade, and was prepared from the whole leaf, and thus embraced the three qualities described under (*a*), (*b*), and (*c*). This lard is not exported, but is consumed at home. The Adulteration Laws of the United States now define leaf lard as 'the lard made from the internal fat of the abdomen, excluding that adhering to the intestines, and having the iodine number 60.'

The portions of the leaf remaining after the rendering of Neutral lard No. 1, are put together with the residues obtained in the preparation of Neutral lard, and 'rendered' by steam heat in open steam-jacketed kettles or in autoclaves (digesters).

Thus (*d*) '**Choice lard**' or '**Choice kettle-rendered lard**' is obtained. The latter term is due to this fat being rendered in steam-jacketed kettles, which represent the survival of the old-fashioned open kettles, in which butchers used to render the lard over free fire. Such lard has the peculiar, pleasant flavour of fried fat, and therefore the name 'Kettle-rendered lard' has been retained, even after the rendering over free fire had given way to heating by means of steam. In large establishments the rendering is carried out under pressure in digesters. The regulations of the Chicago Board of Trade define 'Choice lard' as lard made from leaf and trimmings only, either steam or kettle rendered. The manner of rendering is branded on each tierce. Its flavour is much superior to that of 'Prime steam lard.'

(*e*) **Prime steam lard**, also termed 'Standard prime steam lard,' is obtained from any trimmings not used up in the production of lard (*d*), and all other parts of the hog that will yield lard, with the exception of the liver, lungs, the intestines proper, and that part of the heart which is free from fat. This quality is rendered in digesters in a similar manner to lard (*d*). Such lard is passed solely on inspection, and as the inspector has no authority which enables him to supervise rendering establishments, in order to secure a proper control, we may take it that prime steam lard consists of the fat from any part of the hog, either from the whole animal, or from portions of it (head, foot, &c.).

The foregoing qualities represent the commercial qualities of *edible* fat.

All those parts of the hog which have not been used for the production of the above qualities are worked up in autoclaves, in order to obtain the last portion of the fat they contain. The fat so recovered is termed 'Yellow grease.' With this yellow grease are mixed all the refuse fats resulting in the course of rendering the edible qualities. 'Yellow grease' is also obtained from the fat rendered from all the animals that have died in the 'stock-yards.' If in the working up of animals which have died in transit, the intestines, &c., have been removed, a whiter quality of fat is obtained. This is sold as 'white grease' for manufacturing purposes. A lower kind of grease than the 'Yellow grease' is 'Pig's foot grease,' a by-product obtained in the glue department of the rendering houses. This 'Pig's foot grease' finds an outlet in the manufacture of low class lard oil and of soap.

The two qualities of 'Neutral lard' hardly require refining. After the clear melted lard has settled in the jacketed vessel, it is run off into a receiving tank, in which the last traces of water and any fibres are precipitated by sprinkling salt over the fat. In fact, this part of the manufacture is closely similar to the processes employed in the preparation of 'Premier Jus.' The settled lard is then immediately ready for use in the manufacture of margarine—which is mostly produced in the same works,—or is run into tierces for shipment.

The next qualities of edible lard usually undergo a somewhat more complicated process of refining, consisting in treating the melted fat in a refining vessel with fuller's earth, and blowing it at the same time with air. The fat is thereby also deodorised. It is next pumped through a filter press, from which the clear, bleached lard is run over horizontal cylinders cooled by brine. The warm lard is thus quickly chilled on the cooled surface of the lard cooler, and forms a continuous sheet of solidified fat. Before the cylinder dips again into the warm lard on the other side, the solidified mass is removed by a scraper ('doctor'), and falls into a trough. In this trough a rotating screw conveyer breaks up the sheet of fat and carries it forward into a mixer, in which the lard is agitated by a mechanical arrangement. Here

'lard stearine' is added to 'stiffen' the lard, in case it be too soft.

The lard stearin is obtained by subjecting cooled lard in hydraulic presses to a moderate pressure, when the softer portion—lard oil—exudes. The lard stearin either serves in the manufacture of butter substitutes (margarine, 'oleomargarine'), or is used, as described above, for 'stiffening' soft lard. In this country, where the addition of beef fat for 'stiffening' lard is now forbidden, considerable quantities of lard stearin are used.

Leaf lard is the hardest; the lards from the back, &c., are softer. The consistence of the lard depends not only on the part of the animal from which it has been taken, but also, and chiefly, on the food which has been given to the animal. Hogs fed exclusively on acorns or on 'tankage' yield a harder lard than hogs fed on maize.

Leaf lard has a granular texture and a salve-like consistence, and should be of pure white colour. The lards which represent mixtures from all parts of the body, especially those manufactured in large slaughter-houses, have no longer a crystalline texture, as the object of the last operation in the manufacture is to destroy such texture and give to the product a smooth appearance.

The lard rendered from the leaf, as also from the back, has an agreeable taste. The lower qualities have an insipid taste; this disappears, however, on standing. Some of the steam lards have an 'animal flavour,' which may be judged by an inexperienced person to indicate admixture with tallow or 'beef stearine.' This flavour also disappears on standing or on warming.

Lard consists of the glycerides of lauric, myristic, palmitic, stearic, and oleic acids, and small quantities of linolic acid (and perhaps also of linolenic acid). The proportion of stearic acid determined in a number of commercial lards, varied from 6 to 24·91 p.c.

The analytical differences between lards from different parts of the hog are best expressed by their iodine values. Since important differences exist between North American and European lards, chiefly and almost solely owing to the mode of fattening, it is important to note that American lards have considerably higher iodine values than lards obtained in Europe. The iodine values of the latter range, as a rule, between 46 and 60. The iodine value of American lard reaches, however, higher figures than 60, and may even exceed 70.

Lard (like butter and olive oil) used to be adulterated on the largest scale. Beef fat, beef stearin, cotton seed oil, cotton seed stearin, and other vegetable oils, amongst which during the last few years coconut oil and palm kernel oil predominate, are the adulterants most frequently employed. Such admixtures had been for a long time an openly acknowledged practice in the United States of America, and such expressions as 'refined lard,' 'compound lard,' and 'lard compound' were used to designate a mixture of lard with vegetable oil, chiefly cotton seed oil, and cotton seed stearin. At present, however, the restrictions imposed by law have become much more stringent, and lard exported from the United States under official supervision, may be accepted as guaranteed pure, that is, free from admixture with another animal or with a vegetable fat.

The detection of adulterants in lard plays a most important part in the practice of the public analyst. It is impossible here to follow the various practices of the adulterators of lard and follow up such adulterations through their several stages. The reader must, therefore, be referred to Lewkowitsch, Chemical Technology. It may, however, be pointed out that the chief characteristics which the analyst must determine are: specific gravity, melting-point, iodine value of the fat, iodine value of the liquid fatty acids, and amount of unsaponifiable matter. The proportion of the latter is important, inasmuch as admixture of paraffin wax with lard (which had been practised to a considerable extent in former years, and had then been abandoned) appears to have been resumed during the last few years. Modern methods of chemical analysis have rendered the detection of vegetable oils and fats added fraudulently to lard, a somewhat easy process, as the phytosteryl acetate test permits the detection of even as little as 1 p.c. of admixed vegetable oil or fat, and the endeavours of the adulterator to circumvent this test by the addition of a very small quantity of soft paraffin wax have been frustrated by more refined methods of chemical analysis. The detection of coconut oil and palm kernel oil is rendered (in addition to the phytosteryl acetate test) somewhat easy by the determination of the volatile fatty acids. In this connection, however, a note of warning must be sounded, as it has been shown that hogs fed on copra (as is done in the Philippine Islands) furnish a lard which exhibits the characteristics of lard adulterated with coconut or palm nut oil (the coconut oil having been pushed forward into the body fat, much as feeding cows with oil cake leads to the pushing forward of the vegetable oil into the milk fat). Detection of added beef fat or beef stearin to lard is more difficult, and the (formerly relied upon) Belfield test, which was supposed to rest on the detection of (beef) stearin, has been shown to be entirely nugatory. The so-called Stock-Belfield test, which aimed at a quantitative determination of added 'beef stearin,' has been shown to be utterly fallacious, inasmuch as the crystals, on the isolation of which reliance was placed, are given by the lard stearin itself. A method proposed by Polenske, viz. to determine the so-called 'difference' between solidifying- and melting-points has been shown to be untrustworthy.

A method which has given better results is that based by Bömer (Zeitsch. Nahr. Genussm. 1913, 26, 559; 1914, 27, 153) upon the facts that the distinctive glyceride of lard, α-palmito-distearin, shows a difference of 5·2° between its m.p. and that of its separated fatty acids, whereas in the case of β-palmito-distearin, the distinctive glyceride of beef and mutton fats, the difference is only 0·1°. In the case of lards melting between 61° and 65° the m.p. of the glycerides added to twice the difference between the m.p. of the glycerides and their fatty acids should not be less than 71°. In the case of lards melting between 60° and 61° a difference of less than 5° between the m.p. of glycerides and fatty acids

indicates the presence of beef or mutton fat or 'hardened' oils, whilst for lards melting between 65° and 68·5° a difference of less than 3° is indicative of adulteration. The value of this test has been confirmed by Sprinkmeyer and Diedrichs (Zeitsch. Nahr. Genussm. 1914, 27, 571), who find that it is capable of detecting 5 p.c. of beef or mutton fat or hydrogenated oils in lard.

By crystallising the fat from acetone and determining the m.p. of the fraction it is possible to ascertain which of the specific glycerides predominates, Vitoux and Muttelet (Ann. Falsificat. 1920, 13, 593), and Bömer's method is then applied to the fraction to obtain quantitative results (*Id.*, Ann. Chim. anal. 1921, 3, 208).

A considerable amount of lard is consumed in the manufacture of lard substitutes.

LARD SUBSTITUTES consist chiefly of a mixture of lard, or lard stearin with 'beef stearin' ('oleostearin'), cotton seed stearin, cotton seed oil, maize oil, arachis oil, sesame oil, coconut oil, and palm kernel oil. In the infancy of this industry these artificial products were sold under such names as 'refined lard,' 'commercial lard.' Other products (*e.g.* 'lard compound') contained no lard whatever, being judiciously prepared mixtures of beef stearin and cotton seed oil. At present, however, most lard substitutes proper contain some lard, or at least 'lard stearin,' as a basis, whilst others contain a vegetable oil 'hardened' to the required extent by hydrogenation. The manufacture consists simply in mixing the various fats, in the melted state, and oils in a mixing machine, and cooling the mixture rapidly by running it over cooling cylinders, so as to destroy any tendency to crystallisation.

In order to impart to the finished mixture a pure white colour, it is usual to stir air into the fat until it acquires a salve-like consistence. The stirring with air must not, however, be carried too far, as otherwise the lard substitute not only becomes more liable to rancidity, but easily acquires a foamy consistence. J. L.

LARDERELLITE (*Ammonium borate*). A mineral found in the lagoons of Tuscany. It occurs in small crystalline rhomboidal plates.

B_2O_3 . . .	72·06
$(NH_4)_2O$ . .	9·83
H_2O . . .	18·11
	100·00

(D'Achiardi, Chem. Soc. Abstr. 1900, ii. 600).

LASERPITIN, $C_{15}H_{22}O_4$, is a bitter principle, obtained by Feldmann (Annalen, 1865, 135, 236), by extraction of white gentian root (*Laserpitium latifolium L.*) with light petroleum; yield 1·5 p.c. Crystals, m.p. 118°. Alkalis and acids hydrolyse it to angelic acid and resinous *laserol*; *v.* also Külz (Arch. Pharm. 1883, 221, 161). G. B.

LASURSTEIN *v.* LAPIS-LAZULI and PIGMENTS.

LATERITE. A residual product of rock weathering, met with in tropical regions, consisting mainly of hydroxides of ferric iron and aluminium with intermixed sandy and clayey material. It is reddish-brown with a mottled and streaky distribution of colour, and has a concretionary and cavernous structure. The name, from the Latin *later*, a brick, was introduced by F. Buchanan (Journey from Madras, 1807), on account of the extensive use of the material in India as a building stone. When freshly quarried it is quite soft and easily trimmed into brick-shaped blocks, which harden on exposure. The material forms surface accumulations, up to 30 or 40 feet in thickness, covering rocks of all kinds, particularly igneous rocks (granite, syenite, basalt, &c.) and gneisses, and extending over wide areas in all tropical regions. Whilst in temperate regions aluminous silicate rocks yield on weathering kaolinite and clay products, in tropical regions the silica (of the silicates) is removed together with the alkalis, lime, and magnesia, leaving behind quartz and hydroxides of iron and aluminium. The most abundant aluminium compound is gibbsite ($Al_2O_3{\cdot}3H_2O$), sometimes in a minutely crystalline condition, but more usually in the colloidal form ('kliachite' or 'sporogelite'); diaspore ($Al_2O_3{\cdot}H_2O$) is also sometimes present. The iron compounds, including mainly limonite together with turgite and goethite, are also principally in the colloidal form. Hydrated aluminium silicates, kaolinite and halloysite, and the manganese oxides, psilomelane and wad, are also at times present. The alumina present as gibbsite is soluble in hydrochloric acid, whilst that in the clay minerals is insoluble. Being mixtures of all these minerals in varying proportions the composition of laterite consequently varies between wide limits, as illustrated by the following analyses:—

I, laterite overlying nepheline-syenite (also K_2O, 0·27, Na_2O, 0·47 p.c.); II, ditto, overlying diabase: III, ditto, overlying peridotite; I–III, from French Guinea (A. Lacroix, Les latérites de la Guinée, Nouv. Arch. Mus. Paris, 1913, 5, 255). IV and V, the extreme values shown in twenty-two analyses of Indian laterites (H. and F. J. Warth, Geol. Mag. 1903, 154).

	I.	II.	III.	IV. (max.)	V. (min.)
SiO_2 .	2·21	1·30	12·67	23·32	0·37
TiO_2 .	0·12	1·03	0·55	6·61	0·01
Al_2O_3 .	55·83	60·19	12·59	67·88	6·67

	100·76	100·00	100·00		

Besides being used as a building stone, slabs of laterite are used in India for the construction of irrigation works. The material grades on the one hand into pure bauxite, and on the other into concretionary iron ores and manganese ores, which sometimes occur as workable deposits. A calcareous variety, containing nodules of calcium carbonate, is used for the manufacture of hydraulic cement and mortar, and the clayey varieties for making tiles.

Soc. franç. Min. 1918, 36; G. C. Du Bois, Min. Petr. Mitt. 1903, 22; J. M. Campbell, Mining Mag. 1917, 17. L. J. S.

LAUDANINE, LAUDANIDINE, LAUDANOSINE *v.* OPIUM.

LAUDANON. A mixture of opium alkaloids.

LAUDANUM. Laudanum is understood in this country at the present day to be the simplest liquid preparation of opium available for medical purposes. The word is an old one, and has undergone considerable change of meaning, but its precise origin has never been ascertained with certainty.

According to some authorities, the term is borrowed from *labdanum* or *ladanum*, an oleo-resin of Greek origin, which is collected from various species of *Cistus* (*v.* OLEO-RESINS); while others derive the word from the Latin *laus*, praise, which is supposed to indicate the high esteem in which the medicine has always been held. In a discussion of this question (Pharm. J. [iii.] 17, 404, 424, 503, 584, 644), it is pointed out by Eagle that according to Mathiolus (Comment. Dioscoridis Mat. Med. Lugduni, 1563) certain Italians applied the term laudanum to labdanum, and thus Littré and Robin (Dict. Méd. Paris, 1877) and others give the Italian equivalents of the two words as synonymous. This statement of Mathiolus would appear to have been the source of the view that laudanum is derived from labdanum which has been adopted by several lexicographers and writers on materia medica. Hooper (Lex. Med. London, 1848) and Dunglison (Dict. Med. Sc. Philadelphia, 1868) are, however, on the side of the *laus* derivation, and the remarks of such writers as Crollius (Basilica Chymica, Francofurti, 1611), Bruno (Lex. Castello-Brun. Norimbergæ, 1688), Lemery (Pharm. Universelle, 1716), and others are so decidedly in its favour that the weight of evidence at present appears to be with this hypothesis.

But be this as it may, the term 'laudanum' was applied in the 17th century to indicate solid or semi-solid mixtures which generally, though not always, contained opium (*cf.* Lond. Dispensatory, 1678). These were gradually replaced by liquid preparations, of which the most celebrated was that of the physician Sydenham, 1644–1689, whose life was written by Dr. Johnson. This was the *Laudanum liquidum Sydenhami* of the London Pharmacopœia of 1720, and was represented by the *vinum opii* of later medicine. A *tinctura opii* of simpler composition has, however, long taken the lead among galenical preparations of opium. This is a liquid extract made with dilute spirit, and represents in all important respects the physiological activity of the crude drug. To this tincture the term 'laudanum' was applied, both in this country and in the United States, not only by writers such as Pereira (Mat. Med. 1853, 2135) and Stillé and Maisch (Nat. Dispensatory, 1886, 1537), but more especially in the practice of pharmacy. In accordance with the international agreement of 1906, the British Pharmacopœia of 1914 prescribes that *tinctura opii* must contain in 100 c.c. 1 gram of anhydrous morphine. Limit of error ±0·05 gram. The solvent in the finished preparation is 45 p.c. alcohol. The U.S.P. of 1916 has adopted the same limits (*cf.* OPIUM). G. B.

LAUREL CAMPHOR *v.* CAMPHOR.

LAUREL OIL. Bayberry oil, is obtained from the berries of the laurel tree, *Laurus nobilis* (Linn.), either by pressing the pounded berries or by boiling them with water. The berries contain from 24 to 30 p.c. of fat. Laurel oil has a green colour; at the ordinary temperature it has a buttery consistence; its taste and aromatic odour are characteristic.

Laurel oil is completely soluble in boiling alcohol; on cooling, crystals of trilaurin separate. Judging from its high iodine value, viz. 66 to 96, laurel oil must contain considerable quantities of olein and perhaps also of less saturated glycerides. From the characteristic numbers which laurel oil gives on analysis, the conclusion must be drawn that the proportion of laurin cannot be very high. The presence of laurin is, however, definitively proved by the fact that on distilling laurel oil *in vacuó*, trilaurin is obtained in the distillate. In the unsaponifiable matter of laurel oil, Matthes and Sander identified melissyl alcohol (myricyl alcohol), phytosterol, and laurane, $C_{20}H_{42}$.

A specimen of the pure oil examined by Fabris and Settimj gave the following values: sp.gr. 0·953; m.p. 32°–33°; Reichert-Meissl value, 5·4; and iodine value, 96·4. The discrepancies in the published values are attributable to the crude oil containing variable proportions of a volatile oil. Laurel oil gives a coloration similar to that given by cotton seed oil in the Baudouin test.

Laurel oil is only used in veterinary practice, It is stated to be adulterated with other fats (lard), coloured green with copper salts.

J. L.

LAUREL WAX. *Myrtle berry wax* (*v.* WAXES).

LAURIC ACID $C_{12}H_{24}O_2$ is present in many vegetable fats, notably in coconut oil, laurel oil, dika fat, and tangkallak fat. It crystallises in needles melting at 43·5°, boils at 176° under 15 mm. pressure, and at 225° under 100 mm. pressure, but cannot be distilled without decomposition at atmospheric pressure. Sp.gr. at 20°/4°, 0·883; $n_D^{20}=1·42615$. It is slightly soluble in hot water, and can be slowly distilled in a current of steam, so that it occupies an intermediate position between the volatile and non-volatile acids. The laurates of alkali metals require much more salt to separate them from their aqueous solutions than the alkali salts of higher fatty acids. For example, sodium stearate can be 'salted' out by the addition of 5 p.c. of sodium chloride, whereas sodium laurate requires 17 p.c. For this reason fats containing a considerable proportion of lauric acid are used in the manufacture of soaps intended for use with sea water. The salts of the heavier metals are only sparingly soluble in water, but are more soluble in alcohol. The methyl ester of lauric acid melts at 5° and boils at 141° under 15 mm. pressure, whilst the ethyl ester boils at 269° at the ordinary pressure. The triglyceride, trilaurin $C_3H_5(O{\cdot}C_{12}H_{23}O)_3$ crystallises in needles (m.p. 46·4°), and has sp.gr. at 100°/4°, 0·8687; $n_D^{60}=1·44039$. It is readily soluble in ether, but only slightly soluble in cold alcohol.

C. A. M.

LAURIN *v.* LAURUS NOBILIS (Linn.).

LAURITE. Sulphide of ruthenium RuS_2, crystallised in the cubic system, probably with parallel hemihedrism and isomorphous with

pyrites. The crystals are octahedral in habit with a perfect octahedral cleavage, a dark iron-black colour, and bright metallic lustre. The material is very brittle, H 7–8, sp.gr. 6·99. The only analysis of the natural mineral gave S 31·79, Ru 65·18, Os [3·03] = 100 p.c. (F. Wöhler, 1869); this approximates to the formula $(Ru,Os)_2S_3$, but artificially produced crystals agree closely with RuS_2 in composition. Before the blowpipe it decrepitates, gives first sulphurous and then osmic fumes, and is fusible. It is not attacked by aqua regia or fused hydrogen potassium sulphate, but is decomposed by fused potassium hydroxide and nitrate. It is of rare occurrence as minute octahedra and grains mixed with fine-grained platinum from the platinum washings at Pontijn in the Tanah-Laut district in Borneo; and has also been reported as occurring with platinum in Oregon. L. J. S.

LAUROLENE and *ISO*-**LAUROLENE**, hydrocarbons of the formula C_8H_{14}, first obtained by the distillation of various camphor acids or their salts. (*See* Wreden, Annalen, 1877, 187, 171; Reyher, Inaug-Dissert. Leipzig, 1891, 51; Aschan, Annalen, 1896, 290, 185; Noyes, Amer. Chem. J. 1895, 17, 432; Koenigs and Meyer, Ber. 1894, 27, 3470; Damsky, Ber. 1887, 20, 2959; Moitessier, J. 1866; Walker and Henderson, Chem. Soc. Trans. 1896, 753.)

Laurolene, Δ^{1}-1 : 2 : 3-*trimethyl-cyclo-pentene*,

$$\begin{array}{l} CH(CH_3)\text{——}C{\cdot}CH_3 \\ \quad\vdots\qquad\quad\| \\ CH_2\text{—}CH_2\text{—}C{\cdot}CH_3 \end{array}$$

(Eijkmann, Chem. Zentr. 1907, ii. 1208).

Preparation.—(1) By slowly distilling camphanic acid in an atmosphere of CO_2 (Aschan, *l.c.*); (2) by heating sulphocamphylic acid at 170°–180° with aqueous H_3PO_4 (Koenigs and Meyer, *l.c.*); (3) by treating amino-lauronic acid with HNO_2 (K. and M.). Synthesised from $\alpha\delta$-dimethyladipic acid *via* 1 : 2 : 3-trimethyl-*cyclo*-pentanol (Noyes and Kyriakides, J. Amer. Chem. Soc. 1910, 32, 1064).

Properties.—Colourless liquid; b.p. 120°–122°; sp.gr. 0·8097 at 4°/4°, 0·8048 at 10°/10°, 0·8010 at 15°/15°, 0·7974 at 20°/20°, 0·7939 at 25°/25°; mol. mag. rot. 8·987; mol. refraction 61·114 (Crossley and Renouf, Chem. Soc. Trans. 1906, 26); has a sweet odour resembling camphor and turpentine. Rotation very irregular, varies from 0° to +23° and −29°. Combines with 2 mols. Br in chloroform solution; oxidised by HNO_3 to oxalic acid (Crossley and Renouf); oxidised by dilute alkaline $KMnO_4$ to a diketone, b.p. 204° at 750 mm. (corr.), which yields a disemicarbazone, m.p. 194° (corr.) (Noyes and Derick, J. Amer. Chem Soc. 1909, 148, 1609; Noyes and Kyriakides, *ibid.* 1910, 32, 1064; Noyes, *ibid.* 1910, 32, 1068; 1910, 32, 1061). With fuming HI on the water-bath yields *laurolene hydriodide*, a greenish-brown, unstable liquid which, heated with zinc dust in 90 p.c. alcohol, yields *dihydrolaurolene*, 1 : 2 : 3-trimethyl-*cyclo*-pentane, as a colourless liquid, b.p. 111·5°–114° at 760 mm.; unacted on by Br or $KMnO_4$. It has sp gr. 0·7718 at 4°/4°; 0·7670 at 10°/10°; 0·7633 at 15°/15°; 0·7596 at 20°/20°; 0·7567 at 25°/25°; mol. mag. rot. 8·332; mol. refraction 61·138.

For its synthesis *v.* Noyes and Kyriakides *l.c.* It has the structure Δ^{1}-1 : 2 : 3-trimethyl-*cyclo*-pentene (*cf.* Eykman, Chem. Weekblad, 1907, 4, 191; Bredt, J. pr. Chem. 1911, [ii.] 83, 400.

iso-**Laurolene**, Δ^{2}-1:1:2-*trimethyl-cyclo-pentene*

$$\begin{array}{l} C(CH_3)_2\text{——}C{\cdot}CH_3 \\ \quad\vdots\qquad\quad\| \\ CH_2\text{—}CH_2\text{—}CH \end{array}$$

(Blanc, Bull. Soc. chim. 1898, 19, 699; Compt. rend. 1906, 142, 1084). Formed by dry distillation of campholytic acid, sulphocamphylic acid, *iso*-campholytic acid, &c. (Walker and Henderson, Chem. Soc. Trans. 1896, 753). Prepared from *iso*-lauranolic acid by heating in sealed tubes for 4 hours at 300° (Blanc, Bull. Soc. chim. 1898, 19, 699); or by distilling with 1½ times its weight of pure anthracene (Crossley and Renouf, Chem. Soc. Trans. 1906, 41). Blanc synthesised it from $\alpha\alpha$-dimethyladipic acid *via* dimethyl-*cyclo*-pentanone (Compt. rend. 142, 1084).

It is a colourless, mobile liquid, with sweet camphoraceous odour; b.p. 108°–108·2° at 742 mm.; sp.gr. 0·7953 at 4°/4°; 0·7907 at 10°/10°; 0·7867 at 15°/15°; 0·7830 at 20°/20°; 0·7795 at 25°/25°; mol. mag. rot. 8·749; mol. refraction 60·565 (Crossley and Renouf). Oxidised by HNO_3 to oxalic acid; oxidised by dilute $KMnO_4$ to dimethyl hexanonoic acid.

$$CO(CH_3)C(CH_3)_2CH_2{\cdot}CH_2{\cdot}COOH,$$

with $HgCl_2$ solution gives a sticky amorphous precipitate. Combines with 2 atoms Br, forming 2 : 3-dibromo-1 : 1 : 3-trimethyl-*cyclo*-pentane, m.p. 80°–85°. Heated at 125° with fuming HI yields the *hydriodide*, which, on reduction with zinc-dust in 90 p.c. alcohol, yields *dihydro*-iso-*laurolene* (1 : 1 : 2-trimethyl-*cyclo*-pentane).

Dihydro-*iso*-laurolene can also be obtained by heating *iso*-laurolene with HI at 200° or with conc. H_2SO_4 (Zelinsky and Lepeschkin, J. Russ. Phys. Chem. Soc. 1901, 33, 549; also 1899, 31, 407). It is a colourless liquid, having a sweet camphoraceous odour, b.p. 113°–113·5° at 750 mm.; sp.gr. 0·7847 at 4°/4°; 0·7800 at 10°/10°; 0·7762 at 15°/15°; 0·7727 at 20°/20°; 0·7694 at 25°/25°; mol. mag. rot 8·249; mol. refraction 61·078 (Crossley and Renouf); Blanc, Bull. Soc. chim. 1909, [iv.] 5, 24; Kondakoff and Schindelmeiser, J. Russ. Phys. Chem. Soc. 1911 43, 992.

LAUROTETANINE $C_{19}H_{23}O_5N$ occurs in the bark of *Litsea citrata* (Blume), and in many East Indian lauraceous plants (Greshoff, Ber. 1890, 23, 2546). It crystallises in needles, m.p. 134°, gives crystalline salts, behaves as a secondary amine, contains three ·OMe groups, and probably one hydroxyl group. It exerts a tetanising action in frogs, but is less powerful than strychnine (Filippo, Arch Pharm. 1898, 236, 601).

LAURUS NOBILIS (Linn.). *Bay, Sweet Bay* (*Laurier commun*, Fr.; *Lorbeer*, Ger.).

The classic or noble laurel or bay tree is indigenous to the Levant and is found all along the shores of the Mediterranean. The leaves are used as a flavouring agent, and both the leaves and fruit were formerly employed in medicine.

The fruit, or so-called bay berries, was analysed by Bonastre (J. Pharm. Chim. [ii.] 10, 30) and by Grosourdi (J. 1851, 562). Besides common constituents, bay berries contain *solid and liquid fat, volatile oil*, and a *peculiar camphor*.

From the fat, Marsson (Annalen, 41, 330)

isolated *lauric ac'd* $C_{12}H_{24}O_2$. It was subsequently found in numerous other fats (*cf.* Heintz, J. pr. Chem. [i.] 66, 1). Glycerin trilaurate or *trilcurin* $C_3H_5(C_{12}H_{23}O_2)_3$ is associated in the nut with the glycerides of oleic, linoleic, palmitic, myristic, and stearic acids (Staub, Nat. Disp. 1886, 874).

The analytical constants of the expressed oil after being freed from the volatile oil are given by Matthes and Sander (Arch. Pharm. 1908, 246, 165), who have also investigated the resinous unsaponifiable matter which is present in the fatty oil. This was found to contain myricyl alcohol; a *phytosterol* $C_{27}H_{44}O,H_2O$, colourless needles, m.p. 132°–133°; a hydrocarbon, *laurane* $C_{20}H_{42}$, which crystallises from alcohol in slender needles, melting at 69°; and an aromatic unsaturated oily substance.

Bonastre (J. Pharm. Chim. [ii.] 10, 36; 11, 3) was the first to distil a volatile oil from bay berries; yield 1 p.c. It has been studied by Forcke (Arch. Pharm. [ii.] 17, 177); Brandes (*ibid.* [ii], 22, 160); Bley (Rep. Pharm. 48, 96); Gladstone (Chem. Soc. Trans. 17, 3; 25, 1); Blas (Annalen, 134, 1); Wallach (*ibid.* 252, 94); and Brühl and Müller (Ber. 25, 547). The specimen examined by the last-mentioned investigators distilled between 175° and 275° under ordinary pressure and left a viscid residue. The distillate contained lauric acid, and after treatment with potash and digestion with sodium, yielded a liquid, b.p. 167°–171°. This liquid was found to consist of cineol, pinene, and other hydrocarbons, and is probably the substance described as laurene by the earlier observers. The crude oil also contains large proportions of alcoholic or ketonic compounds which, like menthol or camphor, combine with sodium, the salts so formed being decomposed by water.

Bay camphor or *laurin* $C_{22}H_{30}O_3$ was isolated by Bonastre (J. Pharm. Chim. [ii.] 10, 32) and further investigated by Delffs (J. pr. Chem. [i], 58, 434) and Marsson (Annalen, 41, 329). The yield is about 1 p.c. It consists of prismatic crystals without taste or smell. It is insoluble in water, but soluble in alcohol and ether, and is chemically neutral and indifferent.

The leaves of *Laurus nobilis* also contain a volatile oil, D 0·9215–0·9361; α_D–15·95°; yield 2·4 p.c. Examined by Thoms and Molle (Arch. Pharm. 1904, 242, 161), free acetic, *iso*butyric, and (*iso* ?) valeric acids were found to be present, also about 1·7 p.c. of free eugenol and about 0·4 p.c. of eugenolic esters. The acid obtained by hydrolysing the oil by alcoholic potassium hydroxide consisted mainly of acetic acid; the other volatile acids present were probably valeric and hexoic. A monobasic acid $C_{10}H_{14}O_2$, m.p. 146°–147°, was also obtained. On fractionating the oil, after the removal of the free acids, phenols, and esters, cineol was obtained. The yield of cineol was equal to 50 p.c. of the original oil. From fractions between 212° and 230°, geraniol was isolated. The fractions of a still higher boiling-point contain oxygenated compounds, probably a sesquiterpene alcohol associated with a sesquiterpene. These fractions, and also the original oil, give an intense blue coloration when dissolved in glacial acetic acid and bromine vapour is blown over the surface of the solution.

The volatile oil of the leaves of the allied Californian laurel, *Umbellularia californica* (Nutt.), contains the following substances in approximately the percentages given: eugenol, 1·7; *l*-pinene, 6·0; cineol, 20·0; umbellulone, 60·0; safrole, a very small proportion; eugenol methyl ether, 10·0; and traces of fatty acids. *Umbellulone* $C_{10}H_{14}O$ is a colourless oil, boiling at 219°–220° (749 mm.), $[\alpha]_D$–37°, and has an odour somewhat resembling mint. It is a ketone; for constitution and properties *v.* Semmler, Ber. 1908, 41, 3988; *cf.* also Tutin, Chem. Soc. Trans. 1908, 93, 252.

The volatile oils obtained from *Laurus nobilis* must not be confused with others bearing similar names, such as commercial bay oil or bayberry leaf oil (*Oleum Pimentae*, U.S.P.) distilled from the leaves of the West Indian tree *Pimenta acris* (Kostel.), which is the flavouring agent in the toilet preparation known as bay rum (Markoe, Pharm. J. [iii], 8, 1005; Ruse, *ibid.* [iii], 13, 39); laurel oil of Guiana, natural oil of laurel, or ocotea oil, derived from a tree of Spanish Guiana (Stenhouse, Chem. Soc. Mem. 1, 43; 2, 121); or oil of common or cherry laurel, *Prunus Laurocerasus* (Linn.) which is similar to volatile oil of bitter almonds. G. B.

LAUTARITE. Calcium iodate $Ca(IO_3)_2$, crystallised in the monoclinic system. The large (up to 20 grams), colourless or yellowish crystals are prismatic in habit and usually arranged in radiating groups. Sp.gr. 4·59; slightly soluble in water; soluble in hydrochloric acid with evolution of chlorine. The mineral is found in the Chilean nitrate deposits, especially at the Lautaro works near Taltal, where it is often embedded in bands of gypsum. Since these deposits are the principal source of iodine, it is probable that the minerals lautarite and dietzeite (*q.v.*) are there widely disseminated. Crystals of calcium iodate have been obtained artificially from fusion in sodium nitrate. L. J. S.

LAUTH'S VIOLET *v.* AMINES; METHYLENE BLUE.

LAVA. A name of Italian origin applied not only to the molten material poured out on the earth's surface by volcanoes, but also to the same material after its solidification as a volcanic rock. The petrological term *magma* is applied to the molten material itself, whether erupted at the earth's surface or not, and from which igneous rocks of whatever kind have consolidated, including the deep-seated plutonic rocks (*e.g.* granite) as well as the surface lavas or volcanic rocks. Such material consists in all cases mainly of silicates, but with a wide range in composition—from 'acid' to 'basic.' The silica percentage may vary between 80 and 40, the balance consisting mainly of oxides of aluminium, iron, calcium, magnesium, potassium, and sodium, together with some water. In the most acid types (*e.g.* rhyolite) the excess of silica over that required to form silicates is present as quartz,[1] whilst in the most basic types (*e.g.* limburgite) the excess of bases separate out as magnetite and ilmenite, or less often as corundum and spinel. As examples of the extremes in composition of lavas, the following analyses (by J. H Player) may be

[1] Except, of course, in the case of wholly glassy rocks, in which no minerals have crystallised out.

quoted: I. rhyolite from C. Antrim; II. limburgite from Haddingtonshire:

	SiO_2	TiO_2	Al_2O_3	Fe_2O_3	FeO	CaO	MgO	K_2O	Na_2O	H_2O
I.	76·4	—	14·2	1·6	—	0·6	—	4·2	1·8	1·5
II.	40·2	2·9	12·8	4·0,	10·4	10·4	11·9	0·8	2·7	3·4

The rocks of the more acid type are paler in colour and lower in density, whilst those of the more basic types are darker and heavier. The former are also much more viscous and less ready to crystallise than the latter. The texture of volcanic rocks depends very much on the conditions under which they have consolidated. When cooling has taken place rapidly glasses are formed (*e.g.* obsidian, *q.v.*, or volcanic glass), whilst if the cooling has been prolonged the whole material may be crystallised. Usually, both glassy and crystalline material are intermingled, the small crystals being set in a glassy base. With the release of pressure accompanying the pouring out of lavas, the water and gases occluded in the magma give rise to vesicular cavities in the mass, in which secondary minerals are frequently segregated. An extreme example of this is afforded by pumice (*q.v.*). Volcanic rocks, representing the lava-flows of ancient volcanoes, occur interbedded with the sedimentary rocks of all geological periods. They find many practical applications, *e.g.* as building stones, paving stones, road-metal, concrete, millstones, &c. The leading types—rhyolite, obsidian, pumice, trachyte, andesite, phonolite, basalt—are further described under their respective headings (*q.v.*).

Much detailed petrographical study and numerous chemical analyses have been made of lavas, and many names have been introduced for special varieties. Reference may be made to the text-books of geology (*e.g.* Sir A. Geikie) and petrology (Sir J. J. H. Teall, A. Harker, F. H. Hatch, J. P. Iddings, H. Rosenbusch, and F. Zirkel). *See also* F. W. Clarke, The Data of Geochemistry, Bull. U.S. Geol. Survey, 1908, No. 330; 4th ed. 1920, No. 695. A large number of analyses are tabulated by H. S. Washington, Prof. Paper U.S. Geol. Survey, 1917, No. 99. The lava lakes of Hawaii afford excellent opportunities for the study of molten lava, *see* F. A. Perret, Amer. J. Sci. 1913, vols. 35 and 36; T. A. Jagger, *ibid.* 1915, vols. 39 and 40.

L. J. S.

LAVENDER, OIL OF, *v.* OILS, ESSENTIAL.

LAXANS, LAXATOL, LAXEN, LAXIN, LAXOIN (*Pergen*). Trade names for phenol phthalein when used as a purgative.

LAZULITE. A comparatively rare mineral occurring as sky-blue monoclinic crystals of pyramidal habit. It is a basic phosphate of aluminium, magnesium, and ferrous iron, $Al_2(Fe,Mg)(OH)_2P_2O_8$. This name is easily confused with the name lazurite (*v.* LAPIS-LAZULI). L. J. S.

LAZURITE *v.* LAPIS-LAZULI.

LEAD. Syns. *Blei*; *Plomb.*; *Plumbum.* Sym. Pb. At.wt. 207·2.

Occurrence.—Native lead is said to have been found at Grassington and Alston Moor, in certain mines in the province of Guanaxuato in Mexico, and according to Koksharow (J. Min. 1875, 873) in the Kirghis Steppe, where it occurs in hornstone associated with heavy spar and cerussite; also in the gold washings of Katharinenburg, in which it occurs in grains together with gold, magnetic and specular iron ores; also in India (Geol. Survey, India, List of Minerals), and in Sweden, where it has been formed from some naturally-occurring compound by reduction with arsenious acid. Some instances of the occurrence of native lead are given by Liversedge, in his Minerals of New South Wales.

A large number of lead compounds are found in nature, but only comparatively few can be considered as ores.

The principal ores of lead in the order of their importance are *galena*, *cerussite*, *anglesite*. Other less important naturally occurring compounds of lead are *pyromorphite*, *mimetite*, *mallockite*, *mendipite*, *phosgenite*, *lead ochre*, *minium*. These are dealt with under special titles.

The association of small quantities of lead with uranium minerals was noted by Hillebrand and made the subject of particular study by Boltwood, who suggested that the lead might be the product of the disintegration of uranium (Amer. J. Sci. 1905, 22, 253; 1907, 23, 77). The development of this idea has led many chemists, in recent years, to the extraction and determination of the equivalent weight of the lead from radio-active minerals (*v. infra*).

Most ores of lead contain silver which may be present either as the native metal or, in the case of sulphide ores, as argentite or some mineral rich in silver, such as tetrahedrite. Oxidised ores (sulphate and carbonate) generally contain silver as halide. The amount of silver varies very greatly; it is usually of the order 0·01 to 0·1 p.c. Some ores, however, especially the sedigenetic ores, are practically free from silver, whilst, at the other extreme, some are so rich as to be regarded as silver ores. Since the silver passes into the lead when the ores are smelted and is almost completely recovered from the lead by the processes of desilverisation and cupellation, and since most of the silver in the world is produced by these methods from argentiferous lead ores, the metallurgy of silver, in so far as this metal is won from lead ores, will be described in the following pages.

Galena is the source of most of the lead of commerce. Its chief modes of occurrence are in veins, more or less vertical and often occupying small fault-fissures; and in flats, or offshoots from veins, usually following roughly the bedding-planes and replacing limestone. Irregular impregnations of porous rocks like sandstone constitute an important source in certain parts of Germany and America. The galena in such cases is usually segregated into nodules, and is remarkably free from silver, and the size of the ore-bodies and the ease with which they can be worked compensates for their low lead-content.

DISTRIBUTION OF LEAD ORES.

In the British Islands, lead ore occurs in rocks of all geological ages from the Ordovician to the Triassic, but it is particularly abundant in veins in the Ordovician and Silurian rocks of Shropshire, Cardiganshire, and Montgomeryshire, of Leadhills and Wanlochhead in Scotland, and of the Isle of Man; and in veins and flats in rocks of Carboniferous (Mountain Limestone) age of Derbyshire, Flintshire, Denbighshire, Northumberland, Durham, and Yorkshire. It occurs also in the granite of Wicklow and the

Isle of Man and in the killas (Devonian) of Cornwall and Devonshire.

In Germany, lead mines are worked in Devonian strata in the valleys of the Lahn and Sieg and in the Hartz. In the latter district there are three centres—viz. (1) that in the neighbourhood of Clausthal; (2) the mines in the vicinity of Andreasberg; and (3) those at Rammelsberg, near Goslar. The Freiberg mines are in gneiss and yield a highly argentiferous galena. The Silesian lead ores are found in irregular deposits in the muschelkalk, and are associated with ores of zinc and iron. A remarkable stratified deposit of lead ore of Triassic age is that of Mechernich in the Eifel, where a bed of sandstone is studded in places with nodules formed of sand grains cemented together by galena.

The mines of Bleiberg and Raibel in Carinthia are among the most important lead mines in Austria. Here the ore is a very pure galena associated with molybdate of lead, and is found in limestones of the Triassic formation. At Pzibram, in Bohemia, the veins are in Silurian strata, and yield a galena very rich in silver. The mines are from three to four thousand feet deep.

Lead is found in almost every province in Spain, the chief workings being those of the provinces Jaen, Murcia, and Almeria. In the province of Jaen in the neighbourhood of Linares, two distinct systems of veins occur traversing the Triassic sandstone and the underlying granite. In the district round Carthagena in Murcia, the lead ores occur in veins in stratified and irregular deposits in Silurian rocks and trachytes. In the province of Almeria lead is found in veins in the mica schists and clay slates of the Sierra Almagrera. Some of the ore of this district is highly argentiferous.

The chief Italian sources of lead are in Sardinia, and may be divided into three types —(1) Ore masses interstratified in Silurian rocks, as in the mine of Monteponi; (2) veins traversing Silurian clay slates, as in the Montevecchio mine, one of the most important lead mines in Europe; and (3) lodes traversing Silurian limestones, *e.g.* Malacalzetta. The ore of the Montevecchio mine consists of galena mixed with blende, iron pyrites, heavy spar, siderite, and copper pyrites. It is poor in silver, whilst that at Malacalzetta carries about 40 oz. of silver to the ton. In Sardinia, the ore is, in all cases, galena. There are numerous deposits of lead ore (galena) on the mainland. In the Brusmipiano mine, in the district of Milan, galena is found associated with cerussite, iron pyrites, jamesonite, copper pyrites, and malachite. At the Morso Alto mine and at the Boltino mine in the mining district of Florence, the galena worked is rich in silver, and at the latter mine is associated with fahlerz, bournonite, and native antimony ore.

The deposits of lead ores in Portugal are very similar to those in Spain. The most important district is that of Mutola, near the Guadiana. The galena contains about 24 oz. of silver to the ton, and the cerussite and anglesite associated with it are frequently much richer.

In Greece, ores of lead, silver, and zinc occur in mica schists, limestones, granites, and trachytes, sometimes in irregular masses and sometimes in the form of lodes. The chief mining district is that of Laurium, at the southern extremity of Attica. The ore has been wrought and smelted there from the earliest times.

In Sweden argentiferous lead ores occur in veins in granular limestones, interstratified with schists. The chief mines are those of Sala, of Lofas in Dalacarlia, and of Guldmenshytta in Westmanland.

In France galena containing silver and associated with blende and iron pyrites occurs at Poullaouen in lodes traversing clay slates of Silurian age. The lodes at Huelgoët yield, in addition to argentiferous galena, cerussite, pyromorphite, and also native silver and horn silver. Galena is found and worked in several localities in France; the most important mines are those of Pontgibaud in the Puy-de-Dôme, where lead lodes are worked which traverse rocks consisting of granite, gneiss, and schists, broken through by dykes of porphyry, and covered by sheets of basaltic lava and beds of cinder. The galena is argentiferous, and is accompanied by blende or iron pyrites, and occasionally fahl ore.

In Belgium, a productive lead mine exists at Bleiberg, near Moresnet, where a vein is worked which traverses the Carboniferous Limestone and the Coal Measures.

Lead ores are found in various parts of Russia, *e.g.* at Ekaterinenburg in the Urals, and in the Caucasus. In Poland there are deposits of galena in the dolomites of the Muschelkalk, which have been worked for centuries. The most remarkable mines are those near Olkusk and Boleslaw. Lodes of lead ores occur near Chasing and Kielcé in rocks of Devonian age. Galena associated with fahl ore, molybdenite, iron pyrites, copper pyrites, and blende occurs in deposits in the mining district of Nertschinsk in Eastern Siberia.

Rich ores of silver and lead occur in the northern Shan States of Burma, and were formerly worked by the Chinese for the sake of the silver. Interest in this source of lead and silver has been revived, the old slags at Bawdwin have been resmelted and ore has been raised in large quantity during recent years.

Australasia.—In Victoria, galena occurs in several localities; that at St. Arnaud is argentiferous. In New South Wales are the famous deposits of Broken Hill, where the galena is intimately mixed with zinc blende. Much cerussite has also been raised from this locality. In South Australia, the mines of argentiferous galena are situated in the southern part of the colony, near Cape Jervis. In the Champion Bay district of Western Australia both lead and copper ores have been found in gneissic rocks. Argentiferous galena has been found in Tasmania, at the Penguin, and in the neighbourhood of Mounts Roland and Claude. Galena containing silver is occasionally found in the gold-bearing reefs of Coromandel and Thames, New Zealand.

Africa.—Argentiferous lead and copper ores are found in some mines in Algeria, and lead ores are known to exist in different parts of South Africa; these ores are found chiefly in the limestone formation extending from the

junction of the Vaal with the Orange River in a northerly and then in an easterly direction to Rustenburg, in the north-west of the Transvaal. There is evidence of these ores having at one time been worked by the natives.

America.—In the United States of America, argentiferous galena, associated with blende, iron, and copper pyrites, occurs in the form of veins, in the Atlantic States; in the Azoic slates of New York and in the New England States; in the State of New York it occurs in irregular deposits in the Lower Silurian rocks. The chief lead districts are, however, those of the Upper Mississippi Valley and the Missouri. The Upper Mississippi lead district is comprised within the States of Wisconsin, Illinois, and Iowa, the chief lead-producing district being that of the first-named State. The deposits of lead ore are found in the 'galena' or magnesian limestone of the Trenton period of the Lower Silurian formation, and cover an area of about 140 geographical square miles. These deposits assume a variety of forms, *e.g.* the *sheet*, a solid mass of ore filling a vertical fissure; this is the most characteristic mode of occurrence. In addition, other forms are distinguished, such as an *opening, a crevice with pocket openings, cave openings, flat sheets*, and *vertical openings*, in all of which masses of lead ore occur in fissures in the limestone. The principal ore is a very pure galena, poor in silver; it is accompanied by blende and zinc carbonate and a brown iron ore. The chief deposits of the Missouri district are situated in the counties of Washington, Franklin, and Jefferson. The galena is usually associated with iron and copper pyrites, and at the famous Lamotte mine, with nickel and cobalt ores. In Utah and the Western States, large and irregular deposits of highly argentiferous lead ore occur.

In Canada galena is found in several localities around Lake Superior, a remarkable vein occurring at Silver Lake, some six miles northward from Thunder Bay. A finely crystallised variety of galena has been found on the East Main coast of Hudson's Bay, in strata similar to those in which it occurs in the Mississippi district.

In Mexico lead ores are found in the mines at Guanaxuato and La Concepcion, and lodes containing argentiferous galena, quartz and calc spar occur in the mining district of Tatatila and Zomelahuacan.

The lead-production of the world for the year before the great European war (1913) was 1,142,264 metric tons (1 metric ton=1000 kilos =2204 lbs.=0·98 long or ordinary ton). Of this vast quantity no less than 83 p.c. came from the following five countries:—

U.S.A.	396,034	metric tons
Spain	203,000	,,
Germany	181,000	,,
Australia	116,000	,,
Mexico	55,530	,,

Owing to internal conditions, the Mexican output was only about half the normal during that year. The United Kingdom produced 48,962 metric tons, 30,000 of which were derived from imported ores. The production, in thousands of metric tons, from other countries was: Belgium, 35; France, 28; Austria, 22; Italy, 21; Greece, 18; Canada, 17. Smaller amounts, from 1000 to 3000 tons, were produced by Japan, Hungary, Russia, and Sweden.

For methods of assaying lead ores, *v.* art. ASSAYING.

The following are the methods by which the extraction of lead is effected:—

I. Method of double decomposition, otherwise known as the roasting-and-reaction, or air-reduction process. As the last name implies, air aids in the reduction, and it does so in the following manner:

When galena is roasted at a moderate heat, it is partially converted into the oxide, and a portion is also oxidised to the sulphate; if, after this roasting the temperature be raised, the unaltered galena reacts on the lead oxide and sulphate formed in the previous stage, and metallic lead is produced, sulphur dioxide being evolved.

These reactions are represented by the following equations:

$$(a)\ \begin{cases} 2PbS + 3O_2 = 2PbO + 2SO_2. \\ PbS + 2O_2 = PbSO_4. \end{cases}$$

$$(b)\ \begin{cases} PbS + 2PbO = 3Pb + SO_2. \\ PbS + PbSO_4 = 2Pb + 2SO_2. \end{cases}$$

The second equation must be regarded as a summary one, since there is no evidence of the direct oxidation of lead sulphide to sulphate. Probably all the lead sulphate arises from reaction of lead oxide and sulphur trioxide, the latter being produced by oxidation of sulphur dioxide.

The reversibility of the reactions under (*b*) was indicated by Jenkins and Smith (Journ. Chem. Soc. 1897, 71, 666) in their study of the action of sulphur dioxide on lead. Each equation represents a system of three components in four phases and is thus univariant. The pressure of the gaseous phase, when equilibrium is attained, should thus be a function of the temperature. This deduction from the phase law was confirmed by Schenck and Rassbach (Ber. 1907, 40, 2185, 2947; 1908, 41, 2917).

The interpretation of the data of experiment is, however, rendered difficult by the formation of basic sulphates, which increases the number of phases present and disturbs the equilibrium (*see* W. Reinders, Proc. K. akad. Wetensch, 1914, 17, 703). Some idea of the pressure at equilibrium of the sulphur dioxide for the reaction between sulphide and sulphate may be gained from the following table:

Temp. (degrees centigrade).	Pressure (mm. mercury).
600	39
635	98
665	201
695	402
713	590
723	735

The reversible reaction between sulphide and oxide, viz. $PbS + 2PbO = 3Pb + SO_2$, becomes appreciable at a temperature (650°C.), about 100° higher than that between sulphide and sulphate, and similar gaseous pressures are attained at correspondingly higher temperatures.

II. Method of roasting and subsequent reduction of the oxidised compounds by means of carbon.

III. The precipitation or iron-reduction

process, in which iron is used to effect the removal of sulphur.

The treatment of a lead ore frequently requires the use of two, sometimes of all the above processes.

The smelting of lead ores, of which galena is the principal one, is carried out either in reverberatory furnaces, blast furnaces, or shallow hearths. The ore from the mines is dressed and freed as far as possible by mechanical means from the various minerals and gangue material with which it is mixed

Smelting in Reverberatory Furnaces.

The *Flintshire process* is an example of the method by double decomposition carried out in reverberatory furnaces, which vary somewhat in construction and dimensions.

The following is a description given by Phillips of a *Flintshire furnace:*

The length of the hearth is usually about 11 feet, and its width 9 feet, and under this is an arched vault, extending the whole length of the bed to the fire-bridge. The hearth is made of slag, moulded into the proper form when in a plastic and semi-fluid state. Towards the centre of the hearth is a depression in which the fused metal accumulates, and at the bottom of this is situated the tap-hole. The fireplace is at one end, and before reaching the cavity of the furnace the flame has to pass over a fire-bridge about 2 feet in width, and from 12 to 14 inches below the arch. At the opposite extremity of the hearth are openings communicating with the flue in connection with a lofty chimney. The fuel is supplied through a door at one end of the fireplace, in addition to which the furnace is furnished with six working doors, about 9 inches by 12, protected by heavy cast-iron frames built into the brickwork and closed by iron plates, which can be easily removed when required. The bottom of this furnace is made nearly level with the doors on one of the sides, but is inclined towards the other in such a way as to be from 18 to 20 inches below the middle door, where it communicates with the tap-hole, beneath which a cast-iron tapping pot is set in the ground. In the top of the furnace is a hopper, from which a fresh charge of ore is let down as soon as that which is being worked is withdrawn.

In working this process, the charge (consisting of 21 cwt. in N. Wales, and from 12–14 cwt. in the north of England) is let down into the furnace, which is still hot from a previous working, and is spread evenly over the surface of the bed of the furnace, care being taken to prevent it dropping into the depression in the furnace-bed or well. During the first hour and a half, the charge is frequently stirred, and the supply of air carefully regulated so that the temperature is kept sufficiently high to ensure the oxidation of a portion of the galena, but not high enough to cause the charge to melt. At the end of this period the doors are closed, the fire is made up, the temperature raised to bright redness, and maintained at this point for about 25 minutes. The charge becomes plastic, and reaction takes place between the unaltered galena and the oxidised compounds of lead, and the metal so formed runs down into the well of the furnace. At the end of this period, the doors are opened to cool the furnace, and when the charge has become as pasty as ordinary mortar, it is pushed back from the well and spread over the higher part of the bed. The doors are again closed and the temperature raised by addition of fresh fuel; in this way the charge is rapidly run down into the well of the furnace, and when this is accomplished some slaked lime is thrown on to the surface and by means of a rake, thoroughly mixed up with the charge. Thus the slags and unreduced ore are cooled and rendered sufficiently pasty to allow of their being again removed and spread over the higher portions of the furnace bed where they are again calcined as in the first operation. This calcination lasts about half an hour. At the end of this stage, the temperature is again raised, and the whole charge is melted down into the well. During this stage it is customary to throw a little coal slack on to the charge. When the charge has collected in the well, some slaked lime is thrown on to it, and the slags pushed back on to the sloping side of the furnace and allowed to drain. The lead which has collected in the well is now tapped, and the slags, technically known as *grey* slags, are withdrawn in pasty lumps through the doors at the back of the furnace. The surface of the metal in the tapping pot is covered by slags and mattes, which retain mechanically a considerable proportion of metallic lead, the separation of which is effected by stirring with a paddle and throwing on to the surface some coal slack, which is well worked up with the molten metal. A considerable evolution of gas takes place; this is ignited, and the heat produced suffices to melt and liberate the metal confined in the slag. The slag is then skimmed off, thrown into the furnace, and the lead ladled out into cast-iron moulds.

Before introducing another charge, the tap-hole is opened to allow the lead produced from the slag and skimmings to run into the metal pot, where it remains until the next charge is run off. The tap-hole is again closed, and another charge of ore dropped into the furnace from the hopper.

This process may, therefore, be summarised as follows:—

(1) Calcination of the ore at a low temperature, whereby a certain amount of lead sulphide is converted into lead oxide and lead sulphate.

(2) Melting down of the charge, during which the unaltered lead sulphide reacts upon the oxidised products and separation of lead occurs.

(3) The admixture of lime with the molten charge and the 'setting up' of the slag; further separation of lead from the interaction of the sulphide and the oxidised compounds of lead, and the production of an excess of lead oxide and lead sulphate over the lead sulphide present.

(4) The tapping of the metal which has accumulated during the operation, and the drawing of the slags in a pasty condition.

In Flintshire, the ores smelted by this method yield 75–80 p.c. of lead by the dry assay, and of this, 90 p.c. is obtained by smelting in reverberatory furnaces, the remaining 10 p.c. being obtained by subsequent treatment of the slags (of which about 4 cwt. per charge is produced) and fume. The time required for the working of the charge is from 5 to 6 hours.

This method is suitable for rich ores containing limited amounts of silica, pyrites, and calcspar. If the silica exceeds 4 p.c. there is danger of fusible lead silicate being formed. Much pyrites leads to the formation of lead matte, and more than 10 p.c. of calcspar diminishes the fusibility of the slags too much.

In Flintshire, another process of extraction was used, similar to that employed at one time in Cornwall, the two stages of oxidation and reduction being performed in separate furnaces.

The method is a combination of all the different processes for the extraction of lead, utilising

(1) The air-reduction process,
(2) The desulphurisation of galena by iron,
(3) The reduction of oxidised lead compounds by carbonaceous fuel.

The ore treated in Cornwall was essentially a cupriferous galena containing on the average 60 to 70 p.c. of lead and about 35 ounces of silver to the ton.

The calcination was performed in a reverberatory furnace having three working doors, one on either side of the furnace, and the third on the side opposite the fire-bridge, and smaller than the others. Below the bed of the furnace was an arched chamber, into which the calcined ore was raked through holes in the bed opposite each of the lateral working doors. The furnace was built of ordinary rubble-work, lined internally with 9 inches of fire-brick. The doors were hung in a cast-iron framework, or had the sides protected by slabs of granite. The charge was introduced through a hole in the roof merely closed by a slab. The charge varied from 25 cwt. to 3 tons, but usually consisted of about 2 tons, and was spread over the furnace bed and calcined at a high temperature, regulated so as to prevent clotting. The operation lasted from 15 to 18 hours, the charge being raked over every hour. At the end it was raked through the holes in the furnace bed into the vault below, whence it was conveyed into the flowing or melting furnace, which is similar to the Flintshire furnace.

This furnace had five working doors, a pair on either side, and the fifth on the side opposite the fire-bridge, as in the calcining process. Near one of the lateral working doors, the hearth sloped to the one near the bridge, where the tap-hole was situated, from which the metal, &c., ran into an iron pot placed outside the furnace, near to which was a small pit to receive the regulus or slurry. The metal pot was also provided with a channel to convey away the slag.

The charge of two tons of calcined ore was brought into the furnace through the back working doors, spread over the sloping hearth, the doors closed, and the temperature raised until the charge was melted down, requiring some 2 or 3 hours. With pure ores, the lead produced in this stage was tapped off, but more usually the charge was mixed with lime and culm (anthracite coal) and set up on the higher part of the furnace bed. When barytes was present in the charge, fluorspar was used as a flux, and 1 or 2 cwt. of scrap iron was added to assist in the decomposition of the lead sulphide.

The doors were again closed and luted, and the charge melted down. The furnace was then tapped, and the molten metal flowed into the metal pot, followed by the regulus or slurry, consisting chiefly of iron sulphide and containing most of the copper. The regulus ran over from the metal pot into the pit below, and after a time the slag began to make its appearance; the lip of the pot was then stopped with ashes, and the flow of the slag directed along

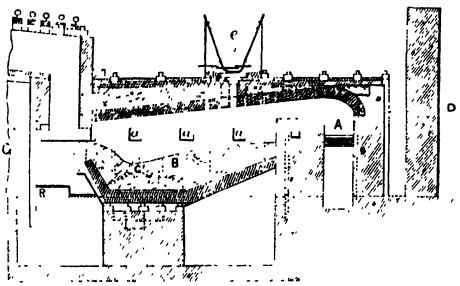

FIG. 1.

the channel by which it was conveyed out of the building.

The whole operation of smelting, from the time of introducing the charge to the tapping of the metal, took about 8 hours. The slag was generally sufficiently free from lead not to require subsequent treatment. The regulus was treated for the lead and silver it contained, and then when sufficiently rich in copper sold to the copper smelter.

In calcination, 6 cwt. of coal were required for every ton of ore, the melting down requiring about 8 or 9 cwt. The lead obtained was usually hard, and required softening at a high temperature to remove the antimony which it contained.

A modification of the Flintshire process is used at Couëron, Loire Inférieure, France, of which the following is a description taken from Phillips's Elements of Metallurgy. The construction of the furnaces will be understood by reference to the accompanying wood-cuts.

Fig 1. is a longitudinal section.

Fig. 2 is a horizontal section on the line CD.

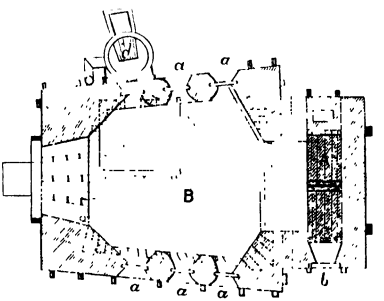

FIG. 2.

Fig. 3 is a transverse section through the tapping-hole.

The fireplace A is of the usual dimensions, and the hearth B, instead of being on an arch, as is commonly the case in North Wales, is supported on iron bars, on which is laid a course of flat tiles. A course of fire-bricks on edge rests on the tiles, and over this is the usual slag

bottom. The furnace has the ordinary number of working doors, *a*, with a fire-door *b*, and a tapping-hole *c*; there is a small fireplace below the pot *d*, to prevent the too rapid chilling of the lead during the process of ladling into moulds.

Although similar in form and dimensions to the ordinary Welsh furnace, it differs from it in one important particular, namely, in having the tapping-pot placed near the flue end instead of under the middle door. This arrangement gives a larger surface to the hearth for roasting the charge, and permits of the lead being collected in the coolest part of the furnace, where it is least exposed to loss from volatilisation.

The mode of working varies with the nature and composition of the ores, and depends principally on the length of time required for roasting. Pure ores, especially those containing a notable proportion of lead carbonate or sulphate, require very little roasting, whilst those containing blende, pyrites, &c., must be calcined for a considerable time before smelting.

In general, the ores treated are derived from Sardinia, and contain on an average about 81 p.c.

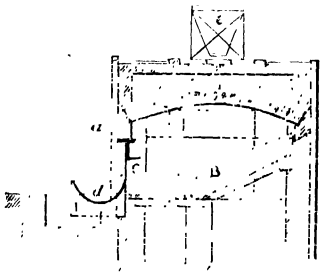

FIG. 3.

of lead, chiefly galena, carrying but little silver. The cobbled ores, before delivery to the furnace, are ground between rollers and passed through sieves of eight holes to the linear inch. A charge of ore weighs 27 cwt.

Two men are employed at each furnace, one of whom, the chief, works on the fore-side and takes the leading part in the work.

In the treatment of rich ores, the ordinary method of working consists in roasting them in such a manner that more than one-half of the lead sulphide present in the ore is converted into a mixture of oxide and sulphate. On raising to bright redness the oxide and sulphate formed in roasting react on the undecomposed sulphide in the charge, producing metallic lead, sulphur dioxide, and slag.

The process is thus divisible into two well-marked and distinct operations:

I. Calcination or oxidation.

II. Smelting or reduction

I. *Calcination.*—Supposing a charge to have been just worked off and the residual slags withdrawn, the furnace will be empty and at a red heat. The damper having been lowered, the charge of ore in the hopper, *e*, is let down through the opening in the arch, and spread evenly over the furnace bottom by means of rabbles. This done, the working-doors are closed, but the fire-door is left open and the fire damped with cinders, in order so to moderate the heat that the charge may become red-hot without clotting. The charge is thus left undisturbed for some time. During the first hour it is once or twice lightly rabbled; at the expiration of that time, after being well turned with the paddle, it will be found to be red-hot throughout. The damper is then lowered so as to leave just sufficient draught for the free escape of the gaseous products of calcination. The working-doors are now left partially open to admit the air necessary for the oxidation of the galena, and under its oxidising action the charge soon acquires a high temperature. Care must, however, be taken to prevent the heat from increasing so much as to cause softening of the ore. When the heat is properly controlled a white crust, consisting of a mixture of lead oxide and sulphate, in which the former predominates, is rapidly formed on the surface of the charge, and no fumes are visible.

The surface is renewed about every quarter of an hour, either by rabbling or by paddling. The requisite heat is maintained in the furnace during this process by firing with cinders only, which are preferable to coal for that purpose, not merely on account of their lower cost, but also because they give a steadier heat and do not yield gaseous hydrocarbons to interfere with the oxidation.

The alternate raking and paddling of the charge is continued at regular intervals, until on examination, it is thought to be sufficiently desulphurised, which is generally the case at the end of from four to four and a half hours.

The grate is then freed from clinker, coal is thrown on the fire, the damper is opened, and a brisk fire is got up; thus in a few minutes the heat in the furnace is so raised that the reaction-period sets in.

II. *Smelting.*—The ore lying at the back and extreme end of the furnace is now raked towards the bridge. With the increase of temperature, the roasted ore soon begins to soften and to give off white fumes, thus showing that the reactions which result in the liberation of metallic lead have commenced. Great care and attention on the part of the smelter are, however, necessary, in order to prevent too great a loss of lead by volatilisation during the heating up of the charge. The ore must on no account be allowed to liquefy, and as often as it shows a tendency to fuse, some slaked lime in powder is thrown on the charge and well worked into it with a rake. The consumption of lime amounts altogether to about 2 p.c. of the ore treated. By this means, and by carefully regulating the draught and firing, the charge can be heated to the required temperature without fusion.

Shortly after reduction begins, globules of lead may be seen on the surface of the charge, and before an hour has elapsed a certain quantity of lead has drained down the slope of the hearth into the well. The reactions are much aided by frequently rabbling and turning the ore; but as the working doors must remain open for this purpose, a large quantity of air enters the furnace, thus oxidising the sulphide in the ore, and so cooling the charge that the flow of lead is checked. When the cooling is judged to have been carried sufficiently far, the charge is rabbled, the doors closed, and the fire so urged as to fill the furnace with flame during

several minutes; then, on re-opening the doors and paddling, the flow of lead recommences.

At the expiration of from two and a half to three hours from the onset of the reaction-period a considerable amount of lead will have accumulated in the well. A first tapping is then made, the lead being received in the tapping-pot, which is kept warm by a small fire, and the tap-hole is stopped with a plug of stiff clay.

The thick dross which rises to the surface of the lead, and contains a certain quantity of sulphide removed from the charge by the hot lead and again separated on cooling, is skimmed off with a shovel and put back into the furnace. A little fine coal, together with some burning cinders and lime, is now thrown on the lead, which is vigorously agitated with a small paddle and stirred until it is clean. It is then skimmed, the skimmings being put on one side and the clean lead ladled into moulds.

The firing, paddling, and cooling of the charge are repeated several times, until at last the residue becomes dry and gives but little lead. Thereupon the heat in the furnace is considerably increased, but not sufficiently to fuse or flow down the charge, and towards the close of the operation the material remaining on the hearth consist to a great extent of oxides.

The pot skimmings, composed of cinders and lead matte, are now thrown into the furnace and well paddled with the charge, the reaction of the lead sulphide and cinders on the oxide and sulphate producing a further yield of lead. When this has ceased and it is seen that no more can be extracted except at a high temperature and by the addition of coal, the grey slag is raked through the middle door at the back of the furnace and the second and last tapping is made.

The whole period of reactions occupies from 5 to 5½ hours. After the withdrawal of the slags, the bottom is examined, and if corroded into holes, or in any way injured, it is repaired by putting into the cavities a mixture of grey slag and lime and beating it smooth with the paddle. It is of great importance to maintain the bottom perfectly smooth and with a good slope on all sides towards the tap-hole. A little lime is now spread over the bottom, and a fresh charge is at once let down into the furnace, the damper having previously been lowered to prevent loss of fine ore by the draught. The weight of coal consumed is equal to 40 p.c. of the ore smelted. The produce of lead per charge of 1350 kilos. of ore (with 81 p.c. of lead) is 15 pigs weighing 901 kilos. and 290 kilos. of slags containing 50 p.c. of lead. Hence the total loss of lead in the reverberatory furnace is 3·52 p.c. by volatilisation; out of this a certain proportion is recovered from the fume collected in the condensers and flues. A larger percentage of lead in pigs might be obtained by adding more coal to the charge towards the end of the process and firing hard, to reduce part of the lead left in the slags. It is, however, considered more economical to limit the production in the reverberatory to about 80 p.c. of the lead contained in the charge, and to carry the richer slags to the blast furnace. This is especially the case when the blast furnace is connected with good condensers and long flues.

It will be seen from the foregoing description that the process of reverberatory smelting adopted at Couëron differs principally from that generally employed in England in that there is no melting or flowing down of the charge, and the period of roasting is greatly lengthened

Spanish furnace or boliche.

In the south of Spain, the smelting of lead ores has been carried on for many centuries in a form of furnace known as the *boliche*. It consists of two chambers, separated from one another by a fire-bridge. One of these only is used for the reduction of the ore, and the second, which is situated between the first and the chimney, serves apparently to moderate the draught.

The fireplace projects from one side of the hearth, and is without a grate; the fuel, consisting of wood, is supplied through a door at the end of the fireplace.

The smelting hearth inclines towards the working door, situated at the end of the longer axis, immediately within which is a receptacle in the floor for the collection of the metal.

The boliche is constructed of rubble work, cemented together by clay and strengthened by buttresses built at the angles.

The interior is lined with fire-brick, and the hearth is made of clay or a mixture of clay and broken galena.

The method of smelting is in principle similar to the Flintshire process. The ore, thrown into the furnace through the working door, is first spread evenly over the surface of the hearth and then calcined. When the calcination is completed, the temperature is raised and the running down of the charge begun. The slags are dried up after the completion of the melting down by throwing into the furnace the ash and breeze from the ashpit. The metal is tapped into a vessel, in which it is stirred with dry leaves, and finally ladled into moulds. The charge consists of 13 cwt. of ore and 1500 to 1750 lbs. of brushwood.

The yield is about 80 p.c. of the lead of the ore as given by the dry assay. The grey slags contain from 45 to 50 p.c. of lead and represent 15 to 17 p.c. of the charge. These slags are subsequently treated in a blast furnace. These furnaces have lately been altered by English companies; coal replaces brushwood as fuel, and the charges have been increased.

Bleiberg process.—At Bleiberg in Carinthia, reverberatory furnaces of a special construction are used, two being usually built side by side and arranged to work into one chimney.

Fig. 4 represents a front elevation, and Fig. 5 a horizontal section. The hearth is about 10 feet long, and at the back near the fire is about 4 feet 10 inches wide. This width is maintained for about half the length of the furnace, when it is gradually reduced, until at the working door it is about a foot wide. The hearth is sloped from the back and also from the two longer sides, thus forming a depression in which the metal may collect and flow into the metal pot, *a*, in front of the working door, *g*.

The hearth is formed of a lower layer of beaten clay and an upper one of fused slags, having a united thickness of about 6 inches. The fireplaces are built parallel to the longer axis of the furnace, and separated from the

latter by a fire-bridge. The products of combustion pass into the chimney, *h*, by a flue above the working door. The grate is of stone, having

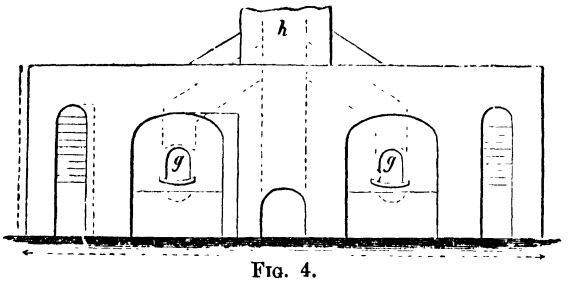

FIG. 4.

a greater inclination than the hearth, and is traversed by openings for the admission of air.

The fuel employed is wood, but in some cases brown coal is used, and then the stone grate is replaced by one with iron bars. The lead ores are delivered to the smelter either in the rough state or in the form of slimes. In the former state on assaying they yield from 65–70 p.c. of lead, in the latter from 60–65 p.c.

In smelting, a charge of 375 lbs. of ore is thrown into the furnace through the working door and spread over the hearth, forming a layer from 1 to 1½ inches thick. This is calcined at a temperature low enough to prevent the softening of the charge—the calcination occupying 3 to 4 hours—the charge being raked over at intervals. The temperature is next raised to bring about the usual reactions between the oxidised compounds and the unaltered galena, the charge being carefully rabbled. This operation lasts from 3 to 4½ hours, the metal produced constantly flowing into the depression, and thence to the metal pot. At the end of this operation the slags are dried up by the addition of ashes and breeze, and then withdrawn from the furnace. The lead produced from the ore in this way, amounting from 125 to 150 lbs., is supposed to be specially pure, and is known as '*Jungfernblei*,' or 'virgin lead.' After the withdrawal of the slags a second charge of ore is treated, the slags produced being left in the furnace, and to them the slags from the previous smelting are added. These slags are free from sulphide and contain lead in an oxidised state only. The temperature is raised and charcoal added, the whole being intimately mixed with the rabble. The oxidised lead compounds are in this way reduced in from 7 to 8 hours, about 150 lbs. of lead being produced.

The complete working of the two charges occupies from 21 to 23 hours, the yield of lead being usually about 2½ p.c. below that obtained in the dry assay. This method is now seldom used.

Smelting galena with iron in reverberatory furnaces.—When galena is heated with iron, sulphide of iron is formed and lead is liberated. This is the basis of the precipitation or iron-reduction process. The reaction is, however, not complete, since some lead sulphide passes into the iron sulphide to form a matte, the amount of lead escaping reduction in this way being greater the lower the temperature. When shaft furnaces are employed, the iron may be charged in the form of oxidised compounds or highly ferruginous slags (*e.g.* tap-cinder), the reduction of which is effected by carbonaceous materials; but with reverberatory furnaces, the iron must be in the metallic condition; the consumption of fuel is large, much lead is volatilised at the high temperature of reaction, and both matte and slag, being rich in lead, require retreatment. Owing to these disadvantages, the reduction is seldom, or never, carried out in reverberatory furnaces.

SMELTING IN HEARTHS.

The extraction of lead from galena by smelting in hearths involves essentially the reactions of the air-reduction process. Whereas, however, in reverberatories the stages of roasting and reduction are in the main separate, in hearths they occur side by side. Some reduction, too, of lead oxide by the fuel of the charge takes place in the hearth process. The ore used in this process must contain at least 68 p.c. of lead and should be poor in silver, otherwise the loss of that metal by volatilisation is great. It is broken up small, about the size of a bean, or if very fine is first sintered. The iron of the hearth is protected from corrosion by the lead which fills the sump, and the charge floats on a bath of molten lead and is not itself melted.

The furnace known as the 'ore hearth,' or 'Scotch hearth,' is the one chiefly used in the northern counties of England and in Lanarkshire. It varies somewhat in dimensions and in external form at different works, but consists essentially of a shallow rectangular hearth built of cast iron, set in brickwork or stone. Fig. 6

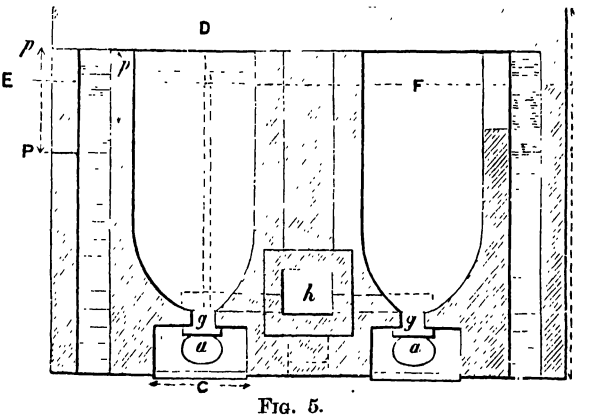

FIG. 5.

is a vertical section of the 'ore hearth,' A the hearth bottom, 22 inches square, the iron plate being about 3 inches thick; the sides are also

composed of iron of the same thickness, and the depth of the hearth is about 4½–6 inches. In front of the hearth is the work-stone B, sloping from the front edge of the hearth to the metal pot C, in which the lead is maintained in a molten state by a fire below. The work-stone is about 3 feet long, 18 inches broad, and 2½ inches thick; it has a raised border about an inch high on its two sides and along the front, and a narrow channel 2 inches wide and 1 inch deep runs diagonally across it. The work-stone is embedded in fireclay or a mixture of slime ore and bone-ash. At the back of the hearth is a prism of iron, called the back-stone, D, upon which rests the bellows-pipe, and above it is another prism E, called the pipe-stone, with an opening below to receive the bellows-pipe. The blast-pipe enters at a height of 6½ inches above the level of the upper end of the work-stone, and when in work is about 4 inches above the level of the metal in the bed. The hearth is covered by a hood of brickwork, opening at the back into a flue leading to the fume chambers. Behind the hearth is a blind flue or pit into which 'hearth-ends' and other materials coming off with the fume may be collected, and from which they are removed as required. At the side of the hood is an opening in the brickwork communicating

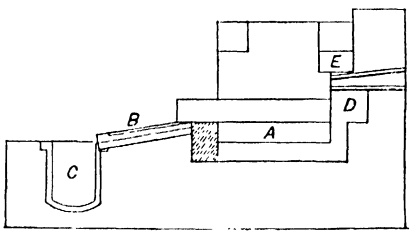

FIG. 6.

with the hearth, through which the ore and fuel are charged. The opening in front can be regulated by a movable iron plate, raised or lowered by a counterpoise so as nearly to close the front of the hearth.

The fuel used is either coal or peat, now more usually coal, and the blast is supplied by a Roots blower, driven by a water-wheel. The mass of agglomerated ore, slag, and coke left at the end of each shift is called the 'browse.' In working, a fire of coal is made on the hearth, and then a moderate blast turned on. Ore is next thrown on, and when the hearth is provided with a shutter, this is closed down. After the lapse of a few minutes, the charge is stirred by a poker and fresh fuel and ore, and a little lime added from time to time, the fuel being thrown in front of the tuyere. At intervals the shutter is raised and a portion of the charge drawn on to the work-stone, the grey slags picked out and the remainder broken up and returned to the hearth. The charge is rabbled so as to distribute the blast. As the lead is formed it trickles into the well, and overflows along the channel in the work-stone into the pot in front of the hearth, from which it is ladled into moulds. Towards the end of a shift fresh ore is not added, but the 'browse' is thoroughly worked up alone, and when the blast is stopped, the grey slags are separated, and a portion of the lead from the metal pot ladled back into the well so as to fill it for the next shift. Each furnace is attended by two men and produces about a ton of lead on a 6-hour shift. The fuel-consumption is small, amounting to 6–8 p.c., since the oxidation of lead sulphide both to oxide and sulphate is strongly exothermal. The grey slags contain 35–45 p.c. of lead, largely in the form of oxide and sulphate, and are well adapted for smelting in shaft furnaces. The effect of sintering the ore before smelting in hearths is shown by the following results obtained by Cookson, in smelting 400 tons of ore, yielding on assay 81 p.c. of lead, one half of which was smelted raw and the other half after roasting (*v.* Local Government Report, 1878–9. Supplement containing the Report of the Medical Officer, 1878, 289).

	200 tons roasted	200 tons raw
Lead, first fire . .	73·10	60·80
Lead in grey slags .	2·50	1·80
Lead in fume, hearth-ends, loss, &c. . .	5·40	18·40
	81·00	81·00

The ore hearth cannot be worked continuously, as it becomes too hot. Usually, after 8–12 hours' working it has to be laid off to cool. Many devices have been suggested and put into practice in order to overcome this difficulty. The American hearth, first introduced at Rossie, New York, is similar in construction and working to the Scotch hearth, but differs in having the two sides and back formed into an air chest, the air from which is led by a pipe to a tuyere at the back of the hearth. In this way the back and sides of the hearth are kept cool and a hot blast is supplied. The latter has not, however, proved an advantage for the loss by volatilisation is greatly increased. This has led to the replacement of this form of hearth by what is known as the American water-back ore hearth, which has the three sides of the furnace formed of a water-cooled, cast-iron jacket.

A recent modification of the ore hearth, in which mechanical rabbling is successfully employed, is the Newnam or St. Louis hearth. The rabble-arms are hung from a carriage travelling on an overhead track, and their motion is similar to that of the hand-rabble. They work in one direction only, and each time the rabbles are withdrawn from the charge they are carried forward 4 inches by the carriage and are then in position for the next stroke. A 'helper' follows the rabble with a long-handled shovel, pushes back the loose charge and picks out the grey slag; behind him comes a 'charger' who spreads fresh ore and fuel. At the end of a trip, the rabbling machine is returned, without rabbling, to the other end of the furnace, and the operations are repeated.

With this arrangement it has been found possible to double the length of the hearth without increasing the manual labour required to work it; at the same time, the consumption of fuel is halved and the production of fume and dust is greatly diminished. The following results are averages for an 8-hour shift, over a period of 4 weeks, for an 8-foot Newnam and a 4-foot hand hearth worked side by side, the labour being the same in each case. The ore

consisted of galena concentrates containing 72·5 p.c. lead and 15·1 p.c. sulphur.

	Newnam hearth.	Hand hearth.
Dry ore charged	13,179 lbs.	5,091 lbs.
Pig lead produced	6,443 ,,	2,030 ,,
Grey slag	3,318 ,,	1,329 ,,
Dust and fume	2,328 ,,	1,481 ,,
Distribution of lead in the products :		
Pig lead	67·44 p.c.	55·00 p.c.
Grey slag	15·18 ,,	16·20 ,,
Dust and fume	17·38 ,,	28·88 ,,
Consumption of coke breeze	3·6 ,,	8·8 ,,
Elimination of sulphur of the charge	87·9 ,,	80·6 ,,

It is claimed that the cost of production of lead from rich ores and concentrates by this process is much below that for sintering and blast-furnace smelting (W. E. Newnam, Trans. Amer. Inst. Min. Eng. 1916, 2139).

Slag hearth.—The rich grey slags consisting largely of oxide and lead sulphate, with some unaltered galena, obtained in the air-reduction process, are sometimes smelted in a low-shaft furnace, known as the slag-hearth. This is a shallow, rectangular furnace made of cast-iron plates, open at the front so that the metal and slags flow away continuously, and furnished with a single tuyere. The bottom- or bed-plate slopes to the opening, and is covered with cinders, well beaten down. The hearth bottom thus formed slopes from the back to the open eye of the furnace and serves as a filter to separate the lead from the slags.

In front of the furnace is a forehearth with two iron pots, one for lead, the other for slag The slag flows over from the first into the second pot, and is there granulated by a stream of water, so that shots of lead, held mechanically by the slag, are liberated.

The charge consists of grey slags and fuel in the form of peat or coke; occasionally, ferruginous materials are added. The chemical changes involved are those of the roasting and reaction process, and reduction by carbon, sometimes combined with precipitation by iron.

Grey slags are now usually smelted in the blast furnace with coke and iron slag.

Smelting in Blast Furnaces.

Smelting in reverberatories and hearths is restricted to high-grade ores and concentrates containing over 60 p.c. of lead and less than 5 p.c. of silica. Ores not conforming to this standard of composition, as well as slags from the air-reduction process, roasted mattes and furnace products rich in lead are smelted in the blast furnace. Surface ores, or similar mixtures of sulphide and oxidised compounds of lead, may be smelted direct; ores which consist largely of sulphides must first be roasted to remove the sulphur and convert the lead into oxide (and sulphate), and the roasted product is then smelted with reducing agents, fluxes being added, if necessary, in order to slag the earthy and silicious materials of the charge. If the charge contains much sulphur this is not, as a rule, eliminated under the conditions existing in the blast furnace, but it enters into combination with iron, copper, and lead to form a matte. As the complete removal of sulphur from an ore by roasting (*i.e.* dead-roasting) is a difficult and expensive operation, and as many lead ores contain copper, some cupriferous matte is generally produced in blast-furnace smelting, and from this matte the copper can be recovered by suitable treatment. The residual sulphur of the charge thus serves as a means of extracting the copper and is itself removed in effecting that end; from a practical point of view, too, the production of a small quantity of matte is advantageous in that it promotes the easy running of the furnace and gives cleaner slags.

The chemical reactions, already described, by which lead is produced from its compounds under metallurgical conditions are all operative in the blast furnace, though to an extent which varies considerably according to conditions and the composition of the charge. The roasting-and-reaction process is generally quite subsidiary, for the atmosphere in the furnace is essentially a reducing one and oxidation of sulphide to sulphate, necessarily, does not take place to any great extent. 'Reaction' between sulphide and sulphate, however, is always possible in the hotter parts of the furnace, when both compounds are present in the charge.

Reduction of galena by iron, or precipitation, is at times an important reaction in the blast furnace, though it carries with it the same drawbacks as were mentioned in the section on reverberatory smelting, viz. the production of excessive amounts of matte, which demands costly treatment for the recovery of lead and copper contained in it. Formerly, metallic iron was added to the charge; now it is customary to add oxide ores of iron, roasted matte, and iron slags, *i.e.* materials reducible in the furnace to iron which is then available for reaction with lead sulphide. With the present methods of smelting, however, the importance of these ferruginous materials is based rather on their slagging properties than on their suitability for bringing about the reaction of iron-reduction.

The typical reaction of blast-furnace smelting is reduction of lead oxide by carbon (and carbon monoxide). Thus the smelting of sulphide ores of lead necessitates two very distinct operations: roasting of the ores to convert the lead into oxide, the sulphur being driven off as volatile oxides; and reduction of the roasted ores in the blast furnace. In no case is roasting complete, in the sense that all the sulphur is burnt off and all the lead left as oxide. The roasted mass always contains some unaltered sulphide of lead (the amount of which compound may be supplemented by subsequent reduction of sulphate), and lead is also present as sulphate and silicate. It should be added that arsenic, to a large extent, and some antimony, if these metals are present, are volatilised during the roasting.

Roasting of the Ores.

The old method of roasting in heaps is sometimes, though rarely, used for pyritic ores poor in lead. The construction of the heaps is simple. The ground is first cleared and levelled, a bed of fine ore is laid down, and then the wood for kindling the heap. Upon the wood, the ore

is piled; first the main bulk of coarse ore, over this the fines and, over all, the slimes, the whole forming a pyramidal heap which may vary very greatly in dimensions. At Port Pirie, N.S.W., the heaps are 250 feet long, 20 feet wide, and 6 feet high, the material being ore-slimes which are dried and cut into blocks. The sulphur-content is reduced from 12 to 7 p.c. by this treatment.

Roasting in Cylinder Furnaces.—There are two types of revolving cylinders, the rotation being either about a horizontal or a sloping axis. The Brückner cylinder exemplifies the first type. The dimensions of these cylinders vary from 12 by 6 feet to 26 by 8 feet, the charges being 4 and 25 tons respectively. They make one revolution in 40 minutes and are supplied either with stationary or movable fire-boxes, the latter being preferable when roasting proceeds of itself after ignition of the ore. The time taken to work off a charge varies from 3 to 24 hours, according to the nature of the materials.

The Oxland cylinder is an example of the second type. It is used at Laurium, in Greece, for roasting concentrates containing Pb, 60 p.c.; S, 20 p.c. This furnace is 42 feet 9 inches long, 3 feet 1 inch diameter inside; it makes one revolution in 4 minutes and roasts the charge down to 4 p.c. of sulphur.

Roasting in Reverberatory Furnaces. — Mechanical reverberatories such as those used in roasting copper ores find a somewhat limited application for the roasting of lead ores. Of these furnaces, some have fixed hearths and movable rabbles, *e.g.* the Wethey, Ropp, and Keller furnaces; others have revolving hearths and fixed rabbles, *e.g.* the Brunton, Heberlein, and Godfrey furnaces. It will suffice for our purpose to describe one of these briefly, and the Ropp Straight Line furnace will be selected as the one which has, perhaps, found most favour in the treatment of lead ores. Reference to the annexed diagram (Fig. 7) will help to make clear the description.

The Ropp is a rectangular furnace with 3 or 4 fireplaces disposed on one of the long sides. Four or six rabbles work on the hearth. The ploughs which stir the ore are set at an angle of 45° to the rabble arms. These are attached to a vertical rod passing through a slot 1½ inches wide which runs continuously down the middle of the hearth. An endless wire rope, driven by power, links up these arms and passes round two pulleys at the ends of the furnace. The com-

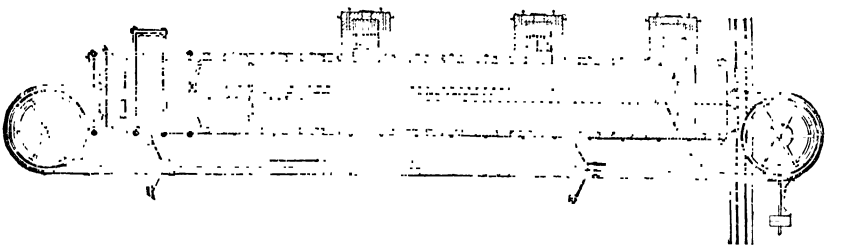

Fig. 7.—The Ropp Furnace.

(*From* Schnabel's 'Handbook of Metallurgy.' Macmillan & Co., Ltd.)

plete revolution of the rabbles takes 3½ minutes, and as they are outside of the furnace for more than half that time, they become cooled and preserved thereby from injury. At each end of the furnace are swinging doors, through which the rabbles enter and leave the furnace. The working doors are placed at suitable intervals along the longer sides of the furnace. The ore is charged at one end of the furnace, traverses it in the direction opposite to that of the hot gases, and is discharged at the other end, remaining in the furnace 6–8 hours. The length of the hearth varies from 100–150 feet, the width from 11–14 feet, in the clear; the large furnaces put through 50–80 tons of ore in 24 hours, with a coal consumption of 13 p.c., and an expenditure of 5–8 h.p. for working the rabbles.

The use of mechanically-rabbled furnaces for roasting lead ores suffers, however, from certain disadvantages. Galena is difficult to roast; it must be finely divided and the temperature must be regulated so that incipient fusion of the mineral is avoided, otherwise the fritted material becomes impervious to air and oxidation is arrested. With progressive conversion of sulphide into oxide and sulphate, the risk of fusion is lessened; at the same time, it is desirable that the temperature should be increased in order to hasten the oxidation of the unaltered sulphide. The advantage of a temperature-gradient in the furnace, coupled with the transportation of the charge as oxidation progresses, from the cooler to the hotter parts, becomes obvious. These conditions are best attained in the long-bedded, hand-worked reverberatories (*Fortschaufelungs* furnace), and these furnaces have been, and still are, extensively used for roasting lead ores.

The construction of this furnace will be understood from the accompanying figures, for the drawings of which and also for much information respecting the present practice of lead smelting, the writer is indebted to Mr. W. Maynard Hutchings.

Fig. 8 is a front elevation of the furnace, which is constructed of brickwork with a lining of fire-brick, and stayed together with iron standards and crossbars. In this is also shown the hopper *a* for charging ore, the ten working doors *b*, the door *c* for the withdrawal of the charge, and the door *d* for charging the fuel.

Fig. 9 represents a vertical section, showing the fire-grate *e*, the fire-bridge *f*, and bed of the furnace, constructed of iron plates supported by pillars of brickwork, which are cooled by circulation of air below; upon these plates are built the materials composing the bed of the furnace. *g* is the opening in the roof through which the ore from the hopper is discharged into

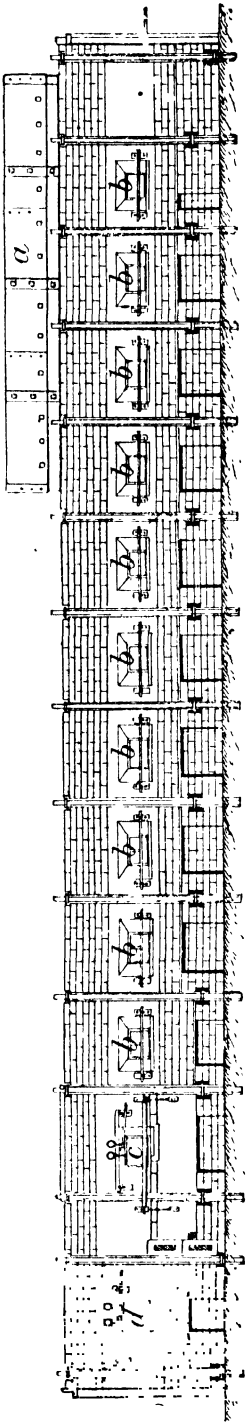

Fig. 8.

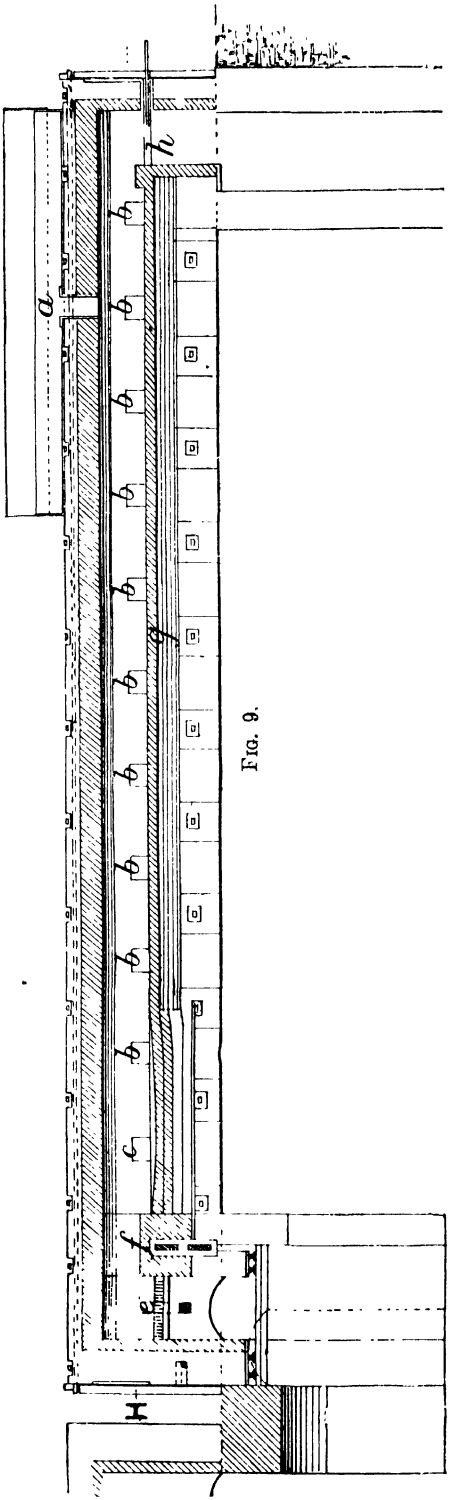

Fig. 9.

the furnace bed, *h* the flue leading to a series of condensing chambers.

Fig. 10 is a plan of the furnace, and Figs. 11 and 12 are vertical sections through CD and FG respectively.

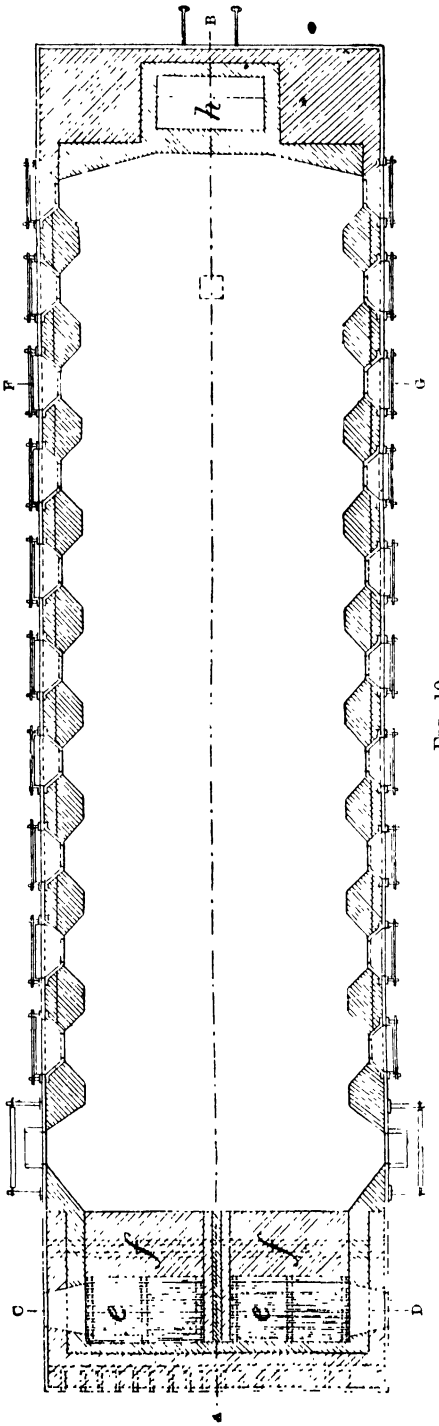

FIG 10.

The usual size of these furnaces is 60 feet by 16 feet; occasionally they are much longer—up to 80 feet—but the breadth is limited by the necessity of working the charge from each side. The bed of the furnace is sometimes divided into four hearths, each with a step of 2 inches towards the fire-bridge, and having two working doors at either side. The ore is charged on the hearth furthest removed from the fire and spread out in a layer 3–6 inches thick. The roasted ore is discharged through an opening in the hearth nearest the fire-bridge, and the ore from each hearth raked up in turn, so that it is subjected

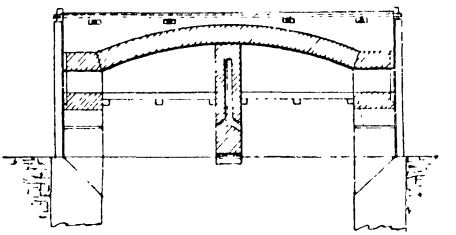

FIG. 11.

to a gradually increasing temperature as the oxidation of the sulphide proceeds. Sometimes the roasted ore is discharged as a powder, in which case it has to be briquetted before smelting; more usually it is sintered, a sump being provided near the fire-bridge (*r*. Fig. 9) in which the semi-fused mass is collected and from which it can be raked into slag pots and agglomerated by tamping. When complete fusion is required (this is not advisable when the ores are rich in silver) the furnace sometimes has a separate hearth next to the fire-bridge, smaller, and at a lower level, than the main ones, and connected with them by a vertical flue about 2 feet 6 inches

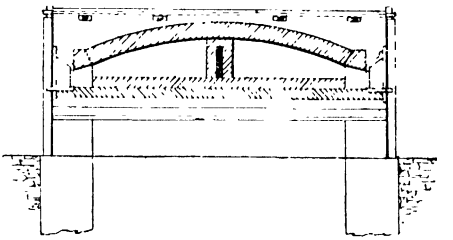

FIG 12.

high. Sand may be strewn on the fusion-hearth before the charge is raked on The effect of this is to decompose the lead sulphate, lead silicate being formed on fusion and sulphur trioxide driven off. As lead sulphate is reduced to sulphide in the blast furnace, this method of treatment lessens the matte-fall. The charge is melted in this hearth, raked into slag pots and broken up before smelting. This method of treatment, slag-roasting as it is termed, is less favoured by smelters than sinter-roasting, which leaves the material in a porous condition suitable for the blast furnace.

Heap-roasting may be combined with cylinder- or reverberatory-roasting, and any

of these with the method of blast-roasting which will now be described.

Blast- or Pot-Roasting.—In 1896 Huntington and Heberlein introduced a method of treating galena, and concentrates consisting of galena mixed with pyrites and blende; by this process the ore is rapidly desulphurised and obtained in a condition suitable for the blast furnace, and incidentally the sulphur dioxide produced may be utilised for the production of sulphuric acid. In this process the ore is mixed with 6 to 15 p.c. of lime or limestone, according to the proportion of sulphur in the ore, and roasted in a reverberatory furnace. The partially desulphurised material is transferred to a pear-shaped pot or converter, made of sheet iron, in which it is submitted to the action of a blast of air; during the blowing in the converter, energetic oxidation takes place, accompanied by other reactions, resulting in a rise of temperature sufficient to bring about agglomeration of the mass. This principle has been modified in various ways and has attained great importance, during recent years, in the practice of lead-smelting. The modifications are concerned with the materials added to the charge and with the manner in which the air is supplied. In the original process the air is blown upwards through the charge, and this arrangement is adopted in the Carmichael-Bradford and Savelsberg modifications, which are thus termed 'up-draught' processes. In the Dwight-Lloyd process the air is drawn downwards, by suction, through the charge, and the term 'down-draught' is therefore applied to this process.

The converter used in the Huntington-Heberlein process is shown in Fig. 13.

The blast enters by a pipe at the bottom of the converter and the charge rests on a false bottom, consisting of an iron grate, which serves to distribute the blast. When in action, the top is covered by a hood through which the fumes escape; after the roasting is completed, the hood is removed, the converter tipped, and the agglomerated mass allowed to fall some distance in order to break it up. Such a converter takes a charge of 8 tons.

To start the operation, a small fire is lighted in the converter and some hot, partly-roasted ore added. A low-pressure blast is turned on, and then the main bulk of the ore, which may be either hot from the reverberatory roasting, or cooled and moistened with water, is added from time to time in suitable quantities, the blast pressure being increased. The method used at Braubach (Prussia) may be quoted as an example. The ores are roasted in reverberatories down to 10 p.c. of sulphur. The pots hold 11 tons. One ton of hot ore is put in first, then 5 tons of cold ore on top. After 8 hours' blow, the remainder of the charge, 5 tons, is added cold and the blow continued for 4 hours longer. The sulphur is reduced, thereby, to 3 p.c. One reverberatory serves $1\frac{1}{2}$ converters.

In the Savelsberg process, limestone and silicious materials are added to the ore and the mixture blown directly in the converter, the preliminary roasting of the charge being omitted.

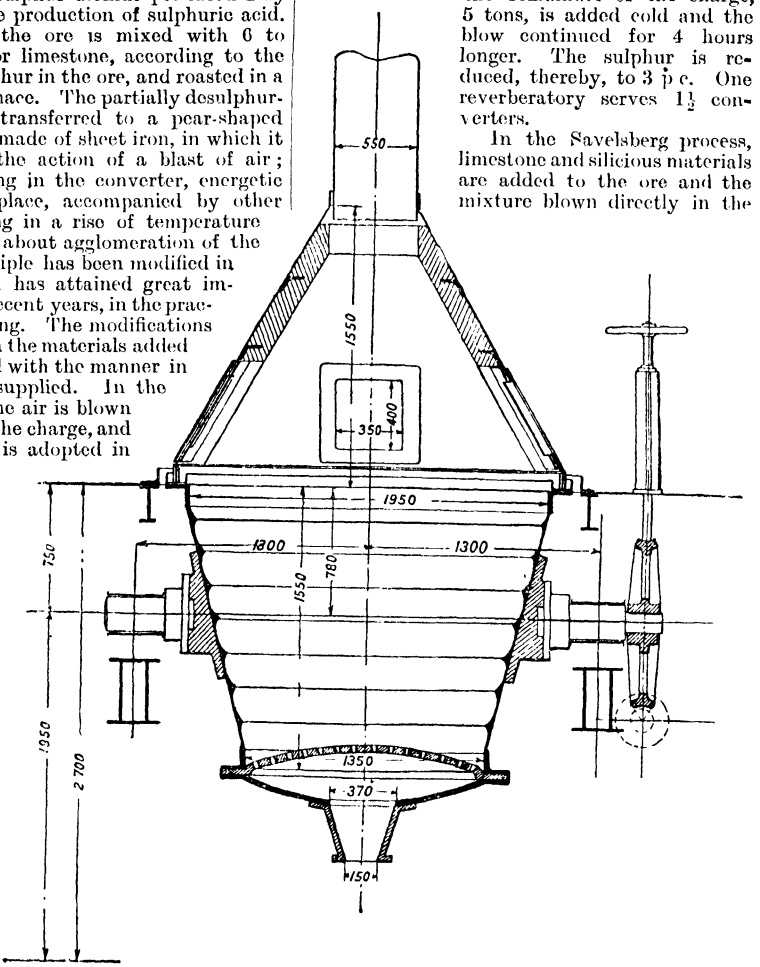

FIG. 13.

(*From* Collins' 'Metallurgy of Lead.' C. Griffin & Sons.)

In the Carmichael-Bradford process, the preliminary roasting of the ores is likewise omitted. The materials are mixed with calcined gypsum and water, and after the mixture has set it is broken up into small pieces and submitted to the pot-roasting process.

The chief shortcomings of these processes are that they are discontinuous, and the capacity of the converters is small. Only a comparatively thin layer of the ore is being oxidised at any particular moment, the main

bulk remaining inert, either in an oxidised or unoxidised condition These disadvantages are avoided in the down-draught method of Dwight and Lloyd, the essence of which is that a thin layer of fine ore is exposed to the air and the process is continuous. As the roasting is quickly accomplished, the capacity of the machines is considerable.

One type of machine, in which the operation is carried out, is shown in Fig. 14. It consists of a continuous series of pallets, 42 inches wide by 24 inches long, composed of cast-iron grates with ¼ inch spaces. In the course of their revolution the pallets pass beneath the charging hopper and receive the moistened ore, which is spread about 4 inches thick; thence they pass to the fire-box where the surface of the charge is ignited by a flame pointing downwards, and then to the suction-box, where the roasting is effected by air drawn through the charge. Finally the roasted ore is discharged automatically at the end of the machine by the fall of the pallets to the lower track; the empty pallets return in course of time to the hoppers and the cycle of operations is repeated. One complete revolution is made in about 45 minutes.

For the efficient working of this process, the sulphur in the charge should not exceed 18 p.c. In the treatment of concentrates, either preliminary roasting in a reverberatory is necessary, or the concentrates must be diluted with poor ores before being roasted by the Dwight-Lloyd process. By the adoption of a double roast, either in Huntington-Heberlein and Dwight-Lloyd converters, or in a double set of the latter, it has been found possible to avoid reverber-

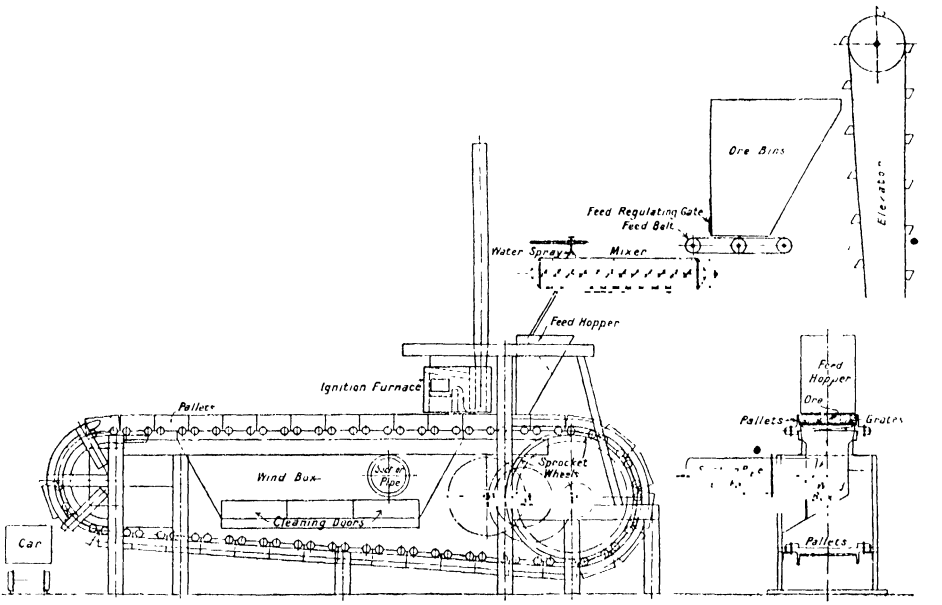

FIG. 14.

(*From* Collins' 'Metallurgy of Lead.' C. Griffin & Sons.)

atory roasting and dilution; sulphur is reduced to 2–3 p.c., and in the subsequent smelting the yields of matte and slag are small.

The chemical reactions taking place during blast-roasting have been the subject of much speculation and discussion. The conversion of lead sulphide into lead oxide is the reaction of prime importance, and this is generally assumed to be the result of the interaction between sulphide and sulphate, as expressed in the equation:

$$PbS+3PbSO_4=4PbO+4SO_2$$

It may be noted that a similar reaction occurs when barium sulphate is heated in the electric furnace, the process being one which might be termed, by analogy, reduction-and-reaction. It is likely, however, that some oxide is formed by direct oxidation of lead sulphide. There are few actual and possible constituents of the converter charge which have escaped the suspicion of acting as catalysts in the oxidation of the lead sulphide, though it cannot be said that the claims of most of them as oxygen-carriers are well established. Most of the controversy on this subject has been centred on the function of the calcium compounds. When lime or limestone is present, there is evidence from the glowing of the charge on gently heating that reaction with galena takes place, the result being, apparently, the formation of calcium sulphide and lead oxide (carbon dioxide being liberated when limestone is used). The calcium sulphide is then rapidly oxidised to calcium sulphate, though by what agency is not apparent. The result is, however, that no matter what compound of calcium is used, the oxidation of the ore is effected, for the

greater part, in presence of calcium sulphate. The facilitation of the roasting-process by means of this compound has been demonstrated (*see* W. M. Hutchings, Eng. and Min. Journ. Oct. 1905). It will be clear that, apart from the possibility of calcium sulphate acting as a catalyst, there are many possibilities of reaction among the oxides, sulphides, and sulphates of lead and calcium, especially in presence of atmospheric oxygen. That some reaction between sulphide and sulphate of lead, like that which is the basis of the roasting and reaction process, takes place is evident from the production of prills of metallic lead (*see* W. R. Ingalls, Amer. Inst Min. Eng. July, 1906).

Of the secondary reactions which occur, particular mention should be made of the formation of silicates of lime and calcium by the interaction of silica with lead oxide, lead sulphate, and calcium sulphate. In the last two cases, sulphur trioxide is evolved and the passage of this, at a high temperature, through the charge has undoubtedly a powerful oxidising action on the unaltered galena (Hutchings, *l.c.*).

The possibility of blast-roasting without the addition of calcium compounds indicates that though these may facilitate the reactions, they are not essential to the effective oxidation of galena, but that the conditions of air-feed peculiar to the converter-process are primarily responsible for the efficiency of this process. Mention should be made, too, of the mechanical effect of the added materials, whatever their nature may be, in keeping open the charge, and preventing premature agglomeration of the ore.

Smelting the Roasted Ores.

There are two types of blast furnace in general use, the round or circular and the rectangular. The first is exemplified by the Pilz, the second by the Raschette furnace. An old form of the Pilz is represented in the accompanying diagram (Fig. 15). It is 25 feet high, 4 feet 11 inches in diameter at the tuyeres, gradually widening to 6 feet 7 inches at the throat, and is supplied with 8 tuyeres.

a is the hearth bottom, composed of four courses of bricks, the lowest of common brick, resting on a circular plate of from 1½ inches thick, then three courses of fire-bricks, all encased in boiler-plate, made in segments screwed together and further strengthened by hoops of wrought iron; *b*, channels extending through the brickwork and open at both ends; these channels, of which there are two, at right angles, allow of the escape of moisture; *c c*, brickwork forming the inner and upper part of the hearth; *c′ c′*, brickwork of the boshes; *c″ c″*, brickwork forming the shaft; *d d*, the tap holes, of which there are four; *e e*, two slag lips, along which the slag flows into the slag pot *p*, consisting of a cast-iron conical vessel; *f f*, blast pipes, the horizontal portions of which can be moved to and from the tuyere holes; the vertical portions are supplied with a sliding screw by means of which they may be moved up and down; *g g g* are wrought-iron water-jackets made in sections the construction of which is shown in detail in the accompanying illustrations. Water-jackets may also be constructed of cast iron, each segment being provided with an aperture for the tuyere and also pipes for conveying the cold water and for the outflow of the heated water; *h h*, ring of angle iron, riveted to the outer case, serving for the support of the shaft during the repairing of the lower part of the furnace; *i i*, blast main of cast iron; *k*, ring of iron supported by the four cast-iron pillars *l l*; *m*, cast-iron cylinder, flanged at the top and inserted into the mouth of the furnace, in order that the fume and waste gases may be drawn off by the pipe *n*; *o*, charging floor; *q*, outer iron casing of the furnace. The water-jackets are ⅛ of an inch in thickness, and are riveted to angle iron 2¾ inches by ¾ inch; *s s* are side plates overlapping by 2¾ inches top and bottom; *t*, pipes for supplying cold water; and *u*, pipe for the outflow of cold water; *v*, tuyeres, which are 2¾ inches in diameter.

The diameter of circular furnaces varies from about 36 to 60 inches, the smaller being used for powdery, the larger for lumpy ores. The number of tuyeres varies from 8 to 24, and the blast pressure from 10 to 50 mm. of mercury. These furnaces are limited in diameter by the range of penetration of the blast, which is about 36 inches. They are chiefly used in small works, and especially in Europe All modern ones are fitted with the Arendts' or automatic syphon tap, which will be described presently, and they are usually boshed for the better utilisation of the heat and reducing gases and the more uniform descent of the charge.

The rectangular furnace is developed from the Raschette and, because of its great capacity, is the one almost universally used in America, where immense quantities of low-grade ore are available. The breadth of these furnaces is limited for the same reason as in the case of the circular furnaces, but the length can vary within wide limits. The dimensions of the smaller furnaces are about 42 by 84 inches, the larger ones 48 by 156 inches; an extreme size is 62 by 212 inches. A view of the lower part of one of the larger furnaces is shown in Fig. 16. This furnace is fitted with steel water-jackets.

Fig 17 shows a drawing of a complete modern rectangular furnace, of which the following is a brief description:

The shaft of the furnace, A, is made of brick and carried on a mantle ring resting on four columns. In this are four charging doors, B, at the feed level. The top is enclosed by a hood closed by a damper, and the fumes are drawn off into the fume chambers and bag-house by a pipe (not shown in the figure). The height of the shaft is 16–20 feet. The zone of fusion is enclosed in water-jackets, C, from 3½–6 feet high. The use of these, and also of cold blast, prevents undue volatilisation and hinders corrosion of the hotter parts of the furnace. The blast is supplied at a pressure of about 130 mm. of mercury and enters the furnace by 14 tuyeres, D, each 4 inches in diameter, which pass through the water-jackets and are distributed along the two longer sides of the furnace. As a rule, there are no tuyeres in the end jackets. The tuyeres are fed from a blast main, E, the connections being well seen in Fig. 16. The lower part of the furnace or crucible, F, is built of fire-brick and magnesia brick, surrounded by brasque and securely held by enclosing iron walls and

bed-plate. A channel 6-8 inches square leads from the crucible to the outside of furnace in the middle of one of the longer sides. This opens out into a basin and constitutes the automatic tap, a. The furnace is worked with the crucible full of molten lead, and the metal naturally stands at the same level in the basin as in the crucible. The lead may be run off in a continuous stream,

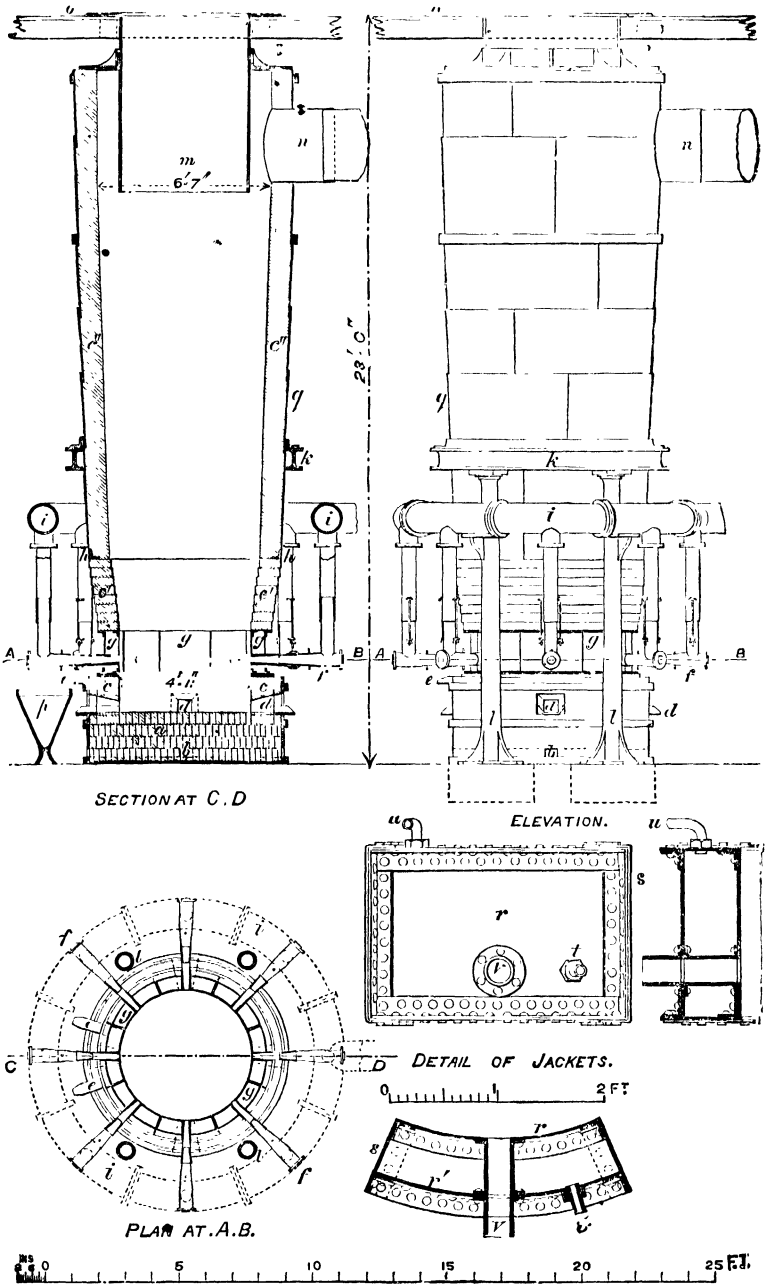

FIG. 15.

or it may be ladled from the basin as required. The advantages of this method are that the unhealthy operation of tapping is avoided, complete separation of lead from matte and slag is effected, and the cooling which would result from emptying the crucible entirely is obviated. The distance of the tuyeres above the level of the lead bath is about 12 inches, and is so

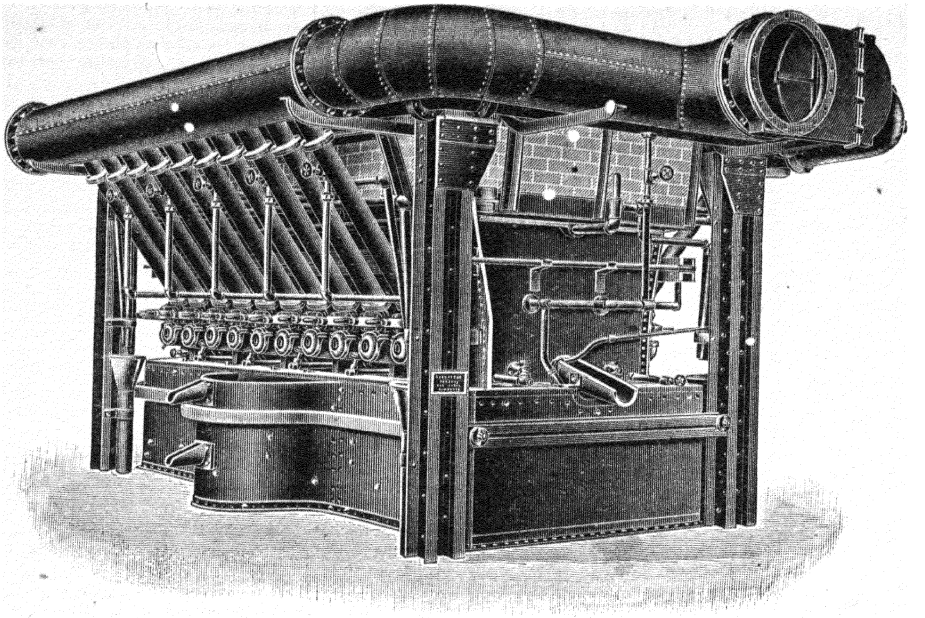

FIG 16.

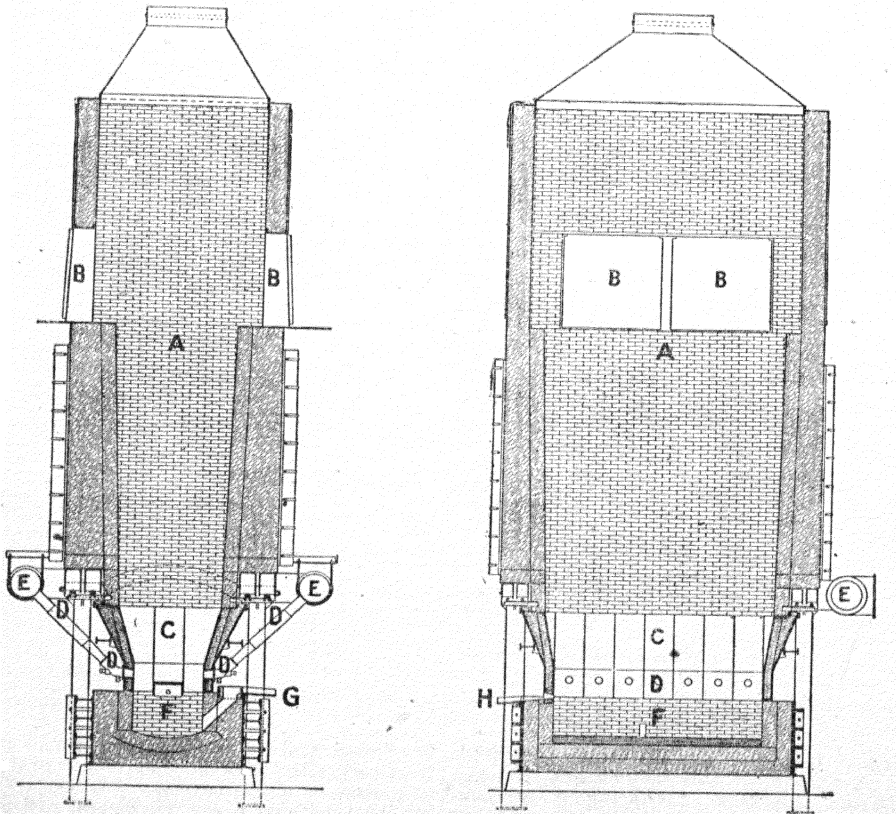

FIG. 17.

arranged that the heat is sufficient to keep the lead molten. Between the lead level and the tuyeres is a slag tap, H, from which slag and matte are continuously discharged. They are collected in settlers or forehearths, sometimes heated by a fire, and the matte tapped off from the slag. Such a furnace will put through 150–250 tons in 24 hours, with a coke consumption of 12 p c. of the charge.

The charge for blast-furnace smelting consists in general of ores and mattes, roasted by the methods already described; earthy and silicious materials either derived from the ores or added to produce the desired slag; slags from previous operations, in amount up to 20 p.c., which are added partly to recover values present in them, and partly to facilitate the furnace-running; and coke, the usual fuel and reducing agent. Sulphide ores rich in silver are generally added direct to the blast-furnace charges, in order to obviate the loss of silver which would occur during roasting. The lead-content of the charge varies considerably; 10–12 p.c. is usually regarded as a minimum consistent with the effective action of the lead as a solvent or vehicle for the silver; 50 p.c. of lead is not uncommon, and the average may be put roughly as 20 p.c.

Great care has to be exercised in the selection of materials to produce the slag. Barren fluxes are avoided if possible, silicious silver ores and iron ores from the gossans, which usually contain some lead and precious metals, being utilised where available. The objects aimed at are to produce a monosilicate, mobile when molten, and having a sp.gr. of 3·5. Analyses of slags of proved merit are given in the following table :—

	$(Fe,Mn)O$	$(Ca,Mg)O$	SiO_2
1.	50	12	28
2.	40	20	30
3.	33	24	33

No. 1 is the Freiberg type and is especially valuable for charges rich in zinc. Slags rich in zinc should be highly ferruginous and correspondingly poor in lime. The amount of zinc should not exceed 15 p.c. (reckoned as oxide). According to Hutchings (Eng. and Min. Journ. Oct. 1903), zinc is present in slags in the form of silicate (willemite), zinciferous magnetite, and zinc spinels. Alumina in slags should be kept as low as possible. Slags, to be 'clean,' should carry less than 1 p.c. of lead and 0·0015 p.c. of silver.

An outline of the chemical reactions which take place in the blast furnace, in so far as these are responsible for the production of most of the lead, has already been given (*v.* p. 50). This may be amplified by a brief consideration of the part which the silicates play in the process. Silicates of lead, iron, and calcium may be already present in the materials charged. In any case, the decomposition of limestone and the reduction of ferric to ferrous oxide, by carbon monoxide, furnish bases which unite with silica in the zone of fusion. Lead silicate may also be formed by reaction of lead oxide and silica. Complete reduction of oxide of iron by carbon yields the metal. Lead silicate is reduced by metallic iron, but it is not decomposed by lime; lime, however, displaces ferrous oxide from ferrous silicate, and as the ferrous oxide is in turn reduced to iron, this becomes available for the decomposition of lead silicate (and lead sulphide). The net result of these reactions is the production of metallic lead and a slag free from lead silicate.

Other metals present in the charge are also reduced and pass to some extent into the lead, and it is, of course, all-important that the precious metals should be very completely dissolved in that medium. Copper is largely recovered as sulphide, Cu_2S, in the matte, though some is invariably taken up in the metallic form by the lead. Arsenic is partly volatilised and partly combines with iron to form a speiss which carries some copper, lead, and silver, and practically all the nickel and cobalt present.

The products of the blast furnace are lead, matte, speiss, slag, and flue dust. The *lead*, known as work-lead or base-bullion, is almost always hard and impure, and is submitted to refining and desilverising processes, which are described later. The *matte* separates from the slag in the settler or forehearth. Its sp.gr. is 5–6, and should be at least one unit greater than the slag, otherwise complete separation is difficult to attain. Mattes usually contain 10–20 p.c. of lead, along with some copper, the composition varying within wide limits, as may be seen from the following analyses :—

Composition of Mattes.

	Oker	Przibram	Laurium	Dapto
Iron . .	30·5	41·3	50·8	46·6
Lead . .	5·1	11·2	7·7	15·4
Copper .	16·8	1·5	1·8	3·9
Zinc . .	16·3	11·5	7·6	6·4
Sulphur .	16·4	22·2	21·8	25·0

Mattes always carry some silver and gold, but silver is relatively more soluble in them than gold. They are roasted and added to blast-furnace charges, whereby the iron becomes available for slagging and reduction purposes, and a new matte, enriched in copper, is formed. When the copper-content rises to 10 p.c., the mattes are roasted down to 3–4 p.c. of sulphur and then smelted with liquation-residues and silicious copper ores. After enrichment to 30–40 p.c. of copper, they are usually sold to the copper smelters and treated for copper by the converter, or some other, process.

Speiss is formed in blast-furnace practice only when the charges are rich in arsenic or antimony and iron. It is essentially an arsenide (and antimonide) of iron, carrying some silver, a relatively large amount of gold, some lead and copper, and practically all the nickel and cobalt. Except in isolated cases, the last two metals are of no importance in blast-furnace products; a speiss rarely contains 5 p.c. of them. Some Freiberg speisses, however, have more than double this amount.

The composition of speiss is illustrated by the following table of analyses (values, per cent.) :—

Composition of Speisses.

	Przibram	Laurium	Leadville	Freiberg
Silver .	0·037	0·011	0·008	0·077
Iron . .	61·3	63·8	60·6	17·8
Arsenic .	18·5	20·7	31·5	23·4
Antimony .	2·4	—	—	6·5
Lead .	1·7	0·5	1·5	11·2
Copper .	1·9	0·6	0·4	24·2
Nickel and cobalt	2·2	—	0·1	1·3
Sulphur .	9·6	4·6	5·8	3·5

Speiss is desilverised by smelting in the blast furnace; copper passes into the matte and nickel and cobalt are concentrated in the new speiss. Thus, a raw speiss containing 6 p.c. of nickel and cobalt and 0·16 p.c. of silver yielded on smelting a new speiss containing 16 p.c. of nickel and cobalt and only 0·05 p.c. of silver. Rich speisses may be roasted with pyrites, when the arsenic is volatilised as sulphide, and the residues smelted with silicious additions in the blast furnace.

Slags have already been considered with respect to their composition and fitness for the smooth running of furnace work. The clean separation of slag from matte (and speiss) is of great importance, and depends largely on their relative fluidities and specific gravities. Matte is dissolved to some extent by slag, acidic slags dissolving less than basic, and calcareous less than ferruginous slags.

Flue dust.—The methods for the collection and treatment of this will be described later. The waste gases from the blast furnace contain 5–10 p.c. of carbon monoxide, and 15–20 p.c. of carbon dioxide, the remainder being chiefly nitrogen.

The loss of lead in the blast furnace is variable, 7 p.c. on the dry assay being considered satisfactory. The loss of silver is very small by this method, whereas in the roasting-and-reaction process the average loss is about 1·5 p.c.

The basis of the modern American and Australian practice of lead-smelting is blast roasting of ores, either by the Huntington-Heberlein or Dwight-Lloyd methods, either singly or combined. This is sometimes preceded by roasting in cylinders or reverberatories and is followed by smelting of the roasted ore, with the addition of suitable fluxes, in rectangular, water-jacketed furnaces of large capacity.

In order to illustrate the principles and methods described above, some examples of blast-furnace smelting will now be considered.

Examples of Smelting.

Smelting at Clausthal.—As an example of the practice of the 'iron precipitation' process, the treatment adopted at Clausthal may be cited.

The ores are dressed and supplied to the smelter in the form of *schlieg*, having the average composition:—

Lead	50·7	to 73·6	p.c.[1]
Silver	0·555	„ 0·185	„
Copper	0·02	„ 0·6	„
Zinc	0·3	„ 4·1	„
Antimony	0·02	„ 0·3	„
Iron	0·4	„ 3·7	„
Sulphur	8·5	„ 14·2	„
Alumina	0·07	„ 1·5	„
Lime	0·2	„ 1·4	„
Insoluble residue	5·9	„ 32·4	„

The furnaces are circular, 25 feet high, 3 feet in diameter at the tuyeres, and 5 feet at the throat; they are furnished with 4 tuyeres.

The charge consist of *schlieg*, lime, roasted lead matte, slags obtained in smelting ore, and slags obtained from the smelting of matte, together with Oker slags, the residue left in the wet extraction of copper ores. These two last-named materials supply the iron required for the reduction of the lead ore, the former as silicate, and the latter as sesquioxide.

The following is an example of the composition of the charge:—

	Cwt.
Ore	100·00
Lead fume	1·01
Lead scrapings from the smelting house	0·63
Roasted lead matte	47·51
Schlieg scrapings from the charging floors	1·21
Oker slags	60·00
Slags from the same process	3·70
Matte slags	42·00
Slags from schlieg smelting	54 00
	310·06

The products obtained are work-lead, lead matte, and a slag containing some lead.

Two analyses of the work-lead are given in the following table:—

Lead	98·8378	98·9648
Copper	0·1862	0·2838
Antimony	0·5743	0·7685
Arsenic	0·0009	0·0074
Bismuth	0·0039	0 0082
Iron	0·0035	0·0028
Zinc	0·0025	0·0028
Nickel	0·0023	0 0028
Cobalt	0·0006	0 0003
Cadmium	trace	trace
	99·6130	100·0414

The lead is refined at Lautenthal, or, if it contains sufficient silver, is desilverised by Parkes' process. The average silver content is 0·14 p.c.

The following analysis gives the composition of the lead matte:

Sulphur	26·877
Iron	53·112
Lead	10·655
Copper	4·620
Silver	0 030
Antimony	0·267
Arsenic	—
Zinc	2 110
Manganese	0·385
Cobalt and nickel	0·306
Lime	0·383
Magnesia	0·054
Silica	0·510
	99·309

The matte is roasted in heaps and then smelted in the ore furnace. When the copper content exceeds 6–7 p.c., the roasted matte is smelted in a low blast furnace with slags from ore smelting and coke. The work-lead from this operation contains 0·4 to 1·5 p.c. of silver; the matte is again roasted and smelted until the copper-content rises to 20 p.c., when it is treated for the extraction of copper.

Smelting at Binsfeld.—The ores containing 70 p.c. of lead are mixed with limestone and sand and roasted in the Dwight-Lloyd machine. The roasted material contains 58 p.c. of lead. 1000 parts of this are mixed with 180 of ferruginous slag, 50 of spathic iron ore, 400 of slags from the same operation, and 100 of

[1] Karl, Grundriss der Metallhüttenkunde, p. 60.

various lead-bearing materials. This is then smelted in rectangular blast-furnaces, 40 by 148 inches at the tuyeres. Each furnace has 19 tuyeres and smelts 250 tons of the charge in 24 hours, yielding 70–80 tons of lead. The slags carry 2 p.c. of lead.

Smelting at Trail (British Columbia).—The chief ores are sulphide, which are mixed with lead matte and limestone so as to have the following composition:—

Lead	40–44 p.c.
Ferric oxide	10–13 „
Limestone	7–10 „
Silica	8–11 „
Sulphur	14–17 „

This mixture is roasted in revolving hearths so as to bring the sulphur down to 8–9 p.c. It is then further desulphurised and sintered by blast-roasting in Huntington-Heberlein pots, of which there are 24, each 8 feet 8 inches in diameter. The charge for the blast-furnace is made up of 85 parts of the sintered material, 2·5 of oxidised lead ores and silicious gold and silver ores, and 12·5 of coke, the average lead content being 40 p.c. and the sulphur below 4 p.c. This is smelted in rectangular blast furnaces 45 by 160 inches at the tuyeres, the blast pressure being 32 ozs. and the height of the column above the tuyeres 17½ feet. The output of work-lead per day from each furnace is 75 tons, and the composition is shown in the following table:—

Lead	98·5 p.c.
Copper	0·22 „
Zinc	0·098 „
Bismuth	0·013 „
Antimony	0·32 „
Arsenic	0 28 „

The base bullion carries 100 ozs. of silver and 0·1 oz. of gold per ton. It is cast into anode plates and refined electrolytically by the Betts' process.

The slags carry 1 p.c of lead and 0·4 oz. silver per ton, and have the following percentage composition: (Fe,Mn)O=24–30; (Ca,Mg)O=18–20; ZnO=7–12; Al_2O_3=8–16; SiO_2=31–33.

Smelting at Freiberg.—The ores are partly native and partly foreign, the latter being chiefly Canadian. They are classified according to their composition, and their treatment depends upon this. Ores containing over 25 p.c. of sulphur are roasted at the sulphuric acid works, the lump ore in kilns and muffles down to 3–6 p.c. of sulphur, the fines in *Schüttofen* down to 8 p.c. of sulphur. Galena, containing over 30 p.c. of lead, and leady ores with 10–30 p.c. lead are mixed with roasted fines, and other materials, and roasted either in long-bedded calciners or Huntington and Heberlein pots.

The reverberatories are 54 feet 6 inches long, and 14 feet wide; they put through 12 tons in 24 hours, the separate charges being 1·5 tons. The charges consist of 2·1 parts of galena and leady ores, 1·2 of dry silicious ores (containing less than 10 p.c each of lead and sulphur), and 2 parts of roasted fines, and they are divided into rich ores, carrying 0·5–0·7 p.c. of silver, and poor ores, carrying 0·1–0·3 p.c. of silver. The composition before and after roasting is given in the following table—

		Lead (p.c.)	Zinc (p.c.)	Copper (p.c.)	Sulphur (p.c.)	Silica (p.c.)	Silver (p.c.)
Rich ores	Before roasting	24	—	0·5	12·5	22	0·48
	After roasting	26	—	1·0	4·3	24	0·64
Poor ores	Before roasting	30	7	—	8·4	22	0 09
	After roasting	33	11	—	2·6	23	0·11

The converters for blast roasting hold 2·3 tons. Roasted fines are added to the ores instead of limestone, and the charge for pre-roasting is made up of 2·4 parts of galena, 0·9 of dry ores, and 1·5 of roasted fines, and averages 36 p.c. of lead and 14 p.c. of sulphur. This is roasted in rotating furnaces, the sulphur being reduced thereby to 10 p.c. and the roasted product mixed with 50 p.c. of the ore-mixture and again roasted in Huntington and Heberlein converters; in this way the sulphur is brought down to 3 p.c.

For smelting, circular furnaces of the Pilz type are used. The largest of these are 36 feet high, 6 feet 6 inches diameter at the tuyeres, and 8 feet at the throat; there are 20 tuyeres, and the blast pressure is 10–15 mm. of mercury. The charge consists of the roasted ore mixed with about two-thirds of its weight of slag from a previous operation, 2 p.c. of burnt pyrites, and small amounts of dry ores. The consumption of fuel (coke) is about 15 p.c. of the charge. The work-lead contains 0·5-2 p.c. of silver; the matte-fall is about 10 p.c., and the matte contains 20–25 p.c. lead, 6–10 p.c. of copper, and 0·1–0·25 p.c. of silver; the slags carry 4–6 p.c. of lead and 0·015 p.c. of silver. It is characteristic of Freiberg practice that no attempt is made to produce clean slags. They are re-smelted with roasted matte and leady additions, the latter being added in such quantity as to yield sufficient lead to keep the new matte poor in precious metals. After one or two slag-smeltings, a clean slag is produced which can be thrown away. A typical analysis of such a slag shows: lead, 1–2; silver, 0·001; copper, 0·3; zinc, 9–12; ferrous oxide, 50; and silica, 30 p.c.

Smelting at Broken Hill.—The concentrates treated by the Associated Smelters' Proprietary Co. contain 60 p.c. of lead, 15 p.c. of sulphur, and 20–25 ozs. per ton of silver. Two processes for roasting the concentrates are used.

1. The ore is mixed with ground limestone and ironstone, moistened and charged on to the Dwight-Lloyd machine. Thence it is conveyed to the rolls, ground and moistened and roasted again in a similar manner.

2. The ore-mixture, as above, is roasted in a Ropp furnace, 156 feet long and 14 feet wide. The roasted material is charged hot into Huntington and Heberlein converters of 10 tons capacity, and air blown through at 1½ lbs pressure. The sintered mass is tipped and broken up and is ready for smelting. The output of 3 Ropp roasters, 20 converters, and 9 Dwight-Lloyd machines is 500–550 tons a day.

The roasted ore is smelted in rectangular blast furnaces 17 feet long, 4 feet 6 inches wide and 25 feet high over all. Three of these are used, and they are capable of putting through 1200 tons of total charge a day. The charge

consists of roasted and sintered ore, ironstone, limestone, slags from a former smelting, and coke. The daily output of base bullion is 400 tons, containing 40–50 ozs. per ton of silver, and, in addition, copper (0·5 p.c.), antimony, and arsenic. The slags are clean and amount to 750 tons a day; 20–25 tons of fume are condensed every week by bag-filtration, and this is collected and re-smelted to recover lead.

Though somewhat premature, an outline of the method of treating the base bullion will be given here for the sake of completeness. The base bullion is run into a drossing furnace and the copper removed. The dross amounts to 5 p.c. of the bullion and contains 10 p.c. of copper. The bullion is then tapped into an improving furnace of 65 tons' capacity and drossed for 12 hours. The antimonial slag (6–7 p.c. antimony) thus produced is smelted in a reverberatory furnace and yields a richer slag containing 12–13 p.c. of antimony; this is then smelted in a blast furnace for antimonial lead.

The purified bullion is submitted to Parkes' process. The first zincing extracts the gold, the second yields a crust containing 1500–2000 ozs. of silver per ton, and the third reduces the silver in the lead to 0·4 oz. per ton. The desilverised lead, containing 0·5 p.c. of zinc, is refined in a softening furnace for 12 hours, and yields market lead of the composition: lead, 99·99+7; silver, 0·0012; copper, 0·0001; zinc, 0·001; antimony, 0 006 p.c.

The first zinc crust is melted in a reverberatory furnace with litharge derived from the cupellation process. Zinc is converted into oxide which forms a slag with the litharge; this is removed and smelted in the blast furnace to recover lead and silver. The lead is tapped from the reverberatory into a desilverising pot and again treated with zinc. This yields a crust enriched in gold. The alloy is distilled in graphite crucibles to remove the zinc and the residual gold-silver-lead alloy cupelled for doré bars which contain 2·5 p.c. of gold. The gold is parted by sulphuric acid, and the silver sulphate reduced to metal on a cupel with fine coal, the metal being 993 fine.

The second crust is distilled and yields zinc, which is used again in the process, and distillery bars containing 2500 ozs. per ton of silver. These are cupelled for silver.

The third crust being poor in silver is used for zincing fresh base bullion (The Metal Industry, May 11, 1917).

Softening of Hard Lead.

The lead obtained by smelting contains variable quantities of the precious metals. Leads from Missouri and Wisconsin, for example, are almost free from them, whereas the silver and gold in some bullion-leads is worth more than the lead which contains them. In addition to the precious metals, work-lead contains a number of base metals, most of which make the lead hard, unfit it for commercial purposes, and render the profitable extraction of silver an impossibility. The following analyses of work-lead illustrate the nature and range of the chief impurities:—

Origin	Per cent.						Ozs. per ton	
	Pb	Cu	Sb	As	Bi	S	Ag	Au
English (Weardale) . . .	99·87	0·015	0·05	0·01	0·001	0·015	7	—
German (Freiberg) . . .	96·67	0·94	0·82	0·28	0·066	0·20	180	—
Spanish (Magarron) . . .	99·20	0·22	0·20	0 15	0·004	0·11	9	0·06

,, (Magapil) . . .	95·72	0·09	2·50	0·90	0·030	0·32	105	0·42

There are also, on occasion, small quantities of tin, zinc, iron, nickel, and cobalt present in work-lead. Almost all of these impurities have a deleterious effect on the desilverisation process, arsenic being one of the worst in that respect, and their removal is consequently an operation of great importance. Many of them are more easily oxidised than lead, and can thus be eliminated by oxidation of the molten metal, the oxides forming a dross on the surface. Bismuth and copper are not so easily oxidised as lead. Copper, however, forms an alloy of fairly high melting-point, and can thus be removed by liquation. The elimination of bismuth is a very difficult matter; fortunately, its effect on the properties of lead is not very harmful for most purposes when present in moderate amounts. In the Pattinson process (*q.v.*) it is retained in the rich alloy and passes eventually into the litharge when the rich alloy is cupelled; it can be completely removed only by the electrolytic method of refining. In general, then, the purification of work-lead is brought about by drossing the oxidisable impurities, a process known as 'improving' or 'softening.' When the work-lead contains much copper, drossing is preceded by liquation.

Liquation is carried out at a low temperature on a hearth with sloping bottom, the lead draining away into kettles, leaving the liquation-residues rich in copper. In Freiberg, the furnaces are 5 feet 8 inches by 5 feet 6 inches; the liquation residues contain all the sulphur, 96 p.c. of the nickel and cobalt, 93 p.c. of the copper, and 25 p.c. of the arsenic which were present in the base bullion. The analysis of these residues show: lead, 62·4 p.c.; copper, 17·97; arsenic, 2·32; antimony, 0·98; tin, 0·04; nickel and cobalt, 1·09. They are treated by smelting either in small cupolas with low-grade matte, or in blast furnaces with galena, the copper being recovered in the matte.

The *improving* or *softening* is effected in a reverberatory furnace. A simple type, which was at one time the standard pattern, consists of a cast-iron pan which forms the lead bath.

It is about 2 inches in thickness, 10 feet long, 5 feet 6 inches wide, and 10 inches in depth. All the angles of the casting are carefully rounded to prevent breakage by expansion or contraction, and the softened lead is drawn off by a hole bored in the bottom, near the outer edge, which is stopped by a well-fitting iron plug held in its place by a weighted lever.

This type of furnace is usually made to hold from 8 to 12 tons of molten lead. The fireplace is about 20 inches wide, and has a length equal to the width of the cast-iron pan, from which it is separated by a bridge 2 feet wide. The height of the furnace above the pan at the bridge end is 16 inches, and at the other end 8 inches.

The charge is introduced either in the form of pigs or is first melted in an iron pot set in brickwork at the side of the furnace, and subsequently ladled into a sheet-iron gutter, by which it is conveyed to the furnace. This kind of furnace is easy to erect, but is too small for present-day conditions where large throughput is required. Modern furnaces are much larger, and have the lead bath built of brick usually set in a wrought-iron pan. They are supported on rails and held up by buckstays. The bottom of the furnace is built of a layer of brasque, and the hearth is rectangular; the size varies according to requirements and the sides are sometimes water-jacketed; the hearth slopes to the tap-hole, which is rammed with clay or furnished with a tapping plug. There are usually two working doors on either side of the furnace through which the lead is charged, and through which the scums are withdrawn. The size of the fire-grate varies considerably. Many smelters prefer small ones, which, though lengthening the period of drossing, reduce the losses by volatilisation. The capacity of these furnaces is 50 to 300 tons of lead.

In the softening process, the molten lead is submitted to the action of heated air, whereby the easily oxidisable impurities are converted into oxides, which, floating on the surface of the bath, are removed by a perforated skimmer; in this way a fresh surface is constantly exposed to oxidation. The progress of the operation is judged by taking a sample in a ladle and casting it in an iron mould; when the drossing is complete the surface presents a peculiar flaky crystalline appearance. The improved or softened lead is then tapped into an iron pot, from which it is ladled into the pig moulds, or is run from the furnace by a movable iron gutter into a series of pig moulds placed in readiness in front of the furnace. It is then ready for delivery to the desilverising plant.

When the work-lead contains tin, this is the first metal to be oxidised, and the oxide separates as a powder. This is followed by the arsenic and then the antimony dross, each of which is liquid; the metals are present as arsenate and antimonate of lead. These stages are, however, not clearly defined, but merge into one another. The complete removal of these impurities is facilitated by the addition of litharge to the bath, and becomes apparent by the change in appearance from the dark oily dross of lead antimonate to the yellow scum of litharge.

The course of the drossing is illustrated by the following partial analyses of Freiberg drosses:—

	First tin dross (powder)	Second tin dross (liquid)	Arsenic dross	Antimony dross
SnO_2 .	14·7	12·2	0·6	0·3
As_2O_5 .	0·9	11·2	16·2	4·0
Sb_2O_5 .	12·5	18·6	8·5	32·2

The duration of the process at Freiberg is 2–14 days, and the yield of refined lead 75–85 p.c.

Drosses from the improving furnace are melted in a reverberatory furnace with a little coal, whereby some lead is liberated and this desilverises the dross; the residue is smelted in blast furnaces and yields an impure antimonial lead. Much of the arsenic is volatilised in the blast furnace.

Desilverisation of Soft Bullion Lead.

The methods used in the extraction of the silver from soft or improved lead vary according to the silver-content of the lead. Low-grade leads are submitted to a concentration-process and the rich alloy thus obtained is cupelled. The concentration is effected by the Pattinson process, or some modification of it. High-grade leads are cupelled; if fairly rich in silver, they are melted, stirred with zinc, and the alloy of zinc, lead, and silver which separates on cooling is worked for silver. This is the Parkes' process.

The concentration of silver in poor silver-bearing lead is founded on an observation made by Hugh Lee Pattinson, of Newcastle-upon-Tyne, that the crystals which first separate from a molten alloy of silver and lead are poorer in silver than the residual alloy. This discovery was made the basis of a patent by Pattinson for 'An improved method of separating silver from lead,' the date of the patent being October 28, 1833, and at the meeting of the British Association held at Newcastle-upon-Tyne in 1838 the process was described by the originator.

The behaviour of a molten silver-lead alloy on cooling is similar to that of a salt solution. The freezing point is lowered proportionately to the amount of silver dissolved, pure solvent crystallises out and the mother-liquors become enriched in the solute with the progress of crystallisation, until finally a stage is reached when the residual liquor freezes as a whole at a constant temperature. This is the eutectic point. The alloy then has the lowest melting point and further concentration of any constituent by the process of crystallisation is impossible since the composition of the eutectic liquid and the crystals derived from it is the same.

The melting point of pure lead is 327° C.; the eutectic mixture of lead and silver melts at 303°C. and contains 2·5 p.c. of silver (about 900 ozs. per ton). In practice, this limit of concentration is never reached, the enrichment not exceeding 1·75 p.c. of silver, *i.e.* 650 ozs. per ton. Further, it is impossible to separate completely the crystals of pure lead from the freezing alloy, since they always carry with them mechanically some of the silver-bearing mother-liquor. To obtain, therefore, effective concentration of silver it is necessary to repeat the operations

several times, so that the process becomes, in fact, one of fractional crystallisation.

These considerations naturally apply only to pure silver-lead alloys. The presence of foreign metals disturbs the crystallisation and concentration processes in various ways.

Copper, arsenic, and antimony have the curious effect of making the crystals of lead small, so that they are difficult to drain and thus carry silver with the retained mother-liquor. Zinc, if present, acts as in the Parkes' process, carrying the silver into the first fractions and thus rendering the process inoperative. Bismuth and nickel remain almost entirely (copper to some extent) in the mother-liquors and so pass on to the cupellation process with the rich alloy.

Pattinsonising, Pattinsonage, Pattinsonizen. The operation is conducted in large cast-iron hemispherical pans, capable of holding 6-10 tons of molten lead. The small 6-ton pots are now rarely used, and in some establishments pots capable of holding 18 tons of lead are employed, the larger size requiring the use of cranes in working the ladles. A series of nine to twelve of these pots is placed side by side in a line and resting on brickwork supports. Each pot is provided with a separate fireplace, the heated gases from which are conducted round the pan by a circular flue and thence pass into a flue running the whole length of the pots by which the gases are conveyed to the chimney. In addition to the large pots, there are sometimes smaller pots placed at the side between the larger pots, and heated by a separate fire; these serve to hold some melted lead for the purpose of heating and cleaning the ladles. Along both sides of the erection in which the pots are built is a platform on which the workmen stand. The pot at one end of the series is smaller than the others, being about two-thirds the size. This is called the *market pot*; the poor lead passes to this pot and is run thence into the pig moulds. The other apparatus used in this process consists of perforated ladles made of iron ½ inch in thickness; when worked by hand the ladle is 16 inches in diameter and 5 inches deep, the holes being ½ inch in diameter, whilst when cranes are used the ladle measures 20 inches in diameter, 6 inches in depth, and the holes ¾ of an inch. The handle of the ladle is 9 feet 6 inches long, and ½ an inch in thickness. In addition to the ladle, a chisel-pointed bar or *slice* is used in stirring the lead.

Fig. 18 shows the arrangement and mode of setting a range of pots.

The method of working will be best understood by supposing the lead to be treated contains some 20 oz. of silver to the ton; the metal in the form of pigs is charged into one of the pots about midway between the *market pot* and the *rich pot*, the fire is set on and the lead melted; on melting the surface of the metal is covered with a layer of dross, which is carefully removed by a ladle and the fire then withdrawn. Water is sprinkled on the surface of the molten bath to promote cooling, and as the metal cools a cake is formed on the surface, which is detached and broken up by means of the slice, and the pieces stirred into the liquid. As the cooling proceeds the mass is kept continually stirred, and after a time crystals begin to separate at the bottom of the pot. These are removed by means of the large perforated ladle,

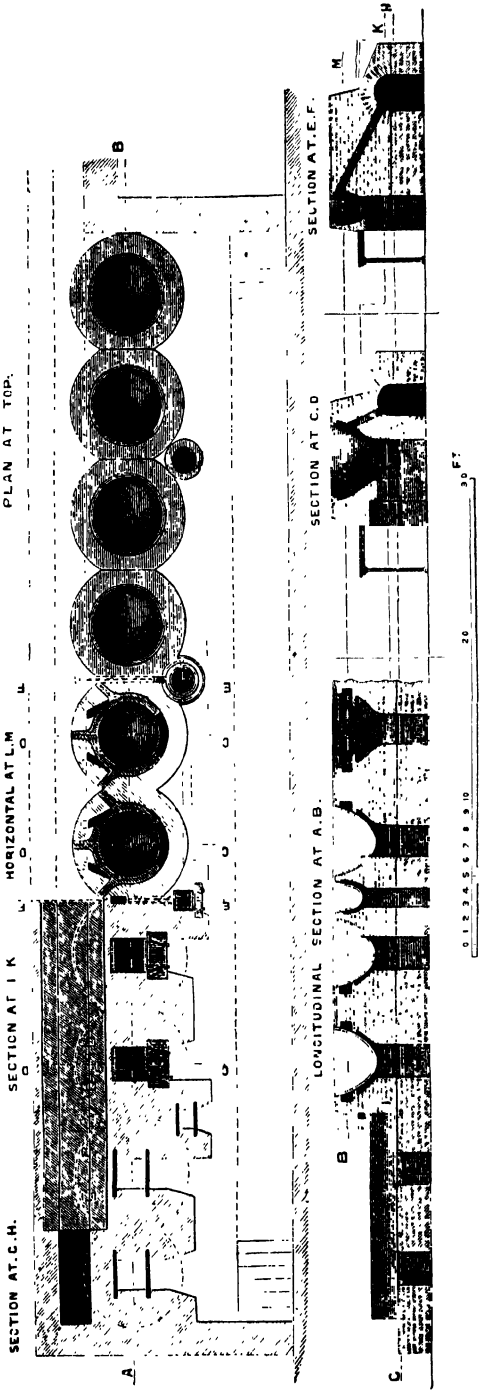

FIG. 18.

which is plunged into the liquid and then gradually raised, the side of the pot serving as a fulcrum; the ladle is raised until it is completely out of the bath and is brought into a tilted position, and the crystals allowed to drain. When drained the contents of the ladle are transferred to the next pot on the left—supposing the market pot to be at the left extremity of the range. This operation is repeated until two-thirds of the original charge has been transferred. The remaining third, which represents the enriched alloy, is transferred to the next pot on the right—*i.e.* toward the *rich pot*. The rich bottoms, as they are called, contain about 40 oz. of silver to the ton, and any lead that may be on hand having a similar silver content is added to the enriched bottoms. The poorer lead from this single operation contains about 11 oz., and similarly any lead to hand of this assay is added to the metal obtained by this operation. A second charge is next introduced into the pot in which the first operation was conducted and the separation effected, as before, into poorer lead and enriched bottoms, the former being transferred to the left hand and the latter to the next pot on the right. The poorer lead is similarly treated, and from it a further quantity of still poorer lead is produced, which is passed on to the next pot to the left and so on until the lead which reaches the market pot contains only 10 dwts. of silver per ton; the enriched lead meanwhile makes its way to the *rich pot*, but in the richer pots the separation is less complete than in the poorer ones, and the enrichment is not so rapid. In working the last pot, after two-thirds of the metal in the form of crystals have been transferred, the enriched bottoms, partly liquid and partly solid, are pressed with the back of the ladle. The fluid portion, richer in silver, runs through the holes in the ladle and is removed by an ordinary ladle. Working in this manner a market lead is obtained at one end of the range in which the silver is reduced to the amount already stated, and at the other end of the range is produced lead containing from 600 to 700 oz. of silver to the ton, beyond which it is not possible to push the concentration by this method.

In the above description it has been assumed that the method of thirds or the high system is employed. This is the method most usually adopted in practice, but for special purposes the low system or method of eighths is sometimes used, in which seven-eighths of the contents of the pots are transferred to the poorer pot. In some works the method of seven-eighths is used for 'riching up' rich leads to the refinery grade of about 600 oz. In the seven-eighths system the lead should treble itself in assay at each operation, but this is seldom the case. In the two-thirds system each operation is supposed to result in the doubling of the silver content of the lead, but in practice this only obtains with leads ranging downwards from about 50–60 oz. of silver per ton.

At each melting of the lead the metal is oxidised and a layer of dross formed on the surface. This is removed by skimming and the drosses collected for future reduction. With a 20-oz. lead, the amount of drosses formed is 25 p.c. of the weight of the metal. The continual drossing of the metal naturally effects a purification of the lead, as the dross produced consists not only of lead oxide, but also of the oxides of other easily oxidisable metals present. The value of the Pattinson process as a means not only of enriching the lead, but also of purifying it, is shown by the fact that lead to be used for white-lead making is frequently pattinsonised, although the amount of silver present may be very small. Further, copper and iron are both separated with the silver in this process when the amount of copper does not exceed 0·025 p.c.

The Rozan process or Pattinsonising by steam.—This process was introduced i.. the works of Luce and Rozan at Marseilles, and was first practised in England at Cookson's works on the Tyne. In this system steam under pressure is forced into molten lead, and by the continual agitation of the mass produced in this manner the production of crystals poor in silver is favoured, and the separation of an enriched fluid lead facilitated. Cookson was inclined to the opinion that the steam serves a second purpose, producing a chemical effect and aiding in the oxidation of the antimony, copper, iron, and arsenic, and other oxidisable metals present. This oxidation may be due to the air carried into the pot by the steam. In any case rich leads containing as much as from a ½ to ¾ p.c. of foreign metals may be treated by this system without having been previously softened. The following is the description of the plant and mode of working taken almost *verbatim* from Cookson (Trans. Newcastle Chem. Soc. 1878):—

The pot marked M (Fig. 19) is simply a

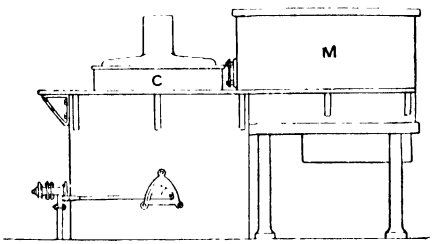

FIG. 19.

melting-pot, and the lower pot C is the working, or, as it is commonly called, the crystallising pot. To illustrate the working, we will suppose the C pot contains 14 tons lead crystals from a previous operation, assaying, say, 80 oz. of silver per ton, and the M pot 7 tons original lead of similar silver content already melted; a moderate fire is set away in the firegrate of the C pot, and the contents of the M pot are skimmed; the hot lead from the pot M is then run on to the warm crystals in the C pot, and, with the assistance of the moderate fire already referred to, the whole contents of this pot (now 21 tons) are rapidly brought into a melted and working condition, when the charge is carefully skimmed; the M pot is at the same time charged with 7 tons of lead containing about 40 oz. silver per ton of lead, as this will be the assay of the crystals resulting from the operation shortly about to commence in the C pot. The fire under this pot is next drawn, and a small fire under each of the

tapping spouts is set away, the object of this being to prevent the lead setting in them when tapping out the rich lead later on. Steam at 50–55 lbs. per square inch is next admitted through the valve v, and is distributed evenly through the pot by the baffle plate *b* (Fig. 20).

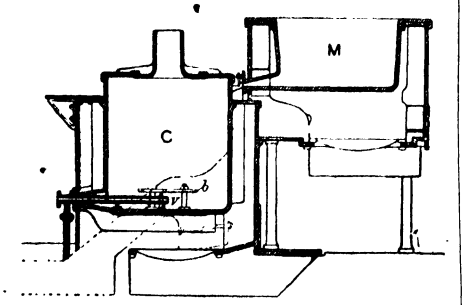

Fig. 20.

To hasten the cooling and consequent crystallisation, thin streams of water are allowed to run on to the surface of the lead. This might be thought to cause the lead to set on the top, but the violent action of the steam entirely prevents this, and a more perfect crystallisation is effected than can be obtained in the old Pattinson process. When the workman sees that the charge is ready, *i.e.* when about two-thirds are in crystals and one-third liquid, he taps out through spouts at either side of the c pot the rich liquid lead, the poorer crystals being retained in the pot by perforated plates. This liquid lead is run into moulds containing 3½ tons each, and the blocks as they set are lifted out by cranes and arranged in a semicircle, where they await their turn to be again operated on. This process of crystallising, as in that of Pattinson, is repeated until the crystals are sufficiently poor in silver not to require further treatment, when, being fit for market lead, they are melted and run into pigs of the usual size, or into 3½-ton blocks, according to the purpose for which they are required; the

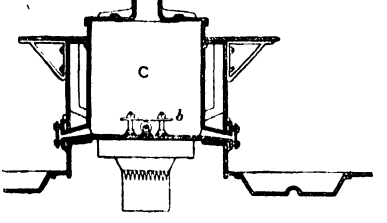

Fig. 21.

rich lead is worked up until its silver contents are of the standard fit for the refinery. A large portion of the foreign metals contained in the original lead is skimmed off in the state of oxides; those from the richer charges are very dark in colour, some in fact almost black, owing to the impurities contained, while those from the poorer charges have the yellowish colour proper to the oxides of lead. Some, however, are carried off up the funnel above the c pot, with the escaping steam, and are deposited in the condensing chambers, of which there are several of large size. The dust contains 80–85 p.c. of lead oxide, a considerable amount of copper and antimony, and small quantities of arsenic, iron, and other metals.

In the accompanying illustration of the plant use' in the Rozan process, Fig. 22 is the

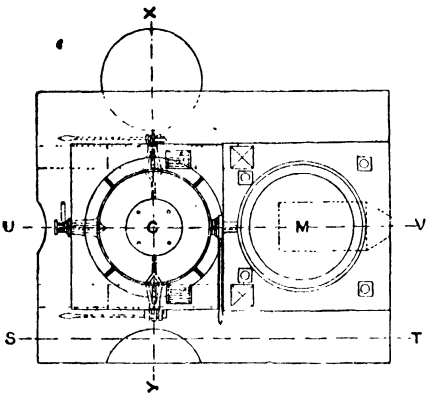

Fig. 22.

plan of a battery, Fig. 19 is an elevation along the line s T, Fig. 20 a section along a line U V, and Fig. 21 a section along the line X Y.

The following table gives the silver assays of twelve crystallisations taken from an average of 350 operations:—

Ounces per ton of lead

570-315-202-112·5-62-33·75-19·5-10-5-2·5-1·25-14 dwts.

Cookson summarises the advantages of the Rozan system as follows:—

'1. The entire saving of the cost of calcining all ordinarily hard leads, and a very large saving in the case of especially hard leads.

'2. A cost for labour not exceeding one-fifth.

'3. A cost for fuel of about two-fifths.

'4. A saving of one-third in the oxides produced, which advantage any lead manufacturer will fully appreciate.

'Its defects are:

'1. A large capital outlay.

'2. A constant expense in repairs and renewals.'

At Omaha there is a modification of the Rozan process, introduced by Tredinnick. The pots, of which there are twelve, hold 50 tons, and each is supported by hydraulic rams, so that it can be raised and the lead or enriched alloy run into a neighbouring pot. There are two outlets to each pot, one fitted with a strainer for running off the alloy from the lead crystals, the other having a free run for pouring out the re-melted crystals. Heating is by gas, which is burnt in brick-lined jackets under the pots and the molten lead is stirred with steam, as in the Rozan process.

One advantage of this method is that the tapped lead does not require re-melting. Much time and labour are thus saved. The operation is done in about 40 minutes.

Newnam, in America, has recently adopted the Tredinnick method for the removal of bismuth

from lead rich in that metal, and has been able to reduce the bismuth content of the lead to about 0·03 p.c.

The Parkes Process.—The method of desilverising lead by means of zinc is now very widely used. It has practically replaced all other methods, and is especially advantageous with leads rich in silver. Patents for this process were granted to Alexander Parkes, of Birmingham, in the years 1850, 1851, and 1852; and in 1859 the method was put in practice at Llanelly. It was subsequently tried at Tarnowitz, and, owing to the difficulties experienced in its working, finally abandoned at both places. The chief difficulties were (1) the removal of the zinc from the desilverised lead, which could not be performed sufficiently well to make the lead marketable; (2) the separation of the silver from the zinc alloy was attended by considerable loss; (3) the recovery of the zinc from the rich lead was somewhat difficult to accomplish. These difficulties have now been in great part overcome.

In brief outline, the process consists of the following operations: Zinc is dissolved in molten argentiferous lead. A light alloy, rich in zinc and containing most of the silver, rises to the surface, solidifies before the lead, and is removed as a solid crust. From this crust the zinc is recovered by distillation and the residual lead-silver alloy is cupelled. The desilverised lead contains a little zinc (about 0·6 p.c.) and is refined to produce market lead.

The relations to one another of the three metals concerned in the process merit further consideration. Silver mixes in all proportions with lead and zinc; lead and zinc, however, are only partly soluble in each other, the degree of solubility increasing with the temperature. Thus, if enough of each metal for mutual saturation be mixed (in the molten condition), separation into two layers takes place, the upper consisting of zinc saturated with lead, the lower, of lead saturated with zinc. For example, if 10 parts by weight of lead and 1 of zinc are mixed at a temperature of 350°, the distribution of the metals (p.c.) in the two layers is as follows:—

	Lead	Zinc
Upper layer . .	0·1	8·5
Lower layer . .	90·9	0·5

Now, if silver be added to the molten lead and zinc, it is distributed between the two layers, dissolving preferentially in the zinc, so that the upper layer contains most of the silver. The following table (C. R. A Wright, Proc. Roy. Soc. 1892, 50, 390) shows the composition (p.c.) of the two layers in three experiments with the triple alloy:—

	Upper layer			Lower layer		
	Lead	Zinc	Silver	Lead	Zinc	Silver
1 . .	3·1	58·0	38·9	96·7	2·0	1·3
2 . .	3·4	51·6	45·0	96·4	1·9	1·7
3 . .	4·2	40·9	54·9	93·2	1·3	5·5

In example 1, the lead, zinc, and silver are mixed in the proportion by weight 5 : 3 : 2; a simple calculation from these data shows that the weights of the two layers are practically identical; now the ratio of silver in the upper and lower layers is 38·9 : 1·3, that is, 30 : 1; or, in other words, about 96 p.c. of the silver has passed into the layer rich in zinc. Similar relations hold in the other two examples and generally. The practical utilisation of this behaviour of the alloys in the desilverisation of lead is rendered possible by the solidification of the upper layer at a higher temperature than the lower one, so that the crusts, rich in silver, can be easily removed from the still molten, partly desilverised lead.

It will be evident that complete desilverisation of lead by this process is impossible; but if the extraction with zinc be repeated two or three times, the amount of silver remaining in the lead is commercially negligible, being of the order of ¼ oz. per ton.

Under similar conditions of treatment, gold behaves like silver, but is even more readily taken up by zinc, so that by using a small quantity of zinc in the first treatment the gold can be concentrated in the first crust and removed, leaving the bulk of the silver in the residual lead; *e.g.* 200–300 lbs. of zinc added to a 35-ton charge removed nearly 2 oz. of gold per ton of lead, along with the copper. The clean separation of the rich alloy from the lead is, of course, impossible in practice; much lead is carried mechanically with the crusts, even when these are squeezed in the Howard press. Poor crusts are often enriched by adding them to fresh baths of silver-bearing lead. The composition of a suitable crust for distillation is generally reckoned at 80 p.c. lead and 20 p.c. zinc and silver. An actual analysis of a crust may be quoted as typical:

Lead . . .	70·30 p.c.
Silver . . .	3·65 „
Zinc . . .	19·34 „
Zinc oxide . . .	2·05 „
Antimony . . .	1·11 „
Arsenic . . .	0·73 „
Copper . . .	2·25 „
	99·43 „

The relatively large amount of copper shown in this table is an indication of the case with which that metal is extracted from lead by means of zinc. In this respect it stands on a level with the precious metals, and its presence is undesirable, as it increases the consumption of zinc. Arsenic and antimony have a similar effect, so that lead has to be thoroughly refined before treatment by Parkes' process.

The process is carried out in cast-iron pots or kettles, each separately fired, holding 25·60 tons of lead. Two of these, worked alternately, are used, and two smaller liquating or draining pots for the reception of crusts are generally arranged alongside of them. The diameter of a 30-ton pot is about 9 feet, and the depth is 3 feet 4 inches. When it is customary to syphon the molten lead, the depth of the pot is naturally limited by the height of the barometric column of lead.

The lead is usually run direct from the softening furnace and skimmed in the pot, though some desilverisers prefer to cast the softened lead into pigs and re-melt these in the zincage pots, since, thereby, better liquation and removal of copper is effected and zinc is economised.

The metal is heated somewhat higher than

the melting point of zinc (418°C.). Zinc is added either in the solid or liquid condition and well stirred for about 20 minutes by means of paddles. A mechanical device, Howard's stirrer, may be used to replace hand-labour. This is a power-driven screw-propeller, fixed in the middle of a cover which rests on the rim of the pot. The whole arrangement is movable along an overhead track and can be placed in position for action and removed when desired. This method enables a very thorough mixing of the metals to be effected, undue oxidation being prevented meanwhile

After stirring, the fire is damped and the alloy allowed to cool down, nearly to the melting point of lead. The crusts which are formed are lifted with a perforated paddle or skimmer, allowed to drain, and transferred to one of the smaller pots. In many works, the excess of lead is squeezed out of the crusts in a Howard press. This is a cast-iron cylinder with a perforated, tilting bottom. Inside is a screw-press with toothed plunger. The mechanism is power-driven, and the whole travels on an overhead track and can be brought into position and lowered into the pot at the suitable time, namely, when the crusts begin to form. After the press has attained the temperature of the metal, the crusts are lifted in and the cylinder raised against the plunger. The cylinder is then lowered, the plunger turned a little so that the teeth will penetrate a different part of the crust, and the pressure again applied, and this operation repeated until the excess of lead has been forced out of the zinc alloy. When the pressing is complete, the apparatus is removed and the bottom tilted, when the drained crust drops out.

After the removal of the first crusts, the pot is heated again, fresh zinc added, and the operations just described are repeated. A third, and even a fourth, zincing are sometimes necessary to complete the process.

The later crusts, which contain excess of unused zinc, serve for the first zincing of fresh lead. They need not be liquated, but are melted and cast into pigs or blocks. If necessary, zinc is added along with these crusts when they are used again for desilverising.

The amount of zinc required depends on the silver-content of the lead and the impurities present: of these copper has perhaps most influence on the zinc-consumption. The following table of Illings is one of many which have been compiled, though none is suitable for all varieties of practice:—

Silver in the work-lead (p.c.)	Zinc required (p.c. on lead)
0·025	1·25
0·05	1·33
0·1	1·5
0·15	1·66
0·3–0·4	2·0

The relationship may be shown in another way, as in the table below, which is based on actual practice:

Silver in the lead (ozs. per ton)	Ratio by weight Zinc : Silver
20	21·8 : 1
27	15·0 : 1
35	13·7 : 1
159	3·5 : 1
170	3·3 : 1
226	3·0 : 1
262	2·6 : 1

The proportions of the total zinc required which are used for each zincing operation vary very much in different places and with different grades of lead. Thus for a 25-ton pot of lead assaying 550 oz. silver, the total quantity of zinc required was 1130 lbs., and of this 430 lbs. were used for the first zincing and 450 lbs. for each of the two following zincings. In another case, 33 tons of lead containing 300 oz. silver per ton were treated with zinc three times, the amounts being 200, 700, and 700 lbs.

In the following example, the data are more complete. Three zincings were given, the first consisting of the melted third crust from the previous charge, with or without the addition of fresh zinc. The progress of the desilverising with each zincing is well shown.

Silver assay (per ton).				Amount of zinc used (lbs.).			
Original lead, ozs.	Lead after first zincing, ozs.	Lead after second zincing, ozs.	Lead after third zincing, dwts.	First zincing.	Second zincing.	Third zincing.	Total.
166	57	8	2·5	3rd crust from previous charge	530	550	1080
350	120	9	3	3rd crust +200 lbs. zinc	886	580	1666
508	132	13	3·5	3rd crust +200 lbs. zinc	855	560	1715

When a pot receives three zincings, a good deal of lead is removed with the crusts, especially if the lead is rich in silver. The level of the lead is thereby greatly reduced, and the yield of finished lead from a pot is less by, perhaps, several tons. It is advisable, in such a case, to fill up the pot with lead of good quality, low in silver, before the third zincing, so that a full charge of lead can be run, when desilverised, into the refining furnace, and thus the output of market lead can be maintained.

The zinc crusts which have not been pressed mechanically are usually liquated before distillation and the liquated lead returned to the

desilverising pot. The rich liquation-residues or the pressed crusts are then distilled in graphite crucibles. The crucibles are heated in small furnaces fired by coke, oil, or gas, and the alloy added in batches, as it is melted down, until the right amount is charged. A hood is then luted on and a condenser of sheet or cast iron attached. The zinc begins to distil at 670°, and the temperature is raised to about 1000°–1200° to complete the distillation. The metal is run from the condenser, cast into slabs, and is used again in the process. The residual lead-silver alloy is ladled from the retort and cast into bars, which contain 2000–4000 ozs. silver per ton.

A certain amount of zinc is oxidised in the distillation-process and constitutes the 'blue powder.' This is sometimes transferred to the zinc smelters. As the desilverised lead holds about 0·6 p.c of zinc, the amount of zinc recovered will depend, in a large measure, on the amount used, *i.e.* on the grade of the silver lead. This is illustrated in the following table, which gives the results obtained at a large works, averaged over a long period :—

	a.	b.	c.	d.
Silver in lead (ozs. per ton)	20	35	169·2	224
Gold in lead (ozs. per ton)	—	—	1·11	1·61
Zinc used (p.c. on lead)	1·36	1·49	1·74	2·09
Zinc recovered (p.c. of total zinc used)	35·3	38·7	49·2	58·9

In America, and occasionally in other countries, the tilting furnace of Faber du Four is used for distilling zinc crusts. This furnace consists of a firebrick box in a cast-iron frame. The retort is laid in a sloping position in the furnace and the neck protrudes outside and is fitted with a condenser. The furnace is mounted on trunnions and can be tilted by hand. When distillation is complete, the condenser is detached and the alloy poured out of the retort by tilting the furnace.

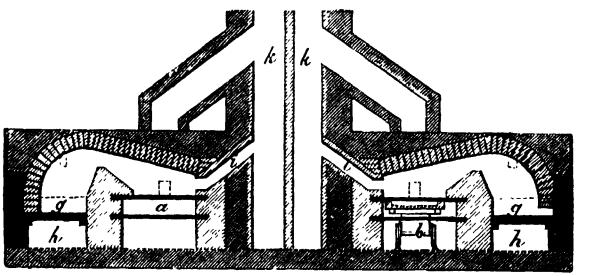

Fig. 24.

The desilverised lead containing about 0·6 p.c. of zinc is tapped, pumped, or siphoned from the pot, and run into an improving furnace placed at a lower level, where it is kept at a red heat for several hours and occasionally skimmed. The progress of refining is watched by withdrawing small samples, which are cast in a mould, and from the appearance presented on cooling the state of the lead is determined. When thoroughly refined the lead is tapped into a cast-iron pot and then run into pig moulds.

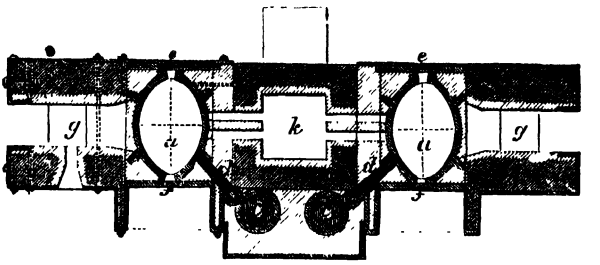

Fig. 23.

Cupellation or Refining.

The English Method.

The enriched lead obtained by one or other of the above methods is next submitted to the process of cupellation or refining, in which the lead is oxidised and converted into litharge, and metallic silver obtained. In England the refining is performed in a reverberatory furnace, the bottom of which, called the test or cupel, is movable, and into this the lead is fed at intervals from a melting-pot containing the rich lead, which is poured by a ladle into an iron gutter, serving to convey it to the test. In some cases the 'rich bars' are pushed down 'feed pipes,' so that they project into the furnace and are melted off as required. The oxidation of the lead is effected by means of a blast of air produced by a fan or other blower or by a steam injector. An English refinery in which two cupels can be worked at the same time is represented in Figs. 23 and 24.

a, *a* are the position of the tests, one of which is shown resting on the iron waggon, *b* : *c*, *c* the melting-pots for the rich lead ; *d*, *d* the iron gutter to supply the test ; *e*, *e* the point where the blast enters ; *f*, *f* the opening along which the litharge flows into an iron pot placed below ; *g*, *g* the fire-grates and *h*, *h* the ash-pits ; *i*, *i* the flues, and *k*, *k* the chimneys.

The test or cupel is made of bone ash finely ground and prepared by moistening with a dilute solution of pearl ashes. Other materials for making the tests which have found favour in recent years are Portland cement, either used alone or mixed with sand or fire-clay and limestone, and mixtures of fire-clay and ground limestone. The mixture is placed within an oval iron framework, consisting of an iron ring *a*, *a* (Fig. 25). This ring, known as the test ring, is held together by iron bars, *b*, *b*.

The mixture is beaten down thoroughly with iron rammers into this framework, and the centre of the mass scooped out by means of a small trowel, giving the test the shape represented in the accompanying illustrations, and

forming a receptacle for the molten metals. It has been proposed to mould these tests by presses worked by hydraulic power. The test before use is allowed to dry in the air for some time and then placed on an iron waggon and run into position under the furnace; it is then wedged tightly against an iron ring built in the masonry. The fire is next lighted, and the test slowly heated, so as thoroughly to anneal it. When perfectly dry, the temperature is raised to a dull redness and the test is filled with rich lead. The lead is first covered by a greyish dross, which, as the temperature rises, gradually gives place to litharge. The blast is now turned on and the oxidation of the lead takes place; the litharge produced is blown by the blast to the mouth of the refinery and flows over the gate into an iron pot, placed below. These iron pots are built on wheels, and when filled with litharge are removed; the cake of litharge is easily

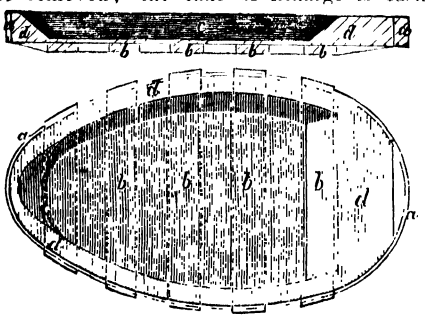

FIG. 25.

detached after cooling, and is subsequently reduced, as will be described later on. As the oxidation proceeds, fresh lead is added to the test, and if a large stock of rich leads have to be treated, then the refining is only conducted sufficiently far to produce an enriched alloy, in which the silver amounts to about 8 p.c. of the contents of the test. The concentrated argentiferous lead is tapped into an iron pot run on wheels, placed under the test bed, which is pierced by a drill. When the enriched lead has been run off, the hole is made up with a pellet of bone ash kept in its place by an iron plate, and another charge is introduced. By this removal of the enriched lead, distribution of silver through a large quantity of litharge is avoided. The rich lead is finally refined in another test. The end of the operation is indicated by the appearance of the surface, the brightening of the plate, as it is called; the blast is then turned off and the fire removed from the grate. The silver is usually tapped out into ingots direct, through a hole in the bottom of the test. In some cases the plate of silver is allowed to set, and when this has taken place the wedges are withdrawn and the test is lowered on to an iron waggon, by which it is removed and allowed to cool. The plate, when solid, is detached from the test, and brushed with an iron brush to remove litharge, slag, or material from the test.

In an ordinary refinery 4–5 cwt. of lead can be worked off in an hour with a fuel consumption of 6–7 cwts. of coal per ton of lead oxidised. The plate of silver varies in weight from 10,000 to 20,000 oz., and is usually pure, containing about 99·7–99·8 p.c. of silver. The test bottoms are saturated with litharge and contain some silver; they are usually broken up and those portions free from lead picked out to be used over again, whilst the remainder is smelted in a blast furnace.

The German Method.

In Germany the rich argentiferous lead is cupelled in a furnace known as the *Treibofen*, consisting of a reverberatory furnace with a circular hearth, and having a fireplace at one side. The bottom of this furnace is not movable, as in the English refinery, but composed of firebricks, on which lies a solid stratum of slag, and this again is covered by a coating of marl, well beaten down with iron rammers. The bottom is regularly hollowed out from the sides towards the middle, where a hollow is cut about an inch deep for the reception of the silver. The layer of marl is renewed for each operation. A dome of iron, plastered over with marl, covers the bed, and is moved as required by means of a crane. There are five openings into the side of the furnace, one serving to admit the flame from the fireplace, two smaller ones, near together, for the tuyeres by which the blast of air is forced on to the surface of the metal, and the litharge produced is blown towards a fourth opening, by which it escapes in a fused state. The tuyeres are usually provided with valves, 'butterflies,' which serve to diffuse the blast over the surface of the metal. The fifth opening into the furnace is provided for the introduction of the lead. In working with unsoftened lead the charge for one operation consists of about 5 tons of metal, some three-fourths of which is introduced into the furnace before lighting up, the remainder being added from time to time as the cupellation proceeds. Much larger charges are treated when softened lead is used. The mode of working is as follows: the charge of lead, in the form of pigs, is piled up in the middle of the hearth, and covered with wood, which is ignited by throwing on to it some burning charcoal. The iron dome is next let down and luted all round with clay. The blast is turned on and the fire in the grate made up. In the course of 3 or 4 hours the lead has melted down and the bath is covered by a layer of dross, which is dark in colour and consists of a mixture of the oxides of the metallic impurities contained in the lead, and is called the *abzug*; it is raked out at the opening for the removal of the litharge. After the removal of the *abzug* the surface of the metal becomes clearer, and in a short time acquires a peculiar circular movement; the dross now rising to the surface is purer and more fluid than the *abzug*. This second product forms what is known as the *abstrich*, and is an impure litharge, which, as it is produced, flows through channels cut in the breast of the furnace. The temperature is kept sufficiently high to maintain the *abstrich* in a state of fluidity. The formation of *abstrich* is succeeded by the production of pure litharge, which flows out of the furnace through the channels already mentioned. After the litharge-stage has commenced, the remainder of the metal to be cupelled is added in small portions at a time; the pigs of lead being so placed that the lead gradually melts and leaves behind the

more refractory *abzug* unmixed with the metal. The full charge of metal having been added, the oxidation is continued and the temperature maintained sufficiently high to keep the silver in a molten state until the greater portion of the lead has been oxidised and the bright metallic surface of the molten silver is observed. The blast is then turned off and the fire is damped down; water is also thrown on to the metal to harden it, and the cake of *blicksilber* is withdrawn from the furnace and freed from marl, litharge, &c. The *blicksilber* contains from 90 to 95 p.c. of silver and is refined in a small reverberatory furnace, the bed of which is made of bone ash, or some material serving, like bone ash, for the absorption of litharge.

The cupellation of a charge of 10–15 tons of lead lasts from 70 to 80 hours, and the loss of metal amounts to 3–6 p.c.

Reduction of Litharge and Pot Dross.

The litharge produced in the cupellation of argentiferous lead, and the drosses formed in the Pattinson process, are reduced in this country in a reverberatory furnace, the sole of which slopes from the fire-bridge to a point near the flue, where an iron gutter, built in the furnace bed, serves to convey the molten lead to an iron receptacle outside the furnace. The reducing agent is coal. The sole of the furnace is prepared by covering it with small coal which is partially coked by the heat, and thus a porous covering is formed on the brickwork of the furnace bottom. On to this sole the litharge broken into lumps and mixed with coal is thrown. The fuel and the reducing gases in the furnace soon effect a reduction of the litharge, and the molten lead trickling through the porous mass gradually finds its way into the metal gutter, by which it is conveyed to the metal pot. The charge is turned over from time to time, and when the reduction is completed the residue, termed *cinders*, is raked out. The litharge cinders, together with other lead refuse, such as test bottoms, are smelted in a cupola, slag-hearth, or blast furnace.

The lead produced by reduction of litharge is softened and desilverised when necessary, and since the litharge produced towards the completion of the cupellation is richer in silver than that formed in the earlier stages, it is frequently reduced apart from the rest, and yields a lead containing from 70 to 100 ozs. of silver per ton. According to Kohlmeyer (Chem. Zeit 1912, 36, 1079), silver dissolves as oxide in litharge; the solubility is 3–6 p.c., and the melting-point of the litharge is reduced 45°.

Refining lead by electrolysis.—A process, due to Keith, for refining lead by electrolysis, was in use at New York for some years, but was, apparently, not a commercial success. The anodes were made of furnace lead, the cathodes of pure lead, and the electrolyte was a solution of lead sulphate in ammonium acetate. The bath was heated to 38°. The lead bullion contained 180 ozs. of silver per ton, the refined lead only 11 grains per ton.

Amongst other electrolytic methods of refining lead that devised by Betts is of special interest. The electrolyte is a solution of lead fluosilicate, a stable salt, easily made and very readily soluble in water. On electrolysing the solution of this salt, there is no formation of lead peroxide or other compounds which give rise to polarisation. The electrolyte is made by percolating broken quartz in a vat with 35 p.c. hydrofluoric acid. The resulting hydrofluosilicic acid is then allowed to act upon white lead; lead fluoride and lead sulphate settle out. The electrolyte is made to contain 5 p.c. of the lead fluosilicate and 10 p.c. of free hydrofluosilicic acid. It loses strength slowly and has to be made up weekly by the addition of fresh solution. Lead is deposited at the cathode in crystalline form, and as the crystals grow they are apt to cause short-circuiting; further, the mesh of crystals encloses electrolyte and thus renders the lead impure. This is obviated by the addition of a little gelatine to the bath; a compact deposit is then obtained of a high degree of purity.

At Trail, B.C., where the method is employed, there are 408 electrolytic cells made of cement and lined with asphalt, with a capacity of 100 tons of lead a day. The anode slabs are cast at the blast furnace; they weigh 320 lbs., and are reduced 80 p.c. in weight before melting again. The starting or cathode sheets are 39 by 27 inches and $\frac{1}{32}$ inch thick, and are made by pouring molten lead over an inclined steel plate. They are wrapped round copper bars connected to the negative leads, and are taken out and stripped twice during each run. The current density is 12 amperes per square foot, and the temperature is maintained at 30°-35° by cooling with water pipes.

The anode slimes contain 8000 ozs. of gold and silver per ton, and in addition copper, antimony, bismuth, arsenic, and lead (10 p.c.). They are washed, pressed, melted in a small reverberatory on a basic hearth, the slags removed, and the doré parted by sulphuric acid.

The only metals which pass into the electrolyte are zinc and iron, the latter to a limited extent. Bismuth remains with the anode mud. The refined lead is very pure, as testified by the following analysis: gold, 0·0027 oz.; silver, 0·6126 oz. per ton; copper, 0·0026 p.c.; iron, 0·0068 p.c.; antimony, 0·0075 p.c. The following table illustrates the gathering of the silver and the impurities in the anode slimes:—

	Lead (p.c.)	Copper (p.c.)	Bismuth (p.c.)	Antimony (p.c.)	Arsenic (p.c.)	Silver (p.c.)
Lead bullion	87·14	1·40	0·14	4 0	7·4	0·64
Refined lead	—	0·001	0·0022	0·0017	tr.	—
Anode slimes	10·13	9·3	0·52	25·32	44·58	4·7

Viewed as a desilverising process, the electrolytic method is probably superior to any of the others; it has the advantage, too, of eliminating bismuth from the lead. (For further details, *see* A. G. Betts, Lead Refining by Electrolysis, J. Willy & Sons, 1908; T. A. Rickard, Min. and Scient. Press., Dec. 23, 30, 1916.)

Condensation of Lead Dust and Fume.

In consequence of the volatility of lead at high temperatures a certain proportion of the metal and some of its compounds are carried away by the heated gases in the operations of smelting, refining, &c. Most lead ores contain zinc and arsenic, both easily volatile, and readily oxidised metals; these, therefore, bulk largely in the fumes from lead works. Solid material from the ores and fluxes is carried over mechanically in the form of a fine powder. This constitutes the 'dust'; it settles out more

easily than the fume. Naturally, there is no hard and fast distinction between dust and fume, but the latter may be taken, in a general way, to consist of the compounds (oxides, sulphides, and sulphates) produced from the volatilised metals from the furnace charges. A certain proportion of silver is always found in fume lead, the amount being considerably less than in the ores from which it is derived. To prevent the loss and minimise the nuisance which would arise from allowing the gases produced in these various operations to pass direct into the chimney, the furnaces are connected with a series of flues or condensing chambers in which the gases are cooled and so deposit some of the solid matter held in suspension, before they issue from the chimney. These flues are cleaned out at intervals, and the 'fume' collected.

The method of fume condensation usually relied on is simply to connect up the smelting and other furnaces with long flues of large transverse area. In some establishments they have an aggregate length varying from 3 to 5 miles, and a cross section of from 6 feet by 7 feet to 8 feet by 9 feet. Sometimes they are spiral or zig-zag to economise space, and baffle walls are interposed to lengthen the path of the gases and expose a large surface for precipitation of the fume. Sheet-iron plates, hung longitudinally, and parallel rows of iron wires in vast numbers are among the methods which have been tried, though with limited success, to effect precipitation of the solid particles.

The following are analyses taken from Percy's Metallurgy of Lead (p. 451) of dust and fume from the flues of the reverberatory furnaces and slag hearths at Bagillt:—

Lead oxide . . .	46·54	62·26	46·88
Lead sulphide . .	4·87	1·05	—
Ferric oxide and alumina	4·16	3·00	10·00
Zinc oxide . . .	1·60	1·60	4·14
Lime	6·07	3·77	6·73
Sulphuric anhydride .	26·51	25·78	14·15
Insoluble residue . .	10·12	1·97	14·40
Carbonaceous matter .	—	—	3·37
	99·87	99·43	99·67

The amount of flue-dust recovered is 4 p.c. of the ore at Pertugola, 4·7 p.c. at Tarnowitz, and 4·8 p.c. at Freiberg. It is usually briquetted with lime and clay and added to blast-furnace charges. At Freiberg, the average composition is: lead, 35·4; arsenic, 14·1; silver, 0·0276 p.c. Lead averages 40 p.c. in the flues near the furnaces; it decreases to 30 p.c. and then rises to 36 p.c. beyond the point where lead oxide is condensed; arsenic increases regularly, with the distance, from 7 to 25 p.c. The treatment at Freiberg depends on the arsenic-content. When this is below 7 p.c. the dust is briquetted and smelted with ore; when between 7 and 15 p.c. it is roasted before briquetting, and when over 15 p.c. it is roasted to recover arsenic and the residue smelted.

Jets of steam and water have in some cases been introduced at different points in the flues with the object of facilitating the fume deposition; but lead smelters differ in opinion as to the advantages gained by the use of either steam or water. Various devices have been proposed to effect a condensation of lead fume without the necessity of constructing long flues or large condensing chambers.

Stagg's condenser consists of a large rectangular chamber divided by partitions springing alternately from the top and bottom of this chamber, leaving free spaces above and below; the lower part of the chamber is filled with water, so that the gases pass first down one side of a partition through the water, and rising in the next compartment pass over the next partition and down again through the water. The gases are drawn through the chamber by means of air-pumps attached to the exit flue. The fume in its passage through the condenser is thus drawn through water and robbed of part of the suspended solids.

Stokoe's condenser consists of two chambers divided into several compartments by partitions which alternately reach the top and dip below the surface of water at the bottom of the chamber. The chamber is divided horizontally by two floors made of open joists upon which faggots are laid, thus forming filtering beds, which are washed by water in the form of fine spray. The gases are forced through the compartments of the condenser, meet the fine spray of water, and pass through the filtering beds, where the fume as it collects is washed away. When the water has reached a certain height it is drawn off into tanks, where the solid matter gradually separates.

In 1878 Messrs. Wilson and French patented a condenser, which was adopted at the Sheffield Smelting Company's works, and by Messrs. Bewick and Partners, Limited, of Hebburn-on-Tyne. The condenser consists of a wooden box *aa*, Fig. 26, having a shelving bottom where the

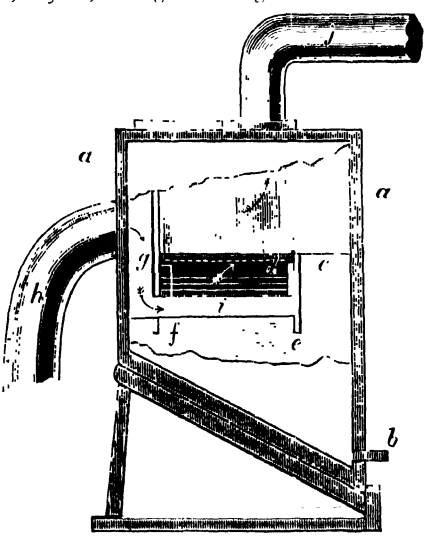

FIG. 26.

solid matter collects, and at the lowest point a tap, *b*, by which the contents of the condenser are run off from time to time. The box is filled with water to the level of *c*. The gases are forced into the box by a fan, along the pipe *h*, which opens into a chamber *g*, formed by a partition running parallel with the side of the box. Below, this chamber opens into a series of triangular tubes *i*, running across the box; these tubes are perforated above, and through

the fine openings the gases are forced into the water. Near the surface of the water at *d* are fixed three or four screens made of wickerwork or copper wire, held in position by the supports *e* and *f*. The gases pass out finally by the pipe *j* in the top of the box, and are conducted by flues to the chimney. By this arrangement intimate contact between the water and the particles of the fume is insured. The fume collects in the lower part of the box, is drawn off into settling tanks, and after removing the greater portion of the water, is dried and smelted. With three wire-gauze screens and a depth of 8½ inches of water, Mr. French states that at the Sheffield Smelting Company's works, the quantity of lead and silver arrested amounts to from 95 to 98 p.c. of that contained in the smoke as it leaves the furnace.

Wet methods of fume-condensation have proved unsatisfactory. Recent progress in this field has been along two lines, viz.: filtration and electrical precipitation, the fume in each case being operated on in the dry condition.

The suggestion of Percy, in 1870, to filter the fume through cloth was worked out on a practical scale by Lewis and Bartlett, and has been extensively developed. The filters are in the form of bags, 30 feet long and 16 inches wide, made with one lateral seam. The material is either cotton or wool, the latter being found more serviceable, especially when the natural oil and sweat have not been removed by washing. Hundreds or thousands of these bags are hung in a brick chamber or bag-house; the tops are tied tight, the bottoms fit round holes in the floor of the house. Under the floor is a smaller chamber into which the furnace gases are forced by fans. The gases escape upwards, are filtered through the bags and pass into the open air through ventilators in the roof of the bag-house The fume is detached from the fabric periodically either by shaking the bags or by causing them to collapse by suction. It falls to the lower chamber and when a layer 2 feet thick has collected the furnace gases are diverted and the powder is ignited by a small fire. The fume, containing much oxidisable matter, burns easily and yields a grey cinder suitable for smelting in the blast furnace.

At the Murray Plant, Utah, the bag-houses are 216 by 90 feet and 90 feet high There are 4000 bags with a surface area of 570,000 square feet, which cope with 165,000 cubic feet of gas per minute, *i.e* 1 cubic foot of gas passes through 3·5 square feet of filter per minute. Fig. 27 is a diagram of a bag-house at the Globe Smelting Works, Utah. It is stated that 1000 square feet of filtering surface are necessary, in general, for one ton of ore, and the best temperature for filtration is variously given as 80°–120°C. Gases from roasters are not suitable for bag-house treatment, as the oxides of sulphur rot the fabric. The life of cotton bags at Utah is 17 months and of woollen bags 4 years. At these works, 1·27 p.c. of the lead and 0·063 p c. of the silver in the charge are recovered from the bag-house, and the fume contains: lead, 52·5; arsenic, 14·2; sulphur, 5·4; zinc, 3·0; antimony, 1·6 p.c.

At St. Louis, hearth-smelting yields twice as much bag-house fume as flue-dust. The burnt fume contains 76 p.c. lead and 5·9 p.c. of sulphur; the dust, 62 p.c. lead and 11·1 p.c. of sulphur. The lead in these products is combined as follows (Newnham, *loc. cit.*):

	Flue dust (p.c.)	Burnt fume (p.c.
Lead sulphate .	18·9	53·6
Lead sulphide .	55·4	1·2
Lead oxide .	2·0	41·5

The application of electricity to fume condensation was suggested by Sir O. Lodge, and its use patented by Walker. Experiments made in 1885 by Hutchings, using a power-driven Wimshurst machine and a system of metallic points, at the Bagillt works of Messrs. Walker, Parker & Co., Limited, yielded satisfactory results when working on a small scale, but did

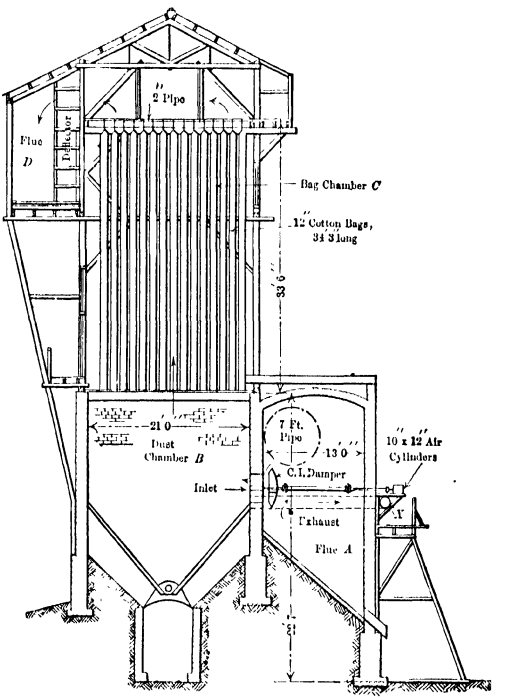

FIG. 27.

(*From* Hofman's 'Metallurgy of Lead.')

not prove successful when applied to the flues of the works.

The development of these early ideas and methods has been due, in great measure, to the labours of F. G. Cottrell (*see* Smithsonian Report, 1913, pp. 653–685). In the glow discharge of electricity from points at high potential, particles in the neighbourhood of the points receive an electrical charge and are repelled. If an earthed plate, or one of opposite polarity, be brought near, the particles are attracted, precipitated on the plate, and lose their charges. It has been found by experience that a high, direct-current voltage is preferable to an alternating one for the precipitation of dust and fume. The ordinary low-voltage alternating current generally available is thus transformed, for this purpose, into high-voltage alternating and then into intermittent high-voltage direct current. Some of Lodge's recent patents are

concerned with the rectification of alternating currents by means of vacuum tubes, which allow the current to pass only in one direction.

In the process, as carried out at present, the discharging electrodes, negatively charged by preference, have a voltage of 75,000 to 100,000. They consist of iron chains carefully insulated, which are hung in the middle of steel pipes 15–20 feet long and 10–18 inches in diameter, through which the gases are drawn. The 'collecting' electrodes, the pipes, are earthed and the precipitated fume is shaken down at intervals by striking them with a hammer.

A Cottrell plant at Trail for the treatment of 100,000 cubic feet of gas per minute consists of 384 pipes. The velocity of the gases for pipes of 12-inch diameter should not exceed 3·5 feet per second.

Fractional precipitation of fume, consisting of materials differing in volatility, is possible by the Cottrell process when operations are carried out at different temperatures. Thus, high grade white arsenic can be separated from lead fume by electrical precipitation of lead and zinc compounds at a temperature at which white arsenic is gaseous; on cooling the escaping gases, the oxide of arsenic becomes solid and can be recovered by repeating the electrical treatment.

Gases from reverberatory and blast-roasting plant which are unsuitable for bag-filtration, owing to the injurious effect of the gases on the cloth, can be treated without difficulty by the Cottrell method, and it would appear that this method had a great future in store, not only for the treatment of lead fume, but also of many kinds of dust, mist, and smoke, which are produced in numerous large-scale operations.

Properties and Uses of Metallic Lead.

Owing to the demand for soft lead in many industries, and the hardening effect of minute quantities of foreign metals on lead; owing, also, to the need of purifying the metal before desilverising and to the refining action of the desilverisation-process itself, commercial leads are usually of a high degree of purity. The following table of analyses of some commercial leads shows the nature of the chief impurities and the extent to which they are present:

—	Best English lead	Good chemical lead	Ordinary English lead	B.H.P. Australia special market lead	B.H.P. Australia ordinary market lead	Electrolytic lead, Trail, B.C.
Lead . .	99·9919	99·985	99·9655	99·9977	99·9917	99·9861

Lead is a bluish-grey metal, the freshly cut surfaces exhibiting a distinct metallic lustre, which soon disappears owing to superficial oxidation. Its crystalline character is well shown by the beautiful fern-like crystalline growths which are seen on the pigs of best market lead, or as they form on the surface of a casting during the cooling of the molten metal. It can easily be obtained in the form of regular octahedrons by melting lead, allowing the molten metal to solidify partially, and pouring off the portion still remaining liquid. It is deposited in arborescent forms, known as the lead tree, by the decomposition of a solution of lead acetate either by zinc or by electricity. Lead is a very soft metal, easily cut by a knife or scratched by the nail; it readily receives impressions and leaves a streak on white paper. Its hardness is 1·5 on Moh's scale. It is very malleable and is ductile. Rolled lead is more ductile than cast lead; both its malleability and ductility are injuriously affected by the presence of impurities. Lead is a metal of feeble tenacity, a wire $\frac{1}{12}$th of an inch will not support a weight of 20 lbs. When struck with a hammer pure lead emits a dull sound; the presence of antimony, however, makes it sonorous, hard lead being easily distinguished from soft lead by this property. The presence of antimony, zinc, arsenic, or silver increases the hardness and brittleness of the metal. Antimony makes the metal hard if present in amount over 0·005 p.c.; small quantities of bismuth are not injurious in this respect.

According to Schweitzer the sp.gr. of lead (Amer. Chem. J. 7, 174) varies between 11·344 and 11·377 at 4°. St. Claire Deville (Phil. Mag. [iv.] 11, 144) gives the following as the results of his observations on lead prepared in different ways:—(1) cooled slowly from fusion 11·254; (2) cooled quickly from fusion 11·363; (3) electrolytic lead, 11·542; (4) lead obtained by electrolysis, then fused and cooled quickly, 11·225. The mean may be taken as 11·35 at 20°C. The influence of pressure on the sp.gr. of lead is shown in the following results obtained by Spring (Ber. 16, 2724). (1) Not pressed, 11·350 at 14°; (2) once pressed, 11·501 at 14°; (3) twice pressed, 11·492 at 16°. The sp.gr. of molten lead is given as 10·37 and 10·65 by Roberts-Austen and Wrightson (Ann. Chim. Phys. [v.] 30, 181), and 10·952 by Quincke (Pogg. Ann.

135, 642). The increase in volume on melting is 3·5 p.c.; 1 cubic foot of solid lead weighs 710 lbs. and one of molten lead, 664 lbs. The melting-point is 327·4°; the boiling-point, that is the temperature of visible ebullition, is stated to be 1525°. The metal is only slightly volatile in the absence of air, but is carried over in considerable quantity by the vapour of zinc.

The specific heat of lead according to Regnault is 0·0314 at temperatures between 10° and 100° (other observers give 0·02925), and for molten lead according to Person it is 0·0402 between 380°–450°. The latent heat of fusion is 5·369 calories; the coefficient of linear expansion between 0° and 100°, 0·0000295; the conductivity for heat, 7·9, and for electricity, 7·8, compared to silver, 100.

Lead is tasteless; it is said to emit a characteristic odour when rubbed between the fingers. It can be welded in the cold by pressing the clean surfaces together.

An allotropic form of lead (or possibly more than one) was prepared by Cohen and Helderman (Zeitsch. phys. Chem. 1915, 89, 733) by suspending lead in 40 p.c. solution of lead acetate containing 10 p.c. nitric acid (D. 1·16). In these conditions the lead becomes wrinkled and denser. Three specimens of density, 11·3415, 11·3129, and 11·3283, were produced in this way from metal of density 11·3299. According to H. Heller (*ibid.* 761) this 'grey' lead is rapidly formed in solution of its acetate if only a little nitric acid be present. H. J. M. Creighton observed the formation of the same allotrope during the electrolysis of nitric acid (D 1·42) when lead formed the cathode (J. Amer. Chem. Soc. 1915, 37, 2034).

When lead is freshly distilled in silica vessels, it is rapidly attacked by water and oxygen, acting together. If, however, the distilled lead be kept some time *in vacuô*, it is much less easily corroded when brought in contact with water and oxygen. This curious behaviour has been accounted for by assuming that freshly distilled lead is not physically homogeneous, the varieties (allotropes) differing in their solution-pressures (B. Lambert and H. E. Collis, Journ. Chem. Soc. 1915, 107, 210). There are no observations as yet which correlate these allotropes with Heller's grey lead; indeed, the very existence of allotropes has been denied by some authors (A. Thiel, Ber. 1920, 53, 1052, 1066).

Speculations concerning the relationship of lead to the products of the radio-active changes of uranium and thorium have stimulated a great deal of interest in the question of the atomic weight of lead. Soddy has pointed out that the older determinations vary considerably. Thus, of 24 values given in Abegg's Handbuch, 19 range almost over a unit, viz.: from 206·8 to 207·6. Recent determinations give fairly consistent results for ordinary lead, but the values for lead derived from radio-active minerals vary considerably. A number of these results are given in the following table:—

	Source of lead	Atomic weight	Observer
1	Radio-active minerals, Colorado	207·00	Richards and Wadsworth
2.	,, ,, Australia	206·34	
3.	Bröggerite	206·12	
4.	Cleveite, Langesund	206·08	
5	Uraninite, N. Carolina	206·46	Richards and Lambert
6.	Pitchblende, Joachimsthal	206·57	
7.	Carnotite, Colorado	206·59	
8.	Thorianite, Ceylon	206·82	
9.	Pitchblende, England	206·86	
10.	Ordinary lead (control)	207·15	
11.	Uranium mineral	206·98	de Coninck and Gerard
12.	Ordinary lead (control)	206·71	
13.	Uranium mineral	206·36 to 206·64	Maurice Curie
14.	Monazite	207·08	
15.	Ordinary lead (control)	207·01	
16.	Thorium mineral (ThO_2 62 p.c., U_3O_8 1·9 ,, PbO 0·39 ,,)	208·4	Soddy
17.	Pitchblende	206·736	Hönigschmid and St. Horovitz
18.	Pitchblende, Joachimsthal	206·405	
19.	Uranium mineral, East African (formerly German)	206·046	
20.	Bröggerite (U_3O_8 79 p.c., ThO_2 4·5 ,, PbO 9·5 ,,) Norway	206·063	
21.	Ordinary lead (control)	207·180	
22.	Samarskite	206·30	Davis
23.	Thorianite, Ceylon	206·88–207·24	Hönigschmid
24.	Thorite, Norway	207·88–207·92	
25.	Spring water, Japan	207·13	Richards and Sameshima

The lowest value, 206·046 (No. 19) and the highest, 207·92 (No. 24) agree very closely with those calculated from the disintegration-theory for uranium-lead and thorium-lead, viz.: 206 and 208 respectively. Opinions differ as to the cause of the variable atomic weights, between these extremes, of the lead derived from radio-active sources. Such leads may be mixtures of ordinary lead and lead isotopes, or ordinary lead may be a distinct variety or a balanced mixture of the isotopes derived from uranium and thorium, or finally it may be an evolutionary product from lighter materials (*see* F. W. Clarke, Proc. Nat. Acad Sci. 1918, 4, 181). Attempts

by Joly and Poole (Phil. Mag. 1920, vi. 39, 372) to separate ordinary lead into isotopes by centrifugalising the molten metal did not meet with success.

The melting points of two varieties of lead, differing by 0·8 in atomic weight, were found by Richards and Hall to agree within 0·05°. The index of refraction and the solubility of the nitrates derived from test lead and lead of atomic weight 206·42 were found to be practically identical by Richards and Scumb (J. Amer. Chem. Soc. 1908, 40, 1403). Richards and Wadsworth, however, found the density of ordinary lead at 20° to be considerably higher (11·377) than that of lead extracted from Australian radio-active minerals (11·288); as the atomic weights vary proportionately to the densities, the atomic volumes are identical, viz.: 18·277 and 18·276. It is evident that the isotopes only differ from one another in respect to mass.

Lead is easily oxidised by exposure to the air, and in the finely divided state, as obtained by the decomposition of the tartrate by heat, is pyrophoric. It is not attacked by air-freed water, nor by dry air free from carbon dioxide, but easily suffers corrosion under the combined influence of air and moisture, or of water and air, lead hydroxide being produced. This dissolves in the water and is converted into a basic carbonate by the carbonic acid present. The action of water on lead is materially influenced by the presence of small amounts of salts; nitrates are supposed to further the action—this is especially true of ammonium nitrate—whereas chlorides, sulphates, carbonates, and phosphates retard the action. Chlorides, sulphates, and carbonates, especially the last, diminish the solvent action of nitrates and in some cases destroy it altogether. Water saturated with carbon dioxide under ordinary pressure has but little solvent action on lead, but under a pressure of six atmospheres, the solvent action is considerably increased. In this case also the presence of ammonium nitrate and of potassium carbonate tends to retard the action. These conclusions are drawn from the observations of Muir (Chem. News, 33, 102, 125, 145; 34, 223, 324), who has also studied the influence of salts on the solubility of the basic carbonate

$$(PbCO_3)_2,Pb(OH)_2.$$

The order of solubility of this compound agrees very nearly with that of metallic lead in solutions of the same salts (Muir, Chem. Soc. Trans. 31, 660). The influence of small quantities of free sulphuric acid on the corrosion of lead by saline solutions has been studied by W. Carleton Williams (J. Soc. Chem. Ind. 6, 111). The presence of 1 grain per gallon of free acid notably increases the action. Allen (Chem. News, 46, 145) found that water taken direct from the main in one town in Yorkshire, and having an acid reaction, when left in contact with lead, dissolved an amount of lead equivalent to 0·42 to 0·56 grain per gallon, but after the water had been made slightly alkaline the amount of lead dissolved was equivalent to 0·14 grain per gallon only. Crookes, Odling, and Tidy ascribe the activity of water towards lead to deficiency of silica, and are of the opinion that from 0·5 to 0·7 part of silica per 100,000 is sufficient to prevent the action. In many cases the corrosion of the lead pipes would appear to be due to the presence of a free acid in the water supply, as is apparently the case with one of the water supplies of Sheffield, and also the water supply at Huddersfield (Allen, *l.c.*, also Chem. News, 46, 88). The waters most liable to act upon lead are those obtained from upland gathering grounds, waters which are soft and usually of remarkable purity. The presence of peat in water increases its action on lead, except when the water is permanently hard (H. Heap, J. Soc. Chem. Ind. 1913, 32, 847). The activity of such waters is by many attributed to the presence of free acid (*cf.* P. F. Frankland, J. Soc. Chem. Ind. 8, 241) (*v.* WATER).

Since air facilitates the solvent action of water, an intermittent water supply is favourable to the contamination of the water, and as lengthened contact with lead in the case of an active water will naturally result in a considerable proportion of the metal being dissolved, it is advisable to run off the water that has been standing over night in the pipes, as such water may be unfitted for drinking purposes.

Lead is dissolved easily by dilute nitric acid; the action of concentrated acid is soon arrested by the formation of a protective layer of lead nitrate on the surface of the metal. Dilute hydrochloric and dilute sulphuric acids do not attack lead, but it is dissolved by boiling concentrated hydrochloric and sulphuric acids, lead chloride and lead sulphate being formed.

Lead is largely used in building construction in the form of sheets, gutters, spouts, &c., also for the manufacture of pipes for gas and water, and of cables, accumulators, and rifle bullets. Its power of resisting the action of acids, &c., renders it of great service in the construction of chemical plant, *e.g.*, sulphuric acid chambers. The lead preferred for this purpose is obtained by remelting old lead, and is hardened by a small amount of antimony. Experiments of Johnson and Calvert (Compt. rend. 56, 401), of Hasenclever (Wag. J. 1872, 239), and of Bauer (*ibid.* 1875, 364) have shown that ordinary leads resist the action of sulphuric acid more effectively than pure lead. Lead is also an important constituent of many alloys, *e.g.* solder, type-metal, bearing-metal, fusible alloys, and pewter. Bullets for smooth-bore small arms are hardened with antimony to give them greater penetrating power.

Sheet lead.—For the manufacture of sheet lead, market lead is cast in a plate several inches in thickness. When the plate is somewhat cooled it is transferred to the rolling mill, which consists of a pair of massive iron rollers, about 18 inches diameter and 8 feet wide, which are worked by engines with reversing gear. The rolls are placed in the middle of a long bench, a little wider than the rollers, and about 3 feet high; at intervals of a foot along the bench are placed wooden rolls on the same level as the rollers, which serve to facilitate the movement of the sheet to and fro. By passing and repassing the plate between the rollers it is gradually extended into a sheet, which, when too long for manipulation in the ordinary way, is cut into smaller sheets which are rolled separately. Or the sheet may be doubled over, the surface being previously chalked to prevent the adhering

of the two sheets, and the doubled sheet rolled out to the required thickness. The lead having been rolled out, the edges and ends of the sheets are cut straight and the sheet wound on to a cylinder at the end of the bench.

Lead pipes are usually made in machines worked by hydraulic pressure. Over the piston of the press is a reservoir which contains the metal, and which may be heated by an annular fireplace. The reservoir is filled with molten lead by a spout through an aperture in the top; when filled the spout is withdrawn and the aperture closed tightly by an iron plug, kept in position by an iron key. The size of the pipe is regulated by a steel die of the diameter of the outside of the pipe fitted at the top, the internal diameter of the pipe being determined by a mandril which passes directly through the centre and is moved upwards by the rising piston, the semi-molten metal being at the same time forced through the die. As the pipe passes out at the top it is coiled on to a drum. The pipes used for gas-services are sometimes made of metal to which either tin and antimony have been added directly, or these metals may be supplied by the addition of a harder lead containing them.

Lead shot is made by alloying the metal with arsenic (0·3–0·8 p.c.), which is added either in the form of white arsenic or arsenical dross from the improving furnace. The addition of arsenic serves to impart a greater fluidity to the metal and increases the tendency of the metal to assume a spherical form in passing through the air. With too little arsenic, the drops are pear-shaped; with too much, the shape is double convex. The molten metal is made to run through cullenders, and to fall a considerable height into water-butts. A small amount of sodium sulphide (about 0·025 p.c.) is added to the water to prevent oxidation of the lead. The height required for the fall is either secured by means of a shot tower, or by a deep well, the shaft of an old coal pit being in some cases adapted for this purpose. The size of the shot is determined by the size of the holes in the cullender, by the height from which the lead falls, and by the temperature and consequent fluidity of the molten metal.

The shot, taken from the vessel in which it has solidified, is sorted by sieving into different sizes, and the imperfect ones separated by causing the shot to roll down an inclined polished metal surface, or a wooden table sloping at 15°. The perfect shot acquire the highest velocity and shoot well over the edge of the table into a bin; the imperfect fall short of this and are gathered apart. The shot is finally polished by shaking with a little graphite in a cask revolving on a horizontal axis.

Lead Compounds used in the Arts.

Lead oxide, lead monoxide, or *plumbic oxide* PbO. The varieties of this compound are *massicot* and *litharge*, the former name referring, strictly, to the unfused, the latter to the fused, compound. The tendency, at the present time, is to use the term 'litharge' for all varieties of lead monoxide. The compound is obtained when molten lead is heated at a moderate temperature in a reverberatory furnace, the molten lead being constantly stirred. It is formed in the first stage of the manufacture of red lead. After grinding, levigation, and drying, it is obtained as a brownish-yellow powder, usually containing some metallic lead, lead peroxide, and grit. It is generally known, commercially, as ground litharge or massicot.

Litharge is produced when the oxidation of lead takes place at a temperature sufficiently high to melt the oxide formed, as in the cupellation process. When manufactured for sale, the purest lead is submitted to cupellation; if the lead used is not quite pure, then the portions of litharge first formed and that produced towards the end of the operation are rejected. The litharge as it forms is collected in large iron pots fitted on wheels, in which it is allowed to cool slowly. When the pots are emptied, the litharge 'falls,' the central portions which have cooled more slowly being somewhat lighter in colour and possessing a scaly crystalline structure. The more friable portion is broken up and passed through a circular temse or screen, and sold as *flake litharge*. That portion of the litharge which does not fall, but remains in hard coherent masses is ground between horizontal stones in a stream of water, run into settling tanks and dried at a low temperature in a reverberatory furnace. This is known as *levigated litharge*.

A mechanical furnace for making litharge was patented by Noad in 1895 and was modified and improved later by Barton and others. It consists essentially of an iron pan, fitted with a cover and stirring paddles and connected with fume-condensing chambers by an upright shaft. Molten lead is fed in through a side pipe during the operation. Lead is heated in the pan to a temperature of 600°C., stirred and splashed by the paddles and treated with a blast of steam and air, which enters through a pipe in the cover. The fume of finely-divided lead and lead oxide, mixed with the gases, escapes through the uptake and passes to the condensing chambers. The litharge-dust collected in these is sometimes levigated to reduce the amount of blue lead in it, sometimes calcined at a high temperature and then sifted. Attempts have been made, by heating the uptake from the pan, to oxidise the blue lead in the effluent fume so thoroughly that subsequent treatment is not required.

The litharge obtained by this method is canary-yellow in colour and very fine in grain. It may contain as little as 0·05 p.c. insoluble in acetic acid and 0·005 p.c. insoluble in nitric acid, and is thus practically free from grit, metallic lead and lead peroxide. It is especially valuable for proofing fabrics and for conversion into pigments.

The colour of lead oxide varies from lemon-yellow to reddish-yellow, and on heating or exposure to light it becomes brownish-red. The yellow variety is also turned red by mechanical compression. The solubility of the red form is 0·029, that of the lemon-yellow 0·047 gm. mols. in normal caustic soda at 20° (Glasstone, Jour. Chem. Soc. 1921, 120, 1689). The sp.gr. of different varieties of lead oxide are given by Geuther (Ann. Chim. Phys. 19, [ii.] 60–61) as follows: yellow cryst. 9·29 at 15°; red cryst. 9·126 at 15°; red cryst. 9·125 at 14°; red powder, 9·09 at 15°; and red, very pure, 8·74 at 14°. The melting-point is variously

given as 776, 879, 888, and 906°C Litharge is reduced by carbon monoxide at 100° and by hydrogen at 310°. It absorbs oxygen when molten and gives it up again on slow cooling, falling into powder the while. When fused with sulphur, iron, zinc, copper, antimony, and several other elements, it oxidises them and the oxides dissolve in the molten litharge, provided this is present in sufficient amount: Thus 1 part each of ferric oxide, zinc oxide, antimony oxide and tin oxide require 10, 8, 5, 12 parts, respectively, of lead oxide for complete solution and fusion. These properties of litharge are utilised in assaying silver ores and refining silver.

Litharge is used in the manufacture of flint glass; as a glaze for earthenware; for the preparation of lead acetate, lead nitrate, lead chromate, lead plaster, for drying oils, for proofing fabrics, and in the manufacture of rubber and electrical accumulators.

The occurrence of native litharge in Kurdistan has been described by Alex. Scott (Min. Mag. 1914, 17, 143). The mineral is red, with a yellowish-brown streak, and partly crystalline. The sp.gr. is 8·61 and analysis shows it to contain PbO, 97·17; CuO, 2·61; Sb_2O_5, 0·30 p.c. E. S. Larsen (Amer. Min. 1917, 2, 18) also records the natural occurrence of crystalline litharge from Austria and California. The mineral is yellow and the constituent crystals are orthorhombic, biaxial, and optically positive. This is surmounted by a reddish fringe of tetragonal, uniaxial crystals, optically negative, which are regarded as native massicot.

Red Lead, *Minium*, or *Plumbic Tetroxide* Pb_3O_4. The manufacture of red lead is effected in two stages, the first being the conversion of the lead into massicot or the 'drossing' of the lead, and the second the conversion of the monoxide into red lead of the required shade. These operations are usually conducted in two different furnaces. The drossing oven, is a low-arched furnace with a bed of firebrick laid on a bed-plate of cast iron having raised borders on each side and at the back. The bed of the furnace is made to slope slightly towards a median line, and also from back to front. On either side of the furnace bed is a low wall, the spaces between which and the wall of the furnace form the two fireplaces. In front are three openings closed by hinged doors of cast iron; the two side ones communicate with the fireplaces, whilst the central one, which is larger than the other two, serves for the introduction and the working of the charge, and for the escape of the products of combustion, which pass into a hood of brickwork in front of the furnace, this hood forming the base of the short vertical chimney attached to each furnace. In front of the working door is hung a chain with a hook at the end; this serves as a fulcrum for the rabble used in working the charge. Below the working door a space is formed by two vertical plates of cast iron on brick walls, resting on a slab of stone or plate of iron on the floor, and supported by the iron plate which forms the lower part of the front of the furnace. This space in front serves to collect any of the oxidised product which may fall in transferring it to the waggons. The length of the furnace is about 11 feet, and the width between the bridges is about 8 feet 4 inches. The 'colour oven' is in most essentials similar to the 'drossing oven'; the bottom is flat and the slope from back to front not so great as in the latter Coal is used as fuel in these ovens; in some cases where the ovens are constructed with fire-grates and ash-pits, small coal may be used.

The mode of working is as follows. A charge of from 22 to 31 cwt. of pig lead is introduced into the furnace, and a dam is made across the furnace of rough oxide intermingled with lead obtained from the grinding and levigation of a previous charge. The temperature is so regulated as to melt the lead, which forms a pool behind the dam; the molten lead is agitated by means of a rabble and splashed over the furnace bottom. In this way the oxidation is promoted, and as the oxide is formed it is pushed toward the back of the furnace, the still unoxidised lead flowing to the front. The oxidation is promoted by adding a small quantity of 1 p.c. antimonial lead and when completed the charge is raked out into iron waggons, and allowed to cool It is next passed to the grinding mill, where it is ground between millstones with a regulated supply of water. The heavier particles of lead oxide and metallic lead which sink in the troughs leading to the settling cisterns are collected and used in the drossing oven to dam up the charge of lead. The finely ground massicot is carried by the stream of water into settling tanks where it subsides, and after the water has been run off, it is conveyed to the 'colouring' oven, spread out in furrows and ridges resembling a ploughed field, and heated at a carefully regulated temperature for some hours, until it has assumed the required shade. When hot, the red lead has a rich purple tint, which becomes bright red on cooling. The red lead is withdrawn from the ovens, and sieved or levigated.

In the manufacture of white lead by the stack process, a certain amount of the white lead (not more than 2 p.c. in a well-conducted operation) becomes stained. This 'off-colour' material is also used in making red lead and is worked either alone or mixed with ordinary materials.

A limited amount of red lead is also made by oxidation of lead (or litharge) with sodium nitrate. The nitrate is melted in iron pans, heated to 340°, and the calculated amount of lead in thin strips added. When the oxidation of the metal is complete, the mass is poured into warm water and the sodium nitrite recovered from the liquors, after these have been neutralised with sulphuric acid, by evaporation. The sodium nitrite is used in the dye industry for the purpose of diazotisation.

Orange lead or orange mineral is a variety of red lead produced by the calcination of white lead. Formerly, the froth from the white lead washing tanks was used for this purpose. The furnace-product is purified either by grinding finely and sifting, or it is water-ground, dried, and sifted. This variety is used for the production of paints, colours, printing inks, and enamels. The finest grades have a vivid orange tint. Orange lead differs from red lead, not only in colour, but also in bulkiness and in its behaviour towards linseed oil. It is much more bulky than red lead; the measures of equal weights of the two being as 7 : 5. This property is of great importance in the printing-ink trade.

When orange lead is mixed with linseed oil or varnish, the mixture remains soft on keeping, whereas red lead soon sets up with these media and the product cannot be thinned again. It is customary, therefore, when using red lead as a paint, to mix it shortly before use.

The cause of the variation in colour of the many grades of red and orange lead is not known. It has been found in laboratory experiments that small quantities (0·1 p.c.) of lead nitrate and caustic soda have a considerable effect, producing, in the first case, a pink colour, and, in the second, an intense red. When red lead is made by heating monoxide and peroxide of lead with caustic potash, the depth of colour depends on the concentration of the alkali. These facts, however, throw no light on the variations observed in large-scale operations. In these, the nature of the original materials, the control of furnacing temperature, and other factors, have a determining effect on the colour of the product.

Commercial varieties of red lead vary considerably in their content of active (peroxide) oxygen. The peroxide equivalent of this in the pure compound, Pb_3O_4 (*i.e.* proximately $2PbO.PbO_2$), is 34·9 p.c. A good average brand may contain 23–25 p.c.; extremes contain 5 and 34 p.c. For similar conditions in the colouring furnace, each kind of monoxide shows a maximum peroxidation, more or less definite, though the time required to establish this varies considerably. The past history of the monoxide affects the progress of oxidation. Thus both yellow and red litharge are roasted to red lead much more slowly after washing with water than after air-separation (O. W. Brown and A. R. Nees, J. Ind. Eng. Chem. 1916, 4, 867).

The effect of various factors on the rate of oxidation of litharge to red lead has been studied by J. Milbauer (Chem. Zeit. 1909, 33, 552, 950; 1910, 34, 139, 1341; 1915, 39, 858). It depends more on the source of the litharge than on the size of the particles, and is decreased by the addition of small quantities of nitric acid and ammonia, but increased by the nitrates of lead and sodium. Of the metals, silver facilitates oxidation at 300°, but its influence is not observable at a higher temperature; bismuth is inert and zinc and antimony act unfavourably. The velocity of oxidation also depends on the temperature and on the partial pressure of the oxygen.

Brown and Nees (*op. jam cit.*) state that the yellow and unfused varieties of litharge are more slowly oxidised than the red and fused forms. They have determined, under laboratory conditions, the optimum temperature of oxidation of various materials to red lead. This is 425°–430° for white lead, and 450°–470° for litharge and lead sponge (the latter obtained by electrolysing both acid and alkaline solutions of lead). According to their experiments, lead is not directly oxidised to red lead, but only *viâ* the monoxide.

These observers have also studied the microscopic structure of red lead and have determined the density of numerous specimens. The following is a brief abstract of the results. Red lead may be either crystalline or amorphous; no definite form can be made out for the crystalline varieties. The specific gravity varies from 8·32 to 9·16; it is lower the more nearly the composition approaches to Pb_3O_4, and its value depends on numerous factors, such as the temperature of oxidation, the length of time of heating, and the physical character of the original material. The apparent density depends mainly on the fineness of the particles, decreasing as the fineness increases up to a certain point.

When heated *in vacuô* to 530°, red lead is rapidly and completely converted into litharge. Heated in a closed space, between certain limits of temperature, the compound is dissociated into litharge (greenish-yellow in colour) and oxygen, and an equilibrium-system of two components in three phases is established. The dissociation-pressure of the compound is thus a function of the temperature. The pressure-temperature curve has been determined by Reinders and Hamburger (Zeitsch. anorg. Chem. 1914, 89, 71) between the temperatures 445° and 607°. It is smooth and gives no evidence of the formation of intermediate compounds or solid solutions. When the oxide has been purified by extraction with solutions of acetate or nitrate of lead, equilibrium is much more slowly attained than when the oxide is crude. (For the action of oxygen on litharge at high temperature and pressure, *see* p. 86.)

Several methods for the preparation of pure Pb_3O_4 have been given by Milbauer (Chem. Zeit. 1914, 38, 477, 559, 566, 587; *v.* also Dumas, Ann. Chim. 1832, 49, 398; and Levol, *ibid.* 1840, 75, 108). For example: (1) extraction with 10 p.c. solution of nitrate or acetate of lead, or with concentrated potash solution, of the oxide obtained by oxidising litharge at 470°, or that obtained by fusing litharge and potassium nitrate. (2) By heating lead peroxide PbO_2 with molten nitre at 470° and extracting the product with water. (3) By heating a mixture of monoxide and peroxide of lead ($3PbO : 2PbO_2$) with a solution of caustic potash containing 200 grams KOH dissolved in 100 c.c. water.

Red lead is regarded by some chemists, following Dumas (*op. cit.*), as lead orthoplumbate Pb_2PbO_4, and its formation as due to the combination of the basic monoxide PbO with the acidic dioxide PbO_2, which is the initial oxidation-product of the monoxide. Under particular conditions of oxidation the meta- or the pyroplumbate may be formed in a similar manner (*v.* p. 86). If a mixture of litharge and red lead of high active oxygen-content be compared with a red lead of lower active oxygen-content, but equal to that of the mixture, it will be observed that they differ, especially with respect to their behaviour towards linseed oil. Such facts have led to speculations on the chemical nature of red lead and its relationship to litharge. Mendeléeff's hypothesis of the polymerisation of lead monoxide (and other oxides) has been applied by Wade to the problem under consideration. It is assumed that the polymeride has some such formula as $Pb_{12}O_{12}$; that oxidation of litharge takes place gradually and uniformly through the mass and in such a way that successive stages, $Pb_{12}O_{13}$, $Pb_{12}O_{14}$, &c., are passed through. When the stage of oxidation represented by $Pb_{12}O_{16}(=4Pb_3O_4)$ is reached then pure red lead is the product.

Many of the present obscurities on this subject will probably vanish when knowledge of the homogeneity or otherwise of the grains of red lead has been acquired.

When heated, red lead assumes a darker shade of red, becoming violet and ultimately black; it regains its original tint on cooling. It is decomposed by nitric acid, lead nitrate and the puce-coloured peroxide PbO_2 being formed; when digested with nitric acid and a little sugar, the red lead is completely dissolved. Alcohol exerts a reducing action similar to that of sugar; the lead passes into solution as nitrate and the alcohol is oxidised to acetaldehyde. Red lead is used as a pigment, and in the manufacture of flint glass and optical glass. When used for the latter it must be free from iron, copper, antimony, metallic lead, and lead sulphate. It is also used as a cement in making steam-joints, and in the manufacture of secondary batteries.

White lead, Céruse, Blanc de Plomb, Bleiweiss. The term 'white lead' has been used in England for at least three centuries to describe the mixture of basic carbonate (or carbonates) of lead and varying quantities of other lead compounds, which is produced by the action of air, moisture, carbon dioxide, and acetic acid upon lead. Within comparatively recent times, other methods of manufacturing white lead have been developed, but most of the output at the present day is still derived from the reaction of the above-named materials and by methods which are only variations of those used by the ancients.

The Stack process.—It is estimated that about 70 p.c. of the white lead produced in England is made by the stack process. This is developed from the old Dutch, and still earlier, processes, in which lead and pots of vinegar were embedded in fermenting horse dung and stable litter. The vinegar is replaced by acetic acid, prepared from pyroligneous acid and the dung by spent tan.

The substitution of spent tan for stable litter minimises the risk of discoloration of the white lead by sulphuretted hydrogen, but the fermentation is somewhat slower, and consequently the conversion of the 'blue' lead into white lead requires a greater length of time. The fermentation of the tan is thought to be due, at first, to bacterial action. In any case, heat is developed and the temperature may rise to 80°C., though 50°-60° is more usual. The carbon dioxide necessary for the process is produced in the fermentation, and the tan parts with much of its water.

The lead used for the manufacture of white lead should be pure, and the manufacturer usually refines it for the purpose. The presence of small amounts of copper or antimony tends to produce a white lead having a dull grey tint. A red or pink colour, at times observed in the white lead, has been attributed to the presence of a suboxide of lead by Bannow and Kraemer (Ber. 1872, 545; 1873, 21), an explanation admitted by Lorscheid, but according to Baker the coloration is caused by the presence of finely divided oxy-compounds of silver. The lead is cast into thin sheets of lattice work or gratings, so as to expose a large surface to reaction, by pouring molten lead on to a sloping grooved iron plate, from which, on solidifying, the crates, buckles, plates, straps, or wickets, as they are variously styled, are easily detached. Some is also cast in thin circular discs or stars. In some of the works in this country and in America, the 'plates' and 'wickets' are cast by machinery. The machine consists of an endless band of square

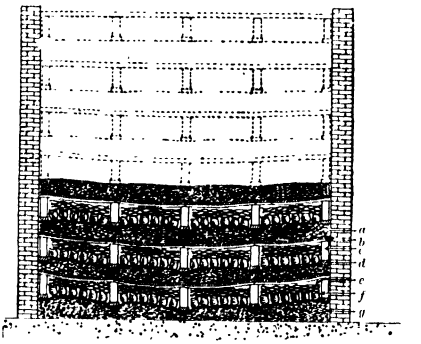

FIG. 28.—THE STACK PROCESS (diagrammatic).

a, Floor boards; *b*, Floor beams; *c*, Wood blocks keeping heights apart; *d*, Beams under wood blocks; *e*, Corroding strips of lead; *f*, Earthenware pots containing dilute acetic acid; *g*, Spent oak bark.

plates of iron linked together, each plate being a mould, into which the lead is poured as the plates are slowly moved under the spout of the lead-pot. The castings are delivered at the end on a leather belt covered with plates of sheet iron to prevent the hot lead injuring the leather. This machine can make from 50-60 castings per minute.

The corroding house or stacks is a brick-work chamber having an area of 12 feet by 20 feet, or 16 feet square, and a height of 25 feet. The front wall of the chamber is provided with an opening, 4 feet wide, running from the top to

the bottom, which serves for the introduction of the materials used in the construction of the stack. As the building of the stack proceeds the opening is closed by boards fitting into slots, the top being, however, left open for the purpose of inspection. The stack is built up as follows: First, the floor of the chamber is

covered with a layer of ashes, upon which is spread spent tan, already in a state of fermentation; the thickness of this first bed of tan is 3 feet. The tan is beaten down and the surface levelled, and on the bed so formed earthenware pots, partially filled with a 2 or 3 p.c. solution of acetic acid, are placed side by side, leaving a space about 6 inches wide between the outside rows and the walls of the chamber. The pots ordinarily used are of two sizes; the larger ones are provided with a rim on the inside, on which discs of the metal rest. They are placed along the edges and support the wooden bearers which carry the flooring boards used to cover in the bed. Sometimes, pots of one size only are used, and the flooring boards are supported by blocks of wood. On the top of the earthenware pots are placed the crates of metallic lead, so as to form a layer of lead about 5 inches in depth; between the lead and the cover of flooring boards is left a space of from 6 to 8 inches. The space between the walls of the chamber and the pots is filled in with tan on all sides, the opening in front being closed by boards. On the bed so constructed another bed is built in exactly the same way, with the exception that in the construction of the upper beds the layer of tan is only about 1 foot in thickness. In this way the chambers are filled up to a height of 20 feet or more, and the topmost bed is covered with a layer of tan. In stacks of area 12 feet by 20 feet, 3 tons of lead are set per height and about 1000 pots of 5½ inches diameter, containing 200 gallons of dilute acetic acid. In stacks 28 feet by 14 feet, each height or set may contain as much as 7 tons of lead, the total for a stack of 12 heights being 84 tons.

After the stack is built it is left to itself for about three months. It is then unloaded, the top covering of tan is removed, and the bark which is not mouldy is used to add to fresh tan in the construction of another stack. The 'corrosions' preserve the form of the castings of the metal, but are more bulky, and present a white opaque appearance. They vary in texture; the best corrosions are hard and porcellanous, and can be easily handled without crumbling, whilst the poorer are of a floury character and crumble easily when touched. In places the white lead is discoloured, owing to the tarry matter present in the acid used or to droppings of water from the tan. Before removal of the corrosions from the stack, each layer as it is exposed is thoroughly moistened with water to keep down the dust. It is usual to find the earthenware pots quite empty and dry, though a few may contain water; the pots are washed and drained, and used again. The pieces of white lead which fall on the bed of tan are picked up by hand, the surface of the bed is also raked, and a further quantity of white lead is got from the tan by washing it on sieves in a stream of water.

The trays of corrosions taken from the stack are sunk in a cistern of water and the contents are directed by means of rakes between corrugated rollers running under a stream of water. After the blue lead has been separated, the white lead is crushed by passing through a pair of smooth rollers, made of gun-metal, and raked about over a perforated plate under a constant spray of water. The coarse white lead next passes to horizontal grinding stones, to which it is fed by a ladle or by an endless band. After passing through these stones, the white lead issues in the form of a thick white mud, and is again passed through other grinding stones until it has been reduced to a state of subdivision so fine that it is carried along by the stream of water to the settling tanks; the white lead which settles out in the troughs used to convey the water to the tanks is returned to the grinding stones. The grinding and levigating are conducted in such a way that the water may be used over again. Before discharging the water, sodium carbonate solution is added to precipitate the lead, present as soluble acetate. Sometimes the sodium carbonate is added during the grinding process and the resulting sodium acetate eliminated in the settling tubs and filter presses. It is essential that white lead should be free from lead acetate.

In the tanks the white lead gradually settles and forms a thick white paste, from which the water is siphoned off, and when the mud has attained a sufficient consistence it is ladled out into the dishes used for drying it. The dishes are shallow clay saucers, 12 inches diameter and 3 inches deep, and made of clay similar to that employed in making flower pots. The dishes are stacked in drying stoves upon shelves made of iron bars, the stoves are heated by iron pipes made to circulate round the floor of the stove, and connected with a fireplace outside the stove, the products of combustion from the fire passing through the pipes. In this way the pulp, which contains 25–30 p.c. of water, is gradually dried; the temperature of the stoves should not rise above 180°F. (62°C.). Drying is also performed in steam-heated copper pans, and under reduced pressure. The white lead when dry is packed in casks or ground and mixed with oil to form a paint. Boiled linseed oil is used for this purpose, and the 'paste' produced contains 6–9 p.c. of oil. During the grinding, some manufacturers add a small quantity of a blue colouring matter such as Prussian blue or indigo to the white lead to modify the somewhat yellowish tint due to the stains from the bark.

To obviate the dangers attending the drying of the pulp, the method patented by Ismay (Eng. Pat. 23969, 1895), and known as 'pulping,' has been adopted with considerable success. In this process, the white lead pulp from the filter presses is mixed with oil and thoroughly agitated in a pug-mill, with the result that the greater portion of the water is displaced by the oil; the last portion of water is driven off by using a pug-mill, provided with a heating jacket, in which the mixture is heated to a definite and regulated temperature in a partial vacuum. This method contributes a considerable hygienic advance.

One of the great disadvantages of the stack process is the lack of control of the fermentation of the tan. In practice, great attention is paid to this subject, the tan being kept under close observation during the building of the stack. Any irregularities in action, arising during the corrosion, naturally affect the development of heat, which influences the evaporation of the acetic acid, and the generation of carbon dioxide.

The Chamber Process has been developed chiefly in Germany and is there used extensively. In this country, Cookson's Chamber Process, modelled on the German, is in operation on the Tyne. The outstanding differences between the chamber and the stack processes are that tan is dispensed with as a source of heat and carbon dioxide; all the necessary materials are passed into the corroding chambers in regulated quantities and very thorough control of temperature and other factors is possible.

The corroding chambers are built of brick and are about 24 feet high and 20-25 feet square. The gases are generated beneath the chambers and enter them through pipes in the floor; at the top of the chambers there are openings for ventilation which can be closed, if necessary, by wooden plugs. Air is admitted through the sides of the chamber, near the base.

The refined lead for corrosion is cast into straps, without perforations, and thinner than those used in the stack process: these are slung over sticks which are carried on arches. The total weight of lead set in an average chamber is 45–55 tons. Carbon dioxide is generated by burning weighed quantities of coke, of known composition, the weight of carbon burnt being only slightly in excess of the amount eventually contained in the white lead, reckoning on an average corrosion. Water and acetic acid are evaporated in fire-heated copper pots, somewhat more acid being used than in the stack process. The temperature is 60°–70°C., and the heat is supplied by the hot gases, supplemented to some extent by the heat of chemical action.

The time of corrosion is from 42 to 60 days, and the proportion of the lead corroded is greater than in the stack process; it depends on the size and weight of the straps and on the quantity of lead set in each height. Before stripping, the chambers are thoroughly drenched with water by means of special sprays placed in the ventilating holes. The corrosions are taken to the grinding mills and are treated in the same manner as those produced in the stack process.

The following analyses of chamber gases are averages, over a long period, for two chambers:

	1	2
Oxygen . .	14·0	15·4
Carbon dioxide .	0·67	0·24

These figures are instructive as showing the extent to which atmospheric oxygen is absorbed in the process. This point may be emphasised by a simple calculation. Suppose that 50 tons of lead are set in a chamber 25 feet cube and that 60 p.c. is corroded in 60 days. The average temperature being 60°C.; then the weight of atmospheric oxygen absorbed is 2·3 tons, which occupies 62,300 cubic feet at 60°. The absorption of oxygen is thus, in round numbers, 1000 cubic feet a day, which is equivalent to one-third the air-contents of the chamber. The atmosphere of the chambers is saturated with water vapour. The pressure of this at 60° is 150 mm., so that the gases contain 20 p.c. of water vapour.

One great merit of the chamber process lies in the control which can be exercised over the temperature and the composition of the reacting gases. The spaciousness of the chambers is possibly also an advantage, since it favours the convection and diffusion of the gases and the establishment of uniform composition. The absence of dirty bark and coloured drippings results in the white lead being cleaner than that produced in the stacks. Comparison of the two products shows the stack white lead to have a pronounced grey colour, whereas the chamber product is pure white. By selection of the composition of the reacting gases, a corroder can naturally cause the composition of the white lead to vary within wide limits; actually, he works for a product of uniform composition. An average analysis shows: PbO=86·4; CO_2=11·3; H_2O=2·3 p.c., which corresponds closely with the formula $3PbO,2CO_2,H_2O$ (calculated: PbO=86·3; CO_2=11·4; H_2O=2·3). For similar grades of fineness, the amount of 'coarse' (normal) carbonate, insoluble in dilute acetic acid of the same strength is only 0·1 to 0·3 p.c. for the chamber white lead, but it varies from 6 to 20 p.c. for the stack white lead. The following figures, which are averages over a long period, illustrate this difference of carbonation in the two processes:

Molecular ratios	Chamber white lead	Stack white lead	
		Ordinary run	Short run
	x	x	x
$xPbCO_3 : Pb(OH)_2$	1·88 to 2·56	2·22 to 2·72	2·07

The greater extent of carbonation of the stack product is thus clearly shown. When the stack is worked on a short run (about half the normal) the carbonation is not so pronounced and the white lead approximates in character and composition to the chamber product.

The Chemistry of White Lead.

Though so much has been written on this subject, it cannot be said that our knowledge of the many changes which take place in the conversion of lead into white lead by the stack or chamber process is in a satisfactory condition, and the general tendency to speak of white lead as a compound, instead of a commercial preparation, has given a spurious air of simplicity to what is, in reality, a very complicated problem.

All are agreed that corrosions are not uniform in composition; they vary from layer to layer and contain one or more basic carbonates of lead and, in addition, acetate and normal carbonate of lead and, possibly, lead hydroxide. The futility of calculating formulæ from the analyses of selected pieces of corrosions is at once apparent.

White lead itself is a more uniform product and is probably simpler from a chemical point of view. Most of the lead acetate, normally present in the corrosions to the extent of 2 p.c., has either been washed out or precipitated as basic carbonate, either by the carbon dioxide of the air or by the addition of sodium carbonate,

and any lead hydroxide which may have been present originally has likewise been converted into basic carbonate during the washing process; and though normal carbonate of lead is probably present in all samples, the quantity of it may be small. The question then arises whether the bulk of the finished white lead can be regarded as consisting of one compound, and, if so, what formula are we to assign to it?

The ability of manufacturers to turn out white lead of fairly constant composition, in tolerable agreement with the formula

$$2PbCO_3,Pb(OH)_2$$

has naturally led most writers on the subject to conclude that this compound is the basis, as it were, of white lead, though it would be legitimate to infer that a complex mixture, say, of normal and basic carbonates of lead was in all cases produced and that uniformity in composition was only a measure of the control of conditions exercised during the manufacturing process.

The difficulty of deciding between these views arises from the poor characterisation of the material and the consequent lack of satisfactory criteria for the existence of any definite compounds in white lead, except the crystalline normal carbonate, which is often only a subsidiary constituent. As, however, a definite basic carbonate of the composition

$$2PbCO_3{\cdot}Pb(OH)_2$$

does exist (Hawley, J. Phys. Chem. 1906, 10, 654), and as it can be prepared by similar methods and resembles white lead in properties, it may be assumed that this compound is a constituent, and possibly an important one, of a good white lead, and the question of the presence of other basic carbonates in white lead may be left open. The old idea, which still crops up on occasion, that white lead is a mixture of hydroxide and carbonate of lead is erroneous, and it might be well to minimise the possibility of this error by writing the formula of the basic carbonate on an analytical basis as $3PbO{\cdot}2CO_2{\cdot}H_2O$. This would have the further advantage of discouraging names with a constitutional connotation, and it might end the absurdity of representing white lead with a structural formula. The statement, so often met with, that a white lead has the 'theoretical composition' must be read in the light of the above qualifications.

The explanation of the corrosion process put forward by Liebig and Hochstetter (1837) is generally accepted, differences of opinion arising over what are, relatively speaking, minor points. The reactions postulated are:

1. Oxidation of lead, in presence of water, by atmospheric oxygen and conversion of lead hydroxide into lead acetate by means of acetic acid;

2. Formation of basic lead acetate by reaction between lead hydroxide and (normal) lead acetate;

3. Double decomposition of basic acetate of lead and carbonic acid, with production of basic carbonate of lead and regeneration of acetic acid. The acetic acid is immediately converted into its lead salt, during active corrosion, and this by combining with more lead hydroxide sets up afresh this cycle of changes. Viewed otherwise, one may regard the normal lead acetate solution as the solvent in which lead hydroxide, produced by direct oxidation of the metal, is continuously dissolving, and from which it is being continuously precipitated as basic carbonate of lead by the carbonic acid.

The assumption of this succession of reactions, though satisfactory enough as concerns the main issue, yet fails to represent the complexity of the corroding-house process, for clearly there must be ceaseless competition of the various bases present for the two acids. Full discussion of this problem would be out of place here, but brief mention may be made of some effects which would follow disturbance of what might be called the normal process of corrosion.

Excess of acetic acid would tend to form normal lead acetate, both from the basic acetate and the basic carbonate; if this were followed by excess of carbonic acid, the normal lead carbonate would be precipitated. The disappearance of the core of blue lead from a corrosion, owing to the complete oxidation of the metal, would stop the feed of lead hydroxide into the reacting system with the result that normal lead acetate would be produced and this again would yield normal carbonate by reaction with carbon dioxide. Finally, excess of carbon dioxide converts the basic carbonate of lead itself slowly into the normal carbonate.

The general result of these changes is thus to increase the amount of normal carbonate of lead in the corrosions, and the relative stability of that compound towards both acetic and carbonic acids tends to its preservation. Thus by the assumption of these simple and probable reactions one can explain the degradation of white lead, that is, the production from the basic carbonate of a preparation rich in coarse carbonate and not conforming to the 'theoretical composition.'

Other methods of making White Lead.—A great many methods have been suggested and put into operation; most of these are now only of historical interest, and none has attained technical importance comparable with the stack and chamber processes. Some of the methods are based on the old process, that is, they use lead acetate as intermediary; examples of these are the French or Clichy, and the Carter processes.

In the French process, basic lead acetate is produced by digesting litharge with acetic acid; or, in a modified form of the process, by oxidising lead powder or ribbon with air in presence of lead acetate solution. The solution is then clarified by settling and carbonated, the white lead separated from the lead acetate solution, and the latter returned to the process for conversion into basic acetate.

The Carter process, used successfully in America, shortens the time of corrosion to 12 days by operating on finely divided lead which is kept in constant agitation. The granulation of the metal is brought about by allowing a jet of high-pressure steam to impinge on a stream of molten lead. This metal is then placed in large wooden drums, which revolve slowly, and is sprayed at intervals with water and acetic acid. Flue gases, containing 10 p.c. of carbon dioxide, purified by bog ore, are passed

through. The unchanged lead is constantly exposed by attrition. The product is levigated in the usual manner.

Basic salts other than the acetate have been suggested or employed in some processes. In one of these the basic nitrate is used; in Milner's process, the basic chloride. The latter compound is prepared from litharge, sodium chloride, and water, and the resulting sludge of basic chloride and caustic soda is carbonated until the liquor is free from alkali. White lead and sodium chloride are thus produced and the salt is removed by washing.

The Bischof process, worked by the Brimsdown Lead Co. in Middlesex, differs, especially in the initial stages, from any of the above. Flake litharge is ground finely and reduced by water-gas to the black sub-oxide of lead, Pb_2O (*v.* p. 85). This is transferred to steel pans, moistened with a limited quantity of water and well stirred by revolving blades. Hydration and oxidation take place. The product is mixed into a paste with water and carbonated, after addition of a little acetic acid. White lead is formed, presumably with simultaneous generation of lead acetate, which forms basic acetate with the hydroxide and thus plays the part of catalyst. The whole operation lasts about two days.

One of the most interesting methods for making white lead is used in America, and is called the Rowley or Mild process. Acetic acid and its salts, as well as salts of other acids (hydrochloric, nitric, &c.) are dispensed with altogether, and the reacting substances are the simplest possible, viz. lead, oxygen, water, and carbon dioxide. The lead, which need not be of a high degree of purity, is finely granulated as in the Carter process, and the black, metallic sludge is agitated 24–36 hours in presence of air, 80–90 p.c. of the metal being thereby oxidised and converted into 'hydrated lead.' This is elutriated and then treated for 36 hours in rotary carbonators with flue gases containing 18 p.c. of carbon dioxide, whereby white lead is produced. The product requires no washing or grinding and is said to have the 'theoretical' composition.

Properties of White Lead.—Commercial white leads are not of uniform composition and they vary a good deal with respect to those important properties upon which their use as a pigment depends. Such variations are, however, not uniquely connected with composition; they depend also on the fineness and uniformity of grain, on the presence of normal lead carbonate and, possibly, on many other conditions. A sample of 'theoretical' composition is not necessarily the best in actual practice. It seems to be admitted, however, that the carbon dioxide should fall between 11 and 13 p.c., otherwise the white lead is defective as a pigment.

So far as it is possible to generalise on a product which is not uniform, it may be stated that white lead is amorphous, of sp.gr. 6·45, and it loses water completely at 150° without parting with carbon dioxide. The grain depends on the method of preparation and the grinding. The grains of mild white lead are uniform in size, whereas those from material prepared by the stack process vary in diameter from 0·00002 to 0·00026 inch. Probably most samples contain crystalline normal lead carbonate, some of which is left as residue when the white lead reacts with dilute acetic acid. The analysis of such a residue from the chamber lead shows it to consist essentially of lead carbonate:

$PbCO_3$ . .	97·81 p.c.
$PbSO_4$ . .	0·84 ,,
$CaCO_3$, $FeCO_3$ . .	0·97 ,,
SiO_2 . . .	0·34 ,,
Organic matter .	0·11 ,,
	100·07 ,,

It is generally admitted that this crystalline carbonate is useless as a pigment.

Much controversy has arisen with regard to the changes which take place when white lead is ground with linseed oil, the main issue being whether hydrolysis of the oil takes place or not. If any particular preparation of white lead contained lead hydroxide, it would be natural to expect hydrolysis or saponification; but if it consisted of a mixture of normal and basic carbonates of lead, there would be no reason *a priori* to anticipate such a reaction. The experimental work of Davis and Klein (J. Soc. Chem. Ind. 1907, 26) has shown that lead soaps are indeed formed from white lead and linseed oil, and that some of these are insoluble and others soluble in ether, but these authors ascribe their formation entirely to reaction of the white lead with the free fatty acids present in the oil. The evidence is against saponification; in any case, very small amounts of lead soaps are formed.

Two objections to the use of white lead as paint are that it is discoloured by hydrogen sulphide, owing to the formation of black lead sulphide, and that it suffers from 'chalking' or 'flouring,' a kind of granulation. The defect last mentioned sometimes becomes evident a few months after the application of the paint. Its cause is obscure and has been variously traced to the presence of fatty acids in the oil, over-heating during grinding, and the presence of lead acetate in the white lead (*see* Holley, Zinc and Lead Pigments).

Substitutes for White Lead.—'Genuine' brands of white lead are pure in England; adulteration of white lead with barium sulphate is recognised both by manufacturers and merchants, and such mixtures are known as 'reduced' white leads. Of substitutes proper, mention may be made of the basic chloride and sulphate of lead.

The basic chloride is now of historical interest only, its manufacture having been patented by Pattinson in 1849 and abandoned after some years' trial. It was prepared from galena by converting this into the chloride with hydrochloric acid and precipitating the solution of lead chloride with half its equivalent of lime. The basic chloride has the same composition as the mineral laurionite, $PbO, PbCl_2, H_2O$.

Bartlett's 'sublimed white lead' is a mixture of basic sulphate of lead and zinc oxide. It is prepared from high-grade galena concentrates, containing some blende, by heating these in a modified form of blast-furnace and directing a powerful blast of hot air upon the mineral. Galena

is readily volatilised at a high temperature, and the vapour on oxidation yields a dense fume which, after passing through coolers and dust-condensing flues, is filtered through bags. When conditions are properly controlled, the product is fairly uniform in compo ition, the range of variation of the chief constituents being:

Lead sulphate . .	75–80 p.c.
Lead oxide . . .	14–20 ,,
Zinc oxide . . .	5–6 ,,

The lead is stated to be present as the basic sulphate $2PbSO_4{\cdot}PbO$, or $3PbO{,}2SO_3$. The product is a white, fine-grained, amorphous powder, having the covering power of white lead. It is less susceptible than white lead to discoloration by hydrogen sulphide and its specific gravity is slightly lower, viz. 6·2. It is especially useful in making mixed paints.

Lead Poisoning.

The compounds of lead, more especially the soluble ones, are strongly poisonous, and since the poison is cumulative, it produces serious results if taken into the system even in minute quantities for any length of time. One way in which lead is introduced into the system is by the use of drinking waters, some of which easily attack the lead of the pipes used for conveying the water. Again, the workpeople engaged in the manufacture of lead and lead compounds, and those who use them in such trades and industries as painting, printing, plumbing, file-cutting, enamelling, the manufacture of accumulators, china and earthenware, are liable to suffer from lead poisoning. The symptoms are pain in the abdomen, constipation, loss of appetite, thirst, a nervous prostration known as lead palsy, epileptic fits, and total paralysis. One of the signs of chronic lead poisoning is a blue line at the edges of the gums, due to the deposition of lead sulphide. This line is, however, not diagnostic; it is a secondary effect arising from a septic condition of the mouth and seldom occurs when the teeth are sound and the gums clean.

Susceptibility towards lead poisoning depends on many things. Women are more susceptible than men, and the underfed are naturally more prone to attack than the well-nourished. Anæmia is one of the chief predisposing causes. Most people become tolerant of the poison to some degree, a certain balance being struck between absorption and secretion. This balance may be upset, with serious results, by the onset of disease or by a sudden increase in absorption.

In cases of industrial poisoning, it would appear that dust is the chief cause of infection, gastro-intestinal and cutaneous absorption being quite of secondary importance. Hence, the use of efficient exhaust ventilation in dusty operations, such as the drying of white lead, has been attended by a very great decrease in the number of cases of poisoning, the official figures for English white lead workers being 399 for the year 1899 and 23 for the year 1913. In 1918 not a single case was recorded. The wet-pulping process is a great improvement in this connection, and other important factors are selection, education and medical inspection of the workfolk, provision of respirators, overalls, and simple medicines, and general attention to hygiene and bodily cleanliness.

A portion of the lead taken into the system is excreted by the kidneys, and in cases of chronic lead poisoning it is stated that the administration of potassium iodide aids in the elimination of lead from the system. The mode in which the compounds of this metal are distributed in the different organs of the body is illustrated by the following results of an examination made by Drs. Bedson and Drummond and Sir Thomas Oliver in the case of three workpeople who succumbed to the influence of this form of poisoning:—

Description of organ, &c.	Lead found expressed as metallic lead in parts per million			Lead in grains calculated on total weight of organ

Other Compounds of Lead.

Oxides. Besides the wto oxides described above several others exist.

Lead suboxide Pb_2O is formed when lead oxalate is heated in the absence of air at a temperature below 300°; or when lead oxide is reduced with carbon monoxide at 300° (Brislee,

Chem. Soc. Trans. 1906, 154). It is a black velvety powder of sp.gr. 8·342 at 18°, which is readily decomposed into the metal and the monoxide when heated or when treated with caustic soda. Dilute acids liberate lead and yield the salts derived from the monoxide.

Lead sesquioxide Pb_2O_3 is generally considered to be either lead metaplumbate $Pb(PbO_3)$ or a compound of the mono- and di- oxides $PbO{\cdot}PbO_2$, into which it is decomposed by acids. It is a yellowish-red powder, formed by adding a solution of sodium hypochlorite to a cold potash solution of lead oxide, or by precipitating an acetic acid solution of red lead with dilute ammonia.

By heating monoxide, peroxide, or carbonate of lead to 400°–450° in oxygen, at a pressure of 100 atmospheres, a dark brown oxide is formed of the composition Pb_5O_8. This may be regarded as lead pyroplumbate $Pb_2(Pb_3O_8)$, and the relation of pyro- to ortho-plumbic acid may be represented:

$$3H_4PbO_4 - 4H_2O = H_4Pb_3O_8$$

(F. Fischer and H. Ploetze, Zeitsch. anorg. Chem. 1912, 75, 19).

Lead peroxide (*Lead dioxide* or *Puce-coloured oxide of lead*) PbO_2 is found native in *plattnerite*, which crystallises in black hexagonal prisms of sp.gr. 9·4. It may be prepared by the action of nitric acid on red lead, by the action of chlorine on a lead salt in the presence of an alkali, or better by the action of bleaching powder on lead chloride (Fehrmann, J. Soc. Chem. Ind. 1882, 407). A lead peroxide suitable to the requirements of the aniline manufacturer may be obtained by adding the required amount of lead oxide to molten caustic soda at the highest possible temperature, with constant stirring, and then sufficient sodium nitrate for oxidation. The mass is then extracted with hot water, washed, and dried (Minor, J. Soc. Chem. Ind. 1894, 940).

Normal or basic lead sulphate may be converted into lead peroxide, by mixing it with magnesia, suspending the mixture in water and passing in chlorine. It is purified by treatment with boiling 10 p.c. caustic soda, then with hot nitric acid. The yield is almost theoretical, and the oxide is of 97 p.c. purity, containing only traces of chlorine (Friedrich, Mallet, and Guye, Monit. Scient. 1906, 20, 514).

The reaction may be represented thus:

$$PbSO_4 + MgO = MgSO_4 + PbO;$$
$$PbO + MgO + Cl_2 = PbO_2 + MgCl_2$$

Lead peroxide may also be obtained electrolytically when water containing less than 1 p.c. of acid, alkali, or salt is electrolysed, using a lead sulphide anode: $PbS + H_2O + 5O = PbO_2 + H_2SO_4$ (D. R. P 162107; *see* also D. R. P. 124512; Eng. Pat. 12186, 1901; J. Soc. Chem. Ind. 1897, 743; *ibid.* 1902, 620; Hollard, Compt. rend. 1903, 136, 229). When a strongly alkaline plumbite is oxidised with potassium persulphate, an active oxide, containing 93 p.c., PbO_2, is formed (Panopolus, Chem. Zeit. 1916, 40, 339). Pure lead peroxide is obtained by oxidising a solution of lead nitrate in caustic soda (20 p.c.) with hydrogen peroxide (Zotier, Bull. Soc. chim. 1917, 21, 244)). (For other methods of preparing the peroxide *see* Eng. Pats. 119ᴬ2, 1889; 6954, 1903; Warren, Chem. News, 1896, 144.) Lead peroxide is a dark brown, almost black, powder of sp.gr. 8·9–9·2, which is said to keep best when moist (Fehrmann, *l.c.*). On exposure to sunlight it forms red lead and dissociates on heating into lead monoxide and oxygen; there is no evidence of the formation of red lead or any other oxide but litharge in this process (Reinders and Hamburger, Zeitsch. anorg. Chem. 1914, 89, 71). It has a powerful oxidising action, taking fire when triturated with sulphur, and igniting sulphuretted hydrogen when the latter is passed over it, the heat of this reaction being such that explosives like guncotton or picrate can be fired and metallic powders ignited by its aid (Vanino and Hauser, Ber. 1900, 33, 625). A large number of organic compounds when triturated with it also cause an evolution of heat and light. It decomposes or oxidises some mineral acids, forming the corresponding lead salt often with violent evolution of gas. Lead peroxide combines readily with sulphur dioxide, forming lead sulphate. It can be used for separating sulphur dioxide from carbon dioxide and is often employed for this purpose and as an oxidising agent in the analysis of organic compounds containing sulphur; it has also been used in inorganic analysis for the removal of excess of sulphuretted hydrogen or ammonium sulphide (Bogdan, Bull. Soc. chim. 1903, 29, 594). Lead peroxide has been used as a mordant and also for the precipitation of other oxides on the fibre (Bonnet, Bull. Soc. Ind. Mulhouse, 1894, 69; Compt. rend. 1893, 117, 518). It has also been used in the voltaic battery and in electrical and metallurgical operations (Eng Pat. 16608, 1886; J. Soc. Chem. Ind. 1888, 37). Lead peroxide acts as a weak basic oxide, forming unstable quadrivalent lead salts and also as an acid-forming oxide yielding the *plumbates*. *Orthoplumbates* of the composition M_4PbO_4 and *metaplumbates* $M_2PbO_3{,}3H_2O$ or $M_2Pb(OH)_6$ have been prepared (Fremy, Ann. Chim. Phys. 1844, [iii.] 12, 490; Grützner and Höhnel, Arch. Pharm. 1895, 233, 512; Bellucci and Parravano, Gazz. chim. ital. 1905, 35, ii. 500).

The orthoplumbates evolve oxygen when strongly heated, and on this fact has been based a method of obtaining oxygen from air on a large scale; the calcium salt has also been used as an oxidising agent (Kassner, Arch. Pharm. 1890, 228, 109; *ibid.* 1894, 232, 375; *ibid.* 1895, 233, 501).

When calcium meta- or orthoplumbate is heated in a current of air at 200°–280°, *calcium perplumbate* $CaPb_2O_6$ is formed (Kassner, Arch. Pharm. 1899, 237, 409; *ibid.* 1900, 238, 449).

When potassium plumbate is treated with water at the ordinary temperature it is completely hydrolysed, and *plumbic acid* H_2PbO_3 remains in solution in the colloidal state (Bellucci and Parravano, Atti. R. Accad. Lincei, 1906, v. 15, ii. 542, 631; Parravano and Calcagni, Gazz. chim. ital. 1907, 37, ii. 264).

Lead hydroxide $Pb(OH)_2$ is formed when potassium nitrate is electrolysed, a lead anode being used (Lorenz, Zeitsch. anorg. Chem. 1896, 12, 436). It may also be prepared by heating lead carbonate with water or steam (Eng. Pat. 9521, 1893), or by treating lead sulphate with excess of alkali hydroxide (U. S. Pat. 787451,

1905; *see* also U. S. Pat 808141, 1905; Fr. Pat. 401473, 1909). It acts as a very weak acid (Hantzsch, Zeitsch. anorg. Chem. 1902, 30, 308; Rubenbauer, *ibid.* 331), and has also been obtained in a colloidal form (Szilard, J. Chim. Phys. 1907, 5, 636). The action of lead hydroxide on sugars is similar to that of the alkali hydroxides, inducing molecular rearrangement (Lobry de Bruyn and Eckenstein, Rec. trav. chim. 1896, 15, 92; U. S. Pat. 726130, 1903).

Two *hydrated lead monoxides* are known, $2PbO{\cdot}H_2O$ or $PbO{\cdot}Pb(OH)_2$ and $3PbO{\cdot}H_2O$ or $2PbO{\cdot}Pb(OH)_2$. The former is obtained as a white powder by the action of air and water on the metal or by precipitating a lead salt with a small quantity of alkali or ammonia. It may also be obtained in hexagonal crystals by exposing a cold solution of lead monoxide in caustic potash to the air (Lüdeking, Amer. Chem. J. 13, 20). The latter basic hydroxide has been prepared by precipitating basic lead acetate with ammonia (Payen, Ann. Chim. 1866, [iv.] 8, 302). It forms a white crystalline powder or glittering octahedra, according to the method of preparation. The accuracy of these formulæ for the hydrated lead monoxides, as well as for lead hydroxide itself, has been recently called into question (S. Glasstone, Chem. Soc. Trans. 1922, 58).

Halogen compounds of lead. The three subhalides have been prepared by heating plumbous oxide in the vapour of the alkyl halides; the chloride at 311°, the bromide at 261°, the iodide at 262°. The first two are grey and the iodide is a bright yellow powder. They are all difficult to prepare, requiring definite conditions and the maintenance of temperature and pressure within narrow limits. They are oxidised by air, especially when moist, and are decomposed into metal and normal halide when heated above their temperature of formation or when brought into contact with acids. They are much less soluble than the normal halides, the solubility-data in milli-equivalents per litre at 25° being: PbCl, 2·2; PbBr, 0·4; PbI, 0·17 (H. G. Denham, Journ. Chem. Soc. 1917, 111, 29; 1918, 113, 249).

The normal halides. *Lead chloride* (*horn lead*, *plumbum corneum*) $PbCl_2$ occurs native in the craters of volcanoes as the mineral *cotunnite*, and may be prepared readily by treating the oxide or carbonate with hydrochloric acid or by precipitating a fairly concentrated solution of a lead salt with a soluble chloride. On a large scale it may be prepared by heating litharge with a slight excess of hydrochloric acid at 200° and 25 atmos. pressure, in an autoclave lined with an acid-resisting material (Eng. Pat. 12953, 1895; *see* also Eng. Pats. 16213, 1889; 8914, 1895; J. Soc. Chem. Ind. 1890, 941; *ibid.* 1895, 873; *ibid.* 1896, 357). In a colloidal form it can be obtained by mixing together lead acetate or the lead salt of any other organic acid with an alkali, or alkali earth chloride (van de Velde, Chem. Zeit. 17, 1908).

Lead chloride forms a white crystalline precipitate or white silky rhombic needles of sp.gr. 5·8. When heated in absence of air it melts at 495°, and boils at 945° at 754 mm. The heat of vaporisation at m.p. is 40,600 cals. It is less soluble in dilute hydrochloric acid and in solutions of chlorides than in water, but dissolves more readily in concentrated hydrochloric acid (André, Compt. rend. 1883, 97, 1302; Lichy, J. Amer. Chem. Soc. 1903, 25, 469). The solubility is at a minimum when there is 10 p.c. of hydrochloric acid in the solution. It dissolves in alkali acetates and in thiosulphates, forming a lead thiochloride $Pb_4S_6Cl_2$ (Hofmann and Wolff, Ber. 1904, 37, 249).

Lead chloride forms double salts with ammonium and other metallic chlorides (André, Compt. rend. 1883, 96, 435; Lorenz and Ruckstuhl, Zeitsch. anorg. Chem. 1906, 51, 71; Ephraim and Barteczko, *ibid.* 1909, 61, 245; Foote and Levy, Amer. Chem. J. 1907, 37, 119; J. Soc. Chem. Ind. 1909, 707).

A large number of lead oxychlorides are known. The compound $PbCl_2{,}PbO$ occurs in nature as the mineral *matlockite*; it forms long thin colourless needles, decomposing at 524° into a mixture of $PbCl_2{,}2PbO$ and PbO, which fuses completely at 615°. The hydrated oxychloride of similar composition constitutes the mineral *laurionite* $PbCl_2{,}PbO.H_2O$. $PbCl_2{,}2PbO$ occurs as *mendipite*, and forms long glistening needles, m.p. 693°. The compound $PbCl_2{,}4PbO$ has m.p. 711°, and forms glistening lamellar crystals, which give an intense yellow powder (Ruer, Zeitsch. anorg. Chem. 1906, 49, 365; *see* also Strömholm, *ibid.* 1904, 38, 429; Berl and Austerweil, Zeitsch. Elektrochem. 1907, 13, 165). The compound known as *Cassel yellow* has the approximate composition $PbCl_2{,}7PbO$, together with a little lead, and is usually prepared by fusing together 1 part ammonium chloride, and about 10 parts massicot, white lead, or minium. It is used as a pigment.

Lead tetrachloride $PbCl_4$ may be formed by passing chlorine into lead chloride, suspended in strong hydrochloric acid at 10°-15°. On adding ammonium chloride, *ammonium plumbichloride* $(NH_4)_2PbCl_6$ separates (Hutchinson and Pollard, Chem. Soc. Trans 1899, 212; Seyewetz and Trawitz, Compt. rend. 1903, 136, 986; Bull. Soc. chim. [iii.] 29, 261; Elbs and Nübling, Zeitsch. Elektrochem. 1903, 9, 776).

When this ammonium compound is added little by little to ice-cold concentrated sulphuric acid, lead tetrachloride separates as a yellow highly refractive oily liquid, which fumes in air, smells like hypochlorous acid, and induces a sweet taste in the mouth. It has sp.gr. 3·183, is stable under sulphuric acid, but is liable to explode, especially when heated, forming chlorine and lead chloride. It solidifies at −15° to a transparent yellow crystalline mass. With hydrochloric acid it forms a crystalline compound H_2PbCl_6, which dissolves on further addition of acid, and is decomposed by water into lead dioxide and hydrochloric acid (Friedrich, Monatsh. 1893, 14, 505; *see* also Ber. 1893, 26, 1434; de Coninck, Bull. Assoc. belge Chim. 1902, 16, 94). Many salts of this chlorplumbic acid have been prepared, some, like the potassium salt K_2PbCl_6, in crystalline form. A great number of salts derived from organic bases are also known. When these are well crystallised, regular and rhombic forms predominate. The chlorplumbates of pyridine and quinoline are stable. Solutions of these organic derivatives, when treated with ammonia, yield precipitates

of lead peroxide; hydrogen peroxide reduces them to plumbous salts. (A. Gutbier and M. Wissmüller, J. pr. Chem. 1914, 90, 491).

Lead chlorite, chlorate, and *perchlorate* are also known.

Lead bromide $PbBr_2$ is obtained by treating lead oxide with aqueous hydrobromic acid or by precipitating a lead salt with a soluble bromide. It forms white shining needles, which darken when exposed to sunlight (Norris, Amer. Chem. J. 1895, 17, 189); sp.gr. 6·6. It resembles the chloride in properties.

It forms double bromides and oxybromides.

Lead iodide PbI_2 is formed by dissolving lead in hydriodic acid or by precipitating a solution of a lead salt with a soluble iodide. It forms yellow crystals of sp.gr. 6·1, which on heating become yellowish-red, bright red, and finally brownish-black. It also forms double salts and basic salts.

The chloride, bromide and iodide yield double salts with pyridine and quinoline (Elbs and Nübling, *l.c.*).

A number of mixed halogen compounds are known (Thomas, Compt. rend. 1898, 126, 1349; *ibid.* 1899, 128, 1234, 1329; Fonzes-Diacon, Bull. Soc. chim. 1897, [iii.] 17, 346; Hertz and Bogg, J. Amer. Chem. Soc. 1897, 19, 820).

Lead fluoride PbF_2 is formed in the same way as the corresponding iodide. It is a white powder, almost insoluble in water and in hydrofluoric acid, but readily soluble in hydrochloric and in nitric acid. It yields a basic fluoride and a chlorofluoride (Fonzes-Diacon, *l.c.*).

Lead tetrafluoride PbF_4 is said to be formed in a colloidal state by the action of strong sulphuric acid on the *acid plumbifluoride* $3KF,HF,PbF_4$, but has never been obtained pure (Brauner, Chem. Soc. Trans. 1894, 393). The above acid plumbifluoride is obtained by the action of hydrofluoric acid and potassium fluoride on lead tetracetate.

Paneth and Nörring (Ber. 1920, 53, 1693) have indicated the existence of a gaseous *lead hydride*, obtained by the action of dilute hydrochloric acid on an alloy of bismuth and radiolead (thorium B). The lead hydride could not be obtained by the action of acids on ordinary lead-magnesium alloys, but traces were formed by a combined electrolysis-spark process.

Lead and nitrogen. *Lead nitrate* $Pb(NO_3)_2$ is formed by dissolving litharge in nitric acid of sp.gr. 1·35. The solution is evaporated until it has the sp.gr. 1·6, and is then allowed to cool. It forms milk-white crystals from water, clear crystals from nitric acid, of sp.gr. 4·5 and dissolves in water with a reduction of temperature. It has an astringent metallic taste, detonates with brilliant sparks when thrown upon red-hot charcoal and deflagrates when triturated with sulphur. When heated it commences to decompose at 283°, and in a sealed tube at 357°, it dissociates thus:

$$Pb(NO_3)_2 \rightleftharpoons PbO + O + 2NO_2$$

(Baekeland, J. Amer. Chem. Soc. 1904, 26, 391; Morgan, J. Phys. Chem. 1904, 8, 416; Colson, Compt. rend. 1909, 148, 837). Lead nitrate is used in dyeing and calico printing, for the preparation of mordants and of chrome yellow. Several basic lead nitrates are known (Senderens, Bull. Soc. chim. [iii.] 11, 365; Mailhe, Compt. rend. 1902, 134, 233; Peters, Zeitsch. anorg. Chem. 1896, 11, 116).

Basic lead nitrate $Pb(OH)NO_3$ is prepared by heating litharge with solution of lead nitrate. It is fairly soluble in hot water, crystallising from the solution on cooling. It is said to be a very useful decolorising agent for sugar solutions (Herles, Zeitsch. Zuckerind. Böhmen, 1896, 21, 189; Neuman, *ibid.* 183; Zeitsch. angew. Chem. 1897, 123; Pellet, Bull. Assoc. Chim. Sucr. Dist. 1897, 14, 794; *ibid.* 1905, 23, 638; Horne, *ibid.* 635).

Lead nitrite $Pb(NO_2)_2$ is obtained by decomposing silver nitrite with lead chloride and concentrating the solution in a vacuum (Lang, J. 1862, 100; *see* also Chilesotti, Atti. R. Accad. Lincei, 1908, [v.] 17, i, 824). It forms yellow prisms, soluble in water, the solution on evaporation losing nitric oxide and yielding a basic nitrite. A number of these basic salts are known (Chilesotti, *ibid.* 1908, v. 17, ii. 173, 288, 377, 474; Meldrum, Chem. Soc. Proc. 1908, 97).

Lead hyponitrite $Pb(NO)_2$ is a yellow crystalline powder, which explodes on heating (Kirschener, Zeitsch. anorg. Chem. 16, 424; Divers, Chem. Soc. Trans. 1899, 121).

Lead nitrohydroxylamine PbN_2O_3 is an unstable salt (Angelico and Fanara, Gazz. chim. ital. 31, [ii.] 15).

Lead imide PbNH is obtained by the action of potassamide on lead iodide in liquid ammonia. It is a reddish-brown explosive substance. If the lead iodide be in excess, a white basic salt $NPb_2I{\cdot}NH_3$ is formed (Franklin, J. Amer. Chem. Soc. 1905, 27, 820).

Lead azide PbN_6 is said to be formed by the action of aqueous ammonia or of nitrides on lead salts (Curtius and Rissom, J. pr. Chem. [ii.] 58, 261).

Lead cobaltinitrite, lead cyanide, and cyanate, the corresponding thio- compounds, and lead ferro- and ferri- cyanides are known.

Lead Phosphates. *Tribasic lead phosphate* $Pb_3(PO_4)_2$ is an amorphous white powder obtained by precipitating an excess of lead acetate with a small quantity of sodium phosphate at 100° or by boiling the dibasic salt in water for 5–6 hours.

Dibasic lead phosphate $PbHPO_4$ is prepared by precipitating a somewhat dilute solution of lead nitrate with hot dilute phosphoric acid at 100°. It forms a fine crystalline powder.

Monobasic lead phosphate $Pb(H_2PO_4)_2$ is formed by dissolving the dibasic salt in strong phosphoric acid by the aid of heat and allowing the solution to crystallise. It may then be recrystallised from phosphoric acid. It forms fine needles stable in air, and is decomposed by cold and even more readily by boiling water, forming first the dibasic and finally the tribasic salt (Alders and Stähler, Ber. 1909, 42, 2261).

Lead pyrophosphates, a number of complex phosphates and *thiophosphates* (Gerhardt, Ann. Chim. Phys. 1848, [iii.] 22, 505; Ouvrard, Compt. rend. 1890, 110, 1334; Friedel, *ibid.* 1894, 119, 260; Ferrand, *ibid.* 1896, 122, 886), and also *lead phosphites* (Amat, *ibid.* 1890, 110, 901), have been prepared.

The following are naturally occurring lead

phosphates and arsenates isomorphous with apatite, a portion of their chlorine often being replaced by fluorine :—

Pyromorphite $Pb_3(PO_4)_2Pb_2ClPO_4$; *Polysphærite* $(Pb,Ca)_3(PO_4)_2(Pb,Ca)_2ClPO_4$; *Mimetite* $Pb_3(AsO_4)_2Pb_2Cl(AsO_4)$; and *Kampylite* $Pb_3[(As,P)O_4]_2Pb_2Cl[(As,P)O_4]$.

Lead arsenate may be formed by suspending litharge in a solution of arsenic acid in the presence of nitric or acetic acid as catalyst (U.S. Pats. 892603, 903389, 1908; J. Soc. Chem. Ind. 1908, 1019, 1203), or by roasting a mixture of white arsenic and a lead salt in combining proportions in the presence of oxygen or an oxidising agent (U.S. Pat. 929962, 1909).

Lead arsenate is used as an insecticide and is largely employed in the United States for the protection of fruit trees from the larvæ of the gypsy moth. For this purpose, it is said to be best prepared by adding a solution of lead acetate or nitrate to sodium arsenate until an iodine test paper shows the presence of excess of lead (Haywood and McDonnell, J. Soc. Chem. Ind. 1910, 1027; *see* also Pickering, Chem. Soc. Trans. 1907, 312). The precipitate is a mixture of basic arsenate $Pb_5OH(AsO_4)_3$ and dibasic lead arsenate, $PbHAsO_4$. For other lead salts of arsenic acid, *see* McDonnell and Smith (J. Amer. Chem. Soc. 1916, 38, 2027). For spraying plants, it is often mixed with lime-sulphur solution; in this case, the normal lead salt should be employed, and it is best to avoid using water containing much alkali carbonate, as the tendency of the latter is to make the arsenic soluble (Brady and Tartar, J. Ind. Eng. Chem. 1910, 2, 328; *see* also Griffen, *ibid.* 1909, 1, 659; Moreau and Vinet, Compt. rend. 1910, 150, 787).

Lead silicates. Silica fuses with lead oxide forming a yellow glass. Lead silicate also forms a constituent of flint glass. Two silicates have been isolated (Cooper, Shaw, and Loomis, Amer. Chem. J. 1909, 42, 461). *Lead orthosilicate* Pb_2SiO_4 forms colourless hexagonal tablets, and has m.p. 746°.

Lead metasilicate $PbSiO_3$ has m.p. 766°, and has been found to exist naturally in Mexico as *alamosite*. It is analogous to *wollastonite*, calcium silicate, and occurs in radial aggregates of colourless transparent fibres (Palache and Merwin, Amer. J. Sci. 1909, 27, 399; *see* also Hilpert and Weiller, Ber. 1909, 42, 2969; Hilpert, Metallurgie, 1908, 5, 535).

Lead silicofluoride is formed by heating galena or other lead-containing material with hydrofluosilicic acid, air being blown through the mixture and water being then added (U.S. Pats. 754667, 1904; 779091, 779092, 1905). (For the use of lead silicate in glazes *v.* FRITTS and GLAZES.)

Lead borates and lead boric glasses have been prepared (Faraday, Phil. Trans. 1830, 1).

The precipitate formed by adding excess of a solution of borax to a solution of a lead salt is lead metaborate $Pb(BO_2)_2,H_2O.PbO,3B_2O_3$ is formed by fusing boric acid and lead carbonate.

Lead and sulphur. *Lead sulphide* PbS occurs in nature as *galena*, usually in the form of cubes, possessing a bluish-grey colour, and sp.gr. 7·25–7·7 (Hannay, J. Soc. Chem. Ind. 1894, 639). It may be formed by passing sulphur vapour over lead, by fusing lead oxide with excess of sulphur, or, in an amorphous condition, by passing sulphuretted hydrogen into a solution of lead nitrate. When heated in a current of certain gases, it sublimes in cubes, whilst if fused with potash and sulphur, it forms octahedral crystals.

Lead sulphide has m.p 1120°±10° (Friedrich, Metallurgie, 1907, 4, 479; *ibid.* 1908, 5, 23); according to Lodin (Compt. rend. 1895, 120, 1164), the m.p. is 935°. It is converted by nitric acid into nitrate and sulphate, and is decomposed by hot strong hydrochloric acid, sulphuretted hydrogen being evolved. Lead sulphide forms double compounds with the halides of lead (Hünenfeld, J. pr. Chem. 1836, 7, 27; Parmentier, Compt. rend. 1892, 114, 299; Lenher, J. Amer. Chem. Soc. 1895, 17, 511; *ibid.* 1901, 23, 680), and also with bismuth sulphide (Ducatte, Compt. rend. 1902, 134, 1061). The reactions between lead sulphide and its oxidation products have been studied in detail by Schenck and Rassbach (Ber. 1907, 40, 2185, 2947; *ibid.* 1908, 41, 2917).

A *polysulphide* PbS_5 is formed as an unstable purple-red precipitate by precipitating lead nitrate at 0° with calcium pentasulphide and washing the precipitate with carbon disulphide (Bodroux, Compt. rend. 1900, 130, 1397).

Lead sulphate is found native as *lead vitriol* or *anglesite*, in transparent rhombic crystals isomorphous with *celestine* and *heavy spar*. It may be obtained as a white powder by precipitating a lead salt with sulphuric acid or with a soluble sulphate, or by the action of sulphur dioxide on lead peroxide (Marino, Zeitsch. anorg. Chem. 1907, 56, 233). It may also be obtained crystalline (Manross, Annalen, 1852, 82, 360). Lead sulphate has sp.gr. 6·2–6·3, and is said to melt without decomposition at a red heat, but according to Schenck and Rassbach (*l.c.*) it does not melt below 1100°. It is soluble in pure water to the extent of 0·0824 gram of lead sulphate per litre or 1 in 12135 at all temperatures, but the solubility diminishes on addition of sulphuric acid (Schnal, Compt. rend 1909, 148, 1394; *see* also Dolezalek and Finckh, Zeitsch. anorg. Chem. 1906, 51, 320). Lead sulphate is also soluble in alkalis, in ammonium and in calcium acetates, and in a number of other salts (Long, Amer. Chem. J. 22, 217; Reichard, Chem. Zeit. 1903, 27, 924, 943; Fox, Chem. Soc. Trans. 1909, 878). It forms double salts with the sulphates of tin (Weinland and Kühl, Ber. 1906, 39, 2951); with potassium (Belton, Chem. News, 1905, 191); and with arsenic (Kühl, Arch. Pharm. 1907, 245, 377). It is reduced by carbon at 550° and by carbon monoxide at 600°–650°, lead sulphide being formed; this reacts with unaltered sulphate yielding lead and sulphur dioxide.

Lead disulphate or *Plumbic sulphate* $Pb(SO_4)_2$ is obtained at the anode when pure sulphuric acid, of sp.gr. 1·7–1·8 is electrolysed between lead electrodes. It is a white or faintly greenish-yellow crystalline powder, giving a green solution in strong sulphuric acid. It is decomposed by water, forming sulphuric acid and lead peroxide, and is a powerful oxidising agent. It forms double salts with the alkali metals and also with aniline and with dimethyl and diethyl aniline (Elbs and Pischer, Zeitsch. Elektrochem. 1900, 7, 343). On the preparation and use of basic lead sulphate, *v.* above.

Lead sub-sulphate is a dark grey substance decomposed by water, prepared by heating lead sub-oxide in methyl sulphate vapour at 280° (Denham, Chem. Soc. Trans. 1919, 109).

Lead sulphite and *lead thionates* are also known.

Lead selenide (Pélabon, Compt. rend. 1907, 144, 1159); *selenites* (Marino, Zeitsch. anorg. Chem. 1909, 62, 173); and *selenates* (Mathers, J. Amer. Chem. Soc. 1908, 30, 1374), also exist.

Lead organic compounds. The lead alkyl compounds are prepared by the interaction of alkyl iodides and lead-sodium or by the action of lead chloride on zinc alkyls (Buckton, Annalen, 1859, 109, 222; Cahours, *ibid.* 1862, 122, 65; Ghira, Gazz. chim. ital. 24, i. 44, 320; Frankland and Lawrence, Chem. Soc. Trans. 1879, 245; Klippel, J. 1860, 383).

Lead ethoxide $Pb(OEt)_2$ has been prepared by suspending thin sheets of lead over absolute alcohol through which a stream of ozone is passed. When washed with alcohol and dried *in vacuô* over sulphuric acid, it forms a light yellow friable powder, soluble in, but readily hydrolysed by, water (Perkin, Chem. Soc. Proc. 1908, 179).

Lead tetraphenyl may be obtained by the action of lead chloride on an ethereal solution of magnesium phenyl bromide (Pfeiffer and Truskier, Ber. 1904, 37, 1125; Polis, Ber. 1887, 20, 3332).

Lead tricyclohexyl $Pb(C_6H_{11})_3$ is prepared by the addition of lead chloride to a solution of magnesium cyclohexyl bromide in dry ether. It forms yellow, hexagonal plates, decomposing at 195°, and combines with iodine at the ordinary temperature to form the iodide $Pb(C_6H_{11})_3I$, from which the hydroxide and other compounds can be prepared by the usual methods. The molecular weight determined cryoscopically agrees with the formula given above, so that the triaryl may be regarded as containing tervalent lead, and thus analogous to Gomberg's triphenylmethyl (E. Krause, Ber. 1921, 54, [B], 2060). A number of other aromatic and aliphatic alkyl and halogen alkyl compounds have been prepared (Pfeiffer and Truskier, *l.c.*; Polis, *l.c.*, and 717).

Lead thiocarbamide halides $Pb(CH_4N_2S)_2X_2$ (X=Cl,Br,I) are described by Rosenheim and Meyer (Zeitsch. anorg. Chem. 1906, 49, 13).

For the lead salts of organic acids, *see* the respective acids. J. A. S.

LEADHILLITE. A rare mineral approximating in composition to the formula

$$PbSO_4 \cdot 2PbCO_3 \cdot Pb(OH)_2$$

The monoclinic crystals have the form of six-sided plates or pseudo-rhombohedra with a perfect basal cleavage and pearly lustre. As indicated by variations in the optical characters and chemical composition, there appear to be at least three varieties or modifications. The mineral is found in the upper oxidised portions of veins of lead ore at but few localities, notably at Leadhills in Scotland. It has also been met with in lead slags left by the Romans. 'Susannite' is a variety from the Susanna mine at Leadhills, and the name 'maxite' has been applied to crystals from Sardinia. L. J. S.

LEAF GREEN. *Chrome Green* (*v.* PIGMENTS).

LEATHER. When the skins of animals are treated with infusions containing any of the vegetable tannins, the gelatinous tissue is converted into the tough imputrescible substance known as leather, while the process by which it is made is called 'tanning.' Certain mineral salts, as well as oils and fats which undergo oxidation in the skin, have a somewhat similar effect, and more recently, aldehydes, and especially formaldehyde, have been successfully employed. Synthetic condensation products of phenolic sulphonic acids with formaldehyde with marked tanning properties (Syntans) have been invented by Stiasny, and have come largely into practical use; and a number of other substances, aromatic derivatives, colloidal precipitates, and even elements such as bromine have proved capable of converting skin into leather. It is proposed in the following article first to describe the structure and chemical composition of skin, and the preliminary processes it has to undergo to deprive it of hair and to render it fit for tanning, and then to deal with the different tanning materials and the various processes by which they are employed in practice.

The skin, as it exists on the animal is much more than a mere covering, and contains a variety of organs, both of sense and of secretion, and some knowledge of its anatomy is necessary to a proper understanding of the tanning process.

The skin consists of two layers, which arise in embryonic development from the inner and outer layers of the ovum, and which throughout retain the strongly marked differences which correspond to this diversity of origin. The *epidermis* or outer layer of the skin is derived from the outer layer (epiblast) of the ovum, while the inner layer, *corium*, *derma*, or *cutis*, together with all the other connective tissues of the body, takes its rise from the middle of the ovum (mesoblast). Though the skins of different animals differ in details, that of the calf, of which a section is illustrated in Fig. 1, may

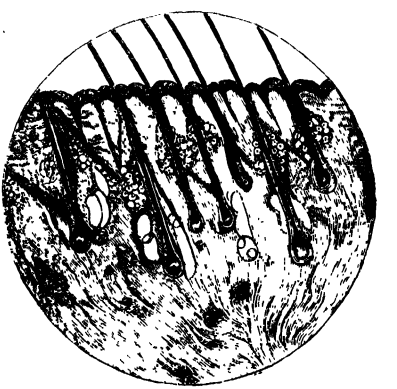

FIG. 1.

serve as a type of most of those used in the manufacture of leather. The outer layer or *epidermis* consists, as has been said, of simple nucleated cells, which at the surface are dead, hardened, and flattened, but where they rest on the *corium* are soft and spherical, and constitute the so-called 'mucous layer' (*rete mucosum*). This is not supplied directly with blood-vessels,

but derives its nourishment from the fluids of the *corium*. Here growth takes place, and the cells probably multiply by fission, though this has not been actually observed. The hairs, though deeply rooted in the *corium*, are really products of the *epidermis* which surrounds them and passes down into the *corium* in the form of a bulb-shaped sheath. The nourishment of the growing hair is supplied by a knob of connective tissue called the hair-papilla, furnished with blood-vessels, and passing up into the centre of the hair-bulb. The hair itself is composed of modified and hardened cells, forming exteriorly irregular overlapping scales, giving the outline a serrated appearance, which is especially marked in wool. Within this 'hair-cuticle,' as it is sometimes called, is the fibrous portion of the hair, composed of long spindle-shaped cells, and sometimes in the centre of this is a cellular pith containing air. The hair, except in white animals, contains a good deal of pigment, and some is also present in the epidermis cells forming the hair-sheath. The new hair, both in fœtal development and in ordinary growth, begins as a thickening of the *epidermis* layer, forming a knob which gradually sinks into the *corium*, and becomes a bulb in which the hair is developed and forces its way to the surface much as an onion does to the surface of the ground. In animals which change their coats in spring, the young hair generally originates in this way from a new bulb formed below the old one, and passes up into the old sheath. This deep-seated origin explains the great difficulty found in removing these young hairs for technical purposes. Besides the hairs, sudoriferous and sebaceous glands are similarly developed from the *epidermis*. The sebaceous glands are seated round the stems of the hairs, and their ducts discharge oily matter which serves as a lubricant into the hair sheaths near the surface of the skin. The sudoriferous glands are more deeply placed, usually extending even below the hair roots; they are less convoluted than in man, and discharge through narrow sinuous ducts to the surface.

The *corium* consists mainly of connective tissue, which, on boiling with water, readily dissolves, and is wholly converted into gelatin. In most animals the principal part of the hide (*pars reticularis*) is composed of bundles of interlacing fibres, each of these bundles being formed of a multitude of fine fibrils. Towards the outer surface these bundles disappear, and the separate fibrils combine in a closely-matted felt (*pars papillaris*), which is technically known as the 'grain.' In the pig, and possibly also in the seal, this close-textured part is thick, and is all that is valuable for tanning, the reticular part being so slightly developed as not to be distinguishable from the looser fatty tissue (*panniculus adiposus*), which underlies the true skin. Consequently, these skins are remarkable for extreme toughness. In addition to this gelatinous structure, the true skin, and especially the grain or papillary part, contains certain yellow fibres called 'elastic,' and distinguished by their very difficult solubility in boiling water, acids, and alkalis. These fibres are digested and removed by tryptic ferments, which do not attack the white connective tissue, but not by peptic ferments which attack both. The removal of the elastin is one of the principal objects of "puering," which is now frequently accomplished by pancreatic extracts combined with ammonium chloride.

Between the *corium* and the *epidermis* is an extremely fine membrane or outer surface, known as the hyaline This is very difficult to demonstrate microscopically, but has been separated in some technical operations, and is probably the cause of the clear brown or buff colour of the grain surface of tanned leather, while the finely matted tissue below it remains nearly white.

The *corium* has also blood-vessels, nerves, and minute muscles for erecting the hairs; but none of these of much technical importance, and for further details the reader may be referred to Procter's Leather Industries Laboratory Book, his Principles of Leather Manufacture, or to an important series of articles by Seymour-Jones in the Journal of the Society of Leather Trade Chemists during 1917 and 1918.

A few words must, however, be said about the practical microscopic examination of skin. For this purpose it is necessary to produce extremely thin sections, and the skin must be previously hardened. To this end it may be cut into strips about ½ inch long by ¼ inch wide, with their length at right angles to the direction of the hair, which should be cut short with scissors, with which also the loose fatty subcutaneous tissue should be removed. The strips are placed in a closed vessel with several times their volume of methylated spirit diluted with an equal quantity of water. The next day this must be replaced by stronger alcohol, and finally by absolute. In 4–8 days, the hide will be hard enough to cut, and may be held between the finger and thumb, and shaved by a drawing cut with a very sharp razor flooded with alcohol and resting on the tip of the forefinger. The cut should begin at the grain side, and must be exactly parallel with the hairs to give good results. For this reason a microtome is of very little service, as it is more difficult to adjust the fragment of hide in it than to make the sections by hand. They are floated off the razor in alcohol, and must be stained in order to make the details visible. Various methods of staining are described in the microscope text-books, one of the simplest being to immerse in aqueous solution of picrocarmine. The carmine stains the connective tissue and the nuclei of the cells red, while the structures derived from the *epidermis*, the *erectores pili* muscles, and the blood-vessels, absorb the picric acid only, and become yellow. The section may now be soaked in glycerol to clear it, and examined in a drop of glycerol under a thin cover-glass; or may be permanently mounted in glycerol or Farrant's fluid; but for this purpose it is generally better, instead of clearing with glycerol, to soak the sections again for some time in absolute alcohol containing a little picric acid, till quite deprived of water, clear in clove oil, and mount in a drop of solution of gum dammar in benzene, or of Canada balsam.

Kathreiner has described a method which, while it is less striking for demonstration of the different tissues, is often useful for practical work when a knowledge of the general appearance of the structures has been attained. The

fresh hide (and it is important in preparing type specimens that the animal should not have been killed more than a few hours) is cut into small strips as described, and then immersed for 4–8 days, according to the thickness of the hide, in about twelve times its volume of an aqueous solution containing 1 p.c. of osmic and 2½ p.c. of chromic acids. This solution must be kept from light and dust in a stoppered bottle and in a cool place. Care must be taken to avoid the fumes, which cause severe catarrh of the mucous membranes. The hide pieces must now be soaked in about twelve times their volume of absolute alcohol several times renewed for 4–8 days, and are then cut as described. No further staining is required, as the chromic acid colours the tissues yellow, while all traces of fat, as for instance, the oily matter of the sebaceous glands, are stained grey or black by the osmic acid. They may be cleared at once with clove oil, in which they may be examined, or mounted in dammar.

A third method may be mentioned which is very useful for rapid observations, especially when it is desired to ascertain how far the cellular structures have been affected in preparing the hide or skin for tanning. The section, which need not be so thin as when intended for more detailed study, may be cut either after a short hardening in alcohol, or in the case of hide swollen with lime, simply by cutting a small strip ¾ through from the grain, and turning it back so as to put the tissue on the stretch, and then cutting from flesh to grain with a razor flooded with distilled water. If the wet section be placed in a drop of water on a slide under a cover glass, and examined by reflected light with a 1-inch objective, the fat glands will be seen as yellow masses embedded in the white fibrous tissue. If now the section be moistened with a mixture of equal parts of glycerol and glacial acetic acid, the connective tissue will become quite transparent, and the glands and hair-roots may be examined, even with a moderately high power, by transmitted light. For more minute study several improvements in technique, and especially in staining methods, have recently been made, with regard to which original papers, mostly in the Journ. of Soc. of Leather Trades Chemists, must be consulted.

The principal chemical constituents of the skin are proteids, fats, and water; and the most important of these is collagen, of which the white fibres, forming the main fabric of the hide, are composed, and which, on boiling with water, is converted into gelatin (glutin). The remaining proteids (keratins, elastins) are mostly albuminoids, but glycoproteins (mucins) and those of the blood and lymph (serum albumens, hæmoglobin, &c.) are also present.

The *epidermis* and its products, hair, horns, hoofs, &c., all belong to the class of keratins, which are allied to coagulated albumen, but differ in their composition (*e.g.* in their percentage of sulphur), and in their behaviour towards chemical reagents. They can hardly be said to be soluble in water, though by prolonged boiling under pressure they are finally dissolved to an extract which does not gelatinize on cooling. The softer structures are easily soluble in dilute caustic alkalis in the cold, whilst hair and horn are gradually softened, but only yield to strong solutions aided by heat. They are reprecipitated by acids, and these precipitates mixed with oil have been proposed as a 'filling' for alumed leather in place of flour and egg-yolk, but have not come into practical use. Lime and other alkaline earths act like the alkalis, and hence milk of lime, while it scarcely attacks the hair, easily loosens it, by dissolving and softening the *epidermis* and root sheaths. Strong solutions of the alkali and alkaline-earth hydrosulphides, on the other hand, seem to attack the harder tissues by preference, and reduce the hair to pulp without affecting the *epidermis* cells so much as milk of lime.

Collagen forms nearly 95 p.c. of the dry matter of the *corium* and is insoluble in cold water, dilute acids, and common salt solution (Reimer's statement that it is soluble in 10 p.c. solution of NaCl has not been confirmed), and it is but slowly attacked by dilute alkaline solutions, but strong acids and alkalis have a hydrolysing action, yielding soluble products. Boiling water has a similar effect, the first stage in this case being gelatin, which is slowly further attacked, continued hydrolysis yielding hemicollin and semiglutin, and later gelatoses and glutin peptones.

Hofmeister, who has studied these changes, proved that the production of gelatin from collagen is merely hydrolytic, with an increase of weight of about ¾ p.c. As final products of prolonged hydrolysis, ammonia, and amino-acids are formed, among the latter, glycine (amino-acetic acid), glutaminic acid, leucine (amino-caproic acid) arginine, lysine and α-proline being the most important, while tyrosin and tryptophan are absent. Thus all the products of collagen belong to the antigroups of proteids, and aromatic groups are almost absent, in this respect showing a marked difference from keratin and the albumins.

Hydrolysis of collagen is also produced by pepsin (in slightly acid solutions), but trypsin has no dissolving action on collagen unless the latter has previously been treated with water at 70° or with acids. Putrefactive bacteria rapidly lead to the final products of hydrolysis (amino acids, &c.).

Elastins form the substance of the 'yellow' or 'elastic' fibres which act as a sort of soft framework to the connective tissue, and are remarkable for their great resistance both to putrefaction and to chemical reagents. They are digested by active tryptic ferments.

Mucins are present both in the mucous layer and in the substance which cements the fibrils into fibre-bundles. The nature of this interfibrillar substance, called coriin by Reimer, has been much disputed. Rollet,[1] who first studied it, considered it of a mucous nature, but Reimer [2] claimed that it differed from mucins, and was a hydrolysis-product of the fibres themselves. Körner [3] held a similar view, taking it to be collagen rendered more soluble in alkalis by swelling and hydration. Both Halliburton [4] and Van Lier,[5] on the contrary, favour its

mucin character, and the latter names it coriomucoid (in distinction from tendo-mucoid). The mucins are easily soluble in even dilute alkaline solutions, and are dissolved during the process of liming, allowing the epidermis to be mechanically removed and isolating the fibrils.

Fats.—A distinction must be made between those of the *epidermis*, which are largely unsaponifiable, and consist mainly of cholesterols and liquid waxes; and those of the fat-cells of the *corium*, which are almost entirely triglycerides like most ordinary fats. The former exist not only as products of the sebaceous glands (wool-fat, &c.), but are combined with the keratins, rendering the *epidermis* more resistant, and thus fulfilling a similar function to the waxes in plants (Liebreich [1]). The fats of the *corium*, like those of the body, vary in composition, and especially in the proportion of olein to stearin and palmitin, with the age, sex, and food of the animal, but are usually of lower melting-point than the corresponding internal fats. They are liquid during life, but in warm-blooded animals solidify after death.

Fresh hides and skins contain 50–70 p.c. of water, of which the larger proportion is in the *corium*, and the total is highest in young animals. In the adipose tissue below the skin, the proportions of fat and water are approximately equal.

Hides and skins reach the tanner in various states. Most of those from animals killed in this country are either fresh or very slightly salted, but those from greater distances are treated in various ways to preserve them. Perhaps the simplest and best is the use of salt, either sprinkled on the flesh side repeatedly, or used in the form of brine. In this way most European hides, and many of those from North and South America, are cured. In countries remote from the sea, hides are frequently first salted and then dried, so as to save weight in carriage, and at the same time to preserve them better. This is called 'drysalting.' A still commoner method, especially where salt is scarce and costly, is simply to dry the hide or skin either by hanging in the shade or by stretching on the ground in the sun. Many hides from Texas and Central and South America are thus treated, as well as smaller skins from more temperate countries. The hides of the small cattle of India, called 'kips,' are plastered on the flesh side with a mixture of a native saline earth containing sodium sulphate and water, to preserve and, incidentally, to weight them, and then dried. Sometimes an addition of arsenic is used to prevent the ravages of insects. It has been proposed in Germany to substitute sodium sulphate for common salt in the curing of skins, both on account of the tax on salt, and because the former retains water, and consequently increases the weight of the hide. The advantage of this to the tanner does not seem obvious. In Russia and other cold climates, hides are sometimes preserved by freezing.

Preparation of hides for tanning.—Preliminary to any other treatment, it is necessary to soften hides and skins, and to free them from blood and dirt. When fresh, a few hours, or at most a day or so in one or two changes of fresh water is sufficient to accomplish this; and for sole leather the cleansing does not need to be so thorough as for the finer sorts, whilst too long soaking is apt to lead to incipient decomposition, and to yield a soft and light-weighing product. Where goods are salted, a much more thorough washing is desirable, and it is advisable to give three or four changes of water to remove the salt as rapidly as possible, and to swell the tissue, which is more or less dehydrated by salting. A final treatment in a washing drum with running cold water is often useful.

When hides have been dried, a mere soaking is in most cases insufficient to produce complete softening, and in addition mechanical and chemical means have to be employed. Eitner has pointed out that the higher the temperature at which the original desiccation took place the greater is the difficulty of softening; calfskin which has been dried at 60° refusing to soften sufficiently for tanning either by soaking or mechanical means. This is analogous to the fact that gelatin dried at 130° becomes insoluble even in boiling water. For thin skins, such as calf or sheep, dried in the open air in temperate climates, a simple soaking of some days in cold fresh water, assisted by working over the beam with a blunt knife, is enough. On the other hand, for the sun-dried kips of India or the heavy ox hides of Texas and South and Central America, such treatment would be quite ineffectual, and the method was formerly adopted in this country of soaking for 2 or 3 weeks in water, which being seldom changed and highly charged with organic matter from previous parcels of hides, was in a state of active putrefaction. Such soaks will soften much more rapidly than fresh water, and are effectual where even prolonged treatment with it would fail. In India, hides are softened by the native tanners within 24 hours, by plunging them into pools in which all the refuse of the tannery is allowed to collect and putrefy. It has, however, come to be recognised by observant tanners that this putrid soaking is very dangerous and unsatisfactory, especially where the hides are destined for sole leather, since it has always a destructive effect on the tissue, and it is found that a much more rapid and satisfactory softening may be effected by the use of very dilute solutions of sodium hydroxide, or sodium sulphide, or of weak acids. A solution of sulphurous acid of about N/20 strength followed by cold water, has been successfully used, and from its antiseptic effect, seems particularly suited for hot climates. When the hides or kips were so far softened that they could be bent sharply without danger of breaking the fibre, they were worked in the 'stocks' or 'hide-mill,' which is a machine in which two large hammers or plungers work the hides with a sort of kneading action, but this violent treatment has been rendered unnecessary by the chemical treatment, and at most a drumming with warm or tepid water in a rotating 'tumbler' like an immense barrel-churn is all that is needed. A machine in use on the Continent for the same purpose consists of two rollers studded with rounded pegs, or of which one is grooved and the other pegged. The hides are passed back and forwards between these, and undergo a sort of kneading action. When the hides or

[1] Virchow's Archiv. 121, 183.

skins are thoroughly softened they are ready for depilation.

Depilation.—With a few exceptions, which scarcely come properly under the head of 'leather,' it is necessary to remove the hair preparatory to the tanning process. Probably the oldest way of doing this is by putrefaction, or as it is technically called, 'sweating.' This was formerly accomplished by leaving the hides or skins, folded or laid together, in a warm and moist place, till the destruction of the *epidermis* liberated the hair. But though the *corium* was somewhat more resistant to putrefaction than the mucous layer of the *epidermis*, the putrefactive change frequently spread into it, and injured at least its surface. This simple form of sweating may now be considered obsolete, and where putrefaction is still employed, it is by what is known as 'cold sweating,' which, though little used in England, is still employed in America in the treatment of dried hides. In this method the hides are suspended from tenter-hooks in well-ventilated chambers, usually almost buried in soil or spent tan, so as to maintain an equable temperature (which is generally somewhere between 15° and 20°, the higher the more rapid being the action). The air is kept saturated with moisture, and the temperature regulated by admitting steam under a false bottom, or a spray of water from pipes provided for the purpose. The hides, which if dried must previously have been thoroughly softened, are ready for unhairing in 3–7 days, and during the latter part of the time must be examined from hour to hour, and, as soon as the hair is loosened, taken down and placed in piles on the floor. As the thick parts take longer to unhair than the thinner, and the process proceeds more rapidly at the top than the bottom of the chamber, the position of the hides must be altered as the action progresses. When the hair is fully loosened, it is removed either by scraping with a blunt two-handled knife on a sloping 'beam,' or by fulling with stocks. Some American tanners now give a light liming before unhairing to slightly plump the goods and check the decomposition. The sweating or 'staling' process is largely employed in Europe for unwoolling sheepskins; in this case to avoid the injurious effect of lime upon the wool. The process is not wholly bacteriological, since ammonia, which is largely evolved, acts as a caustic alkali on the epidermis and is itself capable of loosening the hair without putrefaction.

In England, both for sole and dressing goods, the hair is almost universally loosened by the use of lime. The pits are usually, though by no means invariably, worked in sets of three, of which one is old and nearly exhausted, the second fairly good, and the third freshly made or strengthened. The duration of the process is very variable, ranging from 4 or 5 to 14 days or more, and the quantity of lime used is yet more indefinite, being variously stated at from 1 lb. to 12 lbs. per hide. The fact is, that, lime being very scantily soluble in water, any quantity beyond that required to maintain a saturated solution has but little effect. Lime is only soluble to the extent of about 1¼ oz. per cubic foot, but of course is continuously absorbed by the hide, so that an excess is required which may be less the more often the hides are moved and brought in contact with fresh portions of the lime liquor. Hides lime well and rapidly, suspended from frames in pits, especially if rocked or frequently shaken, and in any case the more frequently they are moved, the better and more uniform is the action; mechanical motion is largely in use on the Continent, and to an increasing extent in England, the solution being generally kept in motion round the suspended hides by the use of compressed air, by which the time required is much shortened and the solution of hide-substance is lessened. In America, the hides are usually tied together by the shanks and wound from one pit to another over a 'reel' or skeleton drum, turned by hand or power. The old lime liquors become charged with ammonia and organic products from the hides, which materially modify their action, rendering more lime soluble, but diminishing its plumping effect. One result of this is that hides unhair more readily out of a somewhat old lime than they do out of one freshly made, and a change from an old into a newer and stronger lime sometimes actually sets the hair firmer at first, by plumping the tissue and so grasping the root-bulbs. Experiments seem indeed to render it probable that lime alone in the complete absence of putrefaction, will not loosen the hair in any reasonable time. If hides be limed for 1 to 4 days in a sharp new lime in which they are frequently drawn, and are then transferred into a pit of water maintained at a temperature of 40°–50° for some hours, they will part readily with their hair, and at the same time be to a considerable extent freed from lime. This plan, which is of American origin, and is sometimes called the 'Buffalo method,' may be highly recommended for sole leather, giving good weight and colour and a firm solid texture. Of course, the relative amount of liming and hot water may be varied to a considerable extent.

Unhairing may also be hastened by warming the limes themselves. The heat increases the solubility of the hide, but at the same time checks the plumping, and the tendency is to produce a soft and porous leather. Hence the method is ill adapted for sole, and even for dressing leather is undesirable, since the same effects are obtained better in other ways.

It has naturally been proposed to substitute the caustic alkalis for lime, and it is probable that it might be done in some cases with advantage, or at any rate that small quantities might be added to the limes to hasten their action; but so far their use has not found much favour with tanners, except as constituents of such secret preparations as 'Inoffensive.' One cause of this is probably that from their easy solubility and powerful action, great care is required, and where used by 'rule of thumb,' serious injury is readily done to large quantities of costly raw material. It is one of the virtues of lime that, from its very limited solubility, it is almost impossible to destroy a pack of hides by its use, and the injury which it does when carelessly handled is often attributed to other causes. It has recently been shown by J. Loeb that, in accordance with the Procter-Wilson theory of swelling, the swelling power of divalent alkalis, such as lime and baryta, is for the same hydroxyl ion concentration, only about half that of the monovalent such as soda and potash.

Naturally it might be thought that the alkalis would be easily removed from the hide by simple washing, and that the solubility of their soaps would favour the removal of grease; but it is found that alkalis form a sort of compound with hide-fibre, from which they can scarcely be removed until they have first been neutralised with acid, while practically the grease is not saponified but merely emulsified, and for this purpose lime answers just as well as a stronger alkali.

In liming sole leather the principal object is to enable the hair to be removed and to free the hide from grease with as little solution of its fibrous structure as possible. The English tanner frequently desires also to raise or swell the hide, and so to split up the fibrous bundles into their constituent fibrils as to prepare it for tanning, though this may also be done by the presence of acid in the earlier tanning liquors, or in some cases by the direct use of an acid bath. It is a question on which there has been much difference of opinion whether the unhairing is best accomplished by the use of strong fresh limes for a short time, or of old limes charged with ammonia for a longer period. It is now, however, generally recognised that the continued action of old limes is too dangerous, usually injuring the grain surface of the hide or skin, and the compromise is usually adopted of beginning the process in the older limes and finishing in fresh ones. It is very dangerous in hot weather to let limes get too stale and loaded with organic matter, as in this case even the presence of caustic lime does not prevent putrefaction, which is fatal to the manufacture of plump and solid leather. In fact, by microscopic examination of such stale limes it is easy to detect the presence of active bacteria. It is a mistake to suppose that such limes are 'weak,' since the excess of lime is always sufficient to maintain them as saturated solutions, and in addition they contain much dissolved lime as organic salts, and considerable quantities of ammonia and bacterial enzymes, which, though they lessen swelling, assist in the solution of the hide. If in any case the liming is too low, it will be impossible to eradicate grease from the hides of very fat cattle, although the leather may be of excellent quality. In the manufacture of dressing leather a somewhat more thorough liming is generally desirable, since it is not only required to remove the hair but to dissolve a proportion of the cementing matter of the fibrous tissue, and so render the leather softer and more pliable. This is especially true in the manufacture of glove or 'glacé' kid and lamb leather, in which the property of stretching in any direction is largely dependent on a proper liming. In the continental manufacture of these goods it is customary to 'sharpen' the limes by the addition of realgar (arsenic sulphide) This produces, with the lime, dicalcium hydrosulphide, sulpharsenate, and some metallic arsenic, and considerably hastens the unhairing. Orpiment, the yellow arsenic trisulphide, may also be used. The calcium sulphydrate is the active agent, V. Schroeder and Schmitz-Dumont (Dingl. poly. J. 1896) having shown that the arsenic compounds are inoperative and not even antiseptic; and, many years since, the desirability of finding a substitute for the very poisonous red arsenic led Böttger to propose the use of calcium hydrosulphide, prepared directly by passing sulphuretted hydrogen into milk of lime. This produces a paste which is greenish from the presence of traces of iron sulphide, and which acts as a rapid depilatory, and if applied as a paste on the hair-side will in a few hours reduce the hair to a pulp, whilst from the rapidity of the action, the hair bulbs and the various glands are much less affected than with an ordinary liming. Mixed with lime in smaller proportion and used in pits in the ordinary way, it loosens the hair rapidly without actually destroying it, principally by attacking the mucous layer, since the harder part of the epidermis frequently comes off with the hair roots in it in sheets of considerable size. Unfortunately for its use in practice, for which otherwise it is excellently fitted, it keeps very badly, and must be freshly made as required which is both costly and troublesome. A concentrated solution of calcium hydrosulphide was formerly produced by the Washington Chemical Company, and promised to be a valuable depilatory; but unfortunately its manufacture proved unremunerative. Gas-lime, which often contains a considerable quantity of calcium hydrosulphide, has been used as a substitute, but is too uncertain in its composition to be satisfactory, and has been almost superseded as a gas-purifying agent by oxide of iron. None of these disadvantages attends the use of sodium sulphide, which has been strongly advocated by Eitner, late Director of the Austrian Government Research Institute at Vienna, to whom the leather trade probably owes much of its impulse to scientific improvement. It is now manufactured commercially, in a crystallised form; it keeps well and possesses great depilatory powers, both alone and in union with lime, with which it forms calcium hydrosulphide and caustic soda. A paste containing 2–4 lbs. to the gallon of water, and thickened with lime to a soupy consistence, will, if painted on the hair side of a hide, completely destroy the hair in a few hours, so that it may be swept off with a stiff brush. This mode of proceeding has been much recommended for sole leather, and it makes a firm and solid article, but the difficulty of getting it so thoroughly brushed into the hair that it will destroy every part of it, is very considerable, while, if any part has been missed, the short hair is very difficult to remove. For this reason, and because it leaves all the hair-roots and glands in the skin and so prevents a clean buff, it is only suitable for very common classes of leather, though it will do good service on dried hides instead of the cold sweat. Such a paste is also much used for unwooling sheepskins, being in this case applied to the flesh side and allowed to penetrate the skin. Used in pits with lime to the extent of $\frac{1}{4}$–$\frac{1}{2}$ lb. per hide, sodium sulphide does not materially injure the hair, while it quickens the unhairing and yields good weight and excellent quality. Strong solution of sodium sulphide or even of caustic soda does not swell from its dehydrating effect, but hides so treated swell rapidly if subsequently placed in water. Where plumpness is not desirable, but a tough, solid texture is required, as in some descriptions of light leathers, its use would promise special advantages. Since sodium

sulphide, however, dissociates in solution to sodium hydrosulphide and sodium hydroxide, the effect of the latter leads to more swelling of the grain than is desired, and it is found that this may be lessened by the addition of an equivalent quantity of calcium chloride which substitutes calcium hydroxide for sodium hydroxide with formation of common salt, and enables the production of leathers with much finer grain than with sodium sulphide alone.

The total soda existing in commercial sodium sulphide as sulphide, carbonate or hydroxide may be determined with standard acid, using methyl-orange as an indicator, since this colour is quite unaffected by the presence of either hydrogen sulphide or carbon dioxide. The sulphur is advantageously estimated by ammoniacal zinc solution, using alkaline lead tartrate as an indicator by placing drops of it and of the solution being tested near each other on filter paper. Solutions containing sodium sulphide together with dissolved sulphur and polysulphides obtained by boiling sulphur with caustic soda or soda ash and lime possess considerable depilatory power, but it is not easy to determine the amount of available sulphur. Somewhat similar solutions are obtained by forcing air through the 'tank waste' of the Leblanc alkali process, suspended in water, or, naturally, in the 'bog-liquor,' which in some works drains from the waste-heaps, and where this can be cheaply obtained, it may in some cases be used advantageously.

Examination of lime liquors.—Considerable information may often be obtained by a simple examination of lime liquors. Free ammonia may be determined by rapid distillation of, say, 30 c.c. of the filtered liquor, preferably with the addition of a little magnesium sulphate to remove caustic lime. The ammonia is absorbed in a measured quantity of standard acid which is titrated back with caustic alkali. If it be desired to estimate free lime in the same sample, the magnesium sulphate must be omitted, which, if the distillation is short, does not lead to serious error. The sample should be drawn from the middle of a lime pit well plunged up, and rapidly filtered in a funnel covered with a clock-glass.

The caustic lime in the portion from which the ammonia has been withdrawn may now be estimated with normal or decinormal acid, using phenolphthalein, and the total lime (and any other alkalis present) existing in a free state or in combination with organic matter and weak organic acids with methyl orange or red as an indicator. Litmus is unsuitable for the purpose from the presence of these weak organic acids, which render its end-reaction quite indefinite, but do not affect methyl-orange so much. For the same reason this indicator will be found very useful for many determinations required in a tannery. Phenolphthalein cannot be accurately used in presence of ammonia. An estimate of the organic matter present is obtained by evaporating 50 c.c. of the filtered liquor to dryness in the water-oven in a platinum crucible, weighing, and then igniting and estimating by loss. This method can of course lay no claims to strict accuracy, but is sufficient to give valuable information as to the condition of the liquor; and, if a uniform course of liming be adopted, as to the amount of matter dissolved out of the hides in the process, or the comparative quantities by different liming methods. For more accurate work the liquor may be evaporated to dryness or very small bulk in a flask with the addition of a little excess of sulphuric acid to retain ammonia, and the nitrogen estimated by Kjeldahl's method. It is easy to calculate very approximately the amount of matter which the nitrogen represents, since both the gelatinous and horny tissues contain about 17·5–18 p.c. of nitrogen. During recent years much attention has been devoted to the more complete analysis of lime-liquors; but the literature is too extensive to be summarised here, and the reader is referred to the pages of 'Collegium,' the 'American Leather Chemists' Journal,' and especially to recent issues of the 'Journal of the Society of Leather Trades Chemists.'

Bating and drenching.—If lime or other alkalis have been used in depilation, they must be removed before tanning, and in sole leather it is desired to do this with as little loss of pelt as possible. Formerly a mere suspension in water was considered sufficient, and when the water is hard, a little lime was added to remove the free carbonic acid and calcium hydrogen carbonate present, which would form insoluble carbonate with the lime contained in the hide, and afterwards by combining with tannin would produce discoloured leather. A further cleansing may be effected by 'scudding,' or working the grain-side with a blunt knife on a beam, which expresses much of the *débris* of hair-roots and fat glands, as well as lime. When a clean buff is desired this precaution should never be omitted.

It is, however, impossible really to remove the whole of the lime by soaking in water, since it forms a loose compound with the fibrous tissue, from which it can only be dislodged by the aid of acids, and at present, even for sole leather, acids are usually employed after removal of as much lime as possible by washing in 'softened' water.

Very dilute sulphuric or hydrochloric acid will perform the service satisfactorily, although great care has to be used to keep the hides in constant motion, to add the acid in small successive doses as it is absorbed by the hides, and to avoid even a small excess. Some trouble is often experienced in the use of commercial acids from the precipitation of the iron which they contain as an impurity on the fibre of the hide, where it subsequently produces stains by combining with the tannin. The ammoniacal salts of the stronger acids may also be used, but boric, formic, acetic, lactic, and other organic acids are generally employed in solutions not exceeding about N/20 strength. Instead of actually removing the lime it might be sufficient in many cases to convert it into a neutral and insoluble form, as, for instance, by the action of acid or neutral phosphates, oxalates, or arsenates. Some of the sulphonic acids of various coal-tar products have also been tried for the purpose with some success; and they are, at the same time, powerful antiseptics.

In the case of most light leathers where softness is aimed at, it is found necessary to use, either alone or as a supplement to some process of removing the lime, a putrefactive or

fermentive bate, which has the effect of reducing ('abateing') the plumpness of the hide, and at the same time of softening it by attacking the fibrous tissue, and especially the elastic fibres. Either an infusion of dung (pigeons', hens,' or dogs') called *bate* or *puer* (the latter probably having some connection with the French *puant*), or of bran (drench), and frequently both, are used successively. The effect seems due to the enzymes and amino-acids produced by the putrefactive organisms, but the problem was partially solved by Wood in England, and by Popp and Becker in Germany, who introduced an artificial puer under the name of 'erodin,' consisting of a suitable culture of selected bacteria and a dry powder which when dissolved in water formed a suitable nutritive fluid for their rapid multiplication.

Dr. Röhm, following up an experiment of Wood's, has, however, introduced under the name of 'Oropon,' a mixture of ammonium chloride with a small quantity of the pancreatic ferment, which, for many leathers, has been very successful; though for the finest leathers, such as glove-kid, it has not completely superseded dog-puer. The exact degree of hydroxyl concentration of a solution has an important influence.

In the preparation of 'shaved' and 'dressing' hides, a bate may contain about 1 peck of hen or pigeon dung to 25 or 30 hides, in which they are handled frequently for 3–7 days. This time may be much shortened by warming the bate and working the goods with a drum or paddle tumbler. The latter consists of a tank or pit, generally having a curved bottom to favour the motion of the liquid, and agitated by a paddle-wheel with 6–8 floats. A short 'stocking' out of the bate was formerly sometimes employed. Tumbling with warm water with a limited quantity of dilute acid before bateing will wash out a good deal of lime and reduce the plumpness, and so save both time and material, but the skin must remain in a slightly alkaline condition; and French tanners make excellent shaved hides and calf-skins without bateing by careful working at the beam, long washing with cold water (during which probably a slight putrefactive action takes place), and the use of weak and stale liquors. Shaved hides are so called because, after the bateing, the thicker parts of the butt are reduced by shaving on an upright beam with a currier's knife having a turned edge.

Still lighter and more flexible sorts of leather, such as morocco and kid, are still often pured with fermented dog-dung, infused in hot water, and strained through a basket. This is frequently followed, after scudding, by a drench made by pouring boiling water on bran, and allowing to ferment. In this case, lactic acid is the most active product, although its plumping action is controlled by some putrefactive fermentation going on at the same time. Wood (J. Soc. Chem. Ind. 9, 27) has shown that starch is destroyed by the active ferment, and considerable quantities of methane evolved. In hot and thundery weather the lactic ferment is liable to be replaced by some other product, when the skins plump rapidly and become transparent, and are finally perforated or dissolved. The best precautions are to scald out the tubs thoroughly, and to wash the bran before using with cold water to remove the flour, which furnishes the nourishment required by the ferment.

In the brief space available it is impossible to give more detail as to these preparatory processes, which are, however, of the first importance from a practical point of view. From the scientific aspect, it must be noted that the plumping and 'falling' which the fibrous tissue suffers through the action of various reagents, is the result of osmotic pressure, and is at least as much a physical as a chemical phenomenon.

Tanning materials. Before speaking of the actual tanning process, a few words must be said about the chemistry of the vegetable products on which the operation depends.

The tannins, or tannic acids, are widely distributed through the vegetable kingdom, and form a large and varied class, differing considerably in chemical constitution as well as in properties. The one point which they all have in common is the power of precipitating gelatin from its solution as an insoluble compound. They are also all derivatives of the aromatic series of carbon compounds, and, so far as is known, all contain either pyrocatechol $C_6H_4(OH)_2$ or pyrogallol $C_6H_3(OH)_3$, and sometimes the isomeride of the latter, phloroglucinol. This difference usually corresponds to well-marked differences in constitution and properties. As a rule, the pyrogallol tannins give a blue-black with ferric salts, and a whitish deposit on the surface of the leather, well known to the tanner as 'bloom'; whilst the pyrocatechol derivatives give a greenish-black, and deposit red insoluble matters, oxides or anhydrides of the tannins. All catechol tannins give insoluble precipitates with bromine water, and with formaldehyde in presence of hydrochloric acid. Oak bark occupies an intermediate position, yielding both bloom and reds, and apparently containing both pyrogallol and pyrocatechol. In such cases, however, it is not very certain whether we have to deal with a complicated tannin or with a mixture of two dissimilar ones, since tannins, being neither crystallisable nor volatile, are very difficult to separate. It is known that many of the bloom-yielding materials, such as myrobalans, contain gallotannic acid, which yields no bloom, and ellagitannic acid, which yields a copious bloom of ellagic acid.

It is, of course, only the pyrogallol tannins which yield gallic acid as a decomposition product, while the pyrocatechol tannins contain the corresponding protocatechuic acid. Many of the pyrogallol tannins yield glucose on decomposition, but in the pyrocatechol class it seems to be absent.

A complete list of tannin-yielding plants would embrace a large part of the vegetable kingdom, but the following are those in most extensive practical use. (*Cf.* art. TANNINS.)

Oak bark is one of the oldest and best of tanning materials, producing excellent but not heavy leather; and, from its comparative weakness in tannin (8–12 p.c.) its action is somewhat slow. It yields a good deal of whitish bloom.

Valonia, the acorn cup of the *Quercus Ægilops* (Linn.) and *Q. Macrolepis* (Kotschy), contains up to 35 p.c. of a tannin somewhat similar to that of oak bark, but giving more

bloom and a darker colour, and at the same time a heavier leather.

Myrobalans, the fruit of *Terminalia Chebula* (Ratz.) (India), contains 25–35 p.c. of gallotannic and ellagitannic acids, and, consequently, blooms freely It gives good colour and fair weight, and though alone it yields a porous and soft leather, it is very useful in mixture with dark-coloured materials, such as mangrove or mimosa extracts, for sole leather, and as a cheaper substitute for sumach, on the lighter descriptions.

Divi-divi, pod of *Cæsalpinia coriaria* (Willd.) (S. America), contains 30–50 p.c. of a tannin somewhat similar in effect to that of valonia. It produces a heavy-weighing leather, but is dangerously liable to a sudden fermentation, which produces a deep red stain on all leather in contact with it.

Sumach, the pulverised leaves of *Rhus Coriaria* (Linn.), &c. (Sicily), yields 20–30 p.c. of tannins very similar to those of myrobalans, but paler in colour. It is principally used for light leathers, though warm sumach liquor is used to brighten the colour of heavy tannages There are also several American species used for tanning.

Mimosa bark, the product of several species of *Acacia*, principally Australian, but naturalised and largely cultivated in Natal, contains 20–40 p.c. of a red tannin derived from pyrocatechol, and yielding no bloom, but giving considerable weight and firmness to the leather. An extract has recently been introduced into commerce. Babool bark, from *Acacia arabica* (Willd.) is one of the principal tanning materials of India (*A. Catechu* (Willd.) and *A Catechu* var. *Sundra*, see below).

Cassia auriculata (Linn.), Turwad, avaram, or Tanghadi bark, from a leguminous bush allied to senna, is the principal tanning material for sheep and goat skins (so called 'persians') in Southern India.

Hemlock bark, known in this country principally in the form of extract, is produced by the hemlock pine, *Tsuga* [*Abies*] *Canadensis*, (Carr.) of North America. The bark contains 8–10 p.c., and the extract 20–30 p.c. of a tannin similar to that of mimosa, but giving a larger proportion of red anhydrides, and consequently a heavier leather, but at the same time one of a still more pronounced colour, which is less easily modified by other agents. It is the staple tanning agent of North America.

Gambier (*Terra Japonica*), pale catechu, an inspissated extract from the leaves of *Uncaria Gambier* (Roxb.) of the East Indies, contains 30–40 p.c. of a peculiar catechol tannin, which penetrates leather somewhat slowly, but has less astringency and adhesion to the hide fibre than most other tannins. These properties, which are apparently due to its large percentage of non-tanning matters, make it very valuable in certain stages of the tanning process, although alone it produces a leather of very inferior quality. Cutch (dark catechu), though somewhat similar in its chemical relations, is a very different product practically, and is derived from the wood of *Acacia Catechu* (Willd.) and *A. Catechu* var. *Sundra*, and, consequently, more allied to the mimosa bark, which has already been described. Gambier comes to this country in blocks of about 2 cwt., covered with mat and pasty in the centre, and also in cubes of about an inch square, which are much purer, and internally are quite white with crystals of catechin. Cutch comes in masses of a glossy dark brown fracture, and is principally used for dyeing.

Quebracho wood from *Quebrachia Lorentzii*, (Griseb.), a large tree of South America, and especially of the Argentine Republic, contains about 20 p.c. of rather difficultly soluble catechol tannin, principally used as extracts which are often decolorised and rendered soluble with bisulphites.

Mangrove barks from various species of *Ceriops* and *Rhizophora*. Extracts principally manufactured in East Indies. Barks vary a good deal in strength but may contain up to 40 p.c. of a dark red but fairly soluble catechol tannin.

Mallet bark from *Eucalyptus occidentalis* (Endl.) or 'flat-topped yate' of Western Australia. Rich in a brown catechol tannin producing rather hard leather if used alone.

Ulmo bark, said to be from *Eucaupia cordifolia* (Cav.) of Chile, produces a dark red extract strongly resembling mangrove.

Artificial tannins.—Although none of the natural tannins can be synthesised, at least at commercial prices, a series of organic compounds have been produced which possess many of their properties, and some of which have come into considerable use in the production of leather. The first and most important of these were the 'syntans' discovered by Dr. Edmund Stiasny, which were produced by the condensation of the sulphonic acids of phenols with formaldehyde, which were patented by the Badische Anilin and Soda Geselschaft, and which have not only been largely manufactured in Germany, but, since the war, in England under license. The master Eng. Pats. are taken out in the name of J. Y. Johnson, the Badische Co.'s agent, and are 8511 and 8512, 1912, but a good many patents have been since taken for other means of preparing tanning compounds, some of them doubtless to protect or evade the original patents, but others possibly of commercial value. Success in the actual manufacture depends on many details not mentioned in the specification, and particularly on the proper adjustment of temperature. The original products are very acid, and require to be partially neutralised before they can be used in tanning. When of good quality they produce a soft and practically white leather, which will resist water, but is easily stripped by alkalies. They form a good preparation for tanning with vegetable materials, and have a great bleaching effect, not only on dark-coloured vegetable tannages but on one-bath chrome leather, which may be made nearly white, and are largely used for this purpose. They precipitate gelatine and give blue-blacks with iron salts, and, like the lignine products, contained in sulphite wood pulp liquors, are precipitated by aniline and hydrochloric acid.

Exhaustion of tanning materials.—Most tanning materials require to be ground before lixiviating. This is accomplished either by a mill, on the principle of the ordinary coffee mill, with grooved iron or steel cones, or by one of the numerous forms of 'disintegrator,' in which

the grinding is done by dashing the material against a serrated or grated casing, by beaters revolving 2000 or 3000 times a minute. Valonia and myrobalans are frequently crushed between fluted or toothed steel rollers. The grinding should not be so fine as to render percolation difficult. The actual exhaustion takes place in this country mostly in large square sunken vats, constructed like the other pits of the tannery and worked in series, the liquors being either pumped from one to the other or allowed to run by gravitation through wooden boxes, connecting the space below the perforated 'false bottom' of one pit with the top of the next. In America the 'leaches,' as the extracting vessels are called, are usually immense circular tubs, fitted with perforated 'false bottoms' and heated by steam coils. These are generally employed in groups of 6 or 8, water or weak liquor being run on the most nearly exhausted, and forced or pumped round the series to the newest and strongest vat. Hot extraction is more rapid than cold, and usually more complete, but the liquor is darker in colour, and contains more non-tanning matters, and the question of temperature must be decided by the particular material and conditions, some tannins being decomposed at temperatures which are not injurious to others.[1]

Tanning extracts now form an important portion of the materials used by the tanner, and in many cases render available materials which from their bulk and low percentage, or their remote origin, would not pay for transit, or yield sufficiently concentrated liquors for modern requirements. Among those of leading importance may be mentioned those of the woods of oak, chestnut, and quebracho, and of the barks of mangrove and hemlock pine. Valonia, myrobalans, and sumach are also extracted. The materials are prepared and extracted as above described, woods being previously reduced to chips or shavings by machines similar to those employed for dyewoods, and heat, occasionally under pressure, being freely used in extraction, especially with the weaker materials, such as oakwood, which only contains 2–3 p.c. of tannin. When this is done, decolorising methods are frequently employed to remove the dark and difficultly soluble matters dissolved by heating; the most approved method being partial precipitation by blood or blood-albumen, dissolved in the warm infusion, which is then heated beyond the coagulation temperature. Metallic precipitants are also sometimes used, and sulphurous acid and bisulphites, not merely as bleaching agents, but to render the phlobaphenes and 'reds' more soluble. A so-called 'pinewood extract' is on the market, made by concentration of the sulphite liquors of cellulose manufacture, which analyses well, but contains no true tannin and is used mainly as an adulterant; though it is absorbed by hide and probably has legitimate uses as a filling agent for sole-leather. After settling or filtering the decolorised liquors, they are concentrated in the vacuum pan to 50–60 p.c. of water for liquid extracts and 20–25 p.c. for those intended to solidify, spray-evaporators being largely used for concentration up to about 20 Bé.

Imperfect exhaustion is one of the most serious sources of waste in tanning, and the residues deserve more careful testing than is usually given to them.

Quantitative determination of tannins.—Many methods have been proposed for the purpose, several of which are capable of application under special conditions, but the only two that have stood the test of general practical work, and are both valuable for different purposes, are the hide-powder method, which is the gradual development of the work of several chemists, among whom Simand may be specially mentioned, and the permanganate and indigo process of Löwenthal.

The first of these permits an actual gravimetric determination of the matters absorbable by hide, but these include colouring matters, acids, and other substances not strictly tannins. It has been found that the absorption of these matters is lessened by a light preliminary chroming of the hide-powder, and it must also be remembered that the method is purely empirical, and must therefore be carried out with absolute adherence to the smallest details if comparable results are to be obtained.

The following is the method of the International Association of Leather Trades Chemists, which is the official standard in Europe and only differs in minor details from that of the American Leather Chemists' Association; but a commission of the Society of Leather Trades Chemists has recently been appointed, who are working for its improvement. Its weakest points are the large proportion of non-tannins absorbed even by chromed hide-powder, and the uncertainty of the so-called 'insoluble matter,' largely consisting of difficultly soluble tannins, which will be removed by filtration. It is not improbable that the use of the Berkefeld 'candle' will be abandoned.

Preparation of infusion.—Such a quantity of material shall be employed as will give a solution containing as nearly as possible 4 grams of tanning matter per litre, and not less than 3·5 or more than 4·5 grams. Liquid extracts shall be weighed in a basin or beaker and washed with boiling distilled water into a litre flask, filled up to the mark with boiling water, and well mixed, and rapidly cooled to a temperature of 17·5°, after which it shall be accurately made up to the mark, again well mixed, and filtration at once proceeded with. Sumach and myrobalans extracts should be dissolved at a lower temperature.

Solid extracts shall be dissolved by stirring in a beaker with successive quantities of boiling water, the dissolved portions being poured into a litre flask, and the undissolved being allowed to settle and treated with further portions of boiling water. After the whole of the soluble matter is dissolved the solution is treated similarly to that of a liquid extract.

Solid tanning materials previously ground till they will pass through a sieve of 5 wires per centimetre, are extracted in Koch's or Procter's extractor with 500 c.c. of water at a temperature not exceeding 50° and the extraction continued with boiling water till the filtrate amounts to 1 litre. It is desirable to allow the material to soak for some hours before commencing the percolation which should occupy not less than 3 hours, so as to extract the maximum of tannin. Any remaining solubles in the

[1] J. Soc. Chem. Ind. 1895, 635; 1898, 116.

material must be neglected, or reported separately as 'difficultly soluble' substances. The volume of liquid in the flask must be made up accurately to 1 litre after cooling

The *total solids* must be determined by drying a weighed portion of the material, or a measured portion of its uniform turbid solution, at a temperature between 98·5° and 100° in shallow flat-bottomed basins, which shall afterwards be dried till constant at the same temperature, and cooled before weighing for not less than 20 minutes in an air-tight desiccator over dry calcium chloride. *Moisture* is the difference between 100 and the percentage of total solids, and *insolubles* the difference between the *total solids* and *total solubles*.

Filtration.—The infusion shall be filtered till optically clear (see below). No correction for absorption is needed for the Berkefeld candle, or for S. & S. 590 paper if a sufficient quantity (250–300 c.c.) is rejected before measuring the quantity for evaporation; and the solution may be passed through repeatedly to obtain a clear filtrate. If other methods of filtration are employed the average correction necessary must be determined in the following manner. About 500 c.c. of the same or a similar tanning solution is filtered perfectly clear, and after thorough mixing 50 c.c. is evaporated to determine 'total soluble No. 1.' The remainder is now filtered in the exact method for which the correction is required (time of contact and volume rejected being kept as constant as possible), and 50 c.c. is evaporated to determine 'total soluble No. 2.' The difference between No. 1 and No. 2 is the correction sought, which must be added to the weight of the total solubles found in analysis. An alternative method of determining correction, which is equally accurate and often more convenient, is to filter a portion of the tanning solution through the Berkefeld candle till optically clear, which can generally be accomplished by rejecting 300 or 400 c.c. and returning the remaining filtrate repeatedly; and at the same time to evaporate 50 c.c. of clear filtrate obtained by the method for which correction is required, when the difference between the residues will be the correction sought.

(NOTE.—It is obvious that an average correction must be obtained from at least 5 determinations. It will be found that this is approximately constant for all materials, and amounts in the case of S. & S. 605, 150 c.c. being rejected, to about 5 mgr. per 50 c.c. and where 2 grams of kaolin are employed in addition, to 7½ mgr. The kaolin must be previously washed with 75 c.c. of the same liquor, which is allowed to stand 15 minutes and then poured off. Paper 605 has a special absorption for a yellow colouring matter often contained in sulphited extracts.)

The *total solubles* must be determined by the evaporation of a measured quantity of the solution previously filtered till optically clear both by reflected and transmitted light; that is, a bright object such as an electric light filament must be distinctly visible through at least 5 cm. thickness, and a layer of 1 cm. deep in a beaker placed in a good light on black glass or black glazed paper must appear dark and free from opalescence when viewed from above.

Hide-powder shall be of woolly texture, thoroughly delimed, preferably with hydrochloric acid, and shall not require more than 5 c.c. or less than 2·5 c.c of N/10 NaOH or KOH to produce a permanent pink with phenolphthalein on 6½ grams of the dry powder suspended in water. If the acidity does not fall within these limits, it must be corrected by soaking the powder before chroming for 20 minutes in 10–12 times its weight of water to which the requisite calculated quantity of standard alkali or acid has been added. The hide-powder must not swell in chroming to such an extent as to render difficult the necessary squeezing to 70–75 p.c. of water, and must be sufficiently free from soluble organic matter to render it possible in the ordinary washing to reduce the total solubles in a blank experiment with distilled water below 5 mgr per 100 c.c. The powder when sent out from the makers shall not contain more than 12 p.c. of moisture, and shall be sent out in air-tight tins.

The detannisation shall be carried out in the following manner:—

The moisture in the air-dried powder is determined and the quantity equal to 6·5 grams actual dry hide-powder is calculated, which will be practically constant if the powder be kept in an air-tight vessel. Any multiple of this quantity is taken according to the number of analyses to be made, and moistened with approximately ten times its weight of distilled water.[1] 0·2 gram per hundred of dry powder of crystallised chromic chloride $CrCl_3,6H_2O$ [2] is now dissolved in water and made basic with 0·6 gram Na_2CO_3 by the gradual addition of 11·25 c.c. of N/1 solution, thus making the salt correspond to the formula $Cr_2Cl_3(OH)_3$. This solution is added to the powder and the whole churned slowly for 1 hour. In laboratories when analyses are frequently made it is more convenient to use a 10 p.c. stock solution, made by dissolving 100 grams of $CrCl_3,6H_2O$ in a little distilled water in a litre flask, and very slowly adding a solution containing 30 grams of anhydrous sodium carbonate, with constant stirring, finally making up to mark with distilled water and well mixing. Of this solution, 20 c.c. per 100 grams or 1·3 c.c. per 6·5 grams of dry powder should be used.[3]

At the end of one hour, the powder is squeezed in linen to free it as far as possible from the residual liquor, and washed and squeezed repeatedly with distilled water, until on adding to 50 c.c. of the filtrate, 1 drop of 10 p.c. K_2CrO_4 and 4 drops N/10 $AgNO_3$, a brick-red colour appears. Four or five squeezings are usually sufficient. Such a filtrate cannot contain more than 0·001 gram of NaCl in 50 c.c.

The powder is then squeezed to contain 70–75 p.c. water, and the whole weighed. The quantity Q containing 6·5 grams dry hide is thus found, weighed out and added immediately to 100 c.c. of the unfiltered tannin infusion along with (26·5–Q) of distilled water. The whole is corked up and agitated for 15 minutes in a rotating bottle at not less than 60 revolutions

[1] Very woolly powders require slightly more than 10 times their weight of water. A powder may be considered 'woolly' if it cannot be poured like sand from a beaker.—H.R.P.

[2] 'Chrom-sesquichlorid cryst,' Kahlbaum. Satisfactory chromic chloride may now be obtained from the 'British Drug Houses'

[3] The solution sometimes changes colour slightly by keeping; but this has been shown to have no influence on results.—H.R.P.

per minute. It is then squeezed immediately through linen, stirred and filtered through a folded filter of sufficient size to hold the entire filtrate, returning until clear, and 60 c.c. of the filtrate is evaporated and reckoned as 50 c.c. or the residue of 50 c.c. is multiplied by $\frac{6}{5}$. The non-tannin filtrate must give no turbidity with a drop of a 1 p.c. gelatin 10 p.c. salt solution.

One gram of kaolin free from solubles must be used either by mixing it with the hide-powder in the shaking bottle or with the liquid before filtration.

All evaporations shall be rapidly conducted at steam temperature in shallow, flat-bottomed basins of not less than 6·5 cm. diameter to apparent dryness; and shall be subsequently dried between 98·5° and 100° in a water or steam oven until of constant weight, and shall be afterwards cooled in small air-tight desiccators over dry calcium chloride for at least 20 minutes, and then weighed rapidly. Not more than two basins shall be placed in one desiccator, and the basins must not be wiped after removal from the desiccator. The residue is 'non-tannins.' The difference between these and 'total solubles,' is 'tanning matters.'

The Löwenthal method is volumetric, and, as very much weaker infusions can be employed, a larger quantity of water can be used in extraction, or it may be applied to very weak infusions without concentration. It has gone out of use for commercial analysis, but the comparison of its results with the hide-powder method is sometimes useful in the detection of mixtures in extracts; and as a control method in tanning (*cp.* Procter and Hirst, J. Soc. Chem. Ind. 1909, 294).

The method depends on the oxidation of the tannin by permanganate in presence of excess of sulphonated indigo, which serves both as an indicator and regulator of the reaction.

The indigo solution is made by dissolving 5 grams of pure sodium or potassium indigo-sulphonate (Geho's *Carminum cœrul. op.* answers well) in a litre of distilled water, adding 50 c.c. of concentrated sulphuric acid and filtering; or a solution of 1 gram 'Indigo pure B. A. S. F.' may be dissolved in 25 c.c. of concentrated sulphuric acid, and made up to 1 litre with water and a further 25 c.c. of acid. Samples which give a brownish instead of a pure yellow solution after oxidation are useless. The solutions keep well, but the weak permanganate is best made up as required, by diluting 100 c.c. of a 5 gram per litre solution to 1 litre.

The titration is best carried out in a beaker of 750–1000 c.c. capacity placed on a white tile; and if many titrations are to be made, should be provided with a screw-vaned stirrer driven by a turbine or other motor; but in any case the stirring must be vigorous and constant. 20–25 c.c. of the indigo solution, according to its strength, and 400 c.c. of good water free from organic impurity are introduced into the beaker, and permanganate solution is added from the burette as rapidly as it can be dropped until near the end-point. Uniformity in stirring and in the rate of dropping is of prime importance.

The colour changes first to green, and then to pure yellow, and as it approaches the latter, the flow must be checked and the last drops added very cautiously. The quantity of permanganate used will be that required to oxidise the indigo. If the process be now repeated with the addition of 5 c.c. of the tannin infusion, the excess required to destroy the blue will correspond to that required to oxidise the astringents added, and must not exceed two-thirds of that required for the indigo alone. A second estimation should not differ from the first by more than 0·1 c.c.; and the results added together will correspond to the total astringents in 10 c.c. of the infusion. But as gallic acid and other bodies always present in tanning materials are oxidised like tannin itself, it is necessary to make a second titration after removing the tannin, and estimate by loss. For this purpose hide powder, either white or chromed, may be used as in the previously described process, or to 50 c.c. of the liquor 25 c.c. of a fresh 2 p.c. gelatin solution and 25 c.c. of a saturated solution of salt containing 50 c.c. of concentrated sulphuric acid per litre. The mixture is shaken with a teaspoonful of kaolin for 15 minutes, filtered, and 10 c.c. titrated. The results of the gelatin method in the separation of gallic from gallotannic acid are nearly exact, but probably by a compensation of errors.

As it is impossible to obtain *pure* tannins against which to standardise the results, which can only be compared with others obtained by a precisely similar mode of titration, pure recrystallised gallic acid has been found the most convenient and reliable standard, 5 c.c. of a freshly made solution of 0·1 gram per litre being titrated in place of the tannin solution. If it be desired to calculate from gallic acid to the results of the gravimetric method, the following figures may be employed, but it must be remembered that except in the case of gallotannic acid the comparison is not with a chemical individual, and the results only represent an average. 1 gram gallic acid = 1·34 gram gallotannic acid, 1·65 gram of the tanning matter of chestnut wood, 1·89 gram of that of oak wood, 1·73 gram of myrobalan, 1·69 gram of quebracho, and averaging all ordinary materials 1·76 gram. Further details are given by Procter and Hirst (*l.c.*).

Tannage of sole leather. As this is a simple and typical case of vegetable tanning it may be described in some detail. Knapp, in his classical essay on the Nature and Methods of Tanning (Natur und Wesen der Gerberei, Munich, 1858), adduces reasons for believing that leather is not an actual chemical combination of the gelatinous fibres of the hide with tannin, but rather that the action is a surface one in which they are coated with an insoluble matter which protects and makes them resistant to solvents and decay. Though this conclusion is not wholly true, it at least describes a reaction which is specially important in the case of sole leather. Whether the actual conversion of hide fibre into leather is the result of a strictly chemical combination, or of the formation of an adsorption compound, its solidification is certainly largely a case of surface-action. It has been said that both acids and alkalis swell the fibrous bundles and split them into finer fibrils, so offering a larger surface and more finely divided texture, and to produce a heavy and solid tannage it is found necessary

that this should take place either before or during the tanning process. The English sole-leather tanner usually accomplishes it by the action of lime in depilation; the American, who unhairs by sweating, has to secure it by a separate treatment with sulphuric acid, while in other cases where sulphides or low liming are the agents of depilation, it is partly accomplished by these and partly by the organic acids present in the earlier tanning liquors. The avoidance of stale or old limes is important, as they plump badly and cause serious loss of weight, but sodium sulphide is useful as shortening the process. When a hide swollen with lime is brought into tanning liquors the weak acids present rapidly neutralise the alkali, and the hide, previously plump and firm, becomes soft and flaccid and falls in thickness. If little acid is present in proportion to tannin this action takes place very gradually, and the tannin penetrates rapidly in the alkaline state of the hide, but does not tan or fix the fibre, but when it is subsequently swollen by acids a plump rapid tannage is obtained, which, however, is often deficient in colour from the tendency of the lime to form tannates which darken in drying. If, on the other hand, the hide, comparatively freed from lime, is brought into liquors where acid predominates over tannin, the tissue, at first soft and flaccid, swells gradually and combines with the tannin in an acid condition, again producing a plump leather and of good colour, since lime tannates are easily soluble in the acids present. But if, on the other hand, the unswollen hide comes into liquors which have insufficient acid to plump it, or if, having been swollen by lime, it is allowed to fall back as before described, the tannin will fix it in this fallen condition, and it will be impossible afterwards to plump it or to make thick leather.

(The free acid capable of dissolving lime tannate in a liquor is easily determined directly by adding saturated lime-water from a burette to a measured quantity of liquor, till it forms a permanent cloudiness; 10 c.c. of liquor should require from 5 to 15 c.c. Some of the acids which dissolve lime are too weak to produce any perceptible plumping effect on the pelt.)

For common sole and strap leather the first of these methods may be adopted with satisfactory results, though a previous deliming of the surface with weak solutions of boric, acetic, lactic, or some other weak acid is becoming increasingly common. If this is not done the hides or 'butts' (from which the bellies and shoulders have been trimmed in the beam-house) are simply suspended in limy water to remove the scud and loosely adhering lime, and are then brought into weak liquors, which have already lost most of their strength in previous use, and which may advantageously contain a considerable proportion of gambier, which has the property of colouring quickly without much contracting or drawing the grain. These liquors should be contained in deep pits in which the hides may be freely suspended, if possible without touching each other, and in which they may be kept in constant motion, at least for the first day, without exposure to the air, which would darken them by oxidising the alkaline tannates. This is best accomplished by suspension from frames to which an oscillating or traversing motion is given by power, but shaking frequently by hand will answer the same purpose. The butts or hides rapidly colour, and must be moved gradually forward into stronger liquors as the grain becomes set. It is difficult at this stage to state the suitable strength of liquor, since the specific gravity of these old liquors depends more on the impurities than on the tannin present, but they may range from 15° to 20° of the barkometer (sp.gr. 1·015–1·020) or even more in mixed tannage, and the liquor should contain no acids strong enough to redden methyl-orange, but should give a purplish-red to litmus paper.

If, on the other hand, it be desired to make a leather of first-rate colour and quality, the hides should be freed as perfectly as possible from lime by scudding and the use of some of the other methods already mentioned, and should come into weak liquors of oak bark, gambier, or other bright-coloured materials, which must contain a sufficient proportion of free acid to prevent entirely the rapid coloration which has been mentioned; the butts should colour much more slowly and then take rather a brown than an orange tint. This acidity may be obtained by using in the later parts of the process such materials as ferment and produce acetic and other acids, as for instance light oak bark and myrobalans, but it will sometimes be difficult to secure sufficient without the direct addition of acetic or other vegetable acid. Mineral acids, such as sulphuric and hydrochloric, must be avoided; but formic, butyric, and lactic acids are suitable, and oxalic acid may be used in small quantities to remove lime and to liberate the natural acids with which it was combined. The goods must gradually be moved into stronger liquors, but care must be taken throughout to keep the acid in excess of the tannin, so that the butts gradually plump up and remain plump, and it must be borne in mind that so far as swelling is concerned, acid and tannin are antagonistic. Putrid or stale liquors (which are often styled 'sour' but contain little or no acid) must be sedulously avoided in every sort of sole-leather tanning. The great importance of the exact 'true acidity' (H ion concentration) is more and more recognised.

In the American treatment of 'acid' sweat-leather the sides are usually slightly coloured before plumping in a sweet and moderately strong hemlock liquor, and very dilute sulphuric acid used with water only, but if the colouring and plumping are done together, a sweet fresh hemlock liquor is used with the vitriol so as to tan the grain before it is much affected by the acid. The butts receive all their plumping in this acid vat, and are then tanned in liquors which contain no vitriol. Good results are not usually attained by adding vitriol in small quantities to the 'handler liquors.'

After the colour is fully set, and the butts by whatever method are fairly plumped in the suspenders, the rest of the process is very simple. The butts are laid flat in 'handler' pits, generally with liquor only, but sometimes with a little solid dusting material as the butts get forward. In these pits the goods are handled once a day or oftener, and the liquors are constantly changed and strengthened. This (or in the

early layers) is the stage in which hemlock and other dark-coloured materials can be introduced with least injurious effect. Instead of this pit-tannage in the middle stage, drumming with much stronger liquors comes more and more into use, greatly shortening the time required, though possibly with some loss of quality; for which reason it is generally used as a secret process. When the butts are coloured quite through, they are placed in 'layers,' with stronger liquor and solid tanning material, such as mimosa bark, myrobalans, and valonia, strewed between them, and they are allowed to remain undisturbed for periods of from 1 to 6 weeks, according to the age and character of the goods and the practice of the tanner. This is repeated till the goods are fully tanned, when they are raised and drained, or sometimes washed from adhering 'dust' and strong liquor in a warm sumach or myrobalans liquor, or are 'vatted.' This process consists in suspension in a strong liquor made with bisulphited or 'bleaching' extract, or, preferably with heradol D (one of Stiarny's 'syntans'). They are then taken up into the drying lofts, where they customarily receive a slight oiling and are hung up until about half dry. They are then laid in a pile to soften and equalise the moisture ('sammed'), and the grain is struck out either by hand with the 'pin' (a two-handled knife with a triangular blade), or more generally by machine; again slightly oiled, somewhat further dried, and rolled twice and finally dried off in a warm loft. The exact dryness or 'temper' for the different operations is a matter of great importance, but is not easy to describe in writing, and it is besides somewhat influenced by the tannage. It is not uncommon to improve the colour of the grain by washing it with an aniline or other colour in the interval between striking and rolling 'off.' In place of 'striking' simple rolling with a rolling machine is coming more and more into use.

Dressing leather. Hides intended for 'shaved' hides are generally light, not exceeding 60 lbs. in raw weight; those for 'dressing' or 'common' hides may be somewhat heavier. They are unhaired with lime and bated with hen or pigeon dung, and 'shaved' hides are shaved over the thick parts of the butt with a currier's knife, the edge of which is turned in a peculiar way, and sharpened with a slender steel. They are coloured by frequent handling, or better by the use of a vat agitated by a rotatory paddle wheel, in a sweet liquor sufficiently strong to colour and set the grain in a distended condition, so that, as the inner portions swell in thickness and shrink in area from the weak acidity of the liquors, it becomes wrinkled up into a network of fine furrows. At this stage hides are often split with a reciprocating knife machine into 'grains,' which are finished in various ways, and 'fleshes,' which when good are usually 'waxed.' After this the tannage is conducted similarly to that of sole leather, but with much weaker liquors and tanning materials, selected to produce a soft and pliable leather. Any considerable acidity of the liquors which would swell the hide and produce a hard leather must be carefully avoided, while stale and so-called 'sour' liquors will soften and supplement the action of the bate, of course at the cost of a further loss of weight and firmness. In the shed, dressing hides are simply oiled and dried, but it is now more general to curry them wet out of the pits, an operation which is rather mechanical than chemical, but which consists in scouring out the bloom or deposit of ellagic acid which has formed in the surface, shaving down, and treating with oil and tallow. The 'stuffing' or impregnation with fats may be done by coating the moistened leather on one or both sides with 'dubbing,' a pasty mixture of tallow and oil of which the more liquid part is slowly absorbed; but it is now more usual to place the moistened leather in a warmed rotating drum, and run in the melted fats, which are absorbed in about 20 minutes. The mechanical processes are now almost entirely done by machines.

Enamelled, patent, or japanned leather. These names are applied to the various kinds of leather which are finished with a bright waterproof surface similar to the lacquered work of the Japanese, the first generally denoting leather so finished on the grain side, and with a grained surface. The colour is commonly, but not invariably, black. The leather may be tanned with a variety of materials, but must be well scoured and curried with but little oil or degras, and it is necessary that the hides should be well freed from grease by careful scudding before tanning, and now usually by the use of petroleum spirit or other solvents in a suitable apparatus. The skins are stretched on boards or frames, and coated with a linseed oil varnish boiled with Prussian blue, and sometimes lampblack, and other pigments. The colour of the japan is not blue, but a brown-black, and the iron of the Prussian blue acts not only as a colouring matter, but as a drier. The frames are then slid into grooves in a sort of closet heated by steam to 40°–60°, and when the coat is dry the process is repeated till the requisite thickness is obtained, each coat being smoothed with pumice before applying the next. In France and Germany the japan is frequently finally hardened in the sun, and ultraviolet rays from the mercury lamp have been successfully used for the same purpose. The American tanners are particularly skilful in treating large thin hides in this way. They are divided by the splitting machine into several thicknesses, and both the grain and flesh splits are frequently enamelled, the flesh split receiving a preliminary coating of thick boiled linseed oil and turpentine to form a sort of artificial grain. In recent times nitrocellulose solutions have been largely used to replace the whole or a part of the linseed oil composition.

Morocco, when genuine, is produced from goat-skins, but an article of equal quality is made from the rough-haired or 'blue-back' seal, and an inferior description, called 'French morocco,' from sheep-skins. The skins are unhaired by liming, puered with dog-dung, and passed through a bran drench, and are tanned with sumach, first in paddle-tumblers, and then in handlers. With sheep-skins the process is frequently much hastened by sewing them into bags, which are filled with sumach liquor and a little air, and are floated in a sumach bath and then laid on a shelf to drain and press. After a day's treatment they are again filled with a fresh sumach liquor, and this is usually

sufficient to complete the tannage. When dried, these are called 'crust-roans.' The dyeing is done either by brushing on a table, or by folding down the back, or pairing, so as to protect the flesh side as much as possible, and drawing through a dye-bath, which is generally of aniline colours or dye-woods. In more recent times the natural have been almost entirely superseded by artificial (coal-tar) colours, and the dyeing is frequently done in a paddle vat or in a drum. The grain receives a slight glaze of albumen and is polished by glazing machines by friction under agate, glass, or hard wood, and is sometimes impressed with an artificial grain by engraved or electrotyped rollers; the grain being afterwards raised or improved by the operation known as 'boarding.'

Russia leather is tanned with willow, birch, and probably other barks, and is dyed with Brazil wood grounded with stannic chloride. Its peculiar odour is due to the essential oil of birch-bark tar, which is applied during the finishing process. Many imitations made in England and on the Continent are scented by a small proportion of this, applied mixed with oil, to the flesh-side.

'Chamois' or **wash-leather** is a totally different product from those which have been already described. The ordinary article is made from the flesh-splits of sheep-skins, and is thoroughly limed so as to dissolve as much as possible of the cementing substance of the fibres, and so produce softness. The lime is then removed by a short bran-drench, and after the superfluous moisture has been pressed out, the skins are oiled on a table with fish or whale oil, folded in cushions, and worked under fulling stocks for 2 to 3 hours, and then shaken out and hung up for a short time to cool and partially dry. (In England the oil is usually gradually added during stocking.) The process is repeated again and again until the water has been entirely replaced by oil, and they are then laid in a pile in a warm place, when a sort of fermentation takes place with a considerable production of heat caused by the oxidation of the oil, and the skins take a yellow colour. The surplus oil is now removed either by pressure ('degras') or by washing with potash or soda lye, from which 'sod oil' is recovered by neutralisation with sulphuric acid. Though it is not known what chemical change takes place in the fibres, the leather is extraordinarily resistant both to boiling water, acids, and alkalis, and yields no gelatin on boiling. It has been supposed that the fibres were merely coated with oxidised oil-products, but this is negatived by the fact that the leather is unaffected by alkalis which readily dissolve oxidised oils, and it is more probable that the tannage is due to aldehydic products of the fatty acids and glycerol. Only oils of which the fatty acids have unsaturated double bonds will produce the result, and the most unsaturated are the most effective. Excellent leathers of a chamois type are produced by direct treatment with formaldehyde and some other aldehydes in a solution rendered alkaline by sodium carbonate (Payne and Pullmann's patent, 2872, 1898).

Crown leather (Preller's, or Helvetia leather). This leather, which is remarkable for its toughness, may be regarded chemically as intermediate between 'chamois' and kid, as it is produced by the action of oils and fats in conjunction with an albuminous 'filling' quite analogous to the egg-yolks and flour which are used in the kid manufacture. As the leather is employed for belting, picker straps, and other mechanical purposes, well-flayed hides of medium substance are most suitable. They are unhaired by sulphides or sweating, or by a very short liming hastened by mechanical motion, so as to lessen injury to the fibre. For the sake of appearance they are often grained and coloured by working for 1–2 hours in a paddle tumbler in a moderately strong chestnut, hemlock, or other tanning liquor. They are then swollen (if not unhaired with lime), by paddling for a few hours with about 3½ oz. of sulphuric acid per hide, washed through clean water, and hung up until half dry. They are next spread on a table and covered on the flesh with a layer of tanning paste ¼ inch thick. This may be composed of 7 parts wheat flour, 7 parts horse grease, 1 part salt, and 1–2 parts tallow. (Originally ox-brains were used in the mixture, but are not necessary.) They are then folded in bundles and are placed in a large drum studded with pegs inside, and warmed by the injection of moist air to about 30° or 40°, according to the hardness of the fats employed, in which they are worked for 8–12 hours; at the end of this time they are again partially dried and coated with the fat-mixture, and the process repeated four or five times. The hides are then washed in water, and sometimes with a little soda, and are curried by setting out on both sides, and boarding to raise the grain. The yield is only about 30–40 p.c. of the raw weight of hide.

Calf- and glove-kid. As it is impossible within the limits of this article to give working details where the greatest nicety is required in every stage of manufacture, and as the general outlines are the same in both these products, it must suffice to take them together, briefly indicating how the different qualities of each are produced; especially as calf-kid has been almost entirely superseded for shoe purposes by chrome leathers. In calf-kid considerable firmness is required, together with great pliability, whilst in glove-kid, which is made from actual kid-skins, as well as to a large extent from fine lambskins, not only the greatest softness, but the property of stretching in every direction without tendency to spring back, is essential. This characteristic difference is due partly to the different character of the skins employed, and to the fact that in the latter case special care is taken in the beam-house so to dissolve the cementing matter of the tissue that the separate fibres can move over each other without adherence. Hence the calf-skins are usually unhaired simply by a rather thorough liming, whilst the kids are treated with limes which, in addition, contain realgar (red sulphide of arsenic), which is mixed with the hot slaked lime. In each case the skin is puered, first with a bate of dogs' dung, and then with a bran drench; and in both cases, but especially in the latter, the washing and working on the beam is very thorough, since unless the fat-glands and scud are very completely got rid of, it is impossible to dye the skins uniformly and properly. The tannage is effected in a drum containing a mixture of flour, alum, salt, and egg-yolks,

with an addition of olive oil, being in principle a combination of mineral tannage with that of oil and albumen as described under 'crown leather.' After tanning, the goods, whether for shoe or glove purposes, are dried, softened by 'staking' or drawing over a blunt knife, and 'aged' by keeping at least a few weeks in a cool warehouse to fix the tan. Calf-kid is then damped and shaved on the flesh, and dyed black after grounding with a mixture of stale urine, or ammonia and potassium dichromate with logwood, sometimes by brushing, and sometimes by folding grain-side out, and passing through a bath of the dye-liquor, and the dye darkened and fixed by a wash of ferrous sulphate. The skins are then re-egged to restore the egg, &c., removed in washing and dyeing, partially dried, and then grounded with a moon-knife (a round knife with a central handle), rubbed over the grain with a mixture of wax, soap, and gum, and ironed to give them a gloss, hand labour being almost entirely superseded by machines.

In glove-kid the dyeing process is much more complicated, and most of the tannage is washed out with warm water, which necessitates a second feeding in the drum with egg-yolk and salt. The colours are produced by a great variety of dyes and mordants, among which the juices of a variety of berries may be mentioned. Aniline dyes are rarely used alone, but are frequently employed as a final wash to brighten the colour. After dyeing, the skins are wrung out or 'sleeked' out with a brass or vulcanite sleeker on a beam, dried, and again slightly damped and stretched by drawing over a blunt knife which is fixed on a post; an operation which is called 'staking.'

Mineral tanned leather. It has long been known that not only aluminium salts, but those of iron and chromium of corresponding type were capable of producing leather, and as early as 1858, Knapp described a method of chrome tanning, which is identical with one of the modern processes; but it is only within recent years that it has been realised that such leathers possess valuable properties, and especially as regards their resistance both to hot and cold water, which justify the much greater expense of chrome as compared with aluminium salts. It is quite possible to produce chrome leathers with chrome alum and salt, but practically Knapp's suggestion of forming a basic salt either by addition of sodium carbonate to the solution or in some other way is always employed in 'one-bath' tannage; while the 'two-bath' process of August Schultz, which curiously came into practical use before that of Knapp, actually produced a basic salt in the skin, by treatment with chromic acid and its subsequent reduction with acidified sodium thiosulphate. In either case the salt in the skin afterwards is rendered still more basic by 'neutralisation' with dilute solutions of borax or some other weak alkaline salt, and the leather is afterwards 'fat-liquored' with a thin emulsion of oil and soap, dyed, and subsequently dried out and softened by 'staking' by machine.

Iron leathers have never attained any commercial importance, although Knapp spent time and money in trying to develop them. Titanium and cerium salts have been shown to possess tanning properties, but are still in the experimental stage. Probably most salts which produce colloidal precipitates are capable of producing a sort of semi-mechanical tannage.

Investigations on chrome tannage have thrown much light on mineral tannages in general. It is now generally admitted that the salts are decomposed by hydrolysis, and the acid combining with one or more of the amino-groups to form a gelatine salt, and the less soluble basic ion adsorbed by the large surface of the separated fibrils. This adsorption is probably partly physical, but there is a good deal of evidence that a salt of chromium is finally formed with the gelatine carboxyl (A. and L. Lumiere and Seyewitz, Bull. Soc. chim 1903, iii, 29, 1077), containing 3·3–3·5 p.c. of Cr_2O_3 on the gelatine. Wilson also (J. Amer. Leather Chem. Assoc. 1917, 108; and Collegium (London) 1917, 105) gives strong reason to believe that an actual compound of about the same composition is formed with hide fibre, but there is no doubt that beyond this, considerable quantities of chrome oxide or a basic chrome salt may be fixed by adsorption. The gelatine compound is insoluble even in boiling water, but is decomposed by both acids and alkalis. Considerable doubt exists whether the so-called basic solutions of chrome salts are really definite salts, colloidal solutions of chrome oxide in the normal salt, or salts of complex ions. Bassett (J. C. S. 1903, 692) shows that sulphuric acid contained in the solution produced by reduction of dichromates with SO_2 no longer reacts with barium chloride. For practical purposes the basicity is estimated by hot titration with NaOH, and compounds corresponding to $CrCl_2(OH)$ are found to be suitable for sole-leather tannage, while for the finer and softer leathers they are advantageously somewhat more basic. Hydroxy-acids form complex ions with Cr which do not tan, and a solution of sodium potassium tartrate (Rochelle salt) will remove the whole of the Cr from chrome leather, while almost the whole of the tartaric acid can be recovered by suitable acidification as acid potassium tartrate (Procter and Wilson, J. Soc. Chem. Ind. 1916, 156). Lamb has also patented the use of oxalic acid for the same purpose.

For the 'one-bath' process of tanning, basic solutions are invariably employed, though soft and lightly chromed leathers can be made with normal chrome salts by the addition of sufficient common salt, but the absorption of chrome is limited to the amount rendered basic by the absorption of acid by the amino-groups of the skin itself, and the salt is necessary to prevent excessive swelling. Knapp made his basic liquor by the addition of sodium carbonate to the normal salt, Martin Dennis by dissolving chromium hydroxide in hydrochloric acid, and adding soda if necessary; and liquors suggested by Procter have been largely used in which either chrome alum solution is rendered basic by soda or bichromate is reduced in presence of a calculated quantity of acid by sugar or glucose, for which other inventors have substituted starch and glycerine. Probably the best basic liquor is that recently suggested by Procter, but apparently already in use as a trade secret by certain firms, in which bichromate is reduced

directly by gaseous sulphurous acid. If the reaction is complete the equation is

$$Na_2Cr_2O_7+3H_2SO_3 = Na_2SO_4+Cr_2(SO_4)2OH+3(H_2O)$$

but it is certainly an equilibrium reaction, and if SO_2 is present in large excess, Bassett's equation

$$K_2Cr_2O_7+4H_2SO_3=K_2SO_3+Cr_2(SO_4)_3+4H_2O$$

is probably partly justified. Practically, however, as H_2SO_3 has little swelling action on the skin, the liquor acts as if the first equation were fulfilled, and gives the same results when titrated with soda. It is thus suitable for sole leather without any addition, but for light leathers should perhaps be made slightly more basic, when it has proved very successful even for chrome-kid. It tans very rapidly, completely tanning thick hide in still suspension within 48 hours. Sodium bichromate is better than the potassium salt, since its much greater solubility enables concentrated solutions (15–18 p.c.) to be made which can be diluted as required.

Single-bath tannage can be carried out either in suspension, or more rapidly in the paddle or drum. The hides or skins are prepared much as has been described for other tannages, and are treated with liquors of increasing strength, or often of slightly increasing basicity, or very successfully, simply by using fresh packs for exhausting the liquors previously used for more advanced goods, as in the case of vegetable tannage.

In Schultz's two-bath tannage the prepared skins are first treated in an acidified solution of a bichromate, about 5 p.c. of bichromate either of soda or potash and 2½ p.c. of hydrochloric acid, or an equivalent quantity of sulphuric, being used on the weight of wet skin. When the skins are thoroughly yellow throughout they are transferred to a bath containing 10 p.c. or more of acidified sodium thiosulphate, in which the skins become bluish-green and the actual tannage takes place. The chemistry of the reduction is very complex, and sulphur is deposited on the skin.

After tannage by either method, and subsequent washing, the skins are 'neutralised' or treated with a weak alkaline solution which renders the absorbed chrome salt more basic and less soluble, and prevents the curdling of the subsequent 'fat liquor.' A weak solution of borax is generally used, but a better method invented by Stiasny consists in the use of a solution containing 4 p.c. of ammonium sulphate and 4 p.c. of crystallised sodium carbonate, of which it is best to add only 2 p.c. at first, and the rest if required. With this solution, owing to the weakness of ammonia as an alkali, and the repressing effect on its ionisation of the excess of ammonium sulphate, it is impossible to over-neutralise, which may easily occur even with borax. The activity of the bath can be restored by the addition of further quantities of soda as required.

The skins are then drummed with a fat-liquor containing a small percentage of soap and emulsified oil, and are dyed, dried out, and finished. The dyeing must take place before drying, as it is impossible so to re-wet the skins as to enable them to absorb the dye. Logwood and iron is generally used for blacks, and acid dyes for colours, as the basic dyes can only be fixed by previous mordanting with tannin.

A skin properly chromed by either process should stand boiling in water without shrinking. 'Semi-chrome,' which is vegetable tannage partially stripped of tan by alkali and re-chromed, is not nearly so resistant.

H. R. P.

LEATHER BROWN-YELLOW, CHRYSANILINE, *v.* ACRIDINE DYESTUFFS.

LECANORIC ACID (*Diorsellinic acid*)

$$C_{16}H_{14}O_7,H_2O$$

was first described by Schunck under the name of 'lecanorin,' and was isolated by him from various species of the *Lecanora* and *Variolaria* lichens. It is also present in some quantity in the *Rocella canariensis*, *R. portentosa*, *R. sinensis*, and *Parmelia perlata* (*l.c.*), and, according to Hesse (Annalen, 139, 24), is best isolated by the following method, which is a modification of that originally devised by Schunck. The finely divided lichen is extracted with ether, the extract evaporated, and the greenish-white crystalline residue treated with lime water. The solution, when neutralised with acid, gives a precipitate of lecanoric acid, which is collected and crystallised from alcohol. In case the product is not quite pure it is treated with ether, which dissolves the acid, but not the impurity.

Lecanoric acid crystallises in colourless needles, m.p. 166° (Hesse, Ber. 37, 4693), the solutions of which possess an acid reaction. With alcoholic ferric chloride it gives a dark purple coloration, and with dilute calcium hypochlorite a blood-red liquid, which, according to Hesse, is characteristic, and can be used to distinguish this substance from the known lichen acids.

Dibromolecanoric acid (Hesse, Annalen, 139, 28) $C_{16}H_{12}O_7Br_2$ consists of minute prisms, m.p. 179°, whereas *tetrabromolecanoric acid* $C_{16}H_{10}O_7Br_4$, prisms, melts at 157°.

Potassium lecanorate $C_{16}H_{13}O_7K,H_2O$; *barium lecanorate* $(C_{16}H_{13}O_7)_2Ba,5H_2O$; *calcium lecanorate* $(C_{16}H_{13}O_7)_2Ca,4H_2O$; *silver lecanorate* $C_{16}H_{13}O_7Ag$; *lead lecanorate*

$$(C_{16}H_{13}O_7)_2Pb+PbH_2O_2$$

and *copper lecanorate* $(C_{16}H_{13}O_7)_2Cu,2H_2O$ have been obtained (J. pr. Chem. [ii.] 57, 264).

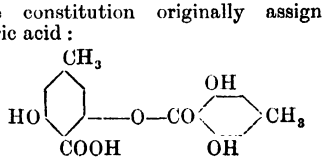
When boiled with water, lecanoric acid yields *orsellinic acid* $C_{16}H_{14}O_7+H_2O=2C_8H_8O_4$; whereas by means of boiling acetic acid or baryta water, orcin and carbon dioxide are simultaneously produced:

$$C_{16}H_{14}O_7+H_2O=C_8H_8O_4+CO_2+C_7H_8O_2$$

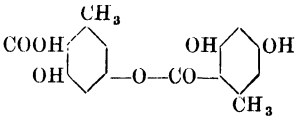
On the other hand, methyl alcohol at 85° gives, in addition to orcin and carbon dioxide, *orsellinic acid methyl ester*:

$$C_{16}H_{14}O_7+CH_3OH=C_7H_7O_2\cdot COOCH_3+C_7H_8O_2+CO_2$$

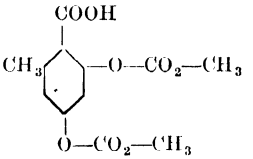
The constitution originally assigned to lecanoric acid:



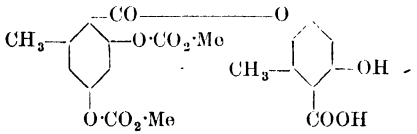
in view of the work of Heinrich (Ber. 37, 1406) on orsellinic acid, is more accurately expressed as follows:



This structure has been confirmed by the synthesis of the acid (Fischer and Fischer, Ber. 1913, 46, 1138). These authors converted *dimethyl-carbonato-orsellinic acid*:



into its chloride (m.p. 53°–56°C.) by the action of phosphorus pentachloride in presence of acetone, dissolved the product in the same solvent and gradually added a well-cooled solution of orsellinic acid in acetone and N aqueous sodium hydrate, whereby *dimethyl-carbonato-orsellinoyl-orsellinic acid*:



needles, m.p. 185°–187° C., was formed. When hydrolysed by means of aqueous caustic soda, this slowly passes into lecanoric acid, colourless needles, which softens at 170°, and is completely melted at 175°, with evolution of gas (*cf.* Hesse). The crystals when air-dried contain 1 molecule of water of crystallisation.

The identity of the product thus obtained with natural lecanoric acid was established by comparing their melting-points, colour reactions with ferric chloride, and with bleaching powder solution, and finally by converting each into *methyl-lecanorate-trimethyl-ether*, $C_{20}H_{22}O_7$.

The trimethyl-ether of methyl-lecanorate has been shown by Fischer (Ber. 1913, 46, 3253) to be identical with the product of the action of diazomethane on evernic acid.

A. G. P.

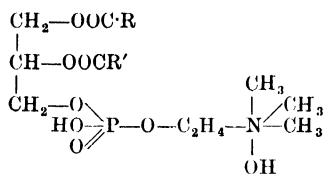
LECITHIN is a monaminomonophosphatide belonging to the group of phosphorus-containing fats known as 'lipins.' The occurrence of these complicated fats was first described by Fourcroy in 1793. Lecithin occurs in practically all animal tissues, and is intimately associated with the cell-protoplasm; indeed, it is necessary for this combination to be broken up, by treatment with alcohol or other means, before the whole of the lecithin can be extracted. The proportion of lecithin in the different tissues varies considerably; in dried ox-heart, 10 p.c. has been found; in egg-yolk, 9·5 p.c.; whilst in the spinal cord of the rabbit as much as 35 p.c. is present (Erlandsen, Zeitsch. physiol. Chem. 1907, 51, 71; Roaf and Edie, Thompson Yates Lab. Report, 1905, 201; Nerking, Biochem. Zeitsch. 1908, 10, 193). In human milk from 0·024 to 0·079 p.c. occurs; in plants, lecithin is present chiefly in the seeds. Schulze found the following proportions in leguminous plants: in beans, 0·30 p.c.; lupins, 0·37; vetches, 0·39; peas, 0·61 (Lands. Versuchstat. 1891, 269).

Preparation (MacLean, J. Path. Bact. 1914, 490).—The tissue, which should be as fresh as possible, is minced and stirred up with several times its volume of acetone or alcohol; after standing, the solid is separated by filtration through a cloth, and pressed out in a laboratory hand-press. The cake remaining is dried at room temperature under an electric fan for half an hour and then ground in a coffee mill to a fine powder. The dried powder is shaken with excess of alcohol for from 2 to 3 hours and the alcoholic layer decanted. The process is repeated four to six times, the alcoholic extracts added together and concentrated at 40° under reduced pressure. The residue is taken up with a small volume of ether and excess of acetone added; the resulting precipitate is rubbed together with a pestle and separated, redissolved in ether, and the process repeated four or five times. The precipitate is then emulsified with water by rubbing it up in a mortar, and a little sodium chloride and half its volume of acetone added; the precipitate is filtered off through a finely-perforated filter-paper and re-emulsified and reprecipitated three times. After drying by acetone, it is taken up with ether, and centrifuged, the process being repeated until a precipitate completely soluble in ether is obtained. The substance is now dissolved in alcohol and any residue allowed to settle; the decanted liquid is then filtered and the alcohol evaporated at 40° under reduced pressure; the residue is dissolved in ether and precipitated by acetone, dried by several changes of acetone, and finally *in vacuô* over concentrated sulphuric acid.

The substance commercially known as lecithin is a mixture of the two phosphatides, lecithin and kephalin, in widely varying proportions according to its method of preparation. Partial purification may be made by extraction with alcohol, lecithin being soluble in this solvent, and kephalin, the other lipin present, insoluble. Ether, unless very carefully purified, tends to increase the amount of alcohol-insoluble substance present.

In preparing lecithin from yolk of egg, Bergell (Ber. 1900, 2584) extracted the dried egg with 96 p.c. alcohol, and precipitated the mixture with an alcoholic solution of cadmium chloride at 0°; the lecithin cadmium chloride salt is suspended in alcohol, extracted with ether, and then boiled with eight times its volume of alcohol (80 p.c.) under a reflux condenser. The cadmium was removed by the addition of ammonium carbonate solution to the boiling alcoholic solution. The filtrate was cooled to −10° and the precipitate which separated was dissolved in chloroform, precipitated with acetone and dried *in vacuô* over sulphuric acid. The high percentage of choline found in certain commercial products is probably due to this method of preparation, as kephalin, the lipin which usually accompanies lecithin, forms a cadmium chloride salt soluble in alcohol and therefore not precipitated by the above method (*cf.* Lecithin, MacLean, Longmans & Co., p. 26).

Constitution.—Lecithin is represented by the formula:



where R and R′ are fatty acids residues. The glycerol forms an ester with 2 molecules of fatty acid and with phosphoric acid, the latter being also combined with choline. Considerable discussion has taken place with regard to (1) the nature of the base; (2) the nature of the fatty acids; and (3) the structure of the glycerophosphoric acid and the nature of its combination with the choline.

(1) Strecker (Ann. 1862, 353) identified the base of lecithin as choline; the amount present in lecithin obtained from different sources varies largely. Unless special means of separation are used, preparations of lecithin contain varying proportions of a second lipin, kephalin. Lecithin contains choline as its base; in kephalin the choline is replaced by β-amino ethyl alcohol (Trier, Zeitsch. physiol. Chem. 1912, 76, 496; 1913, 86, 1; Eppler, *ibid.* 1913, 87, 233; MacLean, Biochem. Zeitsch. 1913, 57, 132; Biochem. J. 1915, 351).

(2) Stearic, palmitic, oleic, and linolic acids have all been described as hydrolytic products of lecithin. The experiments have, however, been carried out with impure lecithin, and it is possible that the kephalin present is the source of the stearic and linolic acids and lecithin of the palmitic and oleic acids. The question is not finally settled (Cousin, Compt. rend. 1903, 68; J. Pharm. Chim. 1906, [vi.] 225; Serano and Palazzi, Chem. Zentr. 1911, [ii.] 772; Levene and Rolf, J. Biol. Chem. 1921, 46, 193, 353; Levene and Simms, *ibid.* 48, 185)

(3) The glycerophosphoric acid. Either the primary or secondary alcohol group of the glycerol might be esterified with the phosphoric acid, but only the ester of the secondary alcohol group would show optical activity. Bailly (Compt. rend. 1915, 160, 395) claims to have isolated both forms of glycerophosphoric acid from lecithin. The choline is regarded as combining with the glycerophosphoric acid through its alcoholic hydroxyl, an ester-like compound being obtained (Strecker, *l.c.*; Gilson, Zeitsch. physiol. Chem. 1888, 585).

Properties.—Lecithin is a yellowish waxy hygroscopic substance; soluble in almost all organic solvents except acetone and methyl acetate. Acetone precipitates it from alcoholic solution, especially in the presence of a small amount of sodium chloride. Lecithin combines with both acids and bases; it forms well-characterised addition compounds with cadmium, mercuric, and platinic chlorides. It forms compounds with proteins, and with carbohydrates, though it seems probable that the latter are not chemical entities but adsorption complexes. It is dextrorotatory; heated in a sealed tube at 100° for some time it becomes inactive. The lævo-form is left unaltered on treating the racemic form with lipase (Mayer, Biochem. Zeitsch. 1906, 1, 81; 1908, 8, 199). Lecithin is readily oxidised, and on standing in air becomes insoluble both in alcohol and in ether; the unsaturated fatty acids present are probably converted into hydroxylated derivatives, but other changes also take place. It should, therefore, be preserved *in vacuo* and in the dark. The presence of iron salts and the impurities present in commercial ether both catalyse the oxidation. Bromine and iodine are readily absorbed by the unoxidised substance (Riedel, D. R. P. 156110, 155629).

Biological properties.—Lecithin has been described as playing an important part in the phenomena of immunity. It is probable, however, that the great variety of the results obtained is due to the impurities accompanying the lecithin used in this work, and it is extremely doubtful whether pure lecithin has any antigenic function. Most of the work carried out on the biological action of lecithin has been done with impure material and is therefore of little value. It is said to act as a stimulating agent for growth (Desgrez and Zaky, Compt. rend. 1902, 1166, 1522; Hatai, Am. J. Physiol. 1904, 57). According to Overton (Studien über die Narkose, 1901, Jena) the lipin cell-membrane plays an important part in regulating the exchange of substances between the cells of the animal organism and the surrounding medium. Vernon (Biochem. Zeitsch. 1912, 47, 374; 1913, 51, 1; 1914, 60, 202) has shown that lipins play an important part in the action of the cell oxidases, the latter being rapidly destroyed by first treating the cells with certain concentrations of organic solvents. From the extent and nature of their distribution it is certain that the function of lecithin in the organism is one of primary importance, but at present we do not know what it is. I. S. M.

LECITHINASE *v.* SNAKE VENOM.

LEDITANNIC ACID, LEDUM CAMPHOR *v.* LEDUM PALUSTRE (Linn.).

LEDUM PALUSTRE (Linn.). *Marsh tea; Wild rosemary. Ledon* (Fr.); *Porsch, Sumpfporst* (Ger.); a shrub (N.O. *Ericaceæ*), some 3 feet in height, inhabiting marshes throughout the northern hemisphere. The leaves possess acrid narcotic properties, and were formerly made use of in medicine. A strong decoction is now sometimes applied in veterinary practice to destroy cutaneous parasites, and it is also employed to kill vermin in furniture. The plant has also been employed as a substitute for hops (Schmidt, Pharmaz. Chemie, 1911, [ii.] 2, 1857). The *volatile oil* obtained by distilling the leaves with water was examined by Williqk (Sitzungsber. Wien. 9, 305) and Fröhde (J. 1861, 692). Yield, 0·4–1 p.c.; $d^{15°}$ 0·932–0·963; reddish, viscid. It contains *acetic, butyric, valeric* acids, a *terpene* $C_{10}H_{16}$, boiling at 160°, an *oxygenated oil* $C_{10}H_{16}O$, perhaps *ericinol*, boiling at 240°–242°, and a camphor.

Ledum camphor $C_{15}H_{26}O$, was examined in 1796 by Rauchfuss (J. Pharm. 3, 1 and 189) and later by others, including Hjelt and Collan (Ber. 1882, 15, 2501). The camphor crystallises out abundantly when the volatile oil is placed in a freezing mixture, and may be separated and purified by recrystallisation from alcohol. It sublimes readily in needles, which melt at 104°–

105°, and boil at 282°–283°. The solution in sulphuric acid is coloured violet by a drop of nitric acid. Heated with acetic anhydride at 150° a sesquiterpene *ledene* $C_{15}H_{24}$ is obtained, which boils at 255°, and at 0° has a sp.gr. 0·9349 (Hjelt, Ber. 28, 308) (*v.* CAMPHORS).

Marsh tea contains small quantities of the glucoside *ericolin* $C_{34}H_{56}O_{31}$ (?) (Rochleder and Schwarz, Sitzungsber. Wien. 9, 308; 11, 371) a compound which occurs generally in ericaceous plants (Kawalier, *ibid.* 9, 297; Thal, J. 1883, 1402). It is an intensely bitter, yellowish-brown, sticky resin (*v.* ERICOLIN). By the action of dilute acids it breaks up into glucose and *ericinol*, $C_{20}H_{26}O$ (?). The latter compound is also a product of the action of dilute acids on pinipicrin, a glucoside occurring in the needles of the fir and other conifers (Kawalier, Sitzungsber. Wien. 11, 350; 13, 515). Ericinol is a colourless oil when first obtained, but it soon oxidises and turns brown when exposed to the air.

Leditannic acid $C_{15}H_{20}O_8$ (?) was examined by Willigk (Sitzungsber. Wien. 9, 302), Rochleder and Schwarz (*ibid.* 9, 307), Rochleder (*ibid.* 44, 493), and Thal (J. 1883, 1402). Perhaps identical with the tannin of the horse-chestnut.

G. B.

LEEK. *Allium Porrum* (Linn.). The Welsh national plant. The taste and odour are due to the presence of allyl sulphide $(C_3H_5)_2S$.

König gives the following analyses :—

	Water	Pro-tein	Fat	Sugar	Other N-free subst.	Crude fibre	Ash	Organic sul-phur
Root and bulb	87·6	2·8	0·3	0·4	6·1	1·5	1·2	0·06
Leaves .	90·8	2·1	0·4	0·8	3·7	1·3	0·8	0·06

The following shows the composition of the ash :—

Per cent. of ash in dry substance	K_2O	Na_2O	CaO	MgO	Fe_2O_3	P_2O_5	SO_3	SiO_2	Cl
Root and bulb	6·3	30·7	14·1	10·4	2·9	7·6	16·7	7·4	7·3	3·1
Leaves .	8·2	40·7	6·9	21·7	4·4	0·6	7·6	4·1	7·3	6·6

H. I.

LEGUMIN. *Vegetable casein* (*Phaseolin*). The distinctive protein of the seeds of the *Leguminosæ*, found also in some other seeds; it closely resembles in composition and in some of its properties the casein of milk. It occurs mixed with other proteins in the seeds, and is with difficulty obtained in a pure state.

Different methods of extraction—especially the use of dilute alkalis—cause alterations in the proteins of plants, and hence a good deal of confusion has arisen both as regards the nature and the names of the various proteins.

Legumin was discovered by Einhof in 1805, and has been investigated by Proust, Vogel, Boullay, Braconnot, Liebig, Dumas, and Cahours, and others, and especially by Ritthausen, and later by T. B. Osborne and his fellow-workers.

Ritthausen divided plant casein into legumin, conglutin, and gluten-casein, which differ a little from each other in their composition and in a few of their properties. The first and third he considered albuminates, and the second a plant globulin

These three forms of plant casein are, according to Ritthausen, only slightly soluble in water, but easily soluble in dilute alkaline solutions, in solutions of alkaline reacting salts, and in very dilute acids. They are precipitated from alkaline solutions by dilute acids and by rennet. Earlier investigators thought that phosphorus was an essential element. Sp.gr. 1·285-1·36 (Dittmar); specific rotation of legumin in 10 p.c. NaCl $[\alpha]_D - 44·09°$ (Osborne and Harris).

Ritthausen obtained legumin from peas, haricots, beans, lentils, vetches, &c., by the following process. The seeds are finely powdered, macerated with about eight times their weight of cold water for 6 hours, the liquid decanted and strained, and the residue again macerated with water. In some cases, notably with beans and lupins, the solution is acid, and in such cases it is desirable to add to the water used in extracting the seed sufficient potassium hydroxide to render the mixture very feebly alkaline, otherwise much less proteïd will be extracted from the seed. The strained extract is allowed to settle for some time at a low temperature, 4°, and when clear, or nearly so, decanted and precipitated with dilute acetic acid (1 : 8), adding only just sufficient acid to complete the precipitation, and keeping the temperature low. The precipitate is collected on a filter washed with 50 p.c. alcohol, which causes it to shrink and separate easily from the filter; the precipitate is then further washed and extracted with dilute alcohol, strong alcohol, and with ether; then pressed, again washed with alcohol, and dried in a vacuum over oil of vitriol.

If the product is still impure it may be purified by dissolving it in the cold in a very dilute solution of potassium hydroxide (0·1–0·2 p c.), and, after decanting from any insoluble matter, reprecipitating with dilute acetic acid.

Conglutin was obtained in a similar manner from sweet and bitter almonds and from lupins. It contains rather more nitrogen, is more glutinous, and more soluble in acetic acid than legumin, besides being completely soluble in dilute salt solution. Also, its compound with copper oxide differs a little from the legumin copper-oxide compound.

Gluten-casein was prepared from the seeds of *graminaceæ* in a very similar way.

Ritthausen formed compounds of plant casein with copper oxide by dissolving the finely powdered proteid in water containing 0·2–0·3 p.c. of potassium hydroxide, largely diluting the solution with water, and adding a solution of blue vitriol and as much caustic potash as is necessary to dissolve the precipitate first formed and give the whole solution a violet colour. The clear solution is then neutralised with dilute sulphuric acid, and the precipitate collected and washed with water till it ceases to give a reaction for sulphates.

Legumin thus treated gives a precipitate containing from 13·5 to 15·5 p.c. of CuO, and the protein is unaltered by the treatment.

Conglutin is, to a slight extent, decomposed by the treatment, and yields a compound containing about 11·6 p.c. of CuO.

Gluten-casein is but slightly altered by this treatment; but its copper oxide compound is somewhat soluble in water, and contains about 14 p.c. CuO.

The legumin obtained from several sources by Ritthausen was found by him to be partially soluble in dilute solutions of salt; but there was little or no difference in composition between

the soluble and insoluble portions. The composition of legumin and its allies, as given by Ritthausen, varies somewhat according to their source. There is no doubt that the use of alkalis in the extraction of the proteins, and also their subsequent precipitation by an acid, led to alterations in composition and properties in the proteins which has led to confusion and some erroneous results.

To T. B. Osborne, of the Connecticut Agricultural Experiment Station, and his fellow-workers, notably G. F. Campbell, S. H. Clapp, R. D. Gilbert, I. F. Harris, F. W. Heyl, and C. G. Voorhees, we are indebted for more exact knowledge of the composition and nature of legumin and other vegetable proteins. Osborne's researches began about the year 1891, and will be found, for the most part, recorded in the Journal of the American Chemical Society and the American Journal of Physiology from that date onwards. A summary of the results is given in The Vegetable Proteins, by Thos. B. Osborne, 1909, in which is a valuable bibliography of the subject.

Osborne has shown that legumin and its congeners are true globulins; he obtains legumin (and similar proteins) without the aid of alkalis. The finely ground material, peas or vetches, is extracted with petroleum naphtha to remove oil and treated with a strong solution (10–20 p.c.) of common salt. After filtering the liquid is treated with ammonium sulphate, the resulting precipitate redissolved in 10 p.c. sodium chloride solution, and the liquid dialysed free from chlorides when the protein separates in spheroids. It is washed with water and alcohol and dried over sulphuric acid.

Legumin thus prepared is insoluble in water; when freshly prepared and not dried it is readily soluble in a 10 p.c. solution of sodium chloride. After washing with alcohol and drying it becomes less soluble. A solution in 10 p.c. sodium chloride is not precipitated by saturating the solution with magnesium sulphate or with sodium chloride; nor by sodium sulphate at the ordinary temperature, but is precipitated at 34°. Saturation with ammonium sulphate at common temperatures completely precipitates it. In a salt solution, legumin is precipitated by picric, tannic, hydrochloric, nitric, sulphuric, or acetic acids, but not by mercuric chloride. It is readily soluble in dilute alkalis and alkaline carbonates.

Hammarsten (Zeitsch. physiol. Chem. 1918, 102, 85) regards the legumin of Osborne (*a*-legumin) which is soluble in dilute salt solutions as different from the insoluble legumin of Ritthausen (*b*-legumin) which appears to be an acid meta-protein. *a*-Legumin forms a compound with acid which, however, is not *b*-legumin, because the latter swells in water, giving a viscid non-filterable solution, whereas the acid compound of *a*-legumin does not swell in water, but gives a limpid milky emulsion which filters rapidly, yielding an opalescent filtrate. There are other differences which indicate that *b*-legumin is not formed by the action of acid, alkali or water, but is a distinct protein.

The monoamino-acids from legumin have been studied by Abderhalden and Barkin (Zeitsch. physiol. Chem. 1906, 47, 354).

The protein described under the name of conglutin by Ritthausen, obtained from almond and peach kernels, has been shown by Osborne to be different in some of its characters from legumin, and he has restored to it the name *amandin*, first given to it by Proust in 1802.

The name conglutin Osborne retains for the protein of lupins.

The percentage composition of some of the typical and purest preparations is as follows:—

—	Legumin from peas and beans. Ritthausen	Legumin from peas and vetches. Osborne	Conglutin or amandin from almonds. Ritthausen	Conglutin or amandin from almonds. Osborne	Conglutin from lupins. Ritthausen	Conglutin from lupins. Osborne
C .	51·5	52·1	50·4	51·3	50·8	51·0
H .	7·0	7·0	6·9	6·9	6·9	6·9
N .	17·1	18·0	18·1	19·3	18·4	18·0
S .	0·4	0·4	0·4	0·4	0·9	0·4
O .	24·0	22·5	23·7	22·0	23·0	23·7

Globulins have been found in walnuts, hazelnuts, candle-nuts (*Aleurites triloba* [Forst.]), para-nuts (*Bertholletia*), castor-oil beans, cherry kernels, plum and apricot kernels, earth nuts (*Arachis hypogæa* [Linn.]), hemp seed, cotton seed, coconuts, sunflower seeds, and several other seeds.

Ritthausen obtained the following percentages of legumin from different seeds:—French beans 11 p.c., peas 5·4–9·4 p.c., horse beans 10 p.c., Mazagan beans 18·7 p.c., and lentils 5·2 p.c. From sweet almonds he obtained 15 p.c. of conglutin, and from lupins 20 p.c.

The whole of the nitrogenous matter of these seeds is not in the form of legumin; other proteins are present. Thus field beans contain about 23 p.c., and lentils 25 p.c. of nitrogenous matter.

The products of the hydrolysis of legumin with acid and alkalis are those of the proteins generally, the nitrogen being found as ammonia, arginine, and other bases, glycine, alanine, leucine, tyrosine, phenylalanine, aspartic acid, glutamic acid, and other amino acids and tryptophan. Osborne and Harris found, on decomposing with strong hydrochloric acid, that of the total nitrogen 9·3 p.c. was obtained as ammonia, 28·4 p.c. as basic nitrogen, mainly in the forms of arginine, histidine, and lysine, and 61·4 p.c. as non-basic nitrogen.

In China and Japan a kind of vegetable cheese, known in the latter country as *tofu*, is made from the seed of the soy bean (*Glycine hispida* [Maxim.]). This leguminous seed contains about 37–40 p.c. of nitrogenous matter, and about 20 p.c. of fat, being a very concentrated food. Its globulin (glycinin) is very like legumin from peas, but contains rather more sulphur (0·8 p.c.) and rather less nitrogen (17·5 p.c.).

The cheese is made by soaking the beans in water, pounding them, and straining through a sieve, which removes most of the starch, boiling the residue with water, and straining the solution through cotton-cloth and pressing the residue. The strained liquor, containing the nitrogenous matter (legumin, &c.) and fat, is precipitated by the addition of the brine formed on the deliquescence of common sea salt; the precipitate

pressed and cut into cakes is ordinary *tofu*. It contains about 89 p.c. of water, the dry matter being nearly two-thirds nitrogenous matter and one-third fat, with small quantities of carbohydrates and ash. A drier product is obtained by freezing these cakes of cheese, and then thawing by exposure to the sun. On thawing, a large quantity of water runs off, leaving a spongy, somewhat horny residue, known as *kori-dofu*.

Analyses of these products gave the following results :—

——	Fresh tofu	Frozen tofu or kori-dofu	Dry matter from frozen tofu
Water . .	89·0	18·8	—
Ash . .	0·5	1·6	2·0
Fat . .	3·2	28·8	35·4
Nitrogenous matter .	6·5	48·8	60·1
Carbohydrates	0·8	2·0	2·5
	100·0	100·0	100·0

E. K.

LEHRBACHITE *v.* SELENIUM.

LEIPSIC YELLOW. *Normal lead chromate* (*v.* CHROMIUM).

LEITHNER'S BLUE. *Cobalt blue* (*v.* PIGMENTS).

LEMNIAN EARTH, *Terra lemnia*, or *Sphragidite*. A red, yellow, or grey earthy substance, somewhat resembling fuller's-earth, and consisting of a hydrated aluminium silicate, with more or less iron. Dana places it under the clay mineral cimolite ($2Al_2O_3 \cdot 9SiO_2 \cdot 6H_2O$). It takes its name from its occurrence at Lemnos, an island in the Grecian Archipelago, where, in consequence of its reputed medicinal virtues, it was formerly regarded as sacred. The earth was dug only once a year, with much ceremony, and, after mixture with goat's blood, was made into small cakes or balls, which were stamped with a seal by the priests, whence it was termed *terra sigillata*.

Lemnian reddle (*Rubrica lemnia*) was a red ochreous earth used as a colouring material.

L. J. S.

LEMON. The fruit of *Citrus medica* (Linn.) [*C. limonum*]. There are many varieties. König gives as the average of 33 analyses—

Mean weight of a fruit	The fruit consists of		
	Skin	Flesh	Seeds
153 grammes	38·5	59·2	2·3

The fruit contains—

Water	Invert sugar	Citric acid	Nitrogenous matter	Ash
82·6	0·4	5·4	0·7	0·6

The juice contains—

Total extract	Invert sugar	Cane sugar	Citric acid	Nitrogenous matter	Ash
10·44	1·42	0·52	5·83	0·32	0·20

The rind of Italian lemons contains—

Water	Nitrogen	Essential oil	Ash
76·38	0·23	1·01	0·52

The ash of lemons (whole fruit) contains—

K_2O	Na_2O	CaO	MgO	Fe_2O_3	Mn_3O_4	P_2O_5	SO_3	SiO_2	Cl
43·2	2·7	30·2	5·1	0·6	0·4	13·6	3·1	0 7	0·5

Boric acid, to the extent of 6 milligrammes per litre, has been detected in lemon juice (Hebebrand, 1902). Lemons are largely used, both in the form of fruit and also for the preparation of citric acid (*q.v.*) and essence of lemon (*q.v.*). Lemon juice, both in its raw and concentrated (5 to 7 times) state, is also an important commercial product. According to the British Pharmacopœia lemon juice should have a sp.gr. of 1·030 to 1·040 and 20 millilitres should require for neutralisation not less than 20 and not more than 25·7 millilitres of N/1 solution of sodium hydroxide, corresponding to a proportion of not less than 7 and not more than 9 grammes of citric acid in 100 millilitres. The residue on evaporation dried at 110° should yield not more than 3 p.c. of ash.

H. I.

LEMON-GRASS OIL *v. Verbena*, art. OILS, ESSENTIAL.

LEMON, OIL OF, *v.* OILS, ESSENTIAL.

LEMON YELLOW *v.* BARIUM CHROMATE and CHROMIUM.

LENICET. Trade name for basic aluminium acetate.

LENTILS. The seeds of *Lens esculenta* (Moench.) [*Ervum lens*]. These are small in size and are largely used as human food. They are very nutritious, but unless thoroughly cooked are difficult of digestion.

There are many varieties, differing considerably in size and also in composition.

Balland (Compt. rend. 1897, 125, 119) found the following range of variation in composition :—

Weight of 100 seeds. grammes	Water	Protein	Fat	N-free extract	Crude fibre	Ash
2·5	11·7	20·3	0·6	56·1	3·0	2·0
to 6·6	13·5	24·2	1·5	62·4	3·6	2·7

Church (Food Grains of India, 1886 and 1891) gives analyses of husked and whole lentils—

	Water	Protein	Fat	N-free extract	Crude fibre	Ash
Husked .	11·8	25·1	1·3	58·4	1·2	2·2
Unhusked .	11·7	24·9	1·5	56·0	3·6	2·3

König quotes as an analysis of the ash—

Per cent. of ash in dry substance	K_2O	Na_2O	CaO	MgO	Fe_2O_3	P_2O_5	Cl
2·07	34·8	13·5	6·3	2·5	2·0	36 3	4·6

Lentils thrive in temperate climates, and best on a dry calcareous soil; their leaves and stems, when cut in the early stages of growth, furnish nutritious food for cattle and yield a hay which is excellent for dairy cows.

H. I.

LENTIN. Trade name for *m*-phenylenediamine hydrochloride.

LENTISCUS or **LENTISK.** The leaves of *Pistacia lentiscus* (Linn.), a small shrub growing wild in Tunis. Contain from 10 to 12 p.c. of tannin and are used in admixture with sumach, the dried leaves of *Rhus coriaria* (Linn.), in tanning. For methods of detecting and estimating lentiscus in sumach, *v.* Scarlata (J. Soc. Chem. Ind. 1900, 779).

LEONITE, Kalibloedite, or Kaliastrakanite. A double salt $K_2SO_4 \cdot MgSO_4, 4H_2O$, crystallised in the monoclinic system and corresponding with bloedite ($Na_2SO_4 \cdot MgSO_4, 4H_2O$). It occurs usually in the massive form, but occasionally as tabular crystals, associated with kainite in the

Prussian salt deposits at Wilhelmshall, Westeregeln, and Leopoldshall. The artificial salt, known as kaliastrakanite, was known previously to the discovery of the natural mineral in 1896.

L. J. S.

LEPIDINE *v.* QUINOLINE

LEPIDOLITE *v.* LITHIUM, also MICA.

LEPTANDRA. *Culver's Root.* The rhizome and rootlets of *Veronica* (*Leptandra*) *virginica* (Linn.) contain a resin leptandrin. It is used as a cathartic in biliousness or constipation.

LEPTOCHLORITE *v.* THURINGITE.

LEPTOSPERMOL. A phenolic substance found in the essential oil obtained from the leaves and terminal branches of *Leptospermum flavescens.* A colourless viscous liquid, of a pleasant odour, giving with ferric chloride in alcoholic solution a brilliant orange-red coloration and an intense blue with copper salts. B.p. 145°–146°/10 mm.; 275°–278°/770 mm. $D^{20}=1{\cdot}073$, $n_D^{20}=1{\cdot}50$. Possibly identical with tasmanol found in certain eucalyptus oils (Penfold, Perf. Ess. Oil. Rec. 1921, 12, 336).

LEPTYNOL. Trade name for colloidal palladous hydroxide in sesamé oil.

LETHAL *see Spermaceti*, art. WAXES.

LETTUCE. - *Lactuca scariola* (Linn.) and other species. Several varieties are known. The leaves are eaten as a salad.

König gives as the average composition of the usual species—

Water	Nitrogenous substances	Fat	N-free extract	Crude fibre	Ash	Organic sulphur
94·3	1·4	0·3	2·2	0·7	1·0	0·01

The ash contains—

K_2O	Na_2O	CaO	MgO	Fe_2O_3	P_2O_5	SO_3	SiO_2	Cl
37·6	7·5	14·7	6·2	5·3	9·2	3·8	8·1	7·6

The juice contains potassium hydrogen citrate.

All lettuces possess slight narcotic properties, and the milky juice of certain species, especially *L. virosa* (Linn.), when evaporated, yields a brown, viscid residue which has been used in medicine under the name "lactucarium" (*q.v.*).

H. I.

LETTUCE OPIUM *v.* LACTUCARIUM.

LEUCACENE (*peri*-diacenaphthylene-rhodacene), a hydrocarbon formed when acenaphthene is distilled through a red-hot tube Forms colourless platelets or silky needles, m.p. 250°; crystallises from benzene as $4C_{54}H_{32},5C_6H_6$. When heated at 175° under reduced pressure it decomposes into acenaphthylene and rhodacene. Becomes pink on exposure to air, and yields naphthoic acid on oxidation with chromic acid (Dziewonski, Ber. 1920, 53 [B], 2173).

LEUCANILINE *v.* TRIPHENYLMETHANE COLOURING MATTERS.

LEUCINE. The name *leucine*, suitably prefixed, is given to the four following monoaminocaproic acids:—

1. *l-Leucine* (*α-amino-γ-methylvaleric acid*)
$(CH_3)_2CH{\cdot}CH_2{\cdot}CH(NH_2)CO_2H$.
2. *d-iso-Leucine* (*α-amino-β-methylvaleric acid*)
$CH_3{\cdot}CH_2{\cdot}CH(CH_3)CH(NH_2)CO_2H$.
3. *n-Leucine* (*α-amino-n-hexoic acid*)
$CH_3[CH_2]_3CH(NH_2)CO_2H$.
4. *ε-Leucine* (*ε-amino-n-hexoic acid*)
$H_2N{\cdot}CH_2[CH_2]_4CO_2H$.

With the exception of the last they all occur among the degradation products of a great many of the proteins.

l-**Leucine**, *α-amino-γ-methylvaleric acid*
$(CH_3)_2CH{\cdot}CH_2{\cdot}CH(NH_2)CO_2H$

is, next to arginine, the most widespread of the amino acids that occur in proteins. It was discovered by Proust (Ann. Chim. 1818, [ii.] 10, 40) in decaying cheese and called "oxide-caséux"; Braconnot (*ibid.* 1820 [ii.], 13, 19) isolated it from the products of the acid hydrolysis of meat, and named it leucine (λευκός) because of the glistening white crystals it forms. Mulder (J. pr. Chem. 1839, 16, 290) established the identity of the two substances and also obtained it by boiling meat with alkali and by the putrefaction of casein.

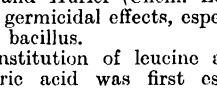
Leucine occurs in the free state in many of the organs of the animal body, in the tissues of the lung (Cloetta, Annalen, 1854, 92, 289), in the thymoid and thyroid glands and the pancreas (Gorup-Besanez, Annalen, 1856, 98, 7; Radziewsky, Zeitsch. Chem. 1866, 416), in the brain (Müller, Annalen, 1857, 103, 131); it is found in the liver and urine under certain pathological conditions (Frerich and Städeler, J. 1854, 678; 1856, 702; 1858, 550; Salkowsky, J. Thierchem. 1880, 457; Valentiner, J. 1854, 675; Sotnitschwski, Zeitsch. physiol. Chem. 1879, 3, 391); in the blood (Abderhalden, Zeitsch. physiol. Chem. 1913, 88, 478; Lippich, *ibid.* 1914, 90, 124). Leucine occurs in the pupæ of butterflies (Schwarzenbach, J. 1857, 538), in spiders and in crayfish, and also in the typhus bacillus, Tamura (Zeitsch. physiol. Chem. 1914, 89, 289). In the vegetable kingdom leucine has been found in the juice of etiolated vetch seedlings (Gorup-Besanez, Ber. 1874, 7, 146; Cossa, Gazz. chim. ital. 1876, 6, 314), also in the young green plants (Schulze, Landw. Versuchs. Stat. 1895, 46, 383); in potatoes (Schulze and Barbieri, *ibid.* 24, 167); in young pumpkin plants (Schulze and Barbieri, Ber. 1878, 11, 1233); in fungi (Winterstein, Zeitsch. physiol. Chem. 1899, 26, 438); in the pod of the broad bean (Bourquelot and Hérissey, J. Pharm. Chim. 1898, [vi.] 8, 385); and in beet juice (Erlich, Zeit. Ver. deut. Zuckerind. 1903, 571, 809).

l-Leucine crystallises in glistening white leaves, melts at 280° when rapidly heated (Trans. Guinness Res. Lab. 1903, i. 57), and has sp.gr. 1·293 in absolute alcohol at 18° (Engel and Vilmain, Bull. Soc. chim. 1874, [ii.] 22, 279). It dissolves in 46 parts of water at 18° (Schulze, Zeitsch. physiol. Chem. 1884, 9, 254); in 1040 parts of cold alcohol (96 p.c.) or in 800 parts of hot alcohol (98 p.c.) (Zollikoffer, Annalen, 1852, 82, 176); in 10·9 parts of glacial acetic acid at 16° or 29·32 parts at 117° (Habermann and Ehrenfeld, Zeitsch. physiol. Chem. 1902, 37, 18). The molecular heat of combustion is 854·9 Cal., and the heat of formation 158·4 Cal. (Berthelot and André, Compt. rend. 1890, 110, 884). Natural leucine or *l*-leucine is lævorotatory in aqueous and dextrorotatory in acid or alkali solution (Lewkowitsch, Ber. 1884, 17, 1439), and has $[\alpha]_D+15{\cdot}6°$ in hydrochloric acid solution (Ehrlich and Wendel, Biochem. Zeitsch. 1908, 8, 399); it remains unchanged on boiling with concentrated hydrochloric acid (Abderhalden and Wurm (Zeitsch. physiol. Chem 1912,

82, 167); when heated with barium hydroxide solution at 150°–160° for three days it is racemised, and the inactive leucine can be resolved by the action of *Penicillium glaucum*, yielding *d*-leucine, the rotation of which is equal in magnitude and opposite in direction to that of the lævo isomeride (Schulze and Bosshard, Zeitsch. physiol. Chem. 1886, 10, 140). *See* Schneider and Hurler (Chem. Zentr. 1914, 1, 401) for its germicidal effects, especially against the typhus bacillus.

The constitution of leucine as α-amino-γ-methylvaleric acid was first established by Schulze and Likiernik (Ber. 1891, 24, 669), who showed that the synthetic α-amino*iso*butylacetic acid (α-amino-γ-methylvaleric acid) prepared by Hüfner (J. pr. Chem. 1870, [ii.] 1, 6) by the action of ammonia and hydrogen cyanide on *iso*valeraldehyde, was identical with the inactive leucine obtained by heating natural *l*-leucine with barium hydroxide. The two compounds have the same solubility in water, 1 part in 105 at 13°; yield the same *d*-leucine when used as a culture medium for *Penicillium glaucum*, and give the same leucic acid (hydroxycaproic acid), m.p. 54·5° on treatment with nitrous acid.

Further syntheses of *r*-leucine are described by (1) Erlenmeyer and Kunlin (Annalen, 1901, 316, 145), who obtained the anhydride



of α-benzoylamino-β-*iso*propylacrylic acid by condensing hippuric acid and *iso*butyraldehyde in the presence of acetic anhydride; the corresponding acid $(CH_3)_2CH{\cdot}CH{:}C(NH{\cdot}COPh)CO_2H$ when heated with excess of ammonia solution at 150°–170° is hydrolysed, yielding *r*-leucine, *iso*valeric, and benzoic acids. (2) Bouveault and Locquin (Bull Soc. chim. 1904, [iii.] 31, 1180) from ethyl α-oximino*iso*hexoate

$$(CH_3)_2CH{\cdot}CH_2{\cdot}C(NOH)CO_2Et$$

obtained by the action of nitrosyl sulphate on ethyl *iso*butylacetoacetate; this on reduction yielded ethyl-α-amino*iso*hexoate

$$(CH_3)_2CH{\cdot}CH_2{\cdot}CH(NH_2)CO_2Et$$

from which by hydrolysis *r*-leucine was obtained. (3) Fischer and Schmitz (Ber. 1906, 39, 351) who obtained *r*-leucine from ethyl *iso*butylmalonate $(CH_3)_2CH{\cdot}CH_2{\cdot}CH(CO_2Et)_2$ by converting into the bromo derivative

$$(CH_3)_2CH{\cdot}CH_2{\cdot}CBr(CO_2Et)_2$$

hydrolysing this ester, and converting the *iso*butylbromomalonic acid thus obtained into *iso*butylbromoacetic acid

$$(CH_3)_2CH{\cdot}CH_2{\cdot}CHBr{\cdot}CO_2H$$

by distillation under reduced pressure; this on treatment with ammonia yielded *r*-leucine $(CH_3)_2CH{\cdot}CH_2{\cdot}CH(NH_2)CO_2H$.

r-Leucine has been resolved into *d*- and *l*-leucine by the fractional crystallisation of certain alkaloid salts of the benzoyl and formyl derivatives (*q.v.*) (Fischer, Ber. 1900, 33, 2370; Fischer and Warburg, *ibid.* 1905, 38, 3997).

Derivatives. *Salts.—Mercury salt*

$$(C_6H_{12}O_2N)_2Hg$$

formed by dissolving mercuric oxide in a solution of leucine (Gössmann, Annalen, 1854, 91, 134); *lead salt* $(C_6H_{12}O_2N)_2Pb,H_2O$ crystallises in leaves (Strecker, Annalen, 1849, 72, 90); *copper salt* $(C_6H_{12}O_2N)_2Cu$, small light blue crystals, soluble in 3045 parts of cold or 1460 parts of boiling water (Hofmeister, Annalen, 1877, 189, 16). The salts with acids are readily soluble; the two *hydrochlorides* $C_6H_{12}O_2N,HCl$ and $(C_6H_{12}O_2N)_2,HCl$ are described (Laurent and Gerhardt, Ann. Chim. Phys. [iii.] 34, 321; Schwanert, Annalen, 1857, 102, 222); the *nitrate* $C_6H_{12}O_2N,HNO_3$ (Laurent and Gerhardt); the *platinichloride* $(C_6H_{12}O_2N)_2,H_2PtCl_6$ forms a yellow crystalline precipitate; dl-*leucine picrolonate* $C_{10}H_8O_5N_4{\cdot}C_6H_{13}O_2N$ crystallises in long, narrow, greenish-yellow prisms which become yellow when dry; they soften at 130° and melt at about 150° (decomp.), Abderhalden and Weil (Zeitsch. physiol. Chem. 1912, 78, 150. Levene and van Slyke, J. Biol. Chem. 1912, 12, 127, obtained rosettes of six-sided crystals); natural leucine picrolonate crystallises into a mixture of long, slender and rhomboid crystals, Levene and van Slyke (*l.c.*).

Anhydride $(C_6H_{12}ON)_2O$, m.p. 272°, obtained together with its *dibenzoyl* derivative

$$(C_6H_{11}ON{\cdot}C_7H_5O)_2O$$

m.p. 80°, by the action of benzoyl chloride on leucine at 100° (Destrem, Compt. rend. 1378, 86, 484; *cf.* Graves, Marshall and Eckweiler, J. Amer. Chem. Soc. 1917, 39, 112). *The potassium salt of trimethylleucine iodide*

$$C_5H_{10}(NMe_3I)CO_2K$$

hygroscopic slender needles obtained by the action of methyl iodide and potassium hydroxide on leucine; the corresponding *chloro* compound forms a yellow *aurichloride*

$$C_6H_{11}O_2NMe_3Cl{\cdot}AuCl_3$$

m.p. 163°, and an orange-yellow *platinichloride* $(C_6H_{11}O_2NMe_3Cl)_2PtCl_4$ (Koener and Menozzi Gazz. chim. ital. 1883, 13, 351).

Leucinimide (3:6-di*iso*butyl-2:5-diketopiperazine) $NH<\begin{matrix}CH(C_4H_9)CO\\CO{\cdot}(C_4H_9)HC\end{matrix}>NH$, m.p. 271° (corr.), yields *leucyl-leucine*

$$NH_2{\cdot}CH(C_4H_9)CO{\cdot}NH{\cdot}CH(C_4H_9)CO_2H$$

on hydrolysis, this crystallises with $1\frac{1}{2}H_2O$, and melts slightly above 270° (Cohn, Zeitsch. physiol. Chem. 1900, 29, 283; Fischer, Ber. 1900, 33, 2370; 1902, 35, 1095; Salaskin, Zeitsch. physiol. Chem. 1901, 32, 592). *l-Leucine methyl ester* has b.p. 79°–79°·5/12 mm., D^{17} 0·9533 and $[\alpha]_D^{17}+16·53°$ (Abderhalden and Spinner, Zeitsch. physiol. Chem. 1919, 107, 1) *Ethyl ester* of *r-leucine* has b.p. 83·5°/12 mm., sp.gr. 0·929 at 17°; the *picrate* has m.p. 136° (corr.), and the *d-tartrate*, m.p. 145° (corr.); the *ethyl ester* of *l-leucine* has $[\alpha]_D^{20°}+13·1°$, and is not racemised on hydrolysis; it forms a *picrate*, m.p. 129·5° (corr.) (Fischer, Ber. 1901, 34, 433; *cf.* Röhmann, *ibid.* 1897, 30, 1978). When the ethyl ester of *r*-leucine is left in contact with water and crude pancreatin, it undergoes asymmetric hydrolysis, that is, the *l*-ester is hydrolysed, whilst the *d*-ester is not (Warburg, Ber. 1905, 38, 187). *n-Propyl ester* of *leucine*

has b.p. 95°–96°/12 mm. (Warburg, Zeitsch. physiol. Chem. 1906, 48, 205).

r-Leucinamide $C_6H_{14}ON_2$, m.p. 106°–107° (corr.), is prepared by the action of liquid ammonia on the ethyl ester; the *β-naphthalene sulphonyl derivative* has m.p. 176°–178° (corr.); and *carbethoxy-dl-leucinamide* $C_9H_{18}O_3N_2$, m.p. 108°, readily yields *β-iso*butylhydantoin by shaking with sodium hydroxide (Koenigs and Mylo, Ber. 1908, 41, 4427).

The *ethyl ester* of *l-leucinecarbimide*

$$CO:N{\cdot}CH(CO_2Et)CH_2{\cdot}CHMe_2$$

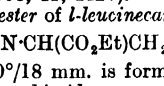
b.p. 120°–130°/18 mm. is formed together with *diethyl leucinecarbimide*

$$CO[NH{\cdot}CH(CO_2Et)CH_2{\cdot}CHMe_2]$$

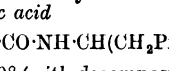
b.p. 180°–190°/18 mm. by the action of carbonyl chloride on the ethyl ester of leucine; *isobutylhydantoic acid*

$$NH_2{\cdot}CO{\cdot}NH{\cdot}CH(CH_2Pr^{\beta})CO_2H$$

m.p. 200°–210° (with decomposition) is obtained by dissolving leucine in excess of carbamide at 130°–135°, and yields *isobutylhydantoin*



m.p. 200°–210°, when heated at 150°; the *ethyl ester* of *isobutylhydantoic acid* is obtained by the action of ammonia on the ethyl ester of *l*-leucinecarbimide, and this on hydrolysis yields the free acid identical with the substance obtained by the action of carbamide on leucine; when aniline is substituted for ammonia the *acid* $NHPh{\cdot}CO{\cdot}NH{\cdot}CH(CH_2Pr^{\beta})CO_2H$ is obtained, m.p. 115° (Hugounenq and Morel, Compt. rend. 1905, 140, 150, 505, 859). *Leucine phenylthiohydantoin*



, m.p. 178°, is formed by the interaction of leucine and phenyl mustard oil in the presence of potassium hydroxide, and its formation affords a convenient method of isolating leucine from the crude material obtained by hydrolysing proteids (Röhman, Ber. 1898, 31, 2188).

Phthalylaminocaproic acid $C_{14}H_{15}O_4N$, prepared by fusing a mixture of phthalic anhydride and leucine, has m.p. 115°–116°; it is lævorotatory, and is converted into the racemic isomeride on dry distillation; the *platodiammonium salt* $Pt(NH_2{\cdot}NH_2C_{14}H_{15}ON)_2$ of the active acid contains $3H_2O$, that of the inactive acid $3\frac{1}{2}H_2O$. *Leucinephthaloic acid*

$$CO_2H{\cdot}C_6H_4{\cdot}CO{\cdot}NH{\cdot}CH(CO_2H)CH_2{\cdot}CHMe_2$$

is obtained by the partial hydrolysis of the preceding compound, the active acid melts and decomposes at 130°–137°, forming phthalylaminocaproic acid; the *potassium salt*

$$K_2C_{14}H_{15}O_5N$$

is crystalline and readily soluble; the *sodium salt* is amorphous; the *barium salt* is crystalline and sparingly soluble; the *platodiammonium salt* forms soluble rhombic plates; the amorphous *copper salt* is soluble in alcohol; the inactive *leucinephthaloic acid* has m.p. 152°–153°, and forms a crystalline *potassium* and an amorphous *silver salt* (Reese, Annalen, 1887, 242, 1; Ber. 1888, 21, 277). The *benzene sulphonic* derivative

$$SO_2Ph{\cdot}HN{\cdot}C_5H_{10}{\cdot}CO_2H$$

of *r*-leucine sinters at 140°, melts at 146° (corr.), and forms soluble crystalline alkali salts, and sparingly soluble lead and silver salts; the corresponding derivative of *d*-leucine crystallises in needles, m.p. 119°–120° (corr.), and has $[\alpha]_D^{20}-39°$ (Fischer, Ber. 1900, 33, 2370; 1901, 34, 449).

Benzoyl-r-leucine

$$(CH_3)_2CH{\cdot}CH_2{\cdot}CH(NH{\cdot}COPh)CO_2H$$

m.p. 137°–141° (corr.), can be resolved by means of its alkaloid salts, the cinchonine salt of the *d*- and the quinidine salt of the *l*-isomeride being sparingly soluble. *Benzoyl-d-leucine* melts at 105°–107° (corr.), dissolves in 120 parts of boiling water and has $[\alpha]_D^{20}-6{\cdot}39°$ in sodium hydroxide solution. *Benzoyl-l-leucine* melts at 105°–107° (corr.), has $[\alpha]_D^{20}+6{\cdot}59°$ (Fischer, Ber. 1900, 33, 2370).

Formyl-r-leucine

$$(CH_3)_2CH{\cdot}CH_2{\cdot}CH(NH{\cdot}CHO)CO_2H$$

forms octahedra, m.p. 115°–116° (corr.); *see* Galeotti (Biochem. Zeitsch. 1913, 53, 485) for the condensation of *r*-leucine with formaldehyde; *formyl leucylchloride*

$$C_4H_9{\cdot}CH(NH{\cdot}CHO)COCl$$

is a crystalline powder. The *brucine* salt of formyl-*d*-leucine is sparingly soluble, and yields on decomposition *formyl-d-leucine*, crystallising in long thin prisms, m.p. 141°–144° (corr.), $[\alpha]_D^{20}$ +18·8° in 10 p.c. alcoholic solution. *Formyl-l-leucine* obtained from the more soluble leucine salt has the same melting-point as the *d*- compound and $[\alpha]_D^{20}-18{\cdot}5°$. *p-Toluenesulphonyl-l-leucine*, m.p. 124°, $[\alpha]_D^{20}+4{\cdot}50°$ in alcoholic solution, yields *p-toluene-sulphonyl-l-N-methyl-leucine* $CHMe_2{\cdot}CH_2{\cdot}CH(NMe{\cdot}SO_2C_7H_7){\cdot}COOH$, m.p. 91–92°, $[\alpha]_D^{18}-21{\cdot}12°$, and this on hydrolysis gives *l-N-methyl-leucine*, $[\alpha]_D^{21}+20{\cdot}76°$ in aqueous solution, it sublimes in needles when carefully heated and yields a crystalline nitrate and hydrochloride and the copper salt

$$C_{14}H_{28}O_4N_2Cu,H_2O$$

forms four or six-sided plates. Fischer and Lipschitz (Ber. 1915, 48, 360). Leucine heated with diphenylmethane at 170°–180° yields cycloleucylleucine, Graziani (Atti. R. Accad. Lincei, 1915 [5], 24, 1, 822); Maillard, Ann. Chim. 1915 [9], 3, 48). For a description of the numerous *polypeptides* containing the leucyl radicle, *see* Fischer and Bargell, Ber. 1903, 36, 2592; Fischer and Brunner, Annalen, 1905, 340, 142; Fischer and Warburg, *ibid.* 152; Fischer and Koelker, *ibid.* 172; Fischer, Ber. 1905, 38, 2914; 1906, 39, 2893; Fischer and Steingroever, Annalen, 1909, 365, 167; Fischer and Gerngross, Ber. 1909, 42, 1485; Fischer and Gluud, Annalen, 1909, 369, 247; Fischer and Fielder, *ibid.* 1910, 375, 181; Abderhalden and Hirszowski, Ber. 1908, 41, 2840; Abderhalden, *ibid.* 1909, 42, 2331; Abderhalden, Hirsch, and Schuler, *ibid.* 1909, 42, 3394; 1910, 43, 907; Abderhalden and Weber, *ibid.* 1910, 43, 2429; Hans Fischer, *ibid.* 1909, 42, 4320; Krause,

Monatsh. 1908, 29, 1119; Hopwood and Weizmann, Chem. Soc. Trans. 1911, 99, 574, 1579; Abderhalden and Fodor, *ibid.* 1916, 49, 561; Zeitsch. physiol. Chem. 1912, 81, 1; Ber. 1916, 49, 561; Weizmann and Hopwood, Proc. Roy. Soc. 1913, A, 88, 455.

For the preparation and properties of the corresponding amino-alcohol and choline from leucine, *see* Karrer, Karrer, Thomann, Horlacher and Mäder (Helv. Chim. Acta, 1921, 4, 76).

Decomposition.—Experiments conducted on dogs show that leucine, like other amino acids, can replace ammonium salts in the formation of urea (Salaskin, Zeitsch. physiol. Chem. 1898, 25, 128). Leucine as well as tyrosine is assimilated by certain plants such as *Algæ* (Loew and Bokorny, J. pr. Chem. 1887, [ii.] 36, 279; Schulze, Landw. Versuchs. Stat. 1901, 56, 97), *Cucumis* species *Aspergillus niger*, *A. repens*, *Penicillium glaucum* (Lutz, Compt. rend. 1905, 140, 380; Petrov, Bull. Agr. Intelligence, 1914, 5, 210). Yeast poor in nitrogen develops rapidly in a sugar solution containing leucine; when racemic leucine is employed the fermentation proceeds at the expense of both optical isomerides, but the natural *l*-leucine is destroyed much more rapidly than the *d*-leucine, which can thus be recovered to the extent of 76 p.c. of the theoretical quantity at the end of the reaction (Ehrlich, Zeit. Ver. deut. Zuckerind, 1906, 608, 840). The degradation of amino acids in the plant and animal economy appears to be deamidisation and oxidation of the terminal carbon atom (Sachs, Biochem. Zeitsch. 1910, 27, 27), this would lead in the case of leucine to the formation of ammonia and amyl alcohol; and Ehrlich (Ber. 1906, 40, 1027) is of opinion that the occurrence of fusel oil during alcoholic fermentation is due to the hydrolysis of *l*-leucine and *d-iso*leucine according to the equations:

$$CHMe_2{\cdot}CH_2{\cdot}CH(NH_2)CO_2H+H_2O = CHMe_2{\cdot}CH_2{\cdot}CH_2{\cdot}OH+CO_2+NH_3$$

$$CHMeEt{\cdot}CH(NH_2)CO_2H+H_2O = CHMeEt{\cdot}CH_2{\cdot}OH+CO_2+NH_3$$

On oxidation with hydrogen peroxide leucine yields *iso*valeraldehyde, *iso*valeric acid, ammonia and carbon dioxide; on further oxidation acetone is formed from *iso*valeric acid, the reaction closely resembling several biochemical reactions in which leucine takes part (Dakin, J. Biol. Chem. 1908, 4, 63).

By the action of nitrous acid leucine is converted into leucic acid (α-hydroxy*iso*hexoic acid) (Strecker, Annalen, 1848, 68, 55); and on reduction with hydriodic acid yields caproic acid and ammonia (Hüfner, Zeitsch. Chem. 1868, 391). *l*-Leucic acid sinters at 78° and melts at 81°–82°, $[\alpha]_D^{20}-27{\cdot}8°$ in alkaline solution; *d*-leucic acid melts at 80° and has $[\alpha]_D+26{\cdot}3°$ in alkaline solution (Scheibler and Wheeler, Ber. 1911, 44, 2684).

Separation and *detection.*—A mixture of leucine and tyrosine is readily separated by the aid of boiling glacial acetic acid in which the leucine is fairly (29·23 at 117°) and the tyrosine very sparingly soluble (0·18 at 117° (Habermann and Ehrenfeld, Zeitsch. physiol. Chem. 1902, 37, 18). To separate tyrosine, leucine, and valine, Levene and Jacobs (Biochem. Zeitsch. 1908, 9, 231) recommend the following method. The mixture is treated with bromine, and the bromo derivative of the tyrosine removed by means of amyl alcohol; the valine and leucine are crystallised from the mother liquor, redissolved, and the leucine precipitated by lead acetate and ammonia. On decomposing the lead precipitate with sulphuretted hydrogen, leucine and *iso*leucine are obtained and can be separated by extracting the copper salts with methyl alcohol in which the copper derivative of *iso*leucine is soluble. Glutamic acid and leucine can be separated by saturating the solution with hydrogen chloride when the insoluble hydrochloride of glutamic acid is precipitated (Étard, Compt. rend. 1901, 133, 1231).

Leucine heated with dilute sulphuric acid and potassium bichromate gives a characteristic smell not given by other monoamino acids (Mörner, Zeitsch. physiol. Chem. 1913, 88, 152).

Like other α-amino carboxylic acids leucine gives a blue colour if carefully treated with triketohydrindenehydrate in alkaline solution (Abderhalden and Schmidt, *ibid.* 1911, 72, 37–43, and *ibid.* 1913, 85, 146).

In order to test for small traces of leucine the uramine reaction may be used and typical crystals of *iso*butyl hydantoic acid obtained (Lippich, Zeitsch. physiol. Chem. 1914, 90, 148; *see* also Ber. 1906, 39, 2953).

***d-iso*Leucine**, *α-amino-β-methylvaleric acid* $CH_3{\cdot}CH_2{\cdot}CH(CH_3)CH(NH_2)CO_2H$ was discovered by Ehrlich (Zeit. Ver. deut. Zuckerind. 1903, 571, 809; Ber. 1904, 37, 1809) in the mother liquor of the beet sugar manufacture to which the strontia desaccharification process had been applied; it is separated from the *r*- and *l*-leucine that occur with it by the aid of its copper salt which dissolves freely in methyl alcohol, the corresponding salt of leucine being only sparingly soluble. *iso*Leucine has also been isolated from the products of hydrolysis obtained by digesting blood fibrin with pancreatic juice, from the hydrolytic products of ovalbumin, from the crude leucine obtained by the putrefaction of beef (Ehrlich, *l.c.*); and from the products of hydrolysis of casein (Weitzenböck, Monatsh. 1906, 27, 831). It is probable indeed that *d-iso*leucine occurs invariably along with *l*-leucine as a primary product of proteid hydrolysis (Ehrlich, *l.c.*; Ehrlich and Wendell, Biochem. Zeitsch. 1908, 8, 399).

*d-iso*Leucine crystallises in shining rods or leaflets, which melt and decompose at 280° when heated in a closed tube; it has $[\alpha]_D^{20}+9{\cdot}74°$ in aqueous, $+36{\cdot}80°$ in 20 p.c. hydrochloric acid, or $+11{\cdot}1°$ in alkaline solution, and dissolves in 25·84 parts of water at 15·5°, the solution having a bitter taste. It is completely racemised and partially converted into *alloisoleucine* after heating for 20 hours at 180° with barium hydroxide solution (Ehrlich, Ber. 1904, 37, 1809).

Locquin (Bull. Soc. chim. 1907, [iv.] 1, 595, 601) finds slightly different physical constants for the synthetic *d*- and *l-iso*leucine; both compounds crystallise from water in brilliant spangles, and have m.p. 280°–290°; *l-iso*leucine has $[\alpha]_D^{20}-10{\cdot}55°$ in aqueous, $-31{\cdot}37°$ in dilute or $-40{\cdot}86°$ in concentrated hydrochloric acid solution, and *d-iso*leucine has $[\alpha]_D^{20}+11{\cdot}29°$ in aqueous or $+40{\cdot}61°$ in concentrated hydrochloric acid solution.

When *d-iso*leucine is subjected to dry distilla-

tion it yields partially racemised *d*-amylamine $CH_3{\cdot}CH_2{\cdot}CH(CH_3)CH_2{\cdot}NH_2$, together with *iso*-leucinimide; and it is decomposed by yeast growing in a sugar solution to form *d*-amylalcohol

$$CH_3{\cdot}CH_2{\cdot}CH(CH_3)CH(NH_2)CO_2H+H_2O = CH_3{\cdot}CH_2{\cdot}CH(CH_3)CH_2{\cdot}OH+NH_3+CO_2$$

It follows, therefore, that *iso*leucine is α-amino, β-methylvaleric acid, and this view of its constitution is confirmed by various synthetic preparations. (1) Bouveault and Locquin (Compt. rend. 1905, 141, 115) prepared an inactive leucine from ethyl *sec*butylacetoacetate

$$CHMeEt{\cdot}CHAc{\cdot}CO_2Et$$

this yields ethyl α-oximino-*sec*butylacetate (α-oximino-β-methylvalerate)

$$CHMeEt{\cdot}C(NOH){\cdot}CO_2Et$$

by the action of nitrosylsulphate, which on reduction is converted into the inactive leucine $CHMeEt{\cdot}CH(NH_2)CO_2H$. On resolving this compound by the fractional crystallisation of the brucine salt of its formyl derivative, *d-iso*-leucine was obtained, identical with Ehrlich's natural product (Locquin, Bull. Soc. chim. 1907, [iv.] 1, 595, 601). (2) Ehrlich (Ber. 1907, 40, 2538) synthesised *iso*leucine from *d*-amyl-alcohol $CHMeEt{\cdot}CH_2{\cdot}OH$, by the following series of reactions, the *d*-amyl alcohol was oxidised to *d*-valeraldehyde $CHMeEt{\cdot}CHO$, which was converted by the action of ammonia and hydrogen cyanide into aminovaleronitrile $CHMeEt{\cdot}CH(NH_2)CN$, and this, on hydrolysis, gave a mixture of *d-iso*leucine and *alloisoleucine* $CHMeEt{\cdot}CH(NH_2)CO_2H$. Allo*iso*leucine is a stereoisomide of *iso*leucine, which contains two asymmetric carbon atoms; it closely resembles *iso*leucine in its external appearance, and in the properties of its derivatives; it has, however, a sweet taste, is lævorotatory, $[\alpha]_D^{20}-14{\cdot}4°$ in aqueous and $-36{\cdot}95°$ in hydrochloric acid solution; and it dissolves in 34·2 parts of water at 20°. (3) Using Fischer's method (Ber. 1906, 39, 351), Ehrlich (*ibid.* 1908, 41, 1453) has synthesised racemic *iso*leucine from secondary butyl iodide and ethyl malonate; on hydrolysing the condensation product of these two compounds, Romburgh's *sec*butylmalonic acid is obtained; this on bromination yields bromo-*sec*butylmalonic acid $CHMeEt{\cdot}CBr(CO_2H)_2$, which decomposes when distilled under reduced pressure yielding α-bromo-β-methylvaleric acid

$$CHMeEt{\cdot}CHBr{\cdot}CO_2H$$

on treating this compound with ammonium hydroxide it is converted into racemic *iso*leucine, m.p. 275° in a closed tube. The same synthesis was made by Brasch and Friedmann (Beitr. Chem. Physiol. Path. 1908, 11, 376).

Derivatives. *Salts.*—*d*-iso*Leucine-hydrochloride* forms stellate needles; the *copper salt* $C_{12}H_{22}O_4N_2Cu$ is deep blue and crystalline, dissolves in 278 parts of water at 17°, in 476 parts of 99 p.c. alcohol, and in 55 parts of methyl alcohol at 17°; the *silver salt* is white flocculent and crystalline; the *lead salt* is strongly lævorotatory; *d*-iso-*leucine picrolonate*, forms long, slender, six-sided crystals grouped in stars, m.p. about 170°, $[\alpha]_D^{20}+32{\cdot}8°$ (Levene and van Slyke, J. Biol. Chem. 1912, 12, 127).

Acyl derivatives of (1) *r-iso*leucine, the *formyl* derivative has m.p. 121°–122°; the *benzoyl* derivative has m.p. 79°, and b.p. 211°/15 mm.; the *benzenesulphonyl* derivative has m.p. 169°; and the *p-toluenesulphonyl* derivative has m.p. 139°. (2) *d-iso*Leucine, *formyl* derivative forms fine translucent crystals from water, m.p. 156°-157°, $[\alpha]_D^{20}+28{\cdot}26°$; *benzoyl* derivative, m.p. 116°–117°, $[\alpha]_D^{20}+26{\cdot}36°$ in alkaline solution; *benzenesulphonyl* derivative, m.p. 149°–150°, $[\alpha]_D^{20}-12{\cdot}04°$ in alkaline solution; the *phenylisocyanate*, m.p. 119°–120°, $[\alpha]_D^{20}+14{\cdot}92°$ in alkaline solution; the *phenylhydantoin* has m.p. 78°–79°; *leucinimide* (*iso*-2 : 5-*diketo*-3 : 6-*diisobutylpiperazine*)

$$CHMeEtCH<\begin{matrix}CO{\cdot}NH\\NH{\cdot}CO\end{matrix}>CH{\cdot}CHMeEt$$

forms slender needles, m.p. 280°–281°, and is slightly dextrorotatory in alcoholic solution. (3) *l-iso*Leucine, *formyl* derivative has m.p. 156°–157°, and has $[\alpha]_D^{20}-27{\cdot}76°$ in alcoholic solution; the *benzoyl* derivative has m.p. 118° and $[\alpha]_D^{20}-26{\cdot}03°$ in *N*/2 sodium hydroxide. For the description of *polypeptides* containing the *iso*leucine radicle, *see* Abderhalden, Hirsch, and Schuler, Ber. 1909, 42, 3394; 1910, 43, 907.

n-**Leucine**, *α-amino-n-hexoic acid*

$$CH_3[CH_2]_3CH(NH_2)CO_2H$$

has not been isolated from the products of hydrolysis of proteins, but *n*-valeric acid is formed when casein is oxidised by bromine (Skraup and Witt, Monatsh. 1906, 27, 663), and this suggests the presence of *n*-leucine in casein. Further evidence in favour of this suggestion was obtained by Heckel (Monatsh. 1908, 29, 15), who found that by oxidising with potassium permanganate that fraction of the leucine esters from casein least soluble in hydrochloric acid, a mixture of acids was obtained about one half of which was *n*-valeric acid. Samec (Monatsh. 1908, 29, 55) also obtained a similar result, using the leucine obtained from the neck band of the ox. Kudielka (Monatsh. 1908, 29, 351) has prepared *n*-leucine by Fischer's method (Ber. 1900, 33, 2320) from both natural and synthetic *n*-hexoic acid, using Kahlbaum's preparation; 100 parts of the former gave 37 parts of *n*-leucine, whilst 100 parts of the latter gave only 6 parts. Racemic *n*-leucine melts at 290° (corr.) in a closed tube. The *copper* salt forms pale blue leaflets, the *nickel* salt is greenish-blue, the *cobalt* salt crystallises in red leaflets; the methylated base yields a yellow *aurichloride* $C_9H_{19}O_2N,HAuCl_4$, m.p. 142°.

The resolution of racemic *n*-leucine has been effected by Fischer and Hagenbach (Ber. 1901, 34, 3764) by the fractional crystallisation of the cinchonine salt of the benzoyl derivative. The *benzoyl* derivative of racemic *n*-leucine has m.p. 134° (corr.); l-*benzoyl*-n-*leucine* crystallises with $\frac{1}{2}H_2O$, has m.p. 53° (corr.), and $[\alpha]_D^{20}-21{\cdot}9°$ in aqueous solution; lævo n-*leucine* prepared from this has $[\alpha]_D-22{\cdot}4°$; *d-benzoyl*-n-*leucine* has $[\alpha]_D+21{\cdot}4°$, and dextro n-*leucine* has $[\alpha]_D+21{\cdot}3°$. l-n-*Leucine picrolonate* softens at 145° and melts at 150°, it has $[\alpha]_D^{20}+19{\cdot}6°$ (Levene and van Slyke, J. Biol. Chem. 1912, 12, 127).

Marko (Annalen, 1908, 362, 333) has similarly

separated *d-* and *l-* *n*-leucine from the racemic compound by crystallising the brucine salt of the formyl derivative of the racemic compound. *r-Formyl*-n-*leucine* has m.p. 113°–115° (corr.); *l-formyl*-n-*leucine* has m.p. 115°–118·5° (corr.), and $[\alpha]_D^{20}$ −17·56°; *lævo* n-*leucine* has $[\alpha]_D^{20}$ −22·99° *d-formyl*-n-*leucine* has $[\alpha]_D^{20}$ +17·63°, and yields *dextro* n-*leucine* $[\alpha]_D^{20}$ +23·14°.

ψ-Leucine has been obtained from the oxime of trimethylpyruvic acid $C_6H_{11}O_3N,H_2O$, by reduction with zinc dust and 50 p.c. acetic acid or with aluminium amalgam in 50 p.c. alcohol; it forms hard laminar crystals that begin to sublime at 250°. The *naphthalenesulphonyl* derivative has m.p. 200°–203°; the *p-toluenesulphonyl* derivative has m.p. 226°; and the *nitrate* has m.p. 151° (Knoop and Landermann, Zeitsch. physiol. Chem. 1914, 89, 157). M. A. W.

LEUCITE. A volcanic mineral consisting of potassium aluminium silicate $KAl(SiO_3)_2$, found as grey crystals with the external form of the cubic icositetrahedron (211). Optical examination of the crystals in thin sections shows them to be birefringent and to consist of a complex intergrowth of twin-lamellæ. At a temperature of 714° the material is optically isotropic and truly cubic, and in the red-hot lavas it, no doubt, grew as a cubic crystal. Sp.gr. 2·47; H. 5½. The mineral occurs abundantly as embedded crystals in the alkali-rich lavas of certain districts, *e.g* Vesuvius, Rome, the Eifel, and the Leucite Hills in Wyoming. Other localities are in Montana, Arkansas, Brazil, Sardinia, Bohemia, Trebizond in Asia Minor, Kilimanjaro in Africa, Cape Verde Islands, Java, Borneo, Celebes, New South Wales, Siberia. It is decomposed by hydrochloric acid, and is readily affected by weathering processes. Containing a considerable amount of potash (K_2O, 21·5 p.c.), attempts have been made to employ this mineral as a source of potassium salts and as a fertiliser. The leucite-bearing rocks of Wyoming contain K_2O 7·99–11·91 (average 10·74) p.c., which is present partly in other minerals besides the leucite, such as mica and orthoclase (*v.* A. R. Schultz and W. Cross, Potash-bearing rocks of the Leucite Hills, Wyoming, Bull. U.S. Geol. Survey, 1912, No. 512). A review, with a full bibliography, of the many attempts that have been made to extract potash from the leucite lavas of Italy is given by H. S. Washington, Metall. Chem. Engin. Jan. 15, 1918. L. J. S.

LEUCOLINE. Syn. for Quinoline.

LEUCOMAÏNES *v.* PTOMAÏNES.

LEUCOPYRITE *v.* LÖLLINGITE.

LEVANT SAPOTOXIN *v.* GLUCOSIDES.

LEVIGATION. Levigation is the mechanical process by which hard substances are reduced to a very fine powder by grinding them with water. The process is used principally in the preparation of pigments. On a small scale the substance is ground with a 'muller.' The muller is a piece of hard stone, convenient in shape and size to hold in the hand, and carefully flattened and polished on one side. The pigment to be ground is mixed with water on a large square slab of stone, preferably marble, and then ground with the muller. The finest artists' colours are ground in this way. On the large scale the pigment is first thoroughly mixed with water in a pug-mill. It is then ground between millstones similar to those used for flour, or under edge runners. Sometimes the millstones are replaced by three horizontal granite rollers, between which the pigment is ground. A mill with stones 2 feet in diameter will grind 15 cwt. of paint in 11 hours.

LEVULIN *v.* DANDELION ROOT.

LEVULOSE, LÆVULOSE *v.* CARBOHYDRATES. For the specific rotation of lævulose, *see* Vosburgh, J. Amer. Chem. Soc. 1920, 42, 1696.

LEVURARGYRE. Trade name for a mercury compound of nucleoprotein.

LEVURETIN, LEVURINOSE *v.* SYNTHETIC DRUGS.

LIBAVIUS, FUMING LIQUOR OF. *Stannic chloride* $SnCl_4$ (*v.* TIN).

LICHENIN *v.* Iceland moss, art. GUMS.

LICHENS. Many species have been employed from the earliest times in medicine, dyeing, and as foodstuffs (Mémoires sur l'utilité des lichens, par Hoffmann, Amoreux et Willemet, Lyon, 1787). From about the year 1300 certain species have been employed for the production of the purple dyestuff 'archil' or 'orchil,' as they contain colourless principles, derivatives of orcin, which under the influence of ammonia and atmospheric oxygen yield the purple colouring matters known as orcein (*v.* ARCHIL). Under the name of *Crottle* or *Crotal*, with various descriptive prefixes, several species have been, and still are to a very limited extent, directly applied in dyeing buff and brown colours on homespun yarn in the Highlands of Scotland, Wales, &c. The dyestuff appears to be ready formed in the plant and is obtained by simple extraction. The best known are *Parmelia Saxatelis* or *Black Crottle*, and *P. omphalodes*, while others are *P. caperata*, or *Stone Crottle*, *P. ceratophylla* or *Dark Crottle*, *P. parietina*, and a few species of *Sticta*, especially *S. pulmonaria* or *Hazel Crottle*. These lichens undergo no preparation, being gathered in July or August, when they are richest in colouring matter, and simply dried in the sun. They dye without addition to the bath and do not form lakes. Fine shades of brown are obtained, fast to acids and alkalis, but less fast to light than a mixture of Melachrome Brown B, and Melachrome Orange 3R (Edge, J. Soc. Dyers and Col. 1914, 30, 186). Those lichens, *e.g.* Iceland moss (*Cetraria islandica*, Ach.), which serve as foodstuffs, contain a starch-like substance termed *lichenin*, which is capable of conversion into glucose.

Our earlier chemical knowledge of the constituents of many of these lichens is mainly due to the work of Knop, Rochleder, Heldt, Schunck, Schmidt, Stenhouse, Stenhouse and Groves, and Weppen, whereas for the later very numerous investigations we are chiefly indebted to the chemists Oswald Hesse and Wilhelm Zopf. As a result, a very large number of new compounds have been isolated and described, the constitutions of which in most cases, however, are as yet undecided. On the other hand, considerable advance has been made as regards the exact structure of some of the more common constituents, viz. atranorin (atranoric acid), barbatic acid, evernic acid, erythrin (erythric acid), lecanoric acid, and ramalic acid, and the chemistry of these substances is dealt with under their special headings.

As the work of Hesse (H.) is mainly to be found in the Journal für praktische Chemie, and that of Zopf (Z.) in the Annalen, to avoid frequent repetition the year only of the papers published in the journals is noted below. For further details, *see* Hesse, J. pr. Chem. 1911, [ii.] 83, 22.

Trachylia tigillaris (Fr.) (*Acolium tigillare*; *Calicium tigillare*, *Cyphelium tigillare*), rhizocarpic acid $C_{28}H_{20}O_7$ (H.), m.p. 177°–178°, and acolic acid (H. 1900).

Acarospora chlorophana, rhizocarpic acid, pleosidic acid $C_{17}H_{28}O_4$, m.p. 131°–132° (Z. 1903).

Alectoria implexa, Nyl. (*A. cana*), zeorin, salazinic acid (Z. 1898). *A. ochroleuca*, usnic acid $C_{18}H_{16}O_7$, and barbatic acid (Z. 1899). *A. sarmentosa*, usnic acid (Z. 1900). *A. jubata*, var. *implexa*, salazinic acid, alectoric acid $C_{28}H_{24}O_{15}$, m.p. 186°. *A. articulata*, *d*-usnic acid, usnaric acid $C_{30}H_{22}O_{15}$, m.p. 240°–260°. *A. canariensis*, *d*-usnic acid, usnaric acid (H. 1902). *A. implexa*, atranorin (H. 1906).

Anaptychia ciliaris, atranoric acid (atranorin). *A. speciosa*, atranorin, zeorin $C_{52}H_{88}O_4$ (Z. 1895–1897).

Aspicilia calcarea, erythric acid, oxalic acid, aspicilin, m.p. 178.5° (H. 1900). *A. calcarea*, var. *farinosa*, erythrin, erythritol (H. 1915). *A. gibbosa*, aspicilic acid m.p. 150° (H. 1904).

Bacomyces roseus, an acid, m.p. 180° (H. 1898).

Biatora lucida, rhizocarpic acid $C_{28}H_{20}O_7$, atranorin (Z. 1897; H. 1907); no usnic acid (*cp.* Knop, 1843). *B. mollis*, diffusic acid (Z. 1905). *B. Lightfootii*, *l*-usnic acid (Z. 1906). *B. granulosa*, gyrophoric acid $C_{16}H_{14}O_7$ (Z. 1906).

Blastenia arenaria (*Callopisma erythrocarpa*), phytosterol, blasterin, m.p. 170° (H. 1898). *B. arenaria*, atranorin, gyrophoric acid $C_{16}H_{14}O_7$ (H. 1898). *P. Jungermanniæ*, parietin (Z. 1906).

Calycium crysocephalum, vulpic acid (H. 1898; Z. 1895). *C. chlorinum* or *chlorellum*, vulpic acid (Z. 1895); pulvic acid and traces of leprarin $C_{19}H_8O_9$ (Kassner, Arch. Pharm. 239, 44; H. 1900). *C. flavum*, chrysocetraric acid $C_{19}H_{14}O_6$ (H. 1900). *C. Stenhammari*, calycin $C_{18}H_{12}O_5$ (Z. 1895).

Callopisma flavovirescens, chrysophanic acid, physcion $C_{16}H_{12}O_5$ (H. 1902). *C. vitellinum*, calycin (Z. 1895); callopismic acid and mannitol (Z. 1897).

Rhizocarpon oreïtes, A. Zahlbr. (*Catocarpus oreïtes*), rhizocarpic acid $C_{28}H_{20}O_7$, psoromic (parellic) acid $C_{21}H_{16}O_9$ (Z. 1905).

Cetraria cucullata (*Platysma cucullatum*), protolichesteric acid $C_{18}H_{32}O_5$ (Z 1902). *C. chlorphylla*, protolichesteric acid and atranorin (Z. 1902). *C. complicata*, protocetraric acid $C_{30}H_{22}O_{15}$, *l*-usnic acid, and atranorin.

Cetraria islandica contains starch not deposited in granules, but uniformly distributed among the cells (lichenin). The lichenin, which is convertible into sugar, is present in such large quantity that this lichen can be used for food (Schmidt, Annalen, 51, 29). There is also said to be present cetraric acid, lichenstearic acid (Knop and Schaedermann, Annalen, 55, 114), protocetraric acid, and proto-*a*-lichesteric acid (Z. 1902; H. 1903 and 1904), *a*-lichenostearic acid $C_{18}H_{30}O_5$ (m.p. 122°–123°), *β*-lichenostearic acid $C_{18}H_{30}O_5$ (m.p. 121°), *γ*-lichenostearic acid $C_{18}H_{30}O_5$ or $C_{19}H_{32}O_5$ (m.p. 121°–122°), parelichenostearic acid $C_{20}H_{34}O_5$, dilichenostearic acid $C_{36}H_{60}O_{10}$, and cetraric acid $C_{26}H_{20}O_{12}$ (H. 1898) contains no cetraric acid as such, it being formed during extraction. Carbohydrates are lichenin, *d*-lichenidin and lichenoin (H. 1916).

C. nivalis, usnic acid (Z. 1904); *l*-usnic acid, nivalic acid $C_{20}H_{26}O_6$; lichenin and *l*-lichenidin $C_{12}H_{22}O_{11}$ (H. 1916). *C. stuppea* protolichesteric acid (Z. 1904), proto-*α*-lichesteric acid, dilichesteric acid, cornicularin and stuppeaic acid $C_{19}H_{26}O_4$ (H. 1911). *C. aculeata* or *Cornicularia aculeata*, protolichesteric acid (Z. 1904); lichenin and lichenic (fumaric) acid, acanthellin $C_{18}H_{34}O_5$, m.p. 188° (H. 1911). *C. pinastri*, pinastric acid $C_{10}H_8O_3$ (Z. 1895). *C. glauca* (*Platysma glaucum*), lichenin (Berzelius). *C. juniperina*, chrysocetraric acid $C_{19}H_{14}O_6$, usnic and vulpic acids (H. 1898). *C. pinastri*, chrysocetraric, usnic and vulpic acids (H. 1898; Z. 1899). *C. fahlunensis*, cetraric acid (Z. 1898).

Candelaria concolor, callopismic acid or ethylpulvic acid $C_{20}H_{16}O_5$, dipulvic acid $C_{32}H_{22}O_9$ (Z.); calycin, and stictaurin $C_{18}H_{12}O_5$ (H.; Z. 1899). According to Hesse, 1898, dipulvic acid is a mixture of calycin and pulvic anhydride. *C. vitellina*, stictaurin (Z. 1899), calycin and pulvic anhydride (Z. 1899).

Cladina silvatica, usnic acid and cetraric acid (Z. 1898). *C. alpestris*, usnic acid (Z. 1898). *C. rangiferina*, cetraric acid and atranorin (Z 1898) and usnic acid (H. 1898). *C. pyxidata*, parellic acid (H. 1898). *C. coccifera*, cocellic acid $C_{20}H_{22}O_7$ (H. 1898). *C. uncialis*, *d*-usnic and thamnolic acids $C_{20}H_{18}O_{11}$ (Z. 1902).

Cladonia amaurocraea, usnic acid (Z. 1898). *C. alcicornis*, usnic acid (H. 1902). *C. deformis*, usnic acid (Z. 1900). *C. cyanipes*, usnic acid (Z. 1900). *C. Floerkeana*, cocellic and thamnolic acids (H. 1900). *C. rangiformis*, atranorin, rangiformic acid $C_{20}H_{32}O_5$·OMe (H. 1898). *C. uncinata* (no usnic acid, *see* Knop, Annalen, 1844, 49, 120); but uncinatic acid $C_{23}H_{28}O_9$ (H. 1900). *C. destricta* (*C. uncialis*), usnic acid and starch (Knop, Annalen, 49, 119); *l*-usnic acid (Salkowski, Annalen, 1901, 319, 391); *l*-usnic acid, cladestin (m.p. 242°–245°), squamatic acid, destritic acid, destrictasic acid, and cladestic acid $C_{15}H_{24}O_2$ (H. 1911). *C. incrassata*, *l*-usnic acid (S.). *C. glauca*, squamatic acid (Z. 1902). *C. strepsilis*, thamnolic acid and strepsilin (Z. 1903). *C. thamnolis*, thamnolic acid $C_{20}H_{18}O_{11}$, and strepsilin. *C. destricta*, *l*-usnic acid (Z. 1903); *l*-usnic and squamatic acids and cladestin (H. 1904). *C. macilenta*, usnic acid and starch (Knop, *l.c.*); rhizonic acid (Z. 1903); coccellic acid, thamnolic acid, rhodocladonic acid (H. 1915). *C. squamosa*, var. *ventricosa*, squamatic acid (Z. 1904). *C. squamosa*, var. *denticollis*, squamatic acid (Z. 1907). *C. fimbriata*, var. *simplex*, fumaroprotocetraric acid and fimbriatic acid (Z. 1907). *C fimbriata*, var *cornuto-radiata*, fumaroprotocetraric acid (Z. 1907); no confirmation of this; probably nemoxynic acid (H. 1915). *C. pityrea*, var. *cladomorpha*, fumaroprotocetraric acid (Z. 1907). *C. silvatica*, var. *condensata*, *l*-usnic acid (Z. 1907), cornicularin $C_{23}H_{44}O_5$ (H. 1915). *C. verticillata*, var. *subcervicornis*, fumaroprotocetraric acid (Z. 1907), atranorin and cervicornin. *C. chlorophœa*, fumaroprotocetraric acid. *C. gracilis*, var. *chordalis*, fumaroprotocetraric acid (Z. 1907). *C. crispata*, var. *gracilescens*, squamatic acid (Z. 1907);

cladonin $C_{30}H_{41}O_6$ (H. 1915). *C. coccifera*, cocellic acid $C_{20}H_{22}O_7$ (H. 1895). *C. incrassata*, *l*-usnic acid (Z. 1905). *C. rangiferina*, usnic acid (Rochleder and Heldt, Annalen, 48, 2); lichenin (Schmidt, *ibid.* 51, 29); cladonic acid (β-usnic acid) $C_{18}H_{18}O_7$ (Stenhouse, *ibid.* 155, 58); *d*-usnic acid (no *l*-usnic) and silvatic acid $CO_2Me{\cdot}C_{16}H_{34}O_3{\cdot}COOH$ (H. 1907); atranorin and fumaroprotocetraric acid (Z. 1906). *C. rangiferina*, var. *vulgaris*, atranorin and protocetraric acid (H. 1898). *C. rangiferina*, var. *silvatica*, *d*-usnic acid (Z. 1906); usnic and protocetraric acids (H. 1898). *C. tenuis*, fumarprotocetraric acid and *d*-usnic acid (H. 1915). *C. pyxidata*, lichenin (Schmidt, Annalen, 51, 29); emulsin (Hérissey, J. Pharm. Chim. 1898, [vi.] 7, 577).

Cornicularia aculeata, rangiformic acid (H. 1902). *C. aculeata*, var. *stuppea*, cornicularin $C_{28}H_{14}O_5$ (H. 1915). *C. aculeata*, var. *acanthella*, dimannitol (H. 1915).

Chiodecton sanguineum (*C. rubrocinctum*), chiodectonic acid $C_{14}H_{18}O_5$.

Cyphelium trichiale, var. *candelare*, calycin (Z. 1906).

Darbishirella gracillima, parellic acid (H. 1898).

Dendographa leucophæa, protocetraric acid (H. 1898); erythrin and orcinol (Ronceray, Bull. Soc. chim. 1904, [iii.] 31, 1097).

Dimelaena oreina, zeorin and usnic acid (Z. 1897).

Diploicia canescens (*Catolechia canescens*), diploicin, m.p. 225°, catolechin, m.p. 214°–215°, and atranorin (Z. 1904).

Diploschistes scruposa, diploschistessic acid $C_{15}H_{16}O_7$ (Z. 1906).

Endocarpon miniatum (α) *vulgare*, phytosterol and an acid (H. 1898).

Evernia divaricata, divaricatic acid (H. 1900) $C_{21}H_{24}O_7$, and usnic acid (Z. 1897); no usnic acid (H. 1911). *E. furfuracea*, usnic acid (Rochleder and Heldt, Annalen, 48, 9); no usnic acid, but erythric acid (Z. 1897), or rather olivetoric acid $C_{27}H_{36}O_8$ (Z. 1900), physodic acid, physodylic acid $C_{23}H_{26}O_8$, and furevernic acid (H. 1907); atranorin, evernuric acid $C_{22}H_{24}O_8$, and furevernic acid, but no erythric or olivetoric acids (H. 1906); emulsin (Hérissey, J. Pharm. Chim. 1898, [v.] 7, 577). *E. prunastri*, evernic acid, atranorin (Z. 1897); evernic acid, usnic acid, and atranorin, and chrysocetraric acid (H. Annalen, 1895) $C_{19}H_{14}O_6$; atranorin and evernic acid when grown on birch, limes, beech, sandstone; usnic acid in addition when on oak (H. 1915). *E. thamnodes*, divaricatic acid, usnic acid (Z. 1897; H. 1900). *E. vulpina*, vulpic acid and atranorin (H.). *E. illyrica* (Dalmatia), divaricatic acid and atranorin (Z. 1904). *E. ochroleuca*, usnic acid (Knop, Annalen, 49, 122).

Everniopsis Trulla, salazinic acid and atranorin (Z. 1897).

Gasparrinia medians (*Physcia medians*) calycin, rhizocarpic acid (H. 1898); pulvic lactone (H. 1903). *G. sympagea*, parietin (Z. 1905). *G. elegans* (*Physcia elegans*), physcion (H. 1898). *G. murorum*, physcion (H. 1898). *G. decipiens* physcion (H. 1898). *G. cirrhochroa*, chrysophanic acid (Z. 1897).

Graphis scripta, salazinic acid (H. 1900).

Gyalolechia aurella, calycin (Z. 1895), callopismic acid (Z. 1897), stictaurin (Z. 1899).

Umbilicaria pustulata (Hoffm.) (*Gyrophora pustulata*), gyrophoric acid $C_{38}H_{36}O_{15}$ (Stenhouse, Annalen, 70, 218) $C_{16}H_{14}O_7$ (H.). *G. hirsuta*, gyrophoric acid (Z. 1898). *G. deusta*, gyrophoric acid (Z. 1898). *G. polyphylla*, umbilicaric acid $C_{25}H_{22}O_{10}$ (Z. 1898); umbilicaric acid and gyrophoric acid (H. 1898, 1901). *G. hyperborea*, umbilicaric acid (Z. 1898). *G. deusta*, umbilicaric acid (Z. 1898). *G. vellea*, gyrophoric acid and gyrophorin, m.p. 189° (Z. 1899). *G. spodochroa*, var. *depressa*, gyrophoric acid (Z. 1900). *G. polyrrhiza*, umbilicaric acid, lecanoric acid, gyrophoric acid (Z. 1905).

Hæmatomma ventosum, divaricatic acid $C_{22}H_{26}O_7$, m.p. 149° (Z. 1898); *d*-usnic acid, divaricatic acid, and an acid resembling alectoric acid (H. 1900). *H. coccineum*, var. *leiphæmum*, leiphæmin, m.p. 193°, atranorin, zeorin (Z. 1902). *H. coccineum*, var. *abortivum*, coccic acid $C_{12}H_{16}O_{10}{\cdot}3H_2O$, m.p. 262°–264°, atranorin, hæmattomin $C_{10}H_{16}O$ or $C_{20}H_{32}O_2$, m.p. 143°–144°, and hæmatommidin, m.p. 194°–196° (Z. 1903); no zeorin (H. 1907). *H. coccineum*, var. (?), lecanoric acid (H. 1907). *H. coccineum*, var. (?) (from Wildbad), coccic acid, atranorin, zeorin, hydrohæmatommin $C_{10}H_{18}O$, m.p. 101° (H. 1906). *H. coccineum*, *l*-usnic acid, zeorin, atranorin, porphyrillic acid, hymenorhodin, and leiphæmin (Z. 1906). *H. leiphæmum*, atranorin, zeorin, leiphæmin, leiphæmic acid $C_{22}H_{38}O_5$, m.p. 114°–115° (Z. 1903). *H. porphyrium*, atranorin, zeorin, porphyrilic acid, leiphæmin, hymenorhodin (Z. 1906).

Pertusaria dealbata, Nyl. f. *corallina*, Cromb. (*Isidium corallinum*) ('white crottle'), calcium oxalate (Braconnot, Ann. Chim. Phys. [ii.] 28, 319).

Lecanora atra, atranoric acid (atranorin) $C_{19}H_{18}O_8$, and a yellow crystalline substance (Paternò and Oglialaro, Gazz. chim. ital. 1877, 7). Hesse (Ber. 10, 1324) considers the atranoric acid to be hydrocarbonusnic acid, and the yellow substance to be cladonic acid. Obtained from certain districts it contains lecanorol (Z. 1897) $C_{27}H_{30}O_9{\cdot}H_2O$. *L. varia*, psoromic acid and *l*-usnic acid (Z. 1905). *L. grumosa*, atranorin and lecanorol (Z. 1897). *L. cenisea*, atranorin and roccellic acid $C_{17}H_{32}O_4$ (*cp.* Schunck and Hesse, *Roccella tinctoria*). *L. sordida*, atranorin, zeoric acid (Z. 1897). *L. sordida*, var. *glaucoma*, atranorin and parellic acid (H. 1898). *L. sordida*, var. *Swartzii*, atranorin, thiophanic acid $C_{12}H_6O_{12}{\cdot}H_2O$, m.p. 242°, roccellic acid, lecasteric acid $C_{10}H_{20}O_4$, m.p. 116°, and lecasteride $C_{10}H_8O_3$, m.p. 105° (H. 1898). *L. campestris*, atranorin (Z. 1897). *L. badia*, stereocaulic acid (Z. 1897). *L. effusa*, atranorin and usnic acid (Z. 1897). *L. subfusca*, atranorin (Z. 1897; H. 1900). *L. epanora*, zeorin and lepanorin, m.p. 131°–132° (Z. 1900). *L. glaucoma* (*L. sordiaa α-glaucoma*) (from Tyrol), atranorin, thiophanic acid, roccellic acid (Z. 1903). *L. sulphurea*, usnic acid (Z. 1903). *L. parella* ('light crottle'), parellic acid, lecanoric acid (Schunck, Annalen, 54, 257, 274; 41, 161). *L. tartarea* (Linn.) (*Patellaria tartarea*, *Parmelia tartarea*), erythric acid, synonymous with Nees. v. Esenbeck's 'remarkable resin' (Brandes' Archiv. Apoth. 16, 135), with Heeren's erythrin, and with Kane's erythrilin (Schweigger's, J., Ch. Phys. 59, 313). Schunck found crustaceous lichens belonging to *Lecanora*, &c., collected

on the basalt rocks of the Vogelsberg in Upper Hessia to contain lecanoric and erythric acids (Annalen, 41, 157). In a specimen from Norway, Stenhouse (*ibid.* 70, 218) found gyrophoric acid. *L. ventosa*, usnic acid (Knops, *ibid.* 49, 122).

Rhizocarpon geographicum, Dl. (*Lecidea geographica*) usnic acid (Knop, *l.c.*). *Lecidea candida* (*Psora candida*), calcium oxalate (Braconnot, Ann. Chim. Phys. [ii.] 28, 319). *L. cineroatra*, lecidic acid $C_{22}H_{27}O_4$·COOMe, m.p. 147°, and lecidol, m.p. 93° (H. 1898). *L. sudetica*, salazinic acid (Z. 1899). *L. confluens*, confluetin, m.p. 147°–148° (Z. 1899). *L. grisella*, gyrophoric acid (H. 1900). *L. aglæotera* (*L. armeniaca*, var. *lutescens*), roccellic and cetraric acids (Z. 1904).

Lepraria latebrarum, leprarin, m.p. 155°, roccellic acid (Z. 1897), and atranorin (Z. 1900); *d*-usnic, hydroroccellic, lepraric, and talebraic acids (m.p. 208°) and atranorin (H. 1903). *L. flava*, calycin, pinastric acid, calyciarin (Z. 1905). *L. xanthina* (from Vorarlberg), physcion (H. 1906). *L. latebrarum* (Baden-Baden), atranorin, leprariaic acid, oxyroccellic acid, and neobraic acid (H. 1906). *L. candelaris*, calycin (Z. 1906). *L. chlorina*, calycin (Z. 1895).

Lepra candelaris (*Lepraria flava*), calycin

$$C_{18}H_{11}O_4\cdot OH,$$

m.p. 240°–242° (H. 1898).

Leprantha impolita (*Arthonia pruinosa*), lecanoric acid, lepranthin $C_{25}H_{40}O_{10}$, m.p. 183°, lepranthaic acid $C_{20}H_{32}O_2$, m.p. 111°–112° (Z. 1904).

Mycoblastus sanguinarius, caperatic acid and atranorin (Z. 1899).

Menegazzia pertusa (*Parmelia pertusa*), atranorin and farinacic acid (capraric and pysodic acids absent) (H. 1907).

Nephroma arcticum, zeorin, nephrin, and *d*-usnic acid (Z. 1909). *N. antarcticum*, zeorin and *d*-usnic acid (Z. 1909). *N. parile*, zeorin and mannitol (Z. 1909). *N. resupinatum*, mannitol (Z. 1909). *N. lævigatum*, mannitol (Z. 1909). *Nephromium lævigatum*, usnic acid and nephrin $C_{20}H_{32}H_2O$, m.p. 168° (H. 1898). *N. tommentosum*, usnic acid and nephrin (H. 1898). *N. lusitanicum*, nephrin and nephromin $C_{16}H_{12}O_6$, m.p. 196° (H. 1898).

Ochrolechia androgyna (*Lecanora subtartarea*), gyrophoric acid and calyciarin (Z. 1905). *O. pallescens*, var. *parella* (from Auvergne), parellic acid and ochrolechiasic acid $C_{22}H_{14}O_9$, m.p. 282° (H. 1906); but no lecanoric acid (*see* Schunck, Annalen, 1845, 54, 274) (Z. 1898). *O. tartarea*, gyrophoric acid (Z. 1898).

Pannaria lanuginosa, hydroxyroccellic acid $C_{17}H_{32}O_5$, m.p. 128°, and pannaric acid $C_9H_8O_4$, m.p. 224° (H. 1901).

Parmelia aleurites, atranorin (Z. 1897). *P. tiliacea*, atranorin and parmelialic acid, m.p. 165° (Z. 1897); the latter is in reality lecanoric acid (H. 1898 and 1900). *P. perlata*, atranorin and hæmatommic acid (Z. 1897); usnic acid, lecanoric acid, and perlatin (H. 1900); imbricaric acid (Z. 1902); no lecanoric acid (H. 1903); atranorin and perlatic acid $C_{27}H_{27}O_9$·OMe,$2H_2O$ (H. 1904). *P. perlata* from certain sources: (*a*) atranorin, (*b*) atranorin, usnic, and vulpic acids, (*c*) atranorin and lecanoric acid, (*d*) atranorin and perlatin $C_{19}H_{14}O_5(OMe)_2$ (H. 1898). *P. saxatilis*, stereocaulic acid and salazinic acid. Latter chief dyeing constituent (Ryan and O'Riordan, Proc. Roy. Irish Acad. 1917, 33, 911). *P. saxatilis*, var. *sulcata*, atranorin and stereocaulic acid (Z. 1897); protocetraric acid only (H. 1900), not protocetraric but pannatic acid (H. 1904); usnic acid (Schmidt, Annalen, 51, 29). *P. saxatilis*, var. *panniformis*, atranorin, protocetraric acid, and usnetic acid $C_{24}H_{26}O_8$ (not $C_9H_{10}O_4$), m.p. 192° (H. 1900). *P. saxatilis retiruga*, atranorin, protocetraric acid, and saxatic acid $C_{25}H_{40}O_8$, m.p. 115° (H. 1903), parmatic acid and not protocetraric acid (H. 1916). *P. physodes* (or *P. ceratophylla*, var. *physodes*) is known as 'dark crottle,' and is employed for dyeing a brown colour on homespun woollen yarn. Contains physodin and two colourless substances (Gerding, Brandes, Arch. Pharm. [ii.] 87, 1), ceratophyllin (H. Annalen, 119, 365); atranorin, physodalic acid, and physodalin (Z. 1897 and 1898); evernuric acid, physodylic acid, capraric acid, and atranorin (H. 1907). *P. parietina*, chrysophanic acid (Rochleder and Heldt, 48, 12); identical with Thomson's (Edin. New. Phil. Jour. 37, 187), parietin, also (H. 1895) physcion $C_{16}H_{12}O_5$, physcianin $C_{10}H_{12}O_4$, m.p. 143°, and physciol $C_7H_8O_3$, m.p. 107°. A variety of *P. parietina* growing on sandstone rock and not on trees like that of Rochleder and Heldt, contained vulpic acid (chrysopicrin) Stein (J. pr. Chem. [i.] 93, 366). *P. caperata* ('stone crottle'), emulsin (Hérissey, J. Pharm. [vi.] 7, 577); capraric acid $C_{22}H_{18}O_8(COOH)_2$, m.p. 240°, usnic acid, caperatic acid COOMe,$C_{18}H_{33}O_2(COOH)_2$, m.p. 132°, and caperin $C_{36}H_{60}O_3$, m.p. 243° (H. 1898), *d*-usnic acid (H. 1900), specimens from oaks contain caperin and caperidin in addition (H. 1915). *P. caperata* from *Castanea vesca*, usnic, capraric and caperatic acids (H. 1904). *P. conspersa*, usnic acid, zeorin, and atranorin (Z. 1898); usnic acid and salazinic acid (H. 1898); *d*-usnic acid and conspersaic acid, m.p. 252° (H. 1903). *P. acetabulum*, atranorin (Z. 1898); atranorin and salazinic acid (H. 1901). *P. excrescens*, zeorin and atranorin (Z. 1898). *P. perlata*, var. *exrescens*, atranorin (Z. 1898). *P. Nilgherrensis*, atranorin (Z. 1898). *P. perforata*, zeorin and atranorin (Z. 1898); lecanoric acid (H. 1900). *P. olivetorum*, atranorin (Z. 1898); lecanoric acid, but no erythric acid (H. 1900); olivetoric acid $C_{27}H_{34}O_8$, m.p. 141°–142 (Z. 1902); atranorin, olivetorin, m.p. 143°, and olivetoric acid $C_{21}H_{26}O_7$ (H. 1903). *P. pertusa*, physodalic acid (Z. 1898). *P. fuliginosa*, atranorin and lecanoric acid (H. 1898). *P. fuliginosa*, var. *ferruginascens*, lecanoric acid (Z. 1899). *P. pulverulenta*, unknown acid (H. 1898). *P. ciliaris*, everninic acid and atranorin (?) (H. 1898) *P. omphalodes* (*P. saxatilis*, var. *omphalodes*). Under the name of 'black crottle' this lichen is employed for dyeing a brown colour in the outer Hebrides (Lewis and Harris); contains stereocaulic acid (Z. 1899), atranorin, usnetic acid, parmatic acid and (Knop's) lobaric acid (?) (H. 1916). *P. tiliacea*, var. *scortea*, lecanoric acid (Z. 1899). *P. verruculifera*, lecanoric acid (Z. 1899). *P. glomellifera*, glomelliferin, m.p. 143°–144° (Z. 1899 and 1902). *P. incurva*, usnic acid (Z. 1900). *P. Borreri*, lecanoric acid (Z. 1900). *P. sorediata*, diffusin (Z. 1900); lecanoric acid (H. 1900). *P. tinctorum*, atranorin (H. 1900). *P. tinctorum* (E. Africa), atranorin and lecanoric

acid (H. 1906). *P. tinctorum* (Madras cinchona bark), atranorin and lecanoric acid (H. 1904). *P. glabra*, lecanoric acid (H. 1902). *P. lacarnensis*, imbricaric acid (Z. 1902). *P. sinuosa*, *d*-usnic and usnaric acids (Z. 1902).

Parmelia cetrata (Java cinchona bark), cetrataic acid $C_{29}H_{24}O_{14}$, m.p. 178°–180° (H. 1903). *P. olivacea*, oliveacein $C_{17}H_{22}O_6{,}H_2O$, m p 156°, and oliveaceic acid $C_{16}H_{18}O_5{\cdot}OMe$, m.p. 138° (H. 1903). *P. revoluta*, atranorin and gyrophoric acid (Z. 1905). *P. pilosella*, atranorin and pilosellic acid, m.p. 245° (Z. 1905). *P. Moëgeotti*, *d*-usnic acid (H. 1906).

Peltigera aphosa, peltigerin $C_{21}H_{20}O_8$ (or $C_{16}H_{16}O_6$), m.p. 170°–180°, and mannitol (Z. 1909). *P. malacea*, peltigerin, zeorin, and mannitol (Z. 1909). *P. horizontalis*, peltigerin, zeorin, and mannitol (Z. 1909). *P. polydactyla*, peltigerin mannitol, polydactylin, m.p. 178°–180°, and peltidactylin, m.p. 237°–240°. *P. venosa*, peltigerin. *P. scabrosa*, peltigerin. *P. propagulifera*, peltigerin and zeorin. *P. lepidophora*, peltigerin. *P. practextata*, mannitol. *P. rufescens*, mannitol. *P. spuria*, mannitol. *P. canina*, caninin (Z. 1909); emulsin (Hérissey, J. Pharm. Chim. [vi.] 7, 577).

Pertusaria lichens on beech contain picrolichenin and salazinic acid, on oak contains no picrolichenin (H. 1916). *Pertusaria amara* (*P. communis β-variolosa*, *Variolaria amara*), emulsin (Hérissey, *l.c.*); cetraric acid, pertusaric acid $C_{24}H_{38}O_6$, m.p. 103°, pertusarin $C_{30}H_{50}O_2$, m.p. 235°, pertusarene $C_{60}H_{100}$, m.p. 286°, and pertusaridin (H. 1898); salazinic acid and picrolichenin (Z. 1900); orbiculatic acid $C_{22}H_{36}O_7$ (H. 1901). *P. lactea*, lecanoric acid and variolaric acid, m.p. 285° (Z. 1902). *P. lactea* (sterile Auvergne), lecanoric acid and ochrolechiasic acid (H. 1906). *P. corralina* (*P. ocellata β-coralline*), ocellatic acid $C_{20}H_{16}O_{11}{\cdot}OMe$, m.p. 208° (H. 1901). *P. rupestris* (*P. communis β-areolata*), areolatin $C_{11}H_7O_6{\cdot}OMe$, m.p. 270°, arcolin, m.p. 243°, and gyrophoric acid $C_{16}H_{14}O_7$ (H. 1903). *P. glomerata* (Wildbad), porin $C_{42}H_{67}O_9OMe$, m.p. 166°, and porinic acid $2[C_{11}H_{12}O_4]{,}H_2O$, m.p. 218° (H. 1903). *P. Wulfenii* (*P. sulfurea*, *P. sulphurella*, *P. fallax*), thiophanic acid (Z. 1904). *P. lutescens*, thiophanic acid (Z. 1904). *P. ocellata variolosa*, atranorin and gryophoric acid $C_{32}H_{24}O_{14}$ (H. 1916).

Placodium gypsaceum, squamaric acid and usnic acid (Z. 1898); parellic acid, but no usnic acid (H. 1901). *P. chrysoleŭcŭm*, usnic acid (Z. 1898). *P. saxicolum*, var. *vulgare*, usnic acid and zeorin (Paternò, Atti. R. Accad. Lincei, 1876, [ii.] 3); zeorin, but no atranorin (H. 1898), *d*-usnic acid (H. 1900). *P. saxicolum*, var. *compactum*, atranorin (H. 1901). *P. melanaspis*, atranorin (Z. 1898). *P. Lagascæ*, psoromic and usnic acids (Z. 1897).

Placodium crassum, atranorin (trace), *l*-usnic acid (H. 1901). *P. circinatum* (*a*) *radiosum*, salazinic acid (H. 1902).

Physcia ciliaris, emulsin (Hérissey, J. Pharm. Chim. [vi.] 7, 577). *P. endococcina*, zeorin and atranorin (Z. 1895), rhodophyscin and endococcin (Z. 1905). *P. caesia*, zeorin and atranorin (Z. 1895); atranorin and zeorin (H. 1902). *P. stellaris*, *f. adscendens*, atranorin (Z. 1895). *P. parietina*, atranorin and placodin, m.p. 245° (H. 1899). *P. parienta*, physcione (frangulaemodin mono methyl ether (Ryan and O'Riordan, *l.c.*). *P. medians*, vulpic acid and calycin (Z. 1895), calycin and callopismic acid (Z. 1897). *P. pulverulenta*, var. *β-pityrea*, atranorin (Z. 1895)

Physcia tenella, atranorin (Z. 1895). *P. aipolia*, atranorin (Z 1895).

Cetraria glauca (*Platysma glaucum*) atranorin and caperatic acid (Z. 1899). *Cetraria cucullata* (*P. cŭcŭllatum*), lichenostearic acid and usnic acid (Z. 1899). *P. diffusum*, diffusin, m.p. 135°–136°, and usnic acid (Z. 1899).

Pleopsidium chlorophanum, rhizocarpic acid (Z. 1895).

Pseudevernia ericetorum, atranorin, physodalin (Z. 1905). *P. olivetorina* (*Evernia furfuracea*, var. *olivetorina*), atranorin and olivetoric acid (H. 1911); olivoric acid $C_{23}H_{28}O_8$ and apo-olivoric acid (H. 1916).

Psora ostreata, lecanoric acid (Z. 1899).

Pulveraria chlorina, calycin, vulpic acid, and lepraric acid, m.p. 228° (H. 1898). *P. latebrarum*, atranorin, parellic acid, latebride, m.p. 128°, and pulverin, m.p. 262° (H. 1898). *P. farinosa*, oxyroccellic acid, and pulveraric acid, m.p. 234° (H. 1898).

Pycnothelia (*Cladonia*) *papillaria*, var. *molariformis*, atranorin, cladonin and proto-α-lichestearic acid (H. 1915).

Raphiospora flavovirescens, rhizocarpic acid (Z. 1895).

Ramalina calicaris, var. *fastigiata*, contains large quantities of starch (lichenin) and a small quantity of saccharic acid (Berzelius, Scherer's Annalen, 3, 97), usnic acid (Rochleder and Heldt, *ibid.* 48, 9). *R. calicaris*, var. *fraxinea*, lichenin and usnic acid (R. and H. *l.c.*); *a*-usnic acid (Hesse, Annalen, 117, 297). *R. ceruchis*, usnic acid and usnaric acid (H. 1898). *R. armorica*, atranorin, armoricaic acid, m.p. 240°–260°, armoric acid $C_{18}H_{18}O_7{,}H_2O$, m.p. 226°–228° (H. 1907). *R. cuspidata*, cuspidatic acid $C_{16}H_{20}O_{10}$, m.p. 218° (H. 1900), *d*-usnic acid (Ryan and O'Riordan, *l.c.*). *R. farinacea*, *d*-usnic acid and ramalic acid $C_{30}H_{26}O_{15}$, m.p. 240°–245° (H. 1903). *R. subfarinacea*, *d*-usnic acid and salazinic acid (Z. 1907). *R. minuscula*, *d*-usnic acid (Z. 1907). *R. Kullensis*, *d*-usnic acid, kullensisic acid $C_{32}H_{18}O_{12}$ (Z. 1907). *R. obtusata*, *d*-usnic acid, ramalinellic acid, m.p. 169°, and obtusatic acid (Z. 1907). *R. Landroënsis*, *d*-usnic acid and landroënsin (Z. 1907). *R. pollinaria*, ramalic acid $C_{16}H_{13}O_3OMe$ and evernic acid (Z. 1897); usnic acid, atranorin, evernic acid, and ramalic acid (H. 1898). *R. fastigiata*, emulsin (Hérissey, J. Pharm. Chim. 1898, [vi.] 5, 577). *R. fraxinea*, emulsin (Hérissey, *ibid.*). *R. polymorpha*, usnic acid (Z. 1897). *R. scopulorum* (*see* Thomson, Annalen, 53, 252), *d*-usnic acid, scopuloric acid $C_{19}H_{16}O_9$, m.p. 260° (Z. 1907). *R. thraŭsta*, usnic acid (Z. 1900). *R. yemensis*, *d*-usnic acid (H. 1902).

Reinkella birellina, roccellic and oxyroccellic acids (H. 1898).

Rhizocarpon geographicum f. contiguum, parellic acid, rhizonic acid $C_{19}H_{20}O_7$, m.p. 185°, rhizocarpic acid $C_{28}H_{22}O_7$ (H. Ber 1898, 31, 663), rhizonic acid is $OMe\,C_{17}H_{14}O_2(OH)_2COOH$ (H.). *R. geographicum f. lecanorinum*, rhizocarpic acid (Z. 1895); parellic acid, rhizocarpinic acid, m.p. 156°, rhizocarpic acid

$COOH{\cdot}C_{24}H_{16}O_3{\cdot}COOEt$

m.p. 177°–178°. Parellic acid

$COOMe{\cdot}C_{17}H_{11}O_3(COOH)_2$

m.p. 262°–265°, is the same as Zopf's psoromic acid, and the squamaric acid and zeoric acid of other writers (H.). *R. geographicum f. gerontica*, parellic and rhizocarpic acids, but not rhizocarpinic acid (H. 1909).

Rhizoplaca opaca (*Lecanora chrysoleuca, β-opaca, Parmelia rubina β-opaca, Squamaria chrysoleuca β-opaca*), usnic acid, placiodilic acid (previously termed placiodilin), and rhizoplacic acid $C_{21}H_{40}O_5$, m.p. 94°–95° (Z. 1905), usnic acid and placiodilic acid $C_{17}H_{18}O_7$, m.p. 156°–157° (Z. 1906).

Roccella fuciformis (*R. tinctoria*, var. *fuciformis*). This well-known 'orchella weed' is imported from Angola, Zanzibar, Madagascar, Ceylon, and Lima for the purpose of manufacturing archil and cudbear. It contains erythric acid (Heeren's erythrin, Kane's erythrilin) and roccellic acid (Schunck, Pharm. J. [iii.] 39, 164; Annalen, 61, 64; Kane, Trans. Roy. Soc. 1840, 273; Heeren and Schweiggers, J. Pharm. Chim. 59, 346). Stenhouse (Annalen, 149, 288) examined a Lima weed in 1848, and found it to contain lecanoric acid, but this was probably *R. tinctoria* and not identical with the *R. fuciformis* examined by him in 1869, and in which he found erythric acid. Compare Hesse (Annalen, 117, 329, and 139, 22) who found Lima weed to contain erythric acid, but not lecanoric acid. Stenhouse considers the *R. Montagnei* from Angola, in which he found erythric acid to be identical with *R. tinctoria*, var. *fuciformis*, examined by Schunck. A stunted variety of *R. fuciformis*, examined by Menschutkin and Lamparter, contained β-erythrin. In a better growing specimen erythrin was obtained (Lamparter, Annalen, 134, 243). A variety of *R. fuciformis*, probably from the west coast of Africa, contained erythric acid and a bitter substance picroroccellin (Stenhouse and Groves, *ibid.* 185, 14). More recently Hesse (1898) has found the weed to contain erythric acid and oxyroccellic acid.

Roccella Montagnei, erythric acid and oxyroccellic acid (H. 1898); orcinol (Ronceray, Bull. Soc. chim. 1904, iii. 1097). *R. fruticosa*, erythric acid (erythrin) (H. Ber. 1904, 37, 4693). *R. phycopsis* (Crete), erythrin, oxyroccellic acid, oxalic acid, and erythritol (H. 1906). *R. peruensis* (*R. fructectosa* and *R. cacticola*), erythrin, oxyroccellic, and roccellic acids (H. 1898), erythrin, erythritol, and oxalic acid (H. 1906). *R. portentosa*, lecanoric acid (H. 1898). *R. decipiens*, lecanoric acid (H. 1898). *R. sinensis*, lecanoric acid (H. 1898).

Roccella tinctoria. This lichen used largely for the manufacture of orchil and cudbear, is imported from the Cape of Good Hope, the Cape Verde Islands, and Chile (Valparaiso Weed). Formerly it seems to have been imported also from Lima (Stenhouse). It contains lecanoric acid (Stenhouse's α- and β-orsellic acid) and roccellinin. The latter is, however, probably a decomposition product of the former (Stenhouse, Annalen, 68, 55; 149, 288; Phil. Mag. [iii.] 32, 300). According to Hesse (1898) it contains erythrin, oxyroccellic acid, roccellic acid, and lecanoric acid, whereas Ronceray (Bull. Soc. chim. 1904, [iii.] 31, 1097) detected in this lichen the presence of lecanoric acid and orcinol (*cp.* Hesse, Ber. 1904, 37, 4693).

Roccellaria intricata, zeorin and roccellaric acid, m.p. 110° (H. 1898).

Squamaria elegans (*Gasparrinia elegans*), chrysophanic acid (Thomson, Phil. Mag. [iii.] 25, 39); physcion (H.).

Solorina crocea, soloric acid, m.p. 199°–201° (Z. 1895); solorinic acid, hydrosolorinol and mannitol (H. 1915).

Sphærophorus fragilis, sphærophorin, m.p. 138°–139°, and fragilin (Z. 1898), sphærophorin $(C_{14}H_{16}O_4)_n$, or $C_{28}H_{34}O_8$, sphærophoric acid, m.p. 206°–207°, and fragilin (Z. 1905).

Sphyridium placophyllum, atranorin (Z. 1898).

Stereocaulon alpinum atranorin, and stereocaulic acid, m.p. 200°–201° (Z. 1895). *S. corallöides*, atranorin and psoromic acid (Z. 1895), usnetic acid, atranorin, and an acid not psoromic acid. Zopf's stereocaulic acid from *S. alpinum* is usnetic acid (H. 1900). *S. incrustatum*, atranorin and psoromic acid (Z. 1895). *S. vesuvianum*, psoromic acid (Z. 1895). *S. denudatum*, var. *genuinum* atranorin (Z. 1895). *S. tomentosum*, atranorin (Z. 1895). *S. pileatum*, atranorin and stereocaulic acid (Z. 1895 and 1899) *S. condensatum*, atranorin (Z. 1895). *S. paschale*, atranorin (Z. 1895). *S. virgatum* f. *primaria*, atranorin (Z. 1895). *S. ramulosum*, atranorin (Z. 1895). *S. salazinum*, salazinic acid, which blackens at 260°–262° (H. 1900). Stereocaulic acid appears to be identical with stictaic acid (Bargellini and Monocada, Gazzetta, 1921, 51, ii. 173).

Sticta fuliginosa, trimethylamine (Z. 1897). *S. aurata*, stictaurin a derivative of pulvic acid (Z. 1899). Stictaurin has the formula $C_{18}H_{12}O_5$ (H. 1900). *S. desfontainii*, calycin and ethylpulvic acid (H. 1900). *S. pulmonaria*, stictaic acid $C_{19}H_{14}O_9$, m.p. 264°, stictinic acid (Knop and Schnedermann, J. pr. Chem. 1846, 39, 365), and not protocetraric acid (H. 1900). This lichen is known as 'hazel crottle.'

Stictina gilva, stictinin, m.p. 160°–161° (Z. 1905).

Thamnolia vermicularis, thamnolic acid, m.p. 202°–204° (Z., Chem. Zentr. 1893, ii. 54). According to Hesse this has the formula $C_{19}H_{15}O_{10}\cdot OMe$ (1898 and 1900).

Thallœdema candidum, probably lecanoric acid (H. 1898).

Thalloschistes flavicans, parietin (Z. 1905) (Brittany); physcion and acromelin (H. 1907).

Tornabenia chrysophthalma, physcion (H. 1907). *T. flavicans*, var. *crocea*, physcion (H. 1907). *T. flavicans*, var. *acromela* (*Physcia acromela*), acromelin $C_{17}H_{16}O_8$, m.p. 242°, and acromelidin $C_{17}H_{20}O_9$, m.p. 162° (H. 1907). *T. flavicans*, var. *cinerascens*, physcion and acromelin (H. 1907)

Umbilicaria pustulata (*Gyrophora pustulata*), gyrophoric acid ($C_{18}H_{18}O_7$ (?) (Stenhouse, Annalen, 70, 218; Z. 1898; H. 1898).

Urceolaria lichens, collected from the basalt rock of the Vogelsberg in Upper Hessia, contain lecanoric and erythric acids (Schunck, Mem. Chem. Soc. 1, 71).

Urceolaria scruposa, var. *vulgaris*, atranorin and lecanoric acid (H. 1898, 1904, 1907); patellaric acid (Z. 1902). *U. cretacea* (*U. scruposa*, var. *gypsacea*), lecanoric acid, and palettaric acid (H. 1898, 1911; *cp.* Zopf, 1897).

Usnea barbata (*Lichen barbatus, Parmelia barbata*), usnic acid (Rochleder and Heldt, Annalen, 48, 8; Stenhouse, *ibid.* 155, 51) and lichenin (Berzelius, Scherer's Annalen, 3, 205;

Hesse, Annalen, 137, 241; Ber. 10, 1324), usnic and barbatic acids (H. 1898); emulsin (Hérissey, J. Pharm. Chim. [vi.] 7, 577). *U. barbata* f. *dasypoga*, usnic acid and usnaric acid $C_{30}H_{22}O_{15}$, m.p. 240°–260° (H. 1898), *d*-usnic, usnaric, and alectoric acids (H. 1900); barbatic, usnic, and usnaric acids, but no alectoric acid (Z. 1902); alectoric acid (H. 1903). *U. barbata*, var. *ceratina*, usnic acid $C_{18}H_{16}O_7$, m.p. 195°–196°, and barbatin (H. Annalen, 1895, 284, 157). *U. barbata α-florida*, *d*-usnic, usnaric, and parellic acids, and usnarin (H. 1902). *U. ceratina*, usnic acid, barbatic acid and barbatin (H. 1898). *U. ceratina* (Black Forest), barbatic and usnic acids (Z. 1902), *d*-usnic acid, barbatic acid, and barbatin (H. 1903) (Java cinchona bark), *d*-usnic, usnaric, and parellic acids and ceratin (H. 1903). *U. ceratina β-hirta*, Bolivian, *d*-usnic, usnaric, plicatic, and barbatic acids (H. 1903). *U. barbata* (*β*-) *hirta*, *d*-usnic, usnaric, and barbatic acids, and usnarin (H. 1902), atranorin (H. 1906). *U. barbata* (*β*-) *hirta*, (St. Thomas), *d*-usnic and usnaric acids, and santhomic acid $C_{11}H_{14}O_4$, m.p. 166° (H. 1902). *U. hirta*, usnic acid (Knop, Annalen, 49, 103), usnic acid, alectoric acid, hirtic acid, m.p. 98°, and hirtellic acid (m.p. 215° decomp.) (Z. 1903). *U. cornuta*, *d*-usnic and usnaric acids (Z. 1902). *U. longissima*, barbatic and usnic acids (Z. 1897; H. 1898). *U. longissima* (from Amani), ramalic acid, *d*-usnic acid, and dirhizonic acid $C_{18}H_{16}O_5(OMe)_2$, m.p. 189° (H. 1906). *U. florida*, usnic acid (Knop, Annalen, 49, 103); usnic acid and hirtellic acid (Z. 1904). *U. schraderi*, *d*-usnic acid and usnaric acid (Z. 1905). *U. microcarpa*, *d*-usnic acid and usnaric acid (Z. 1905). *U. articulata*, var. *intestiniformis* (Indian cinchona bark), *d*-usnic acid, barbatic acid, and articulatic acid $C_{18}H_{18}O_{10}$ (?) (H. 1907). *U. plicata*, *d*-usnic acid, usnaric acid, usnarin, and plicatic acid $C_{20}H_{33}O_8(OMe)$, m.p. 133° (H. 1900). *U. scrŭposa*, atranorin and lecanoric acid (Z. 1902).

Pertusaria dealbata, Nyl. (*Variolaria dealbata*, *Lichen dealbatus*), variolarin (Robiquet, Annalen, 42, 236; 58, 320). Schunck found crustaceous *Variolaria* collected on the basalt rocks of the Vogelsberg in Upper Hessia, to contain lecanoric and erythric acids.

Xanthoria parietina (*Parmelia parietina*, *Physcia parietina*), atranorin and physcion (H. 1898, *X. lychnea*, physcion (H. 1898). *X. candelaria* (*X. controversa*, *X. lychnea*, var. *pygmœa*, *X. parietina*, var. *lychnea*), parietin, m.p. 202° (Z. 1904). A. G. P.

LICKNER'S BLUE. A silicate of cobalt and potassium. A variety of smalt; *v.* COBALT.

LIDDITE *v.* EXPLOSIVES.

LIEBERMANN and KOSTANECKI'S RULE *v.* COLOUR AND CHEMICAL CONSTITUTION.

LIEBERMANN'S REACTION *v.* PHENOL AND ITS HOMOLOGUES.

LIEBIGITE. Hydrated carbonate of uranium and calcium occurring as a thin green coating on pitchblende (of which it is an alteration product) from Adrianople in Turkey, Joachimsthal in Bohemia, and Johanngeorgenstadt and Schneeberg in Saxony. A determination of the optical characters of the minute crystals (E. S. Larsen, 1917) suggests the identity of liebigite with uranothallite of which the formula is $Ca_2U(CO_3)_4 \cdot 10H_2O$. L. J. S.

LIÈGE BLACK. *Blue black v.* PIGMENTS.

LIEN, LIENADEN *v.* SYNTHETIC DRUGS.

LIEVRITE *v.* ILVAITE.

LIGHT CARBURETTED HYDROGEN. *Marsh gas v.* METHYL.

LIGNIN (LIGNOSE) $C_{27}H_{31}O_9$ or $C_{40}H_{45}O_{13}$ (Paschke) ($C_{40}H_{46}O_{15}$, Beckmann) may be prepared from straw by treatment with alkali carbonate, precipitation from the extract with acid, and purified by repeated solution in alkali and reprecipitation with acid (Paschke, Zeitsch. angew. Chem. 1921, 34, 465). A constituent of woody substance, jute, acrogens, &c. The colour reaction produced when wood is treated with phloroglucinol, *p*-nitroaniline, &c., is not due to lignin, but to aldehydes, mainly coniferaldehyde, accompanying the lignin (Crocker, J. Ind. Eng. Chem. 1921, 13, 625).

Lignin heated with ten or twelve times its weight of potassium hydroxide for 40 minutes at 280° gives a 20 p.c. yield of oxalic acid.

LIGNIN DYNAMITE *v.* EXPLOSIVES.

LIGNITE *v.* FUEL.

LIGNOCERIC ACID $C_{23}H_{47}COOH$. A white crystalline solid, m.p. 80·5°, found in the solid paraffin obtained from beechwood tar (Hell and Hermanns, Ber. 1880, 1713) and in earth nut oil (Kreiling, *ibid.* 1888, 880). Found among the products of the dry distillation of oak-bark. Soluble in alcohol. Forms a lithium salt sparingly soluble in methyl alcohol by means of which it may be purified.

LIGNUM COLUBRINUM *v.* NUX VOMICA.

LIMA WOOD. A variety of Brazil wood (*q.v.*).

LIME *v.* CALCIUM; also CEMENTS.

LIME, BISULPHITE OF, *v.* CALCIUM.

LIME BURNING *v.* CALCIUM.

LIME, HYDRAULIC, *v.* CEMENTS.

LIME JUICE. Analyses of lime juice made by Huerre (J. Pharm. Chim. 1919, 20, 5) yielded: sp.gr. 1·052–1·064; citric acid, 7·0–7·5; malic acid, 0·50–0·60; tartaric acid, 0; sucrose, 0·40–0·50; invert sugar, 1·8–2·0; pectins, &c., 0·40; ash, 1·6–1·8 per 100 c.c., *v.* CITRIC ACID.

LIME-OIL *v.* OILS, ESSENTIAL.

LIME, SUPERPHOSPHATE OF, *v.* CALCIUM; also FERTILISERS.

LIMESTONE (*Kalkstein*, Ger.; *Calcaire*, Fr.). A rock composed essentially of calcium carbonate ($CaCO_3$) in the form of the mineral calcite. Owing, however, to the frequent presence of mechanically admixed impurities and to variations in texture, the rocks of this class exhibit wide differences in character (*v.* MARBLE, CHALK, LITHOGRAPHIC STONE, MARL, TRAVERTINE). A snow-white crystalline limestone—*i.e.* a statuary marble—is quite compact, and is pure calcium carbonate, consisting, in fact, of a granular aggregate of calcite crystals. With the admixture of clayey material there may be a gradual passage through argillaceous limestone to calcareous mudstone or to an incoherent marl. Other limestones, containing mechanically admixed impurities of various kinds, are described as siliceous, sandy, carbonaceous, bituminous, ferruginous, and phosphatic limestones. In dolomitic or magnesian limestones, dolomite is present in addition to calcite. Sp.gr. 2·6–2·8 for the denser non-porous varieties; crushing strength, 200–800 tons per square foot. The following analyses are of: I. Bluish-grey, compact

crystalline limestone of Carboniferous age from Horton quarries, Settle, Yorkshire; also P_2O_5, 0·17, MnO trace. II, Carboniferous Limestone ('Hopton Wood stone') from Hopton Wood quarries, Middleton, Derbyshire. III, Dark-cream, coarse-grained, granular limestone ('Mill-grit weatherstone'), Inferior Oolite, from Leckhampton quarries, Cheltenham, Gloucestershire; also FeO 0·26, K_2O+Na_2O 0·29. The majority of limestones are bedded rocks of sedimentary origin, and are composed of the calcareous remains of marine organisms. As a general rule the compactness of a limestone is a measure of its geological age; the harder and more compact varieties belonging to the Silurian and Carboniferous Systems, whilst those of the Jurassic, Cretaceous, and Eocene Systems are less coherent. Limestones may also be formed by the direct precipitation of calcium carbonate from calcareous waters or springs, *e.g.* travertine (*q.v.*) and stalagmitic marble (*v.* MARBLE). Although limestones often resemble some other kinds of rocks in their appearance, they can always readily be recognised by the fact that they easily yield to the knife and effervesce with cold dilute acid (those containing much magnesium effervesce only with hot acid). In addition to their extensive application as building stones, road-metal, &c., limestones are much used for making lime and in the manufacture of mortars and cements of various kinds (*v.* CEMENTS); in the manufacture of soda, carbon dioxide, &c.; as fluxes in smelting; as a polishing material; and as fertilisers, either in the powdered form or burnt as lime. Limestone rocks are also of importance as the depositories of ores of various kinds. Iron-ores and zinc-ores, as well as phosphates, frequently occur as metasomatic replacements of limestone; and veins of lead-ore and fluor-spar are usually richer where they intersect limestones.

Howe, Geology of Building Stones, 1910. On economic questions much has been written in the geological survey publications of the United States. L. J. S.

LIMESTONE, MAGNESIAN, *v.* CALCIUM, MAGNESIUM, and DOLOMITE.

LIMNITE. A hydrated ferric oxide $Fe_2O_3{\cdot}3H_2O$ or $Fe(OH)_3$ containing Fe_2O_3 74·7, Fe 52·3 p.c., and corresponding with gibbsite $Al_2O_3{\cdot}3H_2O$. Whilst, however, gibbsite (*q.v.*) occurs as a definitely crystallised mineral, the existence of limnite is somewhat doubtful. Very few analyses show the presence of a sufficient quantity of water (25·3 p.c.) to satisfy the above formula. Further, since limnite does not differ from some kinds of limonite in its external characters (earthy or ochreous, with brownish-yellow streak), the material has been regarded as being colloidal limonite with extra adsorbed water. The name limnite, from λίμνη, a bog, has practically the same meaning, so far as regards its derivation, as the name limonite (*q.v.*); and it includes also some bog-iron-ores. The mineral was originally described by R. Hermann in 1842 under the name *Quellerz* from bogs in govt. Nizhni-Novgorod. L. J. S.

LIMOGES ENAMELS *v.* ENAMELS.

LIMONITE or **Brown Iron-Ore.** A hydrated ferric oxide $2Fe_2O_3{\cdot}3H_2O$ of importance as an ore of iron (Fe_2O_3, 85·5; Fe, 59·9 p.c.). It is not found as crystals,[1] but often occurs as rounded, stalactitic, or mamillated forms with an internal radially fibrous (crystalline) structure. This fibrous material when examined in polarised light is found to possess quite definite optical characters. The surface of such masses is sometimes black and lustrous with a pitchy appearance (German, 'Glaskopf'), but here, as in all other instances, the streak of the mineral is of a very characteristic brownish-yellow colour. Concretionary (pisolitic) and earthy or ochreous masses are also of common occurrence. Material of this kind is colloidal in character and contains a variable amount of water, grading on one side into xanthosiderite ($Fe_2O_3{\cdot}2H_2O$) and limnite ($Fe_2O_3{\cdot}3H_2O$) (*q.v.*). A. Lacroix (1901) and F. Cornu (1909) have suggested that the term 'stilpnosiderite' be applied to the colloidal forms and limonite restricted to the crystalline. The sp.gr. varies from 3·6 to 4·0, reaching the higher value in the compact, fibrous material. Limonite is of abundant occurrence in nature as the final product of weathering of all iron-bearing minerals. Pseudomorphs of limonite after crystals of iron-pyrites and other minerals are well known; and the 'iron hat' or 'gossan' of mineral-lodes consists mainly of limonite. As an earthy ochreous deposit it separates from the waters of chalybeate springs, and in peat-bogs and at the bottom of pools and lakes. Such deposits are known as bog-iron-ore (*q.v.*), lake-ore, &c., and the name limonite (from λειμών, a meadow) means, in fact, meadow-ore. The phosphates they contain are of organic origin. The brown iron-ores extensively mined in Northamptonshire, the north of Spain, Luxembourg and Lorraine (here an oolitic ore known as 'minette'), and many other places, occur as beds in sedimentary rocks. Ochreous limonite is used for making paint, for colouring and glazing tiles, and in the manufacture of linoleum, brown paper, &c. Bog-iron-ore has been used in gas purifiers, and for extracting the sulphur from waste sulphurous gases. L. J. S.

LINADIN *v.* SYNTHETIC DRUGS.

LINAMARIN *v.* GLUCOSIDES.

LINARIN. A glucoside found in the flowers

[1] The only hydroxide of iron that occurs as definite crystals is goethite, $Fe_2O_3{\cdot}H_2O$ (*q.v.*).

and leaves of *Linaria vulgaris* (Mill.) (Klobb, Compt. rend. 1907, 145, 331).

LINNÆITE. A sulphide of cobalt, Co_3S_4 or $CoO{\cdot}Co_2S_3$, crystallised in the cubic system and analogous to spinel. The cobalt (11–45 p.c.) is usually largely replaced by nickel (0–42 p.c.), iron (2–5 p.c.), and copper (0–4 p.c.). The nickel-rich variety is known as *siegenite*, from Siegen in Westphalia. It is often found as bright octahedra of a steel-grey colour tarnishing to copper-red; also as compact granular masses, and as grains. Brittle; H. 5½; sp.gr. 4·8–5·0; soluble in nitric acid with separation of sulphur. It is found with other metalliferous ores at Bastnäs in Sweden, Müsen near Siegen in Westphalia, Madison Co. in Missouri, Mineral Hill in Maryland, at Santa Fé mine in the state of Chiapas in Mexico. At the last-named locality the mineral carries 0·53 p.c. of gold. L. J. S.

LINOLENIC ACID. Linolenic acid $C_{18}H_{30}O_2$ is a characteristic constituent of drying oils, notably linseed oil, and also occurs in certain animal fats, such as horse fat. It is a colourless oily liquid which rapidly absorbs oxygen from the air and turns brown. Sp.gr. at 15°, 0·9228 (Hehner and Mitchell); b.p. under pressure of 0 mm., 157°–158° (Bedford). It combines with bromine to form a white hexabromide (m.p. 179°–180°), which when reduced with nascent hydrogen yields linolenic acid. When oxidised with alkaline potassium permanganate it yields, as the principal product, hexahydroxystearic acid (linusic acid), m.p. 204°–205°. The existence of an isomeride of linolenic acid, iso*linolenic acid*, was inferred by Hazura from the fact that the liquid fatty acids of linseed oil also yielded an oxidation product (iso*linusic acid*), m.p. 173°–175°; but Bedford's experiments tend to show that Hazura's *iso*linusic acid is sativic acid, the main oxidation product of linolic acid, which has the same melting-point. Bedford concludes that when the insoluble hexabromide obtained by brominating linseed oil fatty acids is reduced by means of zinc and alcoholic hydrochloric acid it yields a mixture of two isomeric acids, α- and β-linolenic acids, the former again yielding the hexabromide on bromination, whilst the latter absorbs four atoms of bromine and yields a liquid tetrabromide $C_{18}H_{30}Br_4O_2$, mistaken by Hazura for *iso*linolenic hexabromide.

Linolenic acid may be quantitatively reduced to stearic acid by hydrogenation in presence of a metallic catalyst. The ethyl ester of linolenic acid boils at 132°–133° at a pressure of 0·001 mm., $n_D^{20}=1{\cdot}46753$. C. A. M.

LINOLIC ACID. Linolic acid $C_{18}H_{32}O_2$ is present as a glyceride in many vegetable oils, and can be separated in large amount from non-drying oils such as maize and cotton-seed oils. It is a pale yellow liquid which remains fluid at −18°. Sp.gr. at 14°, 0·9206. It differs from oleic acid in not yielding a solid compound when treated with nitrous acid (elaidin reaction). It absorbs oxygen rapidly from the air, and combines with bromine to form a tetrabromide $C_{18}H_{32}O_2Br_4$ (m.p. 114°–115°), which is readily soluble in ether, alcohol, and benzene, but sparingly soluble in petroleum spirit. When reduced with nascent hydrogen it yields linolic acid, whilst when oxidised with alkaline potassium permanganate, it yields as its main oxidation product, tetrahydroxystearic acid (sativic acid). According to Bedford there are two isomeric linolic acids, which he terms α- and β-linolic acid, the former yielding the solid tetrabromide (m.p. 114°–115°), and the latter a liquid bromide. Tariric acid, telfairic acid, and elæostearic acid (tung oil) are isomerides of linolic acid. C. A. M.

LINOXYN. The tough elastic product of the oxidisation of linseed oil.

LINSEED. The seeds of *Linum usitatissimum* (Linn.). There are two chief varieties, with white and blue flowers respectively. The plant requires moist heat, but is not suited to great heat and drought or to frosty conditions. It therefore does best on the seacoast or plains and hills where the rainfall is abundant or dews and fogs frequent, and in damp soils rather than in dry ones. It is grown in many countries, but the chief sources of the linseed of commerce are Russia and India.

The average composition, as given by König, as the mean of 61 analyses, is—

Water	Protein	Fat	Nitrogen free substances	Crude fibre	Ash
9·0	22·8	34·4	22·8	6·8	4·2

All the constituents are liable to considerable variation, *e.g.* protein 16–31 p.c., fat 22–40 p.c. The 'protein' of linseed is almost wholly albuminoid in nature, not more than 2–4 p.c. of it being in other forms (a small portion as a glucoside). Linseed contains a characteristic mucilage (about 6 p.c. of its weight), which exists mainly in the membranes of the outer cells and causes the seeds when macerated with water to swell up so much as to burst the cell-walls. When linseed is boiled with water, the mixture thickens owing to the solution of this mucilage.

Linseed is very largely consumed, being used as a food for young calves (as a partial substitute for milk), and in enormous quantities in the preparation of linseed oil, so important in the preparation of varnishes, paints, and linoleum, the by-product linseed cake or linseed meal, also forming an important cattle food, valuable not only for its nutritive value, but also on account of its richness in the manurial substances, nitrogen, phosphoric acid, and potash.

The ash of linseed contains—

K_2O	Na_2O	CaO	MgO	Fe_2O_3	P_2O_5	SO_3	SiO_2	Cl
30·2	2·1	8·1	14·3	1·1	40·5	2·3	1·2	0·2

Of pure linseed cakes there are two types, viz. those from which the oil has been *expressed*, and those from which the oil has been *extracted* by the use of volatile solvents; the former are richer in fat and more digestible, the latter richer in albuminoids and ash. The following average compositions are given by Kellner:—

	Water	Protein	Fat	*N*-free extract	Crude fibre	Ash
Expressed cake	11·0	33·5	8·6	31·7	8·7	6·5
Extracted ,,	10·2	37·4	3·8	32·7	9·1	6·8

It was shown by Jorissen (Bull. Acad. Roy. Belg. 1883, 3, 5, 750) that linseed contains a cyanogenetic glucoside. This glucoside, named *linamarin* by Jorissen, has been shown to be identical with *phaseolunatin* (α-dextrose ether of acetone cyanohydrin) which occurs in the beans of *Phaseolus lunatus* (Linn.) (Dunstan,

Auld and Henry, Proc. Roy. Soc. 1906, B. 78, 145). This substance is present in young linseed plants, in linseed, and also in linseed cake. In the latter, to the extent of yielding 0·03 to 0·04 p.c. of hydrocyanic acid, but the enzyme which hydrolyses the glucoside, and which is present in the seed, is destroyed by the high temperature employed in expressing the oil, and is therefore absent from the cake (Dunstan and Auld, J. Soc. Chem. Ind. 1908, 428). Pure linseed cake is therefore not *likely* to act as a poison, but *might* do so if prepared by cold pressure, or if fed along with any foodstuff containing the enzyme necessary for the hydrolysis of the glucoside. Linseed grown in hot, dry climates contains more hydrocyanic acid and more active hydrolysing enzyme than when grown under cool, damp conditions (Collins and Blair, Chem. News, 1915, 19).

H. I.

LINSEED GUM *v.* GUM.

LINSEED OIL, flax seed oil, is obtained from the seeds of the flax plant, *Linum usitatissimum* (Linn.), a native of Central Asia. The principal countries where it is grown in considerable quantities to yield oil seed are the Argentine, India, the United States, Canada, and Russia. Notable quantities of seed are also produced in Morocco. The seed is also cultivated in Australia and in S. Africa.

Two qualities of Russian seed are recognised in the trade, known, according to their source, as Baltic and Black Sea seed; hence the terms 'Baltic linseed oil' and 'Black Sea linseed oil.' The oil expressed from Indian seed is known as 'East India oil.' The Baltic linseed yields the best drying oil; this is explained by the fact that the Baltic seed is the purest, whereas in Black Sea seed 5 p.c. (and more) of hemp seed and (or) ravison seed are usually present. Indian seed is frequently mixed with mustard, rape, and cameline seed, owing to the plants yielding the latter being grown along with the flax plant. It has been proved that when the Indian linseed is carefully separated from the foreign seeds and then expressed, the oil possesses as good drying properties as does best Russian oil. During latter years, more attention having been paid in India to this growing industry, the quality of seed has improved. Argentine seed, yielding the (River) Plate oil (La Plata oil), being badly harvested, contains much chaff and admixed fibres; if more care were exercised, La Plata oil also would more regularly approach Baltic oil in drying properties. The United States, which, until a few years ago, had been importing East Indian seed, have so considerably increased the home production that they rank occasionally (*i.e.* when the harvest is plentiful) amongst the exporting countries. Canada also is exporting considerable quantities of linseed.

The proportion of linseed oil in the seed varies with the origin of the seed and also with the seasons. It may be accepted that linseed contains from 32 to 42 p.c. of oil, according to the origin. On a large scale the quantity of linseed oil obtained from good seed does not exceed 35 p.c.

The variations in the oil expressed from linseed of different origin are shown in the following results obtained by Sheppard (J. Ind. Eng. Chem. 1912, 4, 14):—

Seed	Oil	Sp.gr. at 15°	Av. weight per seed	Oleaginous impurities	Non-oleaginous impurities	Oil in total impurities
	p.c.		mg.	p.c.	p.c.	p.c.
1 American	39·67	1·1413	4·61	1·5	1·69	10·1
2 ,,	39·40	—	4·53	1·01	1·05	—
3 La Plata	36·98	1·1415	5·56	0·58	5·64	14·1
4 Calcutta	40·82	1·1326	5·41	4·85	5·03	14·9
5 Bombay	41·23	1·1182	7·88	0·81	2·80	—
6 S. Russia	39·11	1·1375	5·74	5·05	1·71	—
7 N. Russia	36·95	1·1458	4·19	3·31	1·97	—

The dark colour of La Plata oil is attributable to the non-oleaginous impurities.

On cold-pressing, a golden-yellow coloured oil is obtained, having a pleasant taste, so that it can be used as an edible oil. Considerable quantities are being expressed for this purpose in Russia, Hungary, Germany, and India. In some parts of Germany the oil is used either as such, or (as 'Leinoelschmalz') in admixture with tallow or (and) lard for edible purposes. By far the largest quantities of oil are, however, employed in the arts. In that case the seed is crushed between rollers and then heated to about 160°F. in the mixing kettle; subsequently the seed is expressed while still warm. The oil so obtained has a yellowish-brown hue, and is somewhat turbid, owing to traces of moisture and mucilaginous matter. The press cakes retain about 10 p.c. of oil; they are used as one of the most valuable and wholesome cattle foods.

On storing the oil, the moisture and the mucilaginous matter gradually settle out, and the oil hereby acquires a higher value, especially for some technical uses, as in the making of varnish. Such oil, sometimes kept for years, is known as 'tanked oil.' The suitability for varnish-making purposes is ascertained by heating rapidly the linseed oil in a test tube. Oil from which gelatinous matter separates is considered unsuitable. Seed pressed in a comparatively fresh ('green') state yields oil containing larger quantities of 'mucilage' than seed three to six months old. The gelatinous matter ('mucilage' or 'spawn' or 'break') contains phosphates and traces of sulphates.

The bulk of linseed oil is at present produced by expression. The main reason for this is that the hot-pressed cake is valuable as cattle food, whilst linseed meal obtained by extraction with solvents could only be used as manure, at any rate in this country. Occasionally linseed has been extracted with solvents, as it was thought that the oil so obtained, being richer in unsaturated acids, and containing less of the mucilaginous matter, would be more suitable for the paint and varnish trades. This has, however, not been borne out in practice, extracted oil having been found unsuitable as a paint oil. Moreover, the oil obtained by extracting with carbon disulphide, petroleum spirit, &c., possesses an inferior colour and a more unpleasant smell than expressed oil. Therefore it would only be profitable to extract damaged seed, which would be unsuitable for cattle food.

A rapid method for removing the impurities in the crude oil is to refine it, which is done on

a large scale by treating crude linseed oil with 1–2 p.c. of a somewhat concentrated sulphuric acid. The charred mass carries down with it the bulk of impurities contained in the crude oil. For the manufacture of the best and finest kinds of linseed oil ('artists' oil'), the refined oil is subjected to 'sun-bleaching,' by exposure in shallow zinc trays under glass to the action of sunlight. Powdered lead placed in the trays accelerates the bleaching process. A method of bleaching linseed oil by exposure to the Cooper-Hewitt mercury lamp has also been introduced. Dark linseed oils intended for soft soap are usually bleached in the soap works by treatment with a small amount of caustic potash. The soap which is formed carries down with it the colouring matters.

The chemical composition of linseed oil is not yet fully known. It may, however, be stated broadly that linseed oil contains about 10 p.c. of solid fatty acids, amongst which palmitic acid, stearic acid, and arachidic acid have been identified. In addition thereto, the oil contains a high proportion of linolenic acid and linolic acid. The proportion of oleic acid, which Hazura gave as amounting to about 5 p.c., may possibly, according to later statements, have to be raised to 15 p.c. The '*iso*linolenic acid,' which Hazura stated to occur in linseed oil has not been definitely proved to be a chemical individual. Rollett (Zeitsch. physiol. Chem. 1909, 72, 422) doubts the existence of a β-linolenic acid, which Erdmann and Bedford state is obtainable from linolenic acid (Ber. 1909, 41, 1324; Zeitsch. physiol. Chem. 1910, 79, 76). On the whole, the balance of evidence supports the view of Erdmann and Bedford.

Several mixed glycerides have been identified in linseed oil. Thus Schicht (Seifenfabr. 1914, 34, 673) separated linolopalmitostearin by chilling a solution of linseed oil in petroleum spirit, alcohol and ether, whilst the mother liquor contained other compounds which, judging by their chemical characters, were probably dioleostearin and linolodistearin. The insoluble bromide yielded by linseed oil is also probably produced by a mixed glyceride in the oil.

Linseed oil has a higher specific gravity than any fatty oil that would be used to adulterate it, with the exception of tung oil. Hence, in the trade a specific gravity lower than 0·93 is considered to indicate adulteration with other fatty oils or mineral oils.

The higher the specific gravity of a linseed oil, the more suitable it is for the purposes of the paint and varnish manufacturer. The value of the oil for this purpose is also expressed in a general way by the magnitude of the iodine value. Linseed oil has, with the exception of perilla oil, the highest value of all known fatty oils. Hence the iodine test is of value for identifying a sample. The iodine value of linseed oil should not fall below 170 (La Plata and North American oils), although much higher iodine values reaching as high a figure as 205 have been recorded. Thus Indian oils usually absorb from 183 to 192 p.c., and Baltic oil from 190 to 200 p.c.

Linseed oil is characterised by giving a high proportion of a bromide insoluble in ether, apparently the bromide of a mixed glyceride (Hehner and Mitchell, Analyst, 1898, 23, 315). A more accurate modification of the test has been devised by Davidson (J. Ind. Eng. Chem. 1921, 13, 801). According to Gemmell (Analyst, 1914, 39, 297) there is a definite relationship between the iodine value of an oil and the amount of insoluble bromide which it yields.

The American Society for Testing Materials has issued the following specifications for raw linseed oil from N. American seed: Sp.gr. at 15·5°, 0·936 to 0·932; at 25°, 0·931 to 0·927; acid value, 6·0 (max.); saponification value, 195 to 189; unsaponifiable matter, 1·50 p.c. (max.); refractive index at 25°, 1·4805 to 1·4790; and iodine value (Hanüs), 178 (min.). All tests must be applied to the oil filtered through paper, at 15·5° to 26·7°, immediately before weighing. (*Cf.* Davidson, J. Ind. Eng. Chem. 1921, 13, 801; in abstr., J. Soc. Chem. Ind. 1921, 817 A.)

When the price of linseed oil is high adulteration is practised to a very considerable extent. For the methods devised for detecting these adulterants the reader is referred to Lewkowitsch's Chemical Technology.

Linseed oil (provided its price is not excessively high) is very extensively used as stock material for soft soaps; for this purpose those oils are especially employed which have a comparatively low iodine value. The presence of mucilage is not objectionable in the case of oils for soap-making.

A further important application of linseed oil is found in the manufacture of boiled oil for paints, varnishes, lithographic varnishes, and for the manufacture of linoleum. No other drying oil approaches the properties of linseed oil, the drying oil *par excellence*. Hence linseed oil is also the best oil for making putty. Linseed oil is further largely used in the preparation of plastic masses.

Boiled-oil is obtained by heating linseed oil with driers to a temperature of about 150°C. The process is carried out by introducing the oil into a cylindrical vessel provided with a heating coil and agitating gear, so as to produce an intimate intermixture between oil and drier while they are heated to the desired temperature.

According to the quality and the amount of drier added, and the length of time during which the oil is heated ('boiled'), pale or dark oils are produced. The former are known in commerce as 'pale boiled oils,' the latter as 'double boiled oils.' The temperature of 'boiling' can be reduced even to 120°C. when 'liquid driers' (solutions of lead linoleate, &c., in linseed oil) are used. They are merely dissolved in the oil and the operation is assisted, if required, by a current of air.

This last process yields somewhat inferior drying oils to those obtained by boiling at 150°C. with lead oxide, &c. It has, however, been inferred therefrom that in order to obtain a quickly drying oil it suffices to prepare a solution of metallic salts in oil. This view has even led to the preparation of 'boiled oils' in the cold, by merely adding to linseed oil a solution of lead linoleate or manganese linoleate, and carefully mixing it with the oil. (An oil having the properties of a 'boiled' oil can also be prepared by carefully grinding linseed oil with manganese borate in the cold.) These 'boiled oils' are, therefore, identical with the product which

painters used to prepare themselves from raw linseed oil by grinding it with a drier. Such oils naturally do not dry so rapidly as do the oils prepared at a higher temperature; they behave more nearly like raw linseed oil as regards the time required to 'dry.' The investigations of Holden and Radcliffe (J. Soc. Dyers and Colourists, 1918, 34, 134) have shown that the rate of drying of linseed oil increases with the temperature, but that the higher the temperature the lower the maximum increase in weight, and the less the influence of added driers. For example, when dried just below 34° linseed oil gains 17 to 18 p.c. in weight, whereas at 100° the maximum increase is much less (7 to 8 p.c.), and at 150° there is no increase in weight, probably owing to the evolution of volatile products. The greater durability of linseed oil films dried at high temperatures must be attributed to the more rapid volatilisation of non-drying constituents. The volatile products of linseed oil oxidised at 100° contain aldehydes (acrolein) and traces of oil.

These results are in accordance with the conclusions of Salway (J. Chem. Soc. 1916, 109, 138), that in the drying of linseed oil oxygenides are first formed, and these tend to form dioxygenides, which would decompose with the formation of a mixture of aldehydes (including acrolein), and carbon monoxide and dioxide, formic, acetic, and acrylic acids. For the factors affecting the oxygen absorption of linseed oil see Waelle, J. Soc. Chem. Ind. 1920, 39, 48 T; Coffey, Chem. Soc. Trans. 1921, 1152. Manganese salts are much more effective than lead salts as driers, whilst cerium linoleate is more active than lead linoleate, but is inferior to manganese and cobalt linoleates (Morrell, J. Chem. Soc. 1918, 113, 111).

The conclusions of Ingle (J. Soc. Chem. Ind. 1917, 36, 319) on the course of the chemical reactions involved in the drying of lead linolenate are supported by the experiments of Morrell (*loc. cit.*) upon the cerium salts prepared from drying oils. When drying oils are heated there appears to be a change in the intramolecular linkings prior to polymerisation.

Experiments by Friend (J. Chem. Soc. 1917, 111, 162) have shown that linseed oil contracts on oxidation. The density of the oil increases as the absorption of oxygen proceeds, whilst the volume first increases and then gradually decreases.

With regard to the employment of other oils in the manufacture of boiled oils and the adulterants of boiled oils, *cp.* Lewkowitsch, Chemical Technology.

Linseed oil is also used in the manufacture of 'vulcanised oils,' and for extracting indiarubber from 'waste rubber.' By heating linseed oil with sulphur, the official *oleum lini sulf.* is prepared.

Owing to the high price of linseed oil during the last few years mixtures of tung oil, menhaden oil, and soya bean oil have been used as substitutes for it in paints and varnishes, special drying agents being used to accelerate the drying properties of the mixtures.

A method of preparing a substitute for boiled linseed oil by blowing superheated steam through fish oils previously heated at 235° to 240° is described in Ger. Pat. 272,465 of 1910. The drying properties are stated to be superior to that of linseed oil. J. L.

LINTONITE *v.* THOMSONITE.

LIPASE, the enzyme which hydrolyses fats to glycerol and fatty acids, is of considerable importance in animal physiology and in germinating seeds. It is used industrially in the manufacture of glycerol and fatty acids, and is concerned in the phenomenon of rancidity. The knowledge of it, however, is still in a somewhat fragmentary state. It was first discovered by Reynolds Green (Proc. Roy. Soc. 1890, 48, 370) in the germinating seed of *Ricinus communis* (Linn.), and has since been found in many other seeds, usually in the germinating rather than in the resting stage; it also occurs in mould fungi and in yeast. Lipoclastic enzymes are present in most animal tissues, the liver being the most active. The enzyme appears to cling to the solid particles of tissue cells.

Vegetable lipase is very sparingly soluble in water, and it is doubtful whether active filtered extracts of the enzyme can be obtained. It has been shown by Connstein and others (*see* summary in Asher and Spiro's Ergebnisse der Physiologie, 1904, 3, 194) that *Ricinus* lipase is effective only in the presence of acid, and that it acts preferentially on the natural fats, other ethereal salts being but little attacked by it.

Animal lipase, on the other hand, is quite active in hydrolysing simple esters and acts on the natural fats with difficulty, though this is perhaps due to the difficulty of securing a satisfactory emulsion (*cp.* H. E. Armstrong, Proc. Roy. Soc. 1905, 76B, 606; 1906, 78B, 376; Kastle and Loevenhart, Amer. Chem. J. 1900, 24, 491).

Commercial pancreatin prepared from the fresh sweetbread of the hog or ox contains a lipase often termed steapsin which acts in an alkaline medium, and is rapidly destroyed by strong alcohol and by all acids except the fatty acids, being the most delicate of the pancreatic enzymes

According to Tanaka (Chem. Soc. Abstr. 1910, i. 800) lipase is present in castor oil seeds in the form of an insoluble zymogen which is readily converted by dilute acid into the insoluble enzyme, the acid acting merely to liberate the enzyme which, when once liberated, is active in a neutral medium. Alternatively, it may be present as a salt which is decomposed by the acid. It is inactive in alkaline solution.

The action of lipase is accelerated by manganese sulphate and by bile salts. All acids are effective in activating the enzyme, action depending on the amount rather than on the concentration of the acid.

Animal lipase may be separated by dialysis, or filtering, into two substances which are inactive singly, but the original activity is restored when they are mixed; the activity of the filtrate is not destroyed by boiling (Magnus, Zeitsch. physiol. Chem. 1904, 42, 149; Rosenheim and Shaw-Mackenzie, J. physiol. 1910, 40). Lipase also exercises synthetic activity (Kastle and Loevenhart, Amer. Chem. J. 1900, 24, 491; Hanriot, Compt. rend. 1901, 132, 212).

It is considered by Falk and Sugiura (J. Amer. Chem. Soc. 1915, 37, 217) that castor oil beans contain two enzymes, one soluble in water and more active towards ethyl butyrate, and the other insoluble and more active towards glyceryl

triacetate and fats. The former is referred to as esterase and the latter as lipase.

Lipase is also present in soya beans.

Lipase occurs in the fat of fowls in the zymogenic form and becomes active only after death, causing the acidity of the fat to increase (Pennington and Hepburn, J. Amer. Chem. Soc. 1912, 34, 210).

Lipase powder (from Ricinus) loses its activity when kept with neutral fats alone without the presence of either acid or water. Triolein exerted greater action than other fats in this respect.

The ferment process is used for the preparation of soap-stock fatty acids (Connstein, Eng. Pat. 22111, 1902). The ground seeds were made into an emulsion with oils and dilute acetic acid, but the original process was abandoned on account of the losses due to the formation of a middle layer between the fatty and aqueous layers. According to Lewkowitsch (Chemical Technology of Oils, Fats, and Waxes, 1909, 3) it is now customary to prepare a 'ferment' by grinding decorticated castor seeds with a large quantity of water and filtering. The creamy liquor is allowed to ferment spontaneously when a creamy emulsion containing the active enzyme rises to the top. The oil is emulsified by air currents in lead-lined vessels with 40 p.c. of water, 5–8 p.c. of the ferment and 0·2 p.c. manganese sulphate, the last substance serving to accelerate the change (Eng. Pat. 25680, 1905). After several days the mixture is warmed to 80°C., and 0·3–0·45 p.c. sulphuric acid (50 p.c.) is added; it is then allowed to settle. Three layers are formed—a bottom aqueous layer containing glycerol, an upper fatty layer and a middle layer consisting of an emulsion, which is allowed to accumulate, and on renewed treatment separates into three layers. The temperature of hydrolysis is maintained above 20°C. and below 42°C.; it should be slightly above the melting-point of a fat. The products so obtained are much lighter in colour than those given by the older processes of hydrolysis.

Tanaka (J. Coll. Eng. Imp. Univ. Tohyo, 1912, 5, 125) has described the preparation of an active lipase from castor oil seeds by digesting the pressed material with a proper amount of acid and then washing to remove all soluble matter. This hydrolyses fats rapidly in the absence of any soluble acid. The shelled seed is crushed in a mortar and the oily mass digested with petroleum spirit for 24 hours, after which the greater part of the oil is removed by squeezing it through calico cloth. The residue is treated twice in the same manner with ether; it is then ground and digested during about 15 minutes with 8 c.c. of N/10 acetic acid to every 10 grams of the meal. The liquid is filtered off and the residue washed several times with water. It is dried in a vacuum desiccator and, when dry, ground fine and sifted through muslin. During washing about 40 p.c. of the material passes into solution. The powder obtained represents about 9 p.c. of the weight of the seeds. It is colourless and tasteless, and may be kept for a long time without undergoing appreciable change (*cf.* Armstrong and Gosney, Proc. Roy. Soc. 1913, B, 86, 586). The enzyme prepared with a weak acid such as acetic is distinctly superior to that obtained when a stronger acid is used.

Prepared as described, if olive oil be digested at 30°C. with about 3–4 p.c. of the powder and from 6–10 times as much water about 90 p.c. of the glyceride is hydrolysed within 7–10 hours.

It is possible to 'overdry' the enzyme when it is required to be used in the absence of water. In such cases the addition of traces of water usually restores the activity. Preparations of the enzyme often vary in activity considerably, a fact which is not surprising when it is remembered that their activity depends on surface condition of the colloid.

The activity of the enzyme is interfered with even by dilute acids, and it is easily rendered inert by excess of acid. Possibly the powder contains an emulsifying constituent on which its activity is largely dependent. Hence it is specially fitted to hydrolyse the oily glycerides of the higher fatty acids and is not suited to act in an aqueous solution. The interaction is inhibited by the products of change, both the fatty acid and glycerol, especially the former.

Under ordinary conditions the hydrolysis of fats by lipase powder is incomplete, and numerous observations are on record to prove that whether of animal or vegetable origin, it can act reversibly. In the case of olive oil and lipase prepared by the Tanaka method, the same equilibrium was attained starting either from the oil in presence of three molecular proportions of water or from the fatty acids and the equivalent of glycerine; the percentage of acid combined being about 38, and the main product a diglyceride indicating that the two primary hydroxyl groups of glycerine are first affected. In presence of more water the rate of both synthetic and hydrolytic changes was decreased, and the equilibrium point established in the direction of greater acidity. Even in presence of 30 molecular proportions of water some synthesis was observed (*cf.* H. E. Armstrong and Gosney, Proc. Roy. Soc. 1914, B, 88, 176).

Rancidity.—The presence of lipase in oily seeds leads to the formation of small quantities of fatty acids, particularly in presence of moisture. Commercial fats of both vegetable and animal origin, if they have not been submitted to a sufficiently high temperature to kill the enzyme during their manufacture, are likely to contain traces of lipase, and this in presence of moisture may cause the formation of free fatty acids. When the fatty acids are further exposed to oxidation, particularly in presence of light, rancidity takes place (*see* further on this point, Lewkowitsch, *l.c.* 1, 35) (*v.* FERMENTATION).

The presence in a fat of other substances on which bacteria can grow increases the probability of rancidity; butter or margarine, for instance, being particularly prone to the change. Fats such as cocoa butter which contain more saturated acids, are less liable to become rancid.

Numerous bacteria exist which split fats anaerobically and oxidise them aerobically, owing to the secretion of lipase. The injurious effect of fat splitting organisms on the quality of dairy products is chiefly due, in addition to their lipoclastic properties, to the production of bitter and odoriferous substances from proteins and casein. The organisms produce lipases

which act both in acid and alkaline solution, Sohngen (Proc. K. Acad. Wetensch Amsterdam, 1911, 13, 1200) finds that the decomposition of fat decreases as the amount of acid rises, and that it ceases entirely when the acidity of the culture liquid is about N/50. Mineral acids are more potent than organic acids. It is considered that rancidity can only take place when owing to the action of alkali-producing bacteria and moulds the acidity of dairy products falls below this limit. The decomposition of dairy fats by lipase is favoured by oxygen and light. Lipase is not soluble in other, fats, or fatty acids.

In commercial palm oil which is prepared in tropical countries under crude conditions, the proportion of fatty acids is considerable and the value of the product much diminished in consequence. Probably much of this development of acid is due to enzyme action. Palm kernels and copra similarly vary greatly in the amount of free acid they contain according to the care taken in their preparation and storage.

LIPOIODIN. Di-iodobrassidic acid ethyl ester.

LIQUATION. 'When an ore or metallic mixture containing ingredients differing sensibly in fusibility is exposed to a degree of heat sufficient only to melt the most fusible which may flow away from the unmelted mass, this process is termed liquation' (Percy's Metallurgy). In certain cases a mixture of two metals can be roughly separated in this way. For instance, if an alloy of lead and copper be heated to a temperature a little above the melting-point of lead, the lead trickles out, leaving a porous mass behind. The lead contains 2–3 p.c. of copper. The copper contains 25 p.c. of lead. This process is used commercially to separate antimony sulphide from the ore, by heating in earthenware pots with a hole in the bottom, through which the melted sulphide flows.

At the Schemnitz silver works impure lead is purified by melting it on the bed of a furnace, the lower end of which is connected with a large iron pot, heated independently, and into which the lead trickles. Fresh lead is thrown into the furnace from time to time; the melted lead flows into the pot and leaves less fusible alloys behind. The lead in the pot is then made hot, skimmed and poled. The purification of a metal by this means depends upon the formation of less fusible alloys between the metal and the foreign metals present. Pattinson's process (*v.* LEAD) for desilverising lead depends on the formation of such alloys, but in that case the solidified alloys are fished out of the melted lead by a ladle, instead of allowing the lead to flow away from them.

LIQUEFACTION OF GASES. The readiness with which many liquids can be converted into vapours similar in many respects to ordinary gases, suggests the possibility of an intimate relationship between the gaseous and liquid states of matter. Van Helmont, to whom we owe the introduction of the term 'gas,' in the latter part of the 16th century, distinguished between 'gases' and 'vapours,' saying that only the latter could be reduced to the liquid state. Boerhaave (1731) in his Elements of Chemistry (Eng. ed., 249), comments on the impossibility of liquefying air either in the sharpest frost or under pressure. Dalton clearly foresaw the result of subjecting gases to low temperatures and high pressures when he said: 'There can scarcely be a doubt entertained respecting the reducibility of all elastic fluids of whatever kind into liquids; and we ought not to despair of effecting it in low temperatures and by strong pressures exerted upon the unmixed gases.'

The statement in Fourcroy's Chemistry, 2, 74, that Monge and Clouet liquefied sulphur dioxide is one of the earliest recorded references to the liquefaction of a substance commonly recognised as a gas. Shortly afterwards, in 1805–1806, Northmore (Nicholson's Journal, 1805, 12, 368; 1806, 13, 233) succeeded in liquefying chlorine, hydrogen chloride, and sulphur dioxide, by compressing the gases into a strong glass receiver. These results, however, did not attract much attention, and no further work on the liquefaction of gases appeared until 1823.

The discovery of the production of liquid chlorine by heating chlorine hydrate in a closed glass tube, led Faraday to undertake a systematic study of the liquefaction of gases. The method employed in his first series of experiments (Phil. Trans. 1823, 113, 189) was simple. Into the sealed limb of a bent glass tube were placed materials for generating the gas. The other limb of the tube was then sealed and cooled in a freezing mixture of ice and salt. The end containing the reacting substance was heated to generate the gas; the pressure steadily increased as the gas was produced, and ultimately the gas liquefied in the cold limb. In this manner Faraday succeeded in liquefying sulphur dioxide, hydrogen sulphide, 'cuchlorine,' cyanogen, ammonia, carbon dioxide, and nitrous oxide, the experiments on the last two gases being often accompanied by violent explosions.

The first experimenter to utilise the evaporation of a liquid under reduced pressure in order to produce low temperatures was Bussy (Ann. Chim. Phys. 1824, 26, 63). By the rapid evaporation of liquid sulphur dioxide he reached temperatures sufficiently low to liquefy chlorine, ammonia, and cyanogen. This method of producing low temperatures soon came into general use.

In 1834 Thilorier (Ann. Chim. Phys. 1835, 60, 427, 432; Annalen, 1839, 30, 122) prepared liquid carbon dioxide on a large scale by what was essentially the method of Faraday, using, however, a wrought iron generator and receiver connected by a copper tube. Moreover, he succeeded in freezing this liquid by allowing it to escape through a jet into a specially constructed drum-shaped box. Solid carbon dioxide has proved of service to subsequent experimenters. A mixture of solid carbon dioxide and ether, often called *Thilorier's mixture*, is even to-day a very valuable refrigerant; by evaporating it under reduced pressure, temperatures as low as −110°C. can be obtained.

In Faraday's second research on the liquefaction of gases (Phil. Trans. 1845, 135, 155) the gases were subjected to the simultaneous influence of high pressure and low temperature. The former was applied by means of two air pumps, and the latter was produced by means of a cooling bath of Thilorier's mixture boiling

under diminished pressure. The gases were condensed in suitably shaped tubes of green bottle-glass, the pressures were measured by means of small air gauges inserted in the tubes, and temperatures were recorded by an alcohol thermometer. In these experiments, ethylene, silicon fluoride, phosphine, and boron trifluoride were liquefied, and hydrogen bromide, hydrogen iodide, sulphur dioxide, 'euchlorine,' hydrogen sulphide, ammonia, cyanogen, and nitrous oxide were solidified. Faraday was, however, unable to liquefy hydrogen, nitrogen, oxygen, nitric oxide, or carbon monoxide, although he predicted that, if the temperature could be sufficiently reduced, these gases would pass into the liquid state.

The work of Natterer (J. pr. Chem. 1844, 31, 375; 1845, 35, 169; 1852, 56, 127; Pogg. Ann. 1844, 62, 132; 1855, 94, 436; Wien. Ber. 1850, 5, 351; 1851, 6, 557, 570; 1854, 12, 199), which began in 1844 and extended over several years, placed at the disposal of experimenters a method for obtaining extremely high pressures. Natterer was the first observer to prepare liquid nitrous oxide in quantity. He repeatedly endeavoured to liquefy hydrogen, oxygen, nitrogen, and carbon monoxide, modifying his apparatus from time to time until the gases were subjected to the enormous pressure of 3600 atmospheres. Even the application of Thilorier's mixture to the gases at this pressure failed to effect their liquefaction.

Critical phenomena and the relation between the liquid and gaseous states.—The classical work of Andrews (Phil. Trans. 1869, ii. 575; also *ibid.* 1876, ii. 421) marks an era in the development of the subject of the liquefaction of gases. The relative values of temperature and pressure in effecting liquefaction had, up to that date, not been understood. As early as 1822, Cagniard de la Tour (Ann. Chim. Phys. 1822, 21, 127; 1823, 22, 411) had performed a series of experiments on heating volatile liquids in closed glass vessels. He showed that such a liquid as ether could be converted wholly into vapour, notwithstanding the existence of an enormous pressure, in a volume less than twice the volume of the liquid from which it was produced. He also observed that there was a definite temperature, independent of the actual amount of ether present, above which the liquid meniscus could not be observed, an indication that ether cannot exist as liquid above a certain temperature. Similar results were obtained with a number of other liquids, but their significance was not generally recognised at the time. Faraday, however, realised that the reason why he was unable to liquefy certain gases was that they were probably in the same condition as the ether vapour in Cagniard de la Tour's experiments when heated above the temperature at which the liquid meniscus disappeared, in which case he added that 'no compression, without the conjoint application of a degree of cold below that we have as yet obtained, can be expected to take from them their gaseous state.' It is curious, therefore, that Faraday made no attempt to realise the Cagniard de la Tour's state with any of the gases he had succeeded in liquefying.

Andrews found that on compressing carbon dioxide in a glass capillary tube at temperatures below 30·9°C., the volume diminished more rapidly than would be indicated by Boyle's Law, until at a certain pressure, depending on the temperature, liquefaction commenced. The pressure then remained constant while the volume was being diminished, until liquefaction was complete. After this, a large increase in pressure again became necessary in order to diminish the volume further. At temperatures above 30·9°C., however, he could obtain no indications of liquefaction at all, whatever pressure was applied. On partially liquefying carbon dioxide, and slowly raising the temperature, the surface of demarcation between the liquid and gas became fainter, lost its curvature, and finally disappeared at 30·9°C. 'The space was then occupied by a homogeneous fluid which exhibited, when the pressure was suddenly diminished or the temperature slightly lowered, a peculiar appearance of moving or flickering striæ throughout the entire mass.'

From these results on carbon dioxide and from analogous results for nitrous oxide, Andrews concluded that there is a perfect continuity between the gaseous and liquid states, and that for each gas there is a definite temperature above which it cannot be condensed to the liquid state. This temperature he called its *critical temperature*. The 'Cagniard de la Tour point,' to which Faraday frequently referred, and the 'absolute boiling-point' of Mendeléeff, correspond to the same temperature. The pressure required to effect liquefaction at the critical temperature is called its *critical pressure*.

Andrews was able from his results to draw a rational distinction between a 'vapour' and a 'gas' by defining them as gaseous substances respectively below and above their critical temperatures.

As a result of the work of Andrews it is clear that the general nature of the isothermals

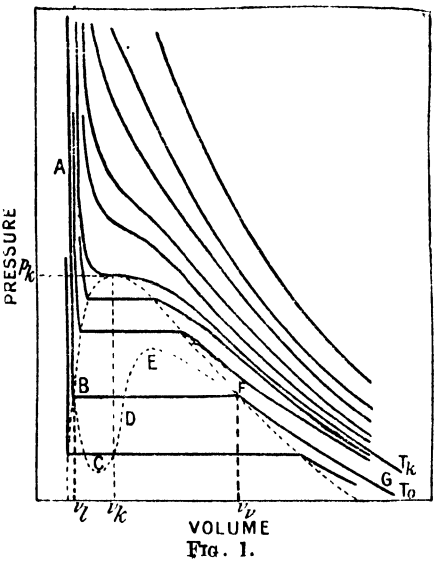

FIG. 1.

for a gas over a range of temperature, including the critical point, is similar to that shown in Fig. 1. Each isothermal below the critical point consists of three distinct parts, the middle

portion being horizontal. The abscissæ of its extremities, *e.g.* v_v and v_l on the T_0 isothermal, represent the specific volumes of the substance, if the diagram refers to unit mass, as saturated vapour and as liquid under its own vapour pressure at T_0 respectively; intermediate volumes correspond to mixtures of liquid and vapour.

The theory of Andrews, that the change from gas to liquid is continuous, and that there is no essential difference between the two states, was adopted by Van der Waals, who, in 1879, put forward an equation to represent the behaviour of any fluid that does not change its molecular complexity on passing from the gaseous to the liquid state (Van der Waals, Die Continuität des gasformigen und flüssigen Zustandes).

The characteristic equation for a perfect gas

$$pv=\mathrm{RT}$$

(where p, v, and T denote pressure, volume, and absolute temperature respectively, and R is a constant) represents the behaviour of ordinary gases accurately only over a small range of pressure, and at temperatures sufficiently removed from the critical point. As p increases, at constant temperature, from atmospheric pressure to one or two hundred atmospheres, the compressibility is initially greater than Boyle's Law indicates, the product pv diminishing as p increases (Regnault, Mém. de l'Acad. 21, 329; Amagat, Ann. Chim. Phys. 1880, [v.] 19, 345; 1881, [v.] 22, 353; 1883, [v.] 28, 456, 464; 1893, [vi.] 29, 68). The value of pv reaches a minimum, and afterwards increases with increase of pressure, so that at extremely high pressures all gases are much less compressible than is expressed by Boyle's Law (Natterer, *l.c.*; Amagat, *l.c.*). The initial diminution in the value of pv for a gas becomes less marked with rise of temperature, and at a sufficiently high temperature it is not observed. In the cases of hydrogen, helium and neon, this temperature, although considerably above the critical point, is much below the ordinary temperature, and the values of pv for these gases at this temperature steadily increase with rise of pressure from atmospheric pressure upwards (Regnault, Amagat, *l.c.*; Wroblewski, Monatsh. 1888, 9, 1067; Witkowski, Bull. Acad. Sci. Cracow, 1905, 6, 305; Kamerlingh Onnes and Braak, Comm. Phys. Lab. Leyden, 1907, No. 97; Burt, Trans. Faraday Soc. 1910, 6, 19).

These results can be represented fairly accurately by the equation of Van der Waals,

$$\left(p+\frac{a}{v^2}\right)(v-b)=\mathrm{RT}$$

the magnitudes of the (small) constants a and b (which may be deduced from the experimental values for p, v, and T) depending respectively upon the extent to which the molecules of the gas attract one another and upon their actual volume. This equation, besides representing the behaviour of compressed gases fairly accurately, also gives some account of the relationship between the liquid and gaseous states.

The equation represents the isothermals of a gas over a range of temperature including the critical point as being of the form shown in Fig. 1, with this difference, that those isothermals below the critical isothermal have the horizontal portions replaced by wavy curves, as indicated in the diagram by BCDEF on the isothermal for $T_0°$. The passage from vapour to liquid is thus represented as a continuous process. The portions BC and EF of the curve correspond with the conditions of superheated liquid and supersaturated vapour respectively, but the portion CDE of the curve, where p and v increase or decrease together, cannot be experimentally realised. At the critical point the specific volumes of vapour and liquid are identical, and the wavy portion of the curve therefore vanishes. Therefore the tangent at the critical point is horizontal, *i.e.* $dp/dv=0$. Since, moreover, the curvature of the critical isothermal changes sign at the critical temperature, $d^2p/dv^2=0$. These two relations give

$$2\ v_k^{-3}=\mathrm{RT}_k(v_k-b)^{-2} \text{ and } 3av_k^{-4}=\mathrm{RT}_k(v_k-b)^{-3}$$

the suffixes denoting critical values; whence

$$v_k=3b \text{ and } \mathrm{T}_k=8a/27b\mathrm{R}$$

Substituting in the original equation, $p_k=a/27b^2$. The critical constants for carbon dioxide, calculated by Van der Waals from these formulæ, were $T_k=32{\cdot}5$C., $v_k=0{\cdot}0069$, $p_k=61$ atmos., in fair agreement with the experimental values 30·9°C., 0·0066 and 70 atmos. respectively. The critical constants for hydrogen were determined by Wroblewski (Monatsh. 1888, 9, 1067) in a similar manner from his observations on the compressibility of the gas at low temperatures; his results agree remarkably well with the experimental values (Dewar, Chem. News. 1900, 81, 136) and afford a good instance of the utility of Van der Waals' theory. For further information concerning Van der Waals' equation, see Nernst's Theoretical Chemistry.

Liquefaction of the so-called 'permanent gases.'—The liquefaction of the five or six gases which Faraday and others had been unable to liquefy, and which had been called the 'permanent gases,' was, in the light of Andrews' researches, seen to depend upon the production of extremely low temperatures, since the lowest temperatures previously obtained had been above their critical points.

The first successful attempts to effect their liquefaction were made in 1877. On December 24th of that year, at the meeting of the French Academy, it was announced that Louis Cailletet of Chatillon-sur-Seine had liquefied both oxygen and carbon monoxide, whilst Raoul Pictet of Geneva had succeeded in liquefying oxygen (Compt. rend. 1877, 85, 1214, 1217, 1220).

The method used by Pictet (Compt. rend. 1877, 85, 1214; Ann. Chim. Phys. 1878, [v.] 13, 145; Arch. des Sci. Phys. et Nat. 1878) is essentially that devised by Faraday. Oxygen was generated by heating potassium chlorate in a wrought-iron flask. A long steel tube, provided at one end with a stop-cock, was attached to the flask. The accumulation of oxygen in the retort and tube created a pressure of 500 atmospheres. The tube was cooled to −120° to −140°, which is below the critical temperature of oxygen, by surrounding it with a copper cylinder through which liquid carbon dioxide, boiling under reduced pressure, was circulated. The liquid carbon dioxide was

obtained by compressing the gas to 4–6 atmospheres, and cooling it externally by means of liquid sulphur dioxide, boiling under diminished pressure at −65°C. The elaborate apparatus employed was so designed that both sulphur dioxide and carbon dioxide could be liquefied, evaporated and re-liquefied repeatedly, so as to produce *continuous cooling*. The oxygen liquefied in the cooled tube, and when the stop-cock was opened, issued as a liquid jet with great violence, since the pressure employed was far in excess of that actually necessary for liquefaction.

The simple apparatus employed by Cailletet (Ann. Chim. Phys. 1878, [v.] 15, 132) is shown in Fig. 2. The gas is introduced into a glass tube, TP, the narrow end of which consists of a stout capillary tube. By means of a metal collar, A, and the nut E′, the tube is screwed into a strong steel cylinder, B, partially filled with mercury. To compress the gas, water is forced into the steel cylinder by a hydraulic pump, through the copper tube U, which is fastened by the screws R and E into the apparatus; a pressure of several hundred atmospheres can thus be applied. A glass jacket M, and a bell-jar C, supported on the plate S, surround the capillary tube. The tap *r* serves to run off any liquid refrigerant in the jacket M.

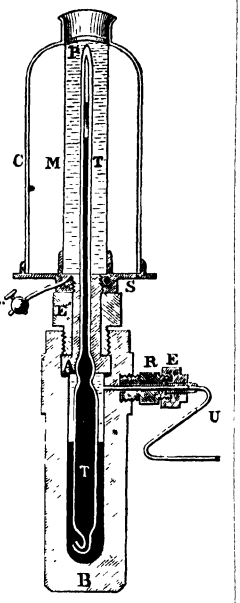

FIG. 2.

With this apparatus Cailletet liquefied acetylene (Compt. rend. 1877, 85, 851) and nitric oxide (*ibid.* 85, 1016), the latter condensing at −11° under a pressure of 104 atmospheres. Methane was not liquefied at 7° under a pressure of 180 atmospheres; but by suddenly releasing the pressure, the temperature of the gas was reduced sufficiently for liquefaction to occur, and a fine mist of liquid methane was formed in the tube. This method was successfully applied to oxygen and carbon monoxide (*ibid.* 85, 1213). The gases were compressed to 300 atmospheres, and cooled to −29°. The pressure was then suddenly released, when the resultant cooling effect was sufficient in both cases to produce partial liquefaction, a mist being formed of minute liquid droplets.

The theory of the process is simple. When a gas expands against external pressure, it performs work. This work is accomplished at the expense of the internal energy of the gas, and a diminution in the internal energy means a fall in temperature. To obtain the greatest fall in temperature possible, it is essential to perform the expansion with great rapidity in order that there may be no appreciable time for the gas to acquire heat from its surroundings. The fall in temperature experienced by a perfect gas when it expands adiabatically from an initial pressure p_1, at absolute temperature T_1, to a final pressure p_2, is given by $T_1 - T_2$, where

$$\frac{T_1}{T_2} = \left(\frac{p_1}{p_2}\right)^{\frac{k-1}{k}}$$

(k denoting the ratio of the specific heats of the gas). In the case of air, where $k = 1{\cdot}41$, if p_1, p_2, and T_1 were 100 atmospheres, 1 atmosphere, and 273° abs. respectively, the final temperature T_2 should be 71·5° abs., or −201·5°C. Although this numerical result is necessarily somewhat inaccurate, owing to the fact that air under the above conditions deviates considerably from the laws of a perfect gas, it is sufficient to indicate that the adiabatic expansion of a gas is capable of producing extremely low temperatures. In Cailletet's experiments, expansion occurred practically under adiabatic conditions.

By this method Cailletet also succeeded in liquefying air and nitrogen, and obtained indications of the liquefaction of hydrogen (Compt. rend. 1877, 85, 1270). He also prepared liquid ethylene, first obtained by Faraday, in large quantities, and recommended its use as a refrigerant (Compt. rend. 1882, 94, 1224; 1883, 97, 1115; Ann. Chim. Phys. 1883, [v.] 29, 153). By cooling compressed methane and oxygen with this reagent boiling under diminished pressure, Cailletet obtained liquid methane and oxygen in the static form (Compt. rend. 1884, 98, 1565; 1885, 100, 1033).

A period of great activity in connection with the liquefaction of gases followed the publication of the successful pioneering experiments of Pictet and Cailletet, the subject being taken up by Wroblewski and Olszewski in Cracow, by Dewar at the Royal Institution in London, and by Kamerlingh Onnes at Leyden. The Polish physicists occupied themselves mainly in determining the physical constants of liquefied gases. To obtain low temperatures, they acted upon Cailletet's suggestion, and employed liquid ethylene, which boils at −102°C., as a refrigerant. They compressed oxygen, nitrogen, and carbon monoxide in a stout glass tube by means of a modified Cailletet pump and cooled the gases to −136° by the rapid evaporation under diminished pressure of liquid ethylene, previously cooled with Thilorier's mixture. Under a pressure of 22·5 atmospheres, oxygen readily liquefied. The liquefaction of the other two gases was only effected by compressing them to 150 atmospheres at −136°, and then slowly reducing the pressure, when a further cooling effect was obtained. In each case a transparent liquid, with a well-defined meniscus, was obtained (Wied. Ann. 1883, 20, 243; Compt. rend. 1883, 96, 1140, 1225; Monatsh. 1883, 4, 415). The later work of these investigators was published separately. Wroblewski, who reached the temperature of −152°C. by rapidly evaporating liquid ethylene, obtained considerable quantities of liquid oxygen; he solidified nitrogen and carbon monoxide, and obtained temperatures below −200° by the rapid evaporation of the corresponding liquids; studied the utility of liquid methane as a refrigerant; obtained indications of the liquefaction of hydrogen; and at the time of his death was engaged in a

study of the compressibility of hydrogen over a wide range of pressure and at very low temperatures (Wroblewski, Compt. rend, 1883, 97, 166, 309, 1553; 1884, 98, 149, 304, 982; 99, 136; 1885, 100, 979; 1886, 102, 1010; Wied. Ann. 1883, 20, 860; 1885, 25, 371; 1885, 26, 134; 1886, 29, 428; Monatsh. 1885, 6, 304).

The independent investigations of Olszewski, in which he solidified ethylene, carbon monoxide, nitrogen, and methane; liquefied oxygen in quantity and used the liquid as a refrigerant; obtained indications of the liquefaction of hydrogen and determined the physical constants of these and other gases, were summarised by himself in 1895 (Phil. Mag. 1895, [v.] 9, 188; 40, 202; *cf.* Compt. rend. 1884, 98, 365, 913; 1884, 99, 133, 184, 706; 1885, 100, 350, 940; 1885, 101, 238; Monatsh. 1884, 5, 124, 127; 1886, 7, 371; 1887, 8, 69; Ann. Phys. Chim. 1889, [ii.] 37, 337; 1895, [ii.] 56, 133).

The work of Dewar at the Royal Institution, from 1880 to 1895, led to the production of liquid air, oxygen, &c., in large quantities by using a liquefying plant constructed of metal

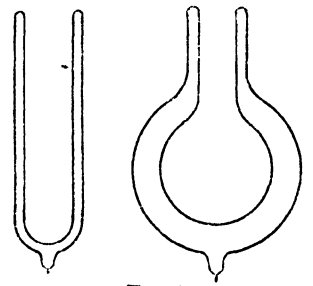

Fig. 3.

and utilising liquid ethylene as refrigerant (Proc. Roy. Inst. 1886, 550; *cf. ibid.* 1884, 148; Phil. Mag. 1884, [v.] 18, 210). Dewar commenced a study of the properties of matter in general at low temperatures, and in this connection he made a most valuable contribution towards the manipulation of liquefied gases by introducing a vessel in which they could be kept with the minimum of loss by evaporation. The *Dewar flask* (Fig. 3) is simply a double-walled flask of convenient shape, from the space between the walls of which the air has been exhausted. The contained liquid is thereby separated from the atmosphere by a vacuum-jacket except at the mouth of the flask. Evaporation of liquid air and similar liquids in these flasks takes place only very slowly, since the heat radiated across the vacuous space is only one-seventh of the total heat which would reach the inner vessel were the jacket to contain air. If desired, the flasks may be silvered on the inside, thus increasing their efficiency (*cf.* Briggs, Proc. Roy. Soc. Edinburgh, 1922, 41, 97).

The method of self-intensive refrigeration (so-called regenerative process).—The experiments of Wroblewski, Olszewski, and Dewar on the production of low temperatures, previously described, involved no new principle; the 'cascade' method of lowering the temperature by stages, originated by Pictet, had been employed, and at times combined with Cailletet's expansion method. In 1895 a new principle, that of producing cold by self-intensive refrigeration, was introduced almost simultaneously by Hampson and Linde. Briefly, it consists in continuously supplying the gas to be liquefied to an apparatus in which it may be cooled by expansion, and utilising each portion of gas, after it has been expanded and cooled, in lowering the initial temperature of the gas about to be expanded, until the cumulative effect of the cooling process is sufficient to produce liquefaction. For this purpose, the highly compressed gas at the ordinary temperature is passed downwards through a long copper spiral tube, expanded through a throttle valve, and the issuing gas passed upwards over the exterior of the copper tube.

For a description of Linde's liquefying plant *v.* the Engineer, October 4, 1895; J. Soc. of Arts, 1897, 1091; *cf.* also Eng. Pat. 12528, 1895; Ann. Phys. Chem. 1895, [ii.] 57, 328; Ber. 1899, 32, 925).

The general arrangement of Hampson's air-liquefying plant is indicated in Fig. 4. Air is

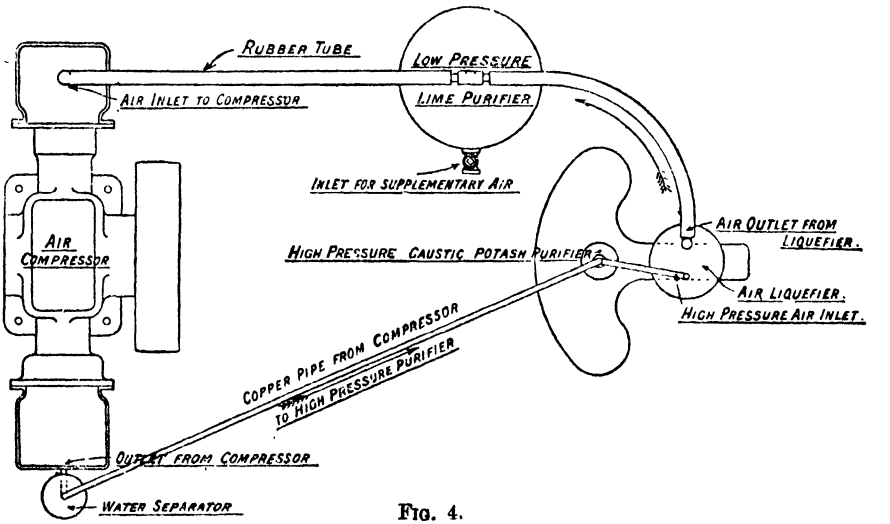

Fig. 4.

drawn into the compressor through the large purifier, containing slaked lime to absorb carbon dioxide, and compressed in two stages to 150–200 atmospheres. The compressor is water-cooled to remove the heat generated by compressing the air. The air is then forced through a separating vessel, in which most of the water used as lubricant separates out, and afterwards through the high-pressure purifier containing potassium hydroxide, in which the remaining water and carbon dioxide are completely absorbed. The purified air then enters the liquefier; that which passes out is usually returned through the low-pressure purifier to the compressor, and used again. The purifiers do not then have to be very often refilled.

The Hampson liquefier, manufactured by the British Oxygen Co. (Eng. Pat. 10165, 1895; 7773, 1898; J. Soc. Chem. Ind. 1898, 17, 411), is shown in section in Fig. 5. In designing it, the following points were kept in view: the necessity for having a large, exposed surface of material of high thermal conductivity between the compressed and expanded air, the thickness of the material being diminished as far as possible; the desirability of having both compressed and expanded air in small masses in close contact with the conducting material, and of reducing the total mass and volume of this heat interchanger to the smallest possible amount, in order to minimise the mass of metal to be cooled down with the gas, and prevent, as far as possible, any access of heat from the surroundings. The liquefier consists of four copper coils, B, wound co-axially about a spindle, D, and joined at their lower ends to a valve, C, which may be opened or closed by turning the hand wheel E attached to the top of the spindle. A metal chamber, G, soldered directly to the casing of the coils, serves to collect the liquid air. The whole is enclosed in a metal chamber and the space between this jacket and the casing of the coils is filled with non-conducting material.

The purified air, the pressure of which is indicated by the gauge O, enters the liquefier through A, travels down the coils and is allowed to escape through the valve C. The released air immediately expands down to approximately atmospheric pressure, and travels back over the exterior of the coils B, finally passing back into the compressor or directly into the atmosphere. The expanded air acts with a self-intensifying cooling effect on the compressed air which is passing down through the coils, and in from 6 to 10 minutes part of the air begins to liquefy and collect in G. This receiver is emptied by turning the wheel T, which opens the valve P, when the liquid flows down the hollow spindle R into a vacuum receiver. A gauge H, connected by the tube J with the receiver G, indicates the amount of liquid in G. About 1½ litres of liquid air per hour can be obtained with an ordinary Hampson apparatus, and no auxiliary refrigerant is required. The interchanger acts so perfectly that the air which leaves the apparatus is only about 1° colder than that which enters it. About 5 p.c. of the air passing through the apparatus is liquefied.

In the liquefying machines of Hampson and Linde, the work done against atmospheric pressure as the gas flows along after expansion is not performed by the gas at the expense of its internal energy; the necessary energy is continuously supplied by the compression pump. A steady stream of gas at high pressure is pumped continuously into the coils of the liquefier, and after passing through the valve, is converted into a steady stream of gas at low pressure. There is a slight thermal effect due to the performance of external work, but its magnitude only depends upon the extent

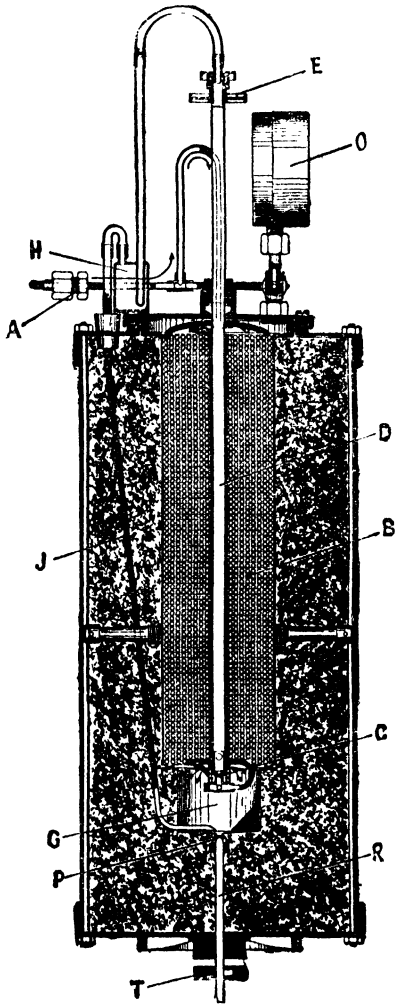

FIG. 5.

to which Boyle's Law is in error in representing the compressibility of the gas. It may be calculated from a knowledge of the specific heat of the gas and its compressibility, and at ordinary temperatures amounts to a slight cooling effect with all gases except hydrogen, helium, and neon. The main thermal change, however, is due to free expansion of the gas, and work is done in increasing the mean distance between the molecules of the gas in opposition to the forces of molecular attraction. This is performed

at the expense of the internal energy of the gas. The subject was studied experimentally by Joule and Thomson (Phil. Trans. 1853, 143, 357; 1854, 144, 321; 1862, 152, 579) for a number of gases, and a slight cooling effect was found to be the net result in each case at ordinary temperatures except for hydrogen. The fall in temperature was proportional to

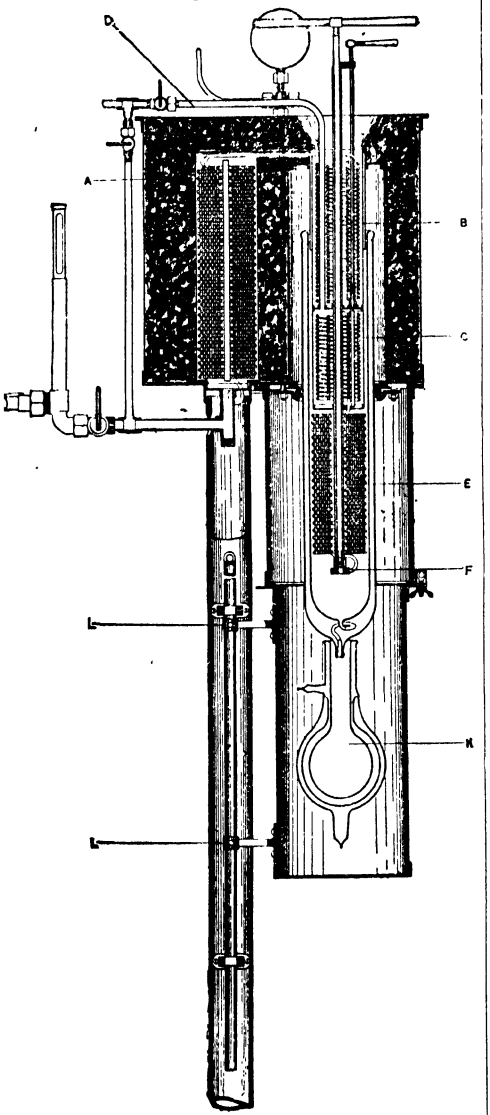

FIG. 6.

the fall in pressure (up to 6 atmospheres), and varied approximately as the inverse square of the absolute temperature. At 17·1°C. the fall in temperature for air is 0·255°C. per atmosphere.

There is a temperature at which the thermal effect produced by free expansion (the Joule-Thomson effect) is zero. According to Olszewski (Phil. Mag. 1902, [vi.] 3, 535) this is −80·5°C. for hydrogen, and below this temperature hydrogen is also cooled by free expansion. The 'inversion temperatures' in the case of air and nitrogen are considerably higher than ordinary temperatures, and appear to vary with the initial pressure of the gas (Olszewski, Bull. Acad. Sci. Cracow, 1906, 792).

To liquefy hydrogen (and helium) it is therefore necessary to cool the gas strongly before applying the self-intensive cooling process. It was by this means that Dewar (Chem. News, 1900, 81, 136) first succeeded in collecting liquid hydrogen. Travers (Phil. Mag. 1901, [vi.] 1, 411) and Olszewski (Bull. Acad. Sci. Cracow, 1902, 619; 1903, 241) have since described modified Hampson liquefiers for preparing liquid hydrogen, in which the hydrogen is cooled by liquid air and then allowed to expand through a specially constructed valve. By cooling helium to the temperature of liquid hydrogen and then applying the self-intensifying process, Kamerlingh Onnes (Compt. rend. 1908, 147, 421; Proc. K. Acad. Wetensch. Amsterdam, 1908, 11, 168) succeeded in obtaining helium in the liquid state.

The hydrogen liquefier designed by Travers and manufactured by the British Oxygen Company, is shown in Fig. 6. Pure dry hydrogen at 150–200 atmospheres pressure, enters the lower end of the coils A and is cooled by the cold hydrogen returning to the gas-holder. It then passes into the top of the coils in the chamber B, which is filled with liquid air, and by the time it has reached the bottom of the coils it is cooled to −190°C. The cold gas has its temperature lowered to below −200°C. as it passes through the coils in chamber C, which is connected by the pipe D to a vacuum pump, and in which liquid air is boiled under diminished pressure. The hydrogen then expands through the valve F at the end of the regenerator-coil E. The cooling-effect is self-intensified in the usual way, the cooled gas passing upwards over the coils E, and the outsides of the chambers B and C, finally cooling the coil A as it passes out of the apparatus. The coils B, C, and E are enclosed in a large, silvered vacuum-jacket. Liquid hydrogen collects in the vacuum vessel K, which is enclosed in a special box, hinged at LL to the supporting column and provided with glass windows.

Claude's process for liquefying gases.—The cooling effect produced when a gas expands with the performance of external work is much greater than that which is produced by the free expansion of the compressed gas. Mechanical difficulties for many years prevented this cooling effect from being intensified by rendering the process continuous, but it has now been effected by Claude. The process, as worked by Claude for the liquefaction of air, consists in compressing the air to 40 or 50 atmospheres and dividing it into two portions. One of these is expanded in a cylinder to 4 or 5 atmospheres, performing external work and thereby becoming cooled, and this cold air is then used to cool the other part, which can be thereby liquefied. This method, when applied on a large scale, needs less power than the Linde process; moreover, it may be used as a means of producing a low temperature preparatory to applying the ordinary self-intensive refrigeration method

(Claude, Compt. rend. 1900, 131, 500; 1902, 134, 1568; 1905, 141, 762, 823; Eng. Pat. 27658, 1902; Fr. Pat. 322107, 1902; Linde, J. Soc. Chem. Ind. 1911, 30, 744). For further information concerning Linde and Claude's processes, *v.* OXYGEN.

LIQUEURS and CORDIALS. The general characters of these beverages have already been described under the heading CORDIALS AND LIQUEURS (vol. II.), the former term being usually applied to British preparations and to such as have only one characteristic flavouring ingredient, and the latter to the foreign varieties which are usually of a more complex character. The term *liqueur* is also applied to certain wines and spirits remarkable for their bouquet as 'Tokay,' 'Liqueur brandy,' &c. *Bitters* are generally classed commercially with liqueurs and cordials, and contain one or more ingredients supposed to possess tonic and medicinal properties.

In ancient times, liqueurs consisted merely of wine flavoured with spices (as cinnamon) and sweetened with honey, and in the Middle Ages various aromatic herbs (as absinth, hyssop, &c.) were employed in a similar manner, the product being known as 'wine of herbs.' The 'liquori' of Italy were, however, the true prototypes of the modern liqueur, as the Italians were the first to extract the aromatic principles of the roots, leaves, flowers, fruit, and seeds of plants by means of spirit. Sometimes gold or silver leaf in a finely divided state was added to the liqueur, not only to give lustre, but also because of certain medicinal virtues these metals were supposed to possess.

At the present time, France is *par excellence* the home of the liqueur, and some of the most celebrated varieties have originated at certain monasteries which formerly derived considerable revenues from their manufacture and sale, *e.g.* *Bénédictine*, *Chartreuse*, *Trappistine*, &c. Other countries have their special preparations as *Anisette d'Hollande* and *Crême de Genièvre* (Holland), *Allasch* and *Kümmel* (Russia), *Alkermes* (Italy), *Maraschino* (Dalmatia), and the various *Cocktails* of the United States of America.

The number and variety of liqueurs and cordials is very great but the best known are comprised in the following list:—

Absinth	Curaçoa
Advocaat	Gin (sloe, &c.)
Alkermes	Kirsch
Allasch	Kümmel
Angostura (bitters)	Maraschino
Anisette	Noyau
Bénédictine	Parfait Amour
Brandy (cherry, &c.)	Peppermint cordial
Chartreuse	Ratafias
Clove cordial	Trappistine
Cocktails (American)	Vermouth
Crême de Menthe	Whiskey (cherry, &c.)

In the manufacture of liqueurs, the purity and good quality of all the ingredients used is a matter of the first importance. The spirits should be highly rectified spirits of wine as free as possible from fusel oil and free acid; the sugar of the finest white crystals or sugar-candy made into a clear syrup with distilled or pure soft water; glycerol (when employed) should be highly refined and colourless; and all the flavouring ingredients (*e.g.* flowers, fruits, rinds, roots, seeds, &c.) should be sound and well-dried.

The simplest method of manufacture, adopted for the commoner kinds of liqueurs, is that of merely adding essential oils to the spirit, and then the necessary amount of sugar syrup or glycerol.

The essential oils should be recently distilled and dissolved in from 5 to 10 times their weight of alcohol before being added. The particular flavour required can thus be better attained and cloudiness or milkiness of the finished liqueur avoided.

The finer qualities, however, are made by macerating the flavouring ingredients in spirit of about 85° to 90° alcohol by volume and distilling the infusion. The distillation was formerly conducted in copper stills heated by direct fire, then double-bottomed coppers were employed, and subsequently a water-bath added, but now steam-jacketed stills only are used in the largest liqueur factories. The middle portion of the distillate is used for the finest liqueurs, the first fractions being rough and the last inferior in character. Syrup is added, and sometimes glucose or glycerol to give density and impart a 'velvety' character to the liqueur, and the whole is heated, well mixed and diluted with water, after which filtration and 'fining' may be found necessary.

Liqueurs are often classified in France according to the proportions of spirit and sugar used, *e.g.* 'crêmes,' 'huiles,' or 'baumes,' which are heavily sweetened to a thick oily consistency, and 'eaux,' 'elixirs,' and 'extraits,' which are perfectly limpid and less highly sweetened. As a rule, the same proportions are employed for the same quality of liqueur. The following grades may be taken as typical:—

	Ordinaire	Demifine	Fine	Surfine
Alcohol at 85°	25 litres	28	32	36
Sugar	12½ kilos	25	37½	50
Water	67 litres	57	46	34

It will be observed that in the superior grades the proportions of alcohol and sugar are increased with a corresponding diminution in the proportion of water.

The flavouring ingredients are extremely numerous and varied in character, and their nature and proportions used are jealously guarded by the manufacturers as trade secrets.

The essential principles are extracted by *infusion* with hot spirit (if the aromatic principle is not too volatile), the ingredients being first moistened with boiling water; or by *maceration* with cold spirit which may require hours, days, or even many months, according to the solubility of the essential principles; by *digestion* or prolonged infusion or maceration in hermetically closed vessels when the aromatic principles are extracted only with difficulty by cold alcohol; or by *distillation* when only the natural essential oils or other volatile flavouring constituents are required. The following plants should always be distilled by steam: *absinth*,

anise, balms, caraway, citronella, fennel, juniper, hyssop, lavender, melilot, mint, orange, rose, sage, and *thyme.*

Aromatic tinctures for use in flavouring liqueurs are sometimes prepared by a kind of fractional filtration. The ingredients in a finely divided state are made into a paste with spirit and placed in a large funnel plugged with cotton-wool. Alcohol is poured in and the extract allowed to filter through drop by drop. The first portions are the purest and strongest, those following decreasing in flavour until the latter becomes too weak or even foreign in character.

Careful *mixing* is essential to the successful manufacture of liqueurs. Two separate vessels should be employed, the one for the essences or flavouring ingredients dissolved in about three-quarters of the total amount of alcohol required by the formula, and the other containing the syrup together with the rest of the alcohol. In this way the danger of the aromatic principles being thrown out of solution on the addition of the syrup is obviated, and the process of clarification expedited. The admixture should always be made in the cold to avoid loss of the flavouring principles, and the vessels may be hermetically sealed and provided with a scale or gauge rod to indicate the quantity of the ingredients admixed. The liqueur should rest for some days after mixing, and any defects, detected by taste, remedied before colouring, clarifying, or filtering.

Filtration, when necessary, should be conducted as quickly as possible. The older methods with cotton, paper, or wool in copper or tin filters are slow and result in loss of spirit and flavour. A better method is to use paper-pulp brought to the consistency of thick soup with some of the liqueur to be cleared. This is added to the bulk of the liqueur and the whole passed through a hair sieve. Natural clearing is best if time permits.

Clarification or '*collage*' with 'fining' materials is best avoided if possible, but is often necessary. The principal materials and the proportions used are as follows: *albumen,* white of egg (one egg for every 10 litres); *gelatin* (30 grams per 100 litres); *isinglass* (10 grams per 100 litres); *milk* (1 litre boiled in 100 litres, with 15 grams of alum). Animal or vegetable carbon, alum, nitre, and various 'filtering powders,' as 'Poudre Lebeuf,' are also employed. For coloured liqueurs, which are apt to suffer by this treatment, filtration is preferable to 'collage.'

Liqueurs containing various flavouring ingredients improve by keeping, as time is required for the intimate blending of the various substances in solution. The effect of this 'maturing' is artificially brought about in ordinary liqueurs and those intended for immediate use by a process known as *tranchage,* which consists either in heating in a water-bath to about boiling-point, or by successive coolings with ice. The object is to suppress the penetrating flavour of the new spirit and to give a smooth uniform character to the product so that none of the different flavouring ingredients can be individually recognised. Tranchage should be carried out *before* the coloration, clarification, or filtration of the liqueur.

The place of *storage* of liqueurs should be kept at a uniform temperature of 15° to 20° and the liqueurs protected from strong light or direct sunshine, as this affects the colour, frequently causing it to change or to be precipitated.

Bitters are considered to be tonic and stomachic and to improve the appetite when taken in moderation. They are prepared by maceration without distillation. The substances most commonly used are cascarilla, gentian, orange peel, quassia and wormwood. The best known preparations are *Angostura, Khoosh, orange,* and *peach bitters.* A fundamental principle in most bitters is gentian. A bitter made according to the following formula, which represents the proportions necessary to make 20 gallons, may be taken as typical: 6 lbs. gentian; 5 lbs. cinnamon; 5 lbs. caraway seeds; 1 lb. juniper berries; ½ lb. cloves. Macerate in spirit of about 90° (or 60 p.c.) for 10 or 12 days; strain, filter, add a syrup consisting of 10 lbs. of sugar to 13 gallons of water, and colour with cochineal.

English bitters may be made by digesting 5 ounces of the outer rind of dried orange peel, 6 ounces of cinchona bark, 6 ounces of gentian, 8 ounces of *Carduus benedictus,* 8 ounces of centaury, 8 ounces of wormwood, and 4 ounces of orris root, with 12 gallons of spirit about proof strength, filtering and sweetening with 12 lbs. of sugar.

In the following brief description of the best known liqueurs and cordials, the formulæ given are not intended, in the case of proprietary articles, as *Angostura, Chartreuse,* &c., to represent the exact composition or mode of preparation of the liqueurs originally known under these names, and the manufacture of which is carefully preserved as trade secrets, but only to serve as a guide to the preparation of a more or less successful imitation or substitute in each instance.

Absinth (*v.* article ABSINTH in vol. I.).

Angostura. A well-known 'bitters' originally made by the Capuchin Friars' Mission on the river Caroni in South America, and called after the ancient name of a city in Venezuela, now Bolivar.

As originally made the essential bitter principle was extracted from the bark of a plant belonging to the order *Rutacea,* genus *Galipea,* which has valuable febrifuge properties. The following formula is taken from the Scientific American Cyclopædia, 1903: 4 oz. gentian root; 10 oz. each of calisaya bark, Canada snake root, Virginia snake root, liquorice root, yellow bark, allspice, dandelion root, and Angostura bark; 6 oz. cardamon seeds; 4 oz. each of Tolu balsam, galanga, and Turkey rhubarb; 1 lb. each of orange peel and alkanet root; 1½ oz. each of caraway seed and cinnamon; ½ oz. cloves; 2 oz. each of catechu, coriander seed, nutmegs, and wormwood; 1 oz. mace; 1¼ lb. red sanders wood and 8 oz. turmeric. The ingredients are pounded and macerated for 15 days in 50 gallons of proof spirit, 30 lbs. of honey added, and filtered. This formula does not purport to represent the composition of 'Angostura Bitters' as made to-day, which is the registered title of a proprietary article, the ingredients in which have not been made known.

Advocaat, a spirit made in Holland from spirit and yolk of eggs and sweetened with sugar. The average strength is about proof.

Alkermes, a liqueur originally made at Florence and highly esteemed in the South of Europe. The original formula for the Alkermes de S. M. Novella is as follows: Bay leaves and mace, 1 lb. each; nutmegs and cinnamon, 2 oz. each; cloves, 1 oz. all bruised; cognac brandy, 3½ gallons; macerate for 3 weeks with frequent agitation. Distil over 3 gallons; add 18 lbs. of clarified spirit of kermes and 1 pint of orange flower water, mix well and bottle.

Allasch, a superior kind of kümmel (*q.v.*) flavoured with caraway seeds, bitter almonds, angelica root, anise, iris root, and orange peel. It is usually supersaturated with sugar which crystallises out in the finished liqueur. Strength about 25 u.p. or 43 p.c. alcohol by volume.

Anisette. The principal varieties, differing somewhat in the flavourings used, are *Anisette d'Amsterdam* and *Anisette de Bordeaux*. This liqueur may be made as follows: 4 oz. aniseed; 1 oz. each of coriander and sweet fennel seeds bruised; ½ gallon of rectified spirits and 3 quarts of water. Macerate 5 or 6 days, distil over 7 pints and sweeten with 2½ lbs. of pure sugar. The alcoholic strength of anisette is usually about 52 p.c. of proof spirit or approximately 30 p.c. of absolute alcohol by volume.

Bénédictine, so called from a monastery of this order in the north of France where the liqueur was first made. It is now produced on a large scale by a company at Fécamp, at a uniform strength of 75 p.c. proof spirit or 43 p.c. of alcohol.

This liqueur may be prepared by the following formula: cloves, 2 grams; nutmegs, 2 grams; cinnamon, 3 grams; balm, peppermint, freshly gathered angelica and genepi of the Alps, each 25 grams; calamus, 15 grams; cardamoms (small), 50 grams; arnica flowers, 8 grams. The materials are crushed and macerated for 2 days in 4 litres of alcohol at 85°; 3 litres of water added and the whole distilled, taking over 4 litres. A cold syrup made with 4 kilos. of sugar and 2 litres of water is added, the mixture brought up to 10 litres with water, coloured, and filtered.

Brandy (apricot, cherry, ginger, lemon, orange, peach, raspberry, &c.) by macerating the fresh fruits often for prolonged periods or mixing the juice with brandy, and sweetening with sugar syrup. Frequently essential oils are used, as ginger-brandy oil, essence of lemon, &c., and plain spirit instead of grape brandy. *Gin* and *whiskey* are similarly used for the preparation of fruit liqueurs, as sloe gin, cherry whiskey, &c., and, as in the case of brandy liqueurs, plain rectified spirit is commonly employed instead of gin or whiskey.

Chartreuse (*see* vol. I.).

Cocktail, a compounded drink much used in America. The spirit basis is brandy, gin, whiskey, or other spirits, and the different varieties, depending upon the kind of flavouring used, are very numerous and sold under fanciful names. A bottle of brandy cocktail may be made as follows: one-half brandy; one quarter water; and a wineglassful each of bitters, curaçoa, and gum syrup. Whiskey and gin cocktails may be made by the same recipe, substituting these spirits for brandy. The strength is usually from 50 to 75 p.c. of proof spirit.

Clove cordial may be prepared by the following formula: Bruised cloves, 1 oz. or essential oil, 1 dram to every 4 gallons of proof spirit. If distilled, this should be done over a quick fire. The necessary deep colouring is sometimes obtained by means of poppy flowers or cochineal, but more commonly with brandy colouring or red sanders wood. The cordial is improved by the addition of 1 dram of bruised pimento or 5 drops of the oil for every ounce of cloves. It is sweetened with about 3 lbs. of sugar to the gallon.

Crême de Menthe is one of the most popular liqueurs in the United Kingdom and is typical of the class of 'crêmes,' which are highly sweetened and usually flavoured with only one characteristic ingredient, *e.g.* crême d'anis, cacao, café, menthe, noyau, orange, thé, vanille, &c.

The inferior grades are made by flavouring plain spirit with essential oils without distillation whilst the superior qualities are produced by macerating the flavouring ingredients (which sometimes include small quantities of others besides the principal one characteristic of the liqueur) with alcohol and subsequent distillation, sweetening, and colouring.

The following recipe for Crême de Menthe is given by De Brevans (The Manufacture of Liquors and Preserves, New York, 1893): Peppermint, 600 grams; balm, 40 grams; cinnamon, 20 grams; sage, 10 grams; orris root, 10 grams; ginger, 15 grams. These are distilled with 5 litres of alcohol at 85°, the distillate sweetened with 3·75 kilos. of white sugar, and made up to 10 litres.

Curaçoa, so called from the principal island of the Dutch West Indies where the peculiar oranges used for the manufacture of this liqueur, and known as 'Curaçoa apples,' are obtained. These are used before ripening and are exceedingly bitter.

The liqueur is now made chiefly in Amsterdam. The dried peel is rasped to a finely divided condition, macerated for several days in dilute spirit and distilled. A tincture made from various spices as cinnamon, mace, or cloves is often added to the distillate, which is then sweetened with syrup and coloured as desired with Brazil wood, saffron, or caramel. The flavour is said to be improved by the addition of about 1 p.c. of Jamaica rum. The alcoholic strength varies from 50 to 75 p.c. of proof spirit, the average being about 60 p.c. proof or approximately 35 p.c. of alcohol by volume.

The following formula is given by De Brevans: rasped skins of 18 or 20 oranges; cinnamon, 4 grams; mace, 2 grams; alcohol at 85°, 5 litres; white sugar, 1·75 kilos. Macerate for 14 days, distil without rectification, and colour with caramel.

Kirsch (see KIRSCHWASSER).

Kümmel, a liqueur made chiefly in Russia and to some extent in the other countries on the shores of the Baltic. The principal flavouring ingredient is caraway seeds. The inferior grades are, as usual, made from plain spirit and essential oils, and the superior qualities by maceration with spirit followed by distillation.

The following formulæ indicate the quantities

necessary to make 20 gallons:—(*a*) inferior quality: 7 gallons of spirits of wine; ¼ lb. essential oil of caraway seed; 7½ drachms of fennel seed oil; 15 drops of bitter almond oil; syrup made with 40 lbs. of sugar in 12 gallons of water. When fined with alum or soda solution, it is ready for use. (*b*) Superior quality: 4 lbs. caraway seeds; ¼ lb. fennel; 2 oz. of Florentine iris root. These are macerated with 10 gallons of spirits of wine and 8 gallons of water, and distilled. The first part of the distillate is set aside because of its rough character, and about 8 gallons are then distilled over for making the fine kümmel, the last fraction of 3 or 4 gallons being used for the inferior grades. To the middle fraction a syrup made with 60 lbs. of sugar in 10 gallons of water is added, and the whole well mixed in an open heated vessel. The liquor is then cooled and made up with water to 20 gallons. It may be fined with isinglass and stored to mature and mellow.

The strength of kümmel varies considerably, viz. from about 60 to 100 p.c. of proof spirit, the average being 75 p.c. proof equivalent to 43 p.c. of alcohol by volume.

Maraschino. This liqueur was originally made at Zara in Dalmatia from the wild *marasca* cherry. The juice was fermented, distilled, aged for two or three years, and subsequently made into liqueur by diluting with syrup. Such liqueur usually contains 30 p.c. to 44 p.c. alcohol and 26 to 36 p.c. sugar. The maraschino prepared from the marasca cherry has a delicate fragrance, quite different from products prepared in a similar way from other varieties of cherry or other fruits. It contains traces of benzaldehyde and of hydrocyanic acid, but usually no added flavouring matters. Genuine maraschino diluted with water, then saturated with sodium bisulphite and extracted with ether, imparts its original odour to ether. French, Dutch and American maraschinos have generally an entirely different flavour from the Dalmatian product and are made by fermenting other varieties of cherries with or without the addition of other fruits (Riley and Sullivan). Other flavouring ingredients are now commonly used, as cherry leaves, kirschwasser, peach kernels, orris root, raspberries, vanilla, &c.

Imitation maraschino may be made from plain spirit flavoured with bitter almonds, raspberry juice and orange flower water, or with essential oils as neroli, noyau, jasmine, and vanilla.

The strength varies from 55 to 75 p.c. of proof spirit, average 69 p.c. proof or 39 p.c. of absolute alcohol by volume.

Noyau is distilled from brandy macerated with or distilled from bitter almonds, sometimes with the addition of other flavourings as cinnamon, coriander seed, ginger, mace, and nutmeg. The almonds are occasionally replaced by apricot or peach kernels or by oil of bitter almonds or its substitute nitrobenzene. The flavour is due chiefly to the presence of prussic acid and the liquor should therefore be used sparingly. It is frequently coloured pink.

Parfait amour may be made by flavouring spirit with the peel of 4 lemons, 1 drachm of essence of vanilla, and 3 lbs. of sugar to the gallon, colouring with cochineal. The essences of lemon, cloves, and mace are also employed in some varieties of this liqueur. The average strength is 60 p.c. of proof spirit or 34·5 p.c. of alcohol by volume.

Peppermint cordial (known also as 'Eau des Chasseurs' or 'Sportsman's cordial') is prepared from oil of peppermint, plain spirit, and sugar. The following is a recipe for making 100 gallons: English oil of peppermint, 5 oz., is added to 3 pints of rectified spirits of wine, well shaken, and placed in a cask capable of holding 100 gallons. 36 gallons of perfectly colourless and flavourless spirit at proof strength are poured in, and the whole well shaken for 10 minutes. A solution of pure sugar, $2\frac{3}{4}$ cwt. in about 35 gallons of pure soft water (preferably filtered rain water) is added, and the contents of the cask well rummaged for 15 minutes. Sufficient water to make the quantity up to 100 gallons, and containing 5 oz. of alum in solution is next added, and the whole again well agitated for a quarter of an hour. The cask is then bunged down and allowed to rest for a fortnight.

On a small scale, peppermint cordial may be prepared by taking a pint each of peppermint water and gin or plain spirit of about 20 u.p. and adding ¾ lb. of sugar. Peppermint water is prepared by macerating peppermint flowers in about 4 times their weight of water containing about 5 p.c. of salt.

Ratafia. This term is applied to liqueurs or cordials the basis of which is the juice of fruits, obtained either by maceration or simple pressure. One of the most important is Ratafia de Cassis, made from black currants, but other pulpy fruits, especially apricots, cherries, gooseberries, oranges, peaches, raspberries, and strawberries are also commonly used. Various other flavourings as spices, ginger, orris root, &c., are occasionally added to give variety of flavour. The following formula for the preparation of cherry ratafia may be taken as typical: 20 litres of cherry juice; 20 litres of alcohol at 85°; 13·5 kilos. of sugar, and 4 to 8 litres of bitter almond water.

Trappistine. Originally prepared at one of the Trappist monasteries in Italy. Recipe: large absinthe, 20 grams; angelica, 40 grams; mint, 80 grams; cardamom, 40 grams; balm, 30 grams; myrrh, 20 grams; calamus, 20 grams; cinnamon, 4 grams; cloves, 4 grams; mace, 2 grams; alcohol at 85°, 4·5 litres; white sugar, 3·75 kilos. The method of preparation is similar to that described for Chartreuse (*v.* vol. I.). After macerating for 2 days, distil and rectify. Add syrup and colour green or yellow.

Vermouth. The principal varieties of vermouth are the French and Italian, the basis in each case being white wine flavoured with various herbs. Inferior kinds are made from brandy or other spirit sweetened and flavoured with essential oils. The French variety is less sweet and stronger in bitter principles, particularly wormwood, than the Italian.

The following recipe by Ollivero may be used for Italian vermouth: 100 litres of white wine of Picardy; coriander, 500 grams; rinds of bitter oranges, 250 grams; orris root, powdered, 250 grams; elder flowers, 200 grams; red cinchona, 150 grams; calamus, 150 grams; 125 grams each of large absinth, holy thistle, (*Carduus benedictus*), elecampane (roots), little centaury, and germander; Chinese cinnamon,

100 grams; angelica root, 65 grams; 50 grams each of cloves, galanga, and nutmegs; and 30 grams of cassia. Digest for 5 or 6 days, draw off the liquor, size with fish glue and allow to stand for 15 days.

—	Specific gravity	Alcohol by volume	Alcohol by weight	Extract	Cane sugar	Other extractives	Ash
Absinth .	0·9116	58·9	—	0·18	—	0·32	—
Anisette de Bordeaux .	1·0847	42·0	30·7	34·82	37·44	0·38	0·040
Bénédictine	1·0709	52·0	38·5	36·00	32·57	3·43	0·043
Chartreuse .	1·0799	43·2	—	36·11	34·35	1·76	—
Crême de Menthe .	1·0447	48·0	36·5	28·28	27·63	0·65	0·068
Curaçoa .	1·0300	55·0	42·5	28·60	28·50	0·10	0·040
Ginger .	1·0481	47·5	36·0	27·79	25·92	1·87	0·141
Kümmel .	1·0830	33·9	24·8	32·02	31·18	0·84	0·058

The strength of vermouth is usually between 23 and 30 p.c. of proof spirit, the average being 27 p.c. or 15·5° of alcohol by volume.

The above table, by König, shows the results of analysis of some of the best known liqueurs and cordials.

J. C.

LIQUEUR DE FERRAILLE. *Ferric acetate v.* ACETIC ACID.

LIQUID STORAX *v.* BALSAMS.

LIQUORICE. The root of *Glycyrrhiza glabra* (Linn.). Cultivated chiefly in Spain, Russia, Italy, and to a small extent in Germany and England. It requires deep, fertile soil. Wild plants supply a considerable quantity in Asia Minor, and in some portions of Russia. The Spanish product is generally preferred to the Russian, since the latter is somewhat bitter.

The following analyses are given by König—

	Water	Protein	Fat	Glucose	Sucrose	Other N-free extract	Fibre	Ash
Spanish liquorice	8·8	12·9	3·7	7·4	2·1	43·0	17·7	4·4
Russian „	8.7	9·3	3·1	6·0	10·4	38·4	18·8	5·4

Liquorice owes its characteristic sweet taste to the presence of *glycyrrhizin* (the calcium and potassium salts of glycyrrhizic acid) which is present to the extent of about 8 p.c. To extract this, the roots are treated with cold water, the liquid boiled to precipitate albuminoids, filtered, and dilute sulphuric acid added, when the glycyrrhizic acid is precipitated in pale yellow flocks, which soon become a dark brown, sticky mass. This is then washed until free from acid and dissolved in dilute ammonia. By evaporation to dryness of this liquid, the "glycyrrhinum ammoniacale" is obtained, which serves as a sweetening agent in the preparation of medicines, in porter-brewing, and also as a sweetmeat.

Liquorice also contains a yellow colouring matter, and from 2 to 4 p.c. of asparagin, malic acid, starch, a little tannin, sucrose, saponins, glycyrrhetic acid, &c. (*cf.* Housemann, Amer. J. Pharm. 1916, 88, 97.

Estimation of Glycyrrhizin in Liquorice Root.—The root is ground to pass a twenty-mesh sieve, and dried at 50°C. to a moisture content of less than 2 p.c. Three grams of the powder are treated in an extraction apparatus with 50 c.c. of ether, dried and transferred to a 100 c.c. centrifuging tube to which 75 c.c. of 75 p.c. alcohol are added. After frequent stirring, followed by standing overnight, the tube is centrifuged, the clear liquid is poured off, and the alcoholic extraction of the residue twice repeated. The mixed extracts are evaporated to dryness, dissolved in 10 c.c. of water, filtered, diluted to 20 c.c., and precipitated by the addition of 3 c.c. of 10 p.c. sulphuric acid. The residue is washed with two 5 c.c. portions of ice-cold water saturated with ether, and dissolved in 30 c.c. of warm 95 p.c. alcohol. The acid solution and washings are mixed and neutralised by the addition of ammonia, evaporated to about 5 c.c. and treated with 2 c.c. of 10 p.c. sulphuric acid, and the precipitate washed with iced ether-water as above. This precipitate is dissolved in 10 c.c. of warm 95 p.c. alcohol, filtered and added to the alcoholic solution of the first residue. To the mixed solutions two drops of 5 p.c. ammonia are added, the solution evaporated to dryness, and the residue dried at 100°C. and weighed. The method yields results considerably higher than do previous methods, and the glycyrrhizin obtained is light in colour, intensely sweet, and free from resins and bitter substances (Housemann, Amer. J. Pharm. 1921, 481–495). H. J.

LIQUORICE ROOT. *Glycyrrhizæ Radix.* B.P.; *Glycyrrhiza*, U.S.P. (*Réglisse*, Fr.; *Süssholzwurzel*, Ger.). The peeled root of the underground stems of the *Glycyrrhiza glabra* (Linn.), a plant inhabiting the south of Europe and Central Asia (*cf.* Bentl. a. Tim. 74). Liquorice, or its solid aqueous extract, the 'Spanish juice' of commerce, has long been a favourite demulcent in throat affections, and is used as a laxative. It finds also a considerable employment in porter-brewing. The U.S.P. admits in addition Russian liquorice from *G. glabra glandulifera* (Regel et Herder).

The root was examined chemically many times since 1808; for an exhaustive bibliography, *see* Linz (Arch. Pharm. 1916, 254, 216). It was found to contain *glycyrrhizin* or *liquoricc sugar*, the most important constituent, together with an *acrid oil*, *asparagin*, *malic acid*, *starch*, traces of *tannin*, and other substances common to plants.

Glycyrrhizin has been further studied more recently by Tschirch and Cederberg (Arch. Pharm. 1907, 245, 97) and Tschirch and Gauchmann (*ibid.* 1908, 246, 545; 1909, 247, 121). It consists of the potassium and calcium salts of a tribasic crystalline acid, *glycyrrhizic acid* $C_{44}H_{64}O_{19}$ ($C_{44}H_{60}O_{18}$ according to Rasenack, Arb. Reichsgesundh. Amt. 1908, 28). Glycyrrhizic acid melts at 205°, it has a sweet taste and is optically inactive. A hexa-acetyl derivative has been obtained, m.p. 210°. Glycyrrhizic acid does not reduce ammoniacal silver solution or Barreswil's (Fehling's) solution. When fused with potash it yields acetic and oxalic acids; distilled with zinc dust, naphthalene; and when oxidised with potassium permanganate, phthalic acid. If glycyrrhizic acid is boiled for 5 hours with water containing 3 p.c. of sulphuric acid, air being excluded, *glycyrrhetic acid* $C_{32}H_{48}O_7$ (hitherto known as *glycyrrhetin*) is precipitated.

It can be obtained crystalline from acetic acid, melts at 210°, is monobasic, and forms a diacetyl derivative melting at 219°. The solution from which this acid has separated contains glycuronic acid, and the hydrolysis is expressed by the equation:

$$C_{44}H_{64}O_{19}+2H_2O=C_{32}H_{48}O_7+2C_6H_{10}O_7$$

Glycyrrhizic acid contains 6 hydroxyl- and 3 carboxyl-groups; the acid potassium and ammonium salts crystallise well. The former, $C_{44}H_{63}O_{19}K$, is one of the sweetest of vegetable substances; the taste is still perceptible at 1 : 20,000.

The drug contains about 6–7 p.c. of glycyrrhizic acid. Mannitol is present in the liquid from which the crude glycyrrhizic acid has been precipitated with sulphuric acid, but it is not present in the original drug.

By distilling Spanish liquorice root, Haensel (Pharm. Centh. 40, 533) obtained 0·03 p.c. of an ethereal oil; the Russian roots yield 0·035 p.c. These oils are not identical, for whilst the Russian oil is dextrorotatory, the Spanish is lævorotatory.

Linz (Arch. Pharm. 1916, 254, 65, 81, 204) has given an elaborate review of 27 methods for determining glycyrrhizic acid in 'Spanish juice' and liquorice root. The best seems that of Parry (Chemist and Druggist, 1910, 26), which was followed in principle by Housemann (Amer. J. Pharm. 1912, 84, 531) and by Linz.

Russian and Persian liquorice root from *G. glandulifera*, W. and K., contains in addition an amorphous bitter substance. Glycyrrhizic acid is also present in the roots of *Polypodium vulgare*, *P. pennatifidum*, *Periandra mediterranea*, in the shoots of *Myrrhis odorata*, in the bark of *Chrysophyllum glycyphlœum*, and possibly in other plants.

Few words have suffered so many distortions as liquorice. The original Greco-Latin *glycyrrhiza*, literally sweet-root, was corrupted into Latin *liquiritia*, whence French *réglisse*, Italian *legoriza*, *regolizia*, and German *Lokritze*. The mid-English form *licoris* would appear to have been influenced by *Orris*, a plant which also had a sweet root, while the modern spelling is perhaps due to *liquor* (Weekley, The Romance of Words).

G. B.

LITCHI NUT. The Chinese hazel nut (*Litchi chinensis*, Sonner) occurs in the tropical countries of the East where it is cultivated for medicinal and edible purposes. Contains ash 1·5, protein 2·9, ether extract 0·2, fibre and nitrogen-free extract 77·5, water 17·9 p.c. The alcoholic extract has a cupric reducing power equivalent to 53 p.c. invert sugar, crude fibre 0·4 p.c. Total acidity 0·25 p.c. citric acid (Read, J. Amer. Chem. Soc. 1918, 40, 817).

LITHARGE *v.* LEAD.

LITHARGITE and **MASSICOTITE.** Mineralogical terms for the native forms of the well-known substances litharge and massicot, which were formerly included together under the one name (litharge or massicot, or sometimes lead-ochre or plumbic-ochre). Lead monoxide PbO is dimorphous, existing as a yellow orthorhombic (pseudo-cubic) modification with sp.gr. 9·29, mean refractive index β 2·61, optically biaxial and positive; and as a red tetragonal modification with sp.gr. 9·125, ω 2·64, optically uniaxial and negative. They have, however, not been obtained in sufficiently good crystals for an exact determination of their characters, and there is some confusion in the optical descriptions (A. Scott, Min. Mag. 1914, 17, 143). E. S. Larsen and E. T. Wherry (Amer. Min. 1917, 2, 18) propose to restrict the name litharge or lithargite to the yellow orthorhombic modification, and massicot or massicotite to the red tetragonal modification. Larsen describes minute brownish-red scales from California and some other localities as being built up of the two minerals—the central portion of the plates consisting of lithargite and the borders of massicotite, the latter being probably an inversion product of the former. As a fine scaly or earthy encrustation one or other of these modifications is not uncommon as an alteration product of lead ores, though generally in small amounts. In particular, it has been recorded from several localities in Mexico, occurring sometimes as a volcanic product; and in certain streams it has been collected in considerable quantities.

L. J. S.

LITHIA MICA *v.* LITHIUM.

LITHIUM. Sym. Li. At.w. 6·94 (Hagen, Mallet, Troost, Diehl, Stas, Dittmar, Richards and Willard). This metal occurs in combination with silica, alumina, and the alkali metals in *lepidolite* or *lithia mica*, *petalite* (containing phosphates of lithium, iron, and manganese), *spodumene*, *triphylene*, and *amblygonite*, usually to the extent of 3 to 6 p.c. (J. Soc. Chem. Ind. 18, 877). Also in psilomelane, in a hexagonal variety of zinc sulphide, schalenblende, and in many radioactive minerals particularly carnotite (Gleditsch, Compt. rend. 145, 1148; 146, 331); Ramsay, *ibid.* 146, 456; McCoy, Nature, 1907, 79).

Lithium is widely distributed. It occurs as chloride in most spring waters and in sea water. A mineral spring at Wheal Clifford, near Redruth, contains 26 grains per gallon (Miller, Brit. Assoc. Trans. 1864, 35); Phillips has found 34 grains per gallon in a salt spring in Huel Seton copper mines in Cornwall. It is found in most plants, especially in the leaves (Tschermak, Chem. Zentr. 1899, ii. 1127). The ash of tobacco has been found to contain 0·44 p.c. of lithium chloride (Fruehot, Compt. rend. 78, 1022). The presence of lithium in excess appears to be generally injurious to plants. It also occurs in all the organs of the human body, particularly the lungs (Herrmann, Pflügers Archiv. 109, 26).

Lithium was first isolated by Brandes, but first prepared in quantity by Bunsen (Pogg. Ann. 94, 107). The metal cannot be obtained by ignition of the carbonate with carbon, or of the hydroxide with iron, but is obtained by the electrolysis of a mixture of equal weights of lithium and potassium chlorides (Guntz, Compt. rend. 117, 732). Ruff and Johannsen (Zeitsch. Elektrochem. 12, 186) recommend a mixture of lithium bromide with 10–15 p.c. lithium chloride, using a carbon anode and two iron rods, 4 mm. diameter, as cathode, the current required being 100 ampères and 10 volts. According to Borschers (Chem. Zentr. 1895, ii. 13), lithium can be obtained from its ores by making the solution of the chlorides of the alkalis and alkaline earths slightly alkaline, evaporating in an iron vessel, fusing the residue thus obtained with ammonium chloride and electrolysing the mass

with a current of 1000 ampères per square metre of cathode surface and 5 volts. The upper rim of the iron crucible is kept cool by a current of cold water, the surface thus being protected from the atmosphere by a thin layer of solidified metal. The metallic globules are then placed in a paraffin bath at 130°–200° when the pure metal rises to the surface. Lithium can also be obtained by heating the hydroxide with magnesium in a tubulated iron retort when the metal distils over (Warren, Chem. News, 1896, 6); or by the electrolysis of lithium chloride in pyridine solution (Kahlenberg, J. Phys. Chem. 1899, 3602). The metal is also deposited electrolytically from other organic solvents of its chloride (Patten and Mott, J. Phys. Chem. 1904, 8, 153).

Lithium is a mixture of two isotopes of masses 6 and 7 (Aston).

The statement that traces of lithium are formed in the degradation of copper by radium emanation (Cameron and Ramsay, Chem. Soc. Trans. 1907, 1593) lacks confirmation (Perman, *ibid.* 1908, 1775; Curie and Gleditsch, Compt. rend. 147, 345).

Properties.—Lithium is a silver-white metal which tarnishes and oxidises less rapidly than potassium or sodium. It is softer than lead, but less tenacious. Its sp.gr. is 0·589 to 0·598 (Bunsen), lower than that of any known solid. It melts at 180° (Bunsen), 186° (Kahlbaum, Zeitsch. anorg. Chem. 23, 220), and volatilises at a bright red heat in a current of hydrogen, forming *lithium hydride* LiH (Guntz, Compt. rend. 122, 244). Electrolysis gives lithium as the cathode and apparently hydrogen as the anode, this being the first observed instance of hydrogen functioning as a negatively charged ion. Sp.gr. 0·816. At a temperature somewhat above its melting-point it burns with an intense white light. When heated, it burns in chlorine, bromine, iodine, and sulphur vapour, and in carbon dioxide. In water it oxidises, but does not fuse. It absorbs nitrogen even in the cold, being the only metal that does so (Deslandres, Compt. rend. 121, 886; Guntz, *ibid.* 245) to form *lithium nitride* Li_3N, m.p. 840°–845°, which rapidly attacks iron, nickel, copper, platinum, porcelain and other silicates. When heated in hydrogen to 250° forms *trilithium ammonium* Li_3NH_4 which on further heating to 480° forms *lithamide* (v. *infra*), an extremely hygroscopic substance, evolving hydrogen and ammonia under the action of water (Dafert and Miklauz, Monatsh. 1910, 31, 981: *ibid.* 1912, 33, 63).

By nitric acid it is rapidly oxidised, often with fusion and ignition. In dilute sulphuric acid and in hydrochloric acid it dissolves quickly; solution is slow in strong sulphuric acid. At a temperature below 200° it attacks silica, glass, and porcelain. Like other alkaline metals it dissolves with formation of a blue solution in liquefied ammonia gas, a similar result being obtained when it dissolves in methylamine (Moissan, Compt. rend. 128, 26). When gently heated to 400° in a current of ammonia, *lithamide* $LiNH_2$ is formed (Titherley, Chem. Soc. Trans. 1894, 517; Moissan, Compt. rend. 127, 685; *ibid.* 133, 715; Ruff and Georges, Ber. 1911, 44, 502; Dafert and Miklauz, Ber. 1911, 44, 809).

At the ordinary temperature, lithium with dry ammonia gas forms a liquid which, when rapidly evaporated at 70°, yields a brownish-red solid, *lithium ammonia* $LiNH_3$ (Moissan, *l.c.*).

Lithium forms several amalgams with mercury (Kerp and Böttger, Zeitsch. anorg. Chem. 25, 1; Schukoffsky, *ibid.* 1911, 71, 403) and alloys with antimony, tin, and lead of the type Li_3M (Lebeau, Compt. rend. 130, 502; *ibid.* 134, 231, 284). These alloys have higher melting-points than the constituents and are powerful reducing agents. It also forms compounds with arsenic (Lebeau, *ibid.* 129, 47) and with silicon (Moissan, *ibid.* 134, 1083; Wallace, Zeitsch. anorg. Chem. 63, 1).

Detection.—Lithium salts produce a fine, crimson colour in the blowpipe flame. They are usually colourless, and when in strong solution give a precipitate on addition of carbonates or sodium phosphate, in presence of ammonia. In presence of sodium, lithium can be detected by making the solution alkaline with ammonia, then adding $\frac{1}{10}$ of its volume of sodium hydrogen phosphate, after which enough alcohol is added to produce a heavy permanent precipitate. On boiling, the solution will become perfectly clear if lithium is absent, for lithium phosphate is insoluble in boiling alcohol (Benedict, Amer. Chem. J. 32, 480).

For its *absorption spectrum*, *see* Bevan, Proc. Roy. Soc. 1911, 85, A, 54.

Estimation.—The estimation usually entails the separation from potassium and sodium. For this separation Mayer's process is most satisfactory (Annalen, 98, 193). The solution containing the alkalis as chlorides is treated with sodium phosphate (*absolutely* free from alkaline earth phosphates), and sufficient sodium hydroxide to keep the solution alkaline, and evaporated to dryness. Sufficient water is added to dissolve the soluble salts, the solution heated gently and filtered after 12 hours. The precipitate is washed with a mixture of 1 part of water and 1 part of ammonia (of which liquid 3920 parts dissolve only 1 part of lithium phosphate); the filtrate and first two washings are evaporated and taken up as before, any residue of lithium phosphate being added to the bulk of precipitate. The precipitate, dried at 100°, has the composition Li_3PO_4.

Kahlenberg and Krankopf (Amer. Chem. J. 30, 1104) recommend the following method. The solution of mixed chlorides is evaporated to dryness and the residue is boiled with pyridine. The solution is decanted through a small filter and the residue is again treated with pyridine several times. The pyridine filtrates are now distilled and the lithium chloride residue is converted into sulphate by evaporation with sulphuric acid and weighed as such. According to Schieffelin and Lamar (Amer. Chem. J. 24, 392) a good way of estimating lithia in lepidolite is to dissolve the alkali chlorides obtained in the usual way in about 10 c.c. of hot water, a drop of hydrochloric acid is added, then a little ammonia and ammonium oxalate; the solution is filtered and the filtrate evaporated until it commences to crystallise (about 1–2 c.c.). A drop of water and of hydrochloric acid is added, then 15 c.c. of amyl alcohol, it is then concentrated to half its volume, cooled and filtered into a platinum dish, the residue is

washed with amyl alcohol until the washings are free from lithium, the amyl alcohol extract is evaporated below the boiling-point and the residue converted to sulphate.

For methods of estimating lithium in mineral waters, compare Carnot (Compt. rend. 107, 336); Waller (J. Soc. Chem. Ind. 1890, 1066); Razoli (Gazz. chim. ital. 31, i. 40).

Extraction of salts.—Finely powdered lepidolite or petalite 10 parts, is mixed with barium carbonate 10, barium sulphate 5, potassium sulphate 3, and ignited at the highest temperature of a wind furnace. Two layers are thus produced, the lower of barium silicate and sulphate, the upper of white sulphate of potassium and lithium. It is lixiviated with water and treated with barium chloride to convert the alkalis into chlorides and to precipitate the sulphuric acid as barium sulphate. The solution is evaporated to dryness and digested with a mixture of equal parts of absolute alcohol and ether, in which the lithium chloride dissolves with only a trace of potassium and sodium chloride (Troost, Compt. rend. 43, 921).

According to Müller (Annalen, 85, 251), *triphylene* is dissolved in hydrochloric acid, the iron oxidised to ferric chloride by the addition of nitric acid, the phosphoric acid precipitated by a persalt of iron, the mixture evaporated to dryness, and extracted with water. Manganous and lithium chlorides are thus dissolved; the former is precipitated with barium sulphide, the excess of barium being removed by the addition of ammonium carbonate or sulphuric acid. The solution is evaporated with oxalic acid and the residual oxalate ignited to carbonate.

The finely ground and sifted lepidolite is made into a thin paste with concentrated sulphuric acid, in a warm brick trough, and digested and stirred until it commences to agglomerate. It is then calcined in a reverberatory furnace, and, while warm, well lixiviated with water and filtered. The lye is mixed with sufficient potassium sulphate to convert all the alumina into alum, and the solution decanted from the alum meal. The remaining alumina is precipitated by milk of lime, the alkalis are converted into chlorides by addition of barium chloride, and the solution evaporated to dryness. The chlorides of lithium and calcium are extracted with absolute alcohol, the alcohol evaporated, and the calcium precipitated by ammonium oxalate, and any heavy metals removed by a little ammonium sulphide. The solution is evaporated to dryness in a silver basin (*v.* A. W. Hofmann, Dingl. poly. J. 219, 183, and Felsinger, *ibid.* 222, 385).

Powdered amblygonite or other lithium ore is intimately mixed with powdered sodium bisulphite and the mixture heated in cast-iron retorts, the hydrofluoric acid and silicon fluoride disengaged being collected. The mass is then transferred to a refractory earthen vessel and heated to redness. The product is lixiviated, filtered, and aluminium, copper, and iron are precipitated by a very small proportion of sodium carbonate. After filtration it is again treated with sodium carbonate when lithium carbonate is precipitated. The insoluble residue of the lixiviated product is said to be rich in phosphorus and can be used as a manure (J. Soc. Chem. Ind. 1906, 884).

Finely powdered lepidolite is mixed with 10 p.c. more than its weight of sulphuric acid and heated with frequent stirring for 8 hours at 112°–340°; 97–99 p.c. of the ore is thus decomposed. The mass is leached with water and the silica separated. The solution is now treated with sufficient potassium sulphate to convert the aluminium sulphate to alum and allowed to stand for 6 days when precipitation is complete, the decanted liquor is treated with whiting, boiled, and the alum precipitated as alunite by adding aluminium hydroxide. The last traces of alumina are removed by again treating the filtrate with whiting. The solution is then boiled, made alkaline with slaked lime and concentrated. Copper sulphate and magnesium and iron oxides are removed in the usual way and the solution consisting of lithium sulphate is added to a solution of potassium carbonate, when lithium carbonate is precipitated, and is washed and dried (Schieffelin and Cappon, J. Soc. Chem. Ind. 1908, 549).

According to Wadman (*ibid.* 1907, 469; 1908, 122), pure lithium carbonate can be obtained by heating the ore with an alkaline sulphate such as K_2SO_4. The solution of sulphates thus obtained is now treated with sufficient ammonia to render the potassium sulphate insoluble and to precipitate iron, aluminium, and magnesium hydroxides. The precipitate is removed and the lithium precipitated as carbonate.

According to Zell (J. Soc. Chem. Ind. 1909, 1126), a pure lithium compound can be obtained by heating a lithium ore in the presence of carbon in an atmosphere of acetylene. Volatile lithium hydrogen carbide is thus formed and is decomposed by water into lithium hydroxide and acetylene.

Lithium oxide Li_2O may be prepared by ignition of the metal in air or oxygen (Holt and Sims, Chem. Soc. Trans. 1894, 443); in solution, by precipitation of the sulphate with barium hydroxide solution. A purer product is obtained by heating lithium hydroxide or its hydrate LiOH, or $Li(OH)\cdot H_2O$, in a platinum crucible in a current of dry hydrogen for about an hour at 780° (Forcrand, Compt. rend. 144, 1321). Lithium carbonate heated similarly at 780°–800° also yields pure lithium oxide (Forcrand, *l.c.* 1402). It is yellowish white and spongy, less soluble than the oxides of potassium and sodium. It melts at 462°, and, as it corrodes platinum powerfully, should be fused in a silver vessel. The hydrated oxide may be obtained in small crystalline grains. Lithium hydroxide is used in a certain type of storage battery.

By mixing lithium hydroxide (Forcrand, Compt. rend. 146, 802) with hydrogen peroxide and then adding an equivalent volume of absolute alcohol, the compound

$$Li_2O_2\cdot H_2O_2,3H_2O$$

is formed which, when placed in a vacuum over phosphorus pentoxide, yields *lithium peroxide* Li_2O_2 (Forcrand, Compt. rend. 130, 1465). Lithium hydroxide gradually dissolves hydrated silicic acid in the cold. A hot solution forms insoluble *lithium silicate* $Li_2SiO_3{}_1H_2O$ as a white granular precipitate.

Lithium chloride LiCl may be prepared by combination of lithium and chlorine, or by

dissolving the carbonate or oxide in hydrochloric acid. When formed at low temperatures the crystals contain two molecules of water; at temperatures above 15° anhydrous octahedral crystals are produced, which are very hygroscopic; various hydrated chlorides are known (Bogorodsky, Chem. Zentr. 1894, ii. 514). It dissolves in absolute alcohol and in a mixture of alcohol and ether. At 0° 100 parts of water dissolve 63·7 parts, and at 100° 145 parts of the chloride.

Lithium chloride melts at 605° and is more volatile than potassium chloride; less so than sodium chloride. Below a red heat it volatilises, losing a little hydrochloric acid and producing an equivalent amount of lithium oxide.

Lithium chloride is used to some extent in pyrotechny.

Lithium dissolves in the chloride, but the subchloride Li_2Cl could not be obtained (Guntz, Compt. rend. 1895, 121, 945; Ann. Chim. Phys. 1907, 10, 13). At −18° the chloride absorbs ammonia rapidly, forming a series of compounds with 1, 2, 3, and 4 molecules of ammonia (Bonnefoi, Compt. rend. 124, 771; *ibid.* 127, 367). With ethylamine and methylamine, it behaves similarly (Bonnefoi, *l.c.* and Compt. rend. 129, 1257). Lithium bromide (Bonnefoi, *ibid.* 130, 1394; Bogorodsky, *l.c.*), lithium iodide (Thirsoff, J. Russ. Phys. Chem. Soc. 25, 467; Bogorodsky, *l.c.*), and their double salts with other metallic halides (Kurnakoff and Sementschenko, Zeitsch. anal. Chem. 1899, 335; Dobroserdoff, J. Russ. Phys. Chem. Soc. 32, 774; Bogorodsky, *l.c.* 515). Lithium bromide and iodide have been used in photography (Duboin, Compt. rend. 141, 1015; Chassevant, *ibid.* 115, 113); lithium periodate (Barker, Chem. Soc. Trans. 1911, 1326); also lithium fluoride (Poulenc, Bull. Soc. chim. [iii.] 11, 15; Wells and Foote, Amer. J. Sci. 1897, 466) have been prepared. (*Cf.* Scarpa, Atti R. Accad. Lincei, 1915, [v.] 24, ii. 476.)

Lithium sulphate Li_2SO_4 is prepared by dissolving the carbonate or oxide in sulphuric acid. It forms monoclinic plates, soluble in alcohol and water. It produces a double sulphate with potassium sulphate, but does not form an acid sulphate or an alum.

Lithium carbonate Li_2CO_3 is prepared by the addition of a hot concentrated solution of lithium chloride to an ammoniacal solution of ammonium carbonate. It is a white powder, which decomposes at 600° (Lebeau, Compt. rend. 136, 1256), is reduced by heating with aluminium (Franck, Chem. Zeit. 1898, 22, 236), and is more fusible than the potassium and sodium salts. It is quite insoluble in absolute alcohol (Kobbe, Pharm. Zeit. 34, 312) and only slightly soluble in water, but more readily so in aqueous solution of the alkalis, particularly ammonium salts (Geffcken, Zeitsch. anorg. Chem. 1905, 43, 197).

Its solubility in cold is greater than in hot water. The solubilities given by different observers are not concordant. According to Bevade (Bull. Soc. chim. [ii.] 43, 123), the solubility in 100 parts of water is as follows:—

Temperature	0°	10°	20°	50°	75°	100°
Parts . .	1·539	1·406	1·329	1·181	0·866	0·728

The solubility increases after continued boiling. V. further Draper (Chem. News, 55, 169) and Flückiger (Arch. Pharm. [iii.] 25, 509).

The commercial salt usually contains about 98·5 p.c. of lithium carbonate. Lithium forms a very soluble *urate*; for this reason the carbonate and citrate are administered to remove uric acid from the blood in gouty affections (Kebler, Amer. J. Pharm. 1898, 600).

Lithium carbonate mixed with carmine is used as a nuclear stain.

Lithium carbide Li_2C_2, is obtained by heating lithium carbonate with sugar carbon in an electric furnace (Moissan, Compt. rend. 122, 362); or by heating lithium and carbon together in a vacuum (Guntz, *ibid.* 126, 1866); or in a stream of carbon di- or monoxide (Guntz, *ibid.* 123, 1273; Moissan, *ibid.* 127, 911). It is a powerful reducing agent; burns in fluorine, chlorine, bromine, iodine, oxygen, and combines with sulphur and selenium; it is not attacked by concentrated acids but readily by water, forming acetylene and lithium oxide.

Lithium nitride Li_3N is prepared by heating lithium in an iron dish very gently in a slow stream of nitrogen (Ouvrard, Compt. rend. 1892, 114, 120; Guntz, *ibid.* 123, 995). It is a brownish-red or black spongy substance, difficult to obtain quite pure and is readily decomposed by water or when heated with hydrogen.

Lithium cyanide is used in X-ray work.

Lithium azoimide LiN_3,H_2O, formed by neutralising a solution of lithium hydroxide with azoimide, HN_3, crystallises in colourless, lustrous, hygroscopic needles which explode between 115°–298° (Dennis and Benedict, Zeitsch. anorg. Chem. 1898, 17. 18; Curtius and Rissow, J. pr. Chem. 1898 [ii.] 58, 261).

Lithium citrate $Li_3C_6H_3O_7$ is prepared by the addition of 100 parts of lithium carbonate to a solution of 186·5 parts of citric acid (Umney, Year-book of Pharmacy, 1875, 559). It may be produced as a white, anhydrous, neutral, non-deliquescent powder, or in crystals containing 4 molecules of water. It is soluble in 25 parts of cold water. The commercial salt usually contains salts of potassium, sodium, and calcium, and frequently lithium carbonate or citric acid, and powdered lepidolite or petalite (C. Thompson, Pharm. J. [iii.] 13, 783; Dott. *ibid.* 1905, 440). The following salts of lithium are employed in medicine:—

Benzoate, caffeine sulphonate, dithiosalicylate, formate, guaiacate, hippurate, and iodate in uric acid diathesis; bitartrate, theobromine salicylate, potassium tartrate and acetate as diuretics; glycerophosphate in neurosthenia; borosulphite, sulphoichthyolate, and sozoiodolate as antiseptics (J. Soc. Chem. Ind. 1898, 736; Kebler, Amer. J. Pharm. 1899, 57).

According to Vulpian (J. Soc. Chem. Ind. 1889, 476) lithium salicylate is of greater effect than sodium salicylate in gout and in acute articular rheumatism.

Lithium quinate is used in the treatment of gout and analogous diseases (Johnson, J. Soc. Chem. Ind. 1899, 1051). According to Dumesnil (J. Pharm. Chim. 1906, 326), lithium theobromine, prepared by adding excess of theobromine to lithium hydroxide solution, is 4 or 5 times as active therapeutically as the same weight of theobromine.

Coal tar products have largely superseded

lithium salts in the treatment of rheumatism and allied affections.

Lithium salts react with casein giving readily digestible compounds suitable for medical purposes (Abel, J. Soc. Chem. Ind. 1899, 398).

Lithium oxalate (Foote and Andrew, Amer. Chem. J. 1905, 153), thymate (J. Soc. Chem. Ind. 1906, 714), and the double salts of lithium and the acid salts of piperazine with oxalic, tartaric, and citric acids (*ibid.* 1897, 758), are also very useful products.

Double urinates (Melikoff and Pissarjewsky, Ber. 30, 2902; Coninck and Chauvenet, Bull. Belg. Roy. Acad. 1905, 51, 182); lithium phosphates and arsenates (Schulten, Bull. Soc. chim. [iii.] 1, 479; Ouvrard, Compt. rend. 110, 1333; Rammelsberg, Chem. Zentr. 1891, ii. 790; Quartaroli, Gazz. chim. ital. 1907, i. 598); zirconates (Ouvrard, Compt. rend. 112, 1444; Venable and Clarke, Amer. Chem. J. 1896, 434); borates (Reischle, Zeitsch. anorg. Chem. 4, 169; Chatelier, Compt. rend. 124, 109); aluminosilicates (Weyberg, Centr. Min. 1905, 646); platinocyanides (Reynolds, Proc. Roy. Soc. 1909, 82, 380), and tungstates (Feist, Ber. 21, 133) have been prepared. Lithium tungsten bronze, LiW_5O_{15} (Hallopeau, Compt. rend. 127, 512) is prepared by the electrolysis of lithium para-tungstate.

LITHIUM-DIURETIN. Trade name for a combination of theobromine-lithium and lithium salicylate.

LITHOFELLIC ACID $C_{24}H_{42}O_5$ occurs in the stones of intestinal origin found in the Benzoar-goat, llama, and other cattle; it is probably formed by reduction of cholic acid (Fischer, Ber. 1914, 2728).

Preparation.—The stone is dissolved in methyl alcohol and the acids precipitated by the addition of light petroleum. These are dissolved in alkali and any lithobilic acid is thrown down by the addition of barium chloride. On acidifying the filtrate with hydrochloric acid, lithofellic acid is precipitated and is recrystallised from alcohol (Jünger and Klages, Ber. 1895, 3045), or ethyl acetate (Fischer, *loc. cit.*)

Properties.—M.p. 205° (corr.). Crystallises from dilute alcohol with 1 mol. H_2O. Insoluble in water, sparingly soluble in ether; $[\alpha]_D^{20} = 13{\cdot}1$. On boiling with alcohol hydrochloric acid gives a lactone, b.p. 245°–248°/16 mm. I. S. M.

LITHOFRACTEUR *v.* EXPLOSIVES.

LITHOGRAPHIC STONE. A fine-grained limestone of uniform texture, breaking with an imperfect conchoidal fracture, and free from spots and veins. It must be compact enough to take a good polish and yet sufficiently porous to absorb the grease of the draughtsman's crayon; whilst being a limestone it can be etched with cold dilute acid. The only stones possessing these properties in a high degree are those from the large quarries at Solenhofen and Pappenheim in central Bavaria. Here the rock is a thin-bedded limestone of Upper Jurassic age. Two qualities are distinguished—a yellowish-drab and a bluish-grey, the latter being rather harder and more serviceable. They consist of 81–96 p.c. $CaCO_3$, 1–18 p.c. $MgCO_3$, with small amounts of alumina, ferric oxide, silica, &c. The quality of the stone depends, however, on physical characters rather than on chemical composition. Many attempts have been made to find lithographic stone at other localities, more particularly in the United States, the most promising being at Brandenburg in Meade Co., Kentucky (*v.* G. P. Merrill, The Non-metallic Minerals, 2nd edit., New York, 1910). L. J. S.

LITHOMARGE. (*Steinmark*, Ger.). An amorphous substance, resembling clay (kaolinite and halloysite) in composition (hydrated aluminium silicate with some iron) and in most of its physical properties, but firmer and more compact. It occurs on a large scale in the basaltic lavas of Antrim, where it is associated with bole, bauxite, and aluminous iron-ore. Some of the Irish lithomarge is of lavender colour, with white specks of bauxite, whilst other varieties are brown or blackish. The substance is known to the workmen as 'marge.' It may have resulted from the alteration of the basalt, and appears to resemble some of the steatitic laterites of India. Where peaty water comes in contact with the lithomarge, it occasionally deposits manganese oxide in considerable quantity (*v.* P. Argall, Journ. Geol. Soc. Ireland, 1886, 16, 102; G. H. Kinahan, *ibid.* 307). The following analyses, I–III, by D. Jardin, of lithomarge from Co. Antrim are quoted from G. A. J. Cole, The Interbasaltic Rocks (iron ores and bauxites) of North-east Ireland, Mem. Geol. Surv. Ireland, 1912. IV is of lithomarge from Cook's Kitchen mine, Cornwall:

	I.	II.	III.	IV.
SiO_2	31·70	41·14	39·17	48·3
TiO_2	4·68	4·80	3·40	—
Al_2O_3	25·99	27·96	28·41	36·4
Fe_2O_3	19·89	1·92	2·67	—
CaO	0·67	1·66	0·70	—
MgO	—	0·77	0·02	—
H_2O	12·70	13·94	12·56	14·5
H_2O (at 110°)	4·18	8·26	13·32	
	99·81	100·45	100·25	99·2

Lithomarge occurs in several Cornish mines; a fine yellowish variety, with purple veins, being found at Cook's Kitchen, near Redruth. Closely allied to lithomarge is the *teratolite* of Saxony, formerly reputed to possess such powerful medicinal qualities that it was described by old writers as *terra miraculosa Saxoniæ*. L. J. S.

LITHOPONE. A pigment prepared by strongly heating a mixture of zinc sulphide and barium sulphate, obtained by mixing solutions of barium sulphide and zinc sulphate. Is a variable mixture of zinc oxide, zinc carbonate, zinc sulphide, normal and basic zinc sulphate, barium sulphate and carbonate, with traces of ferric oxide, alumina, lime, and magnesia. The usual process of manufacture is to heat heavy spar with carbon, dissolve the mass in water and mix with a solution of zinc vitriol. The precipitate is washed, dried, and ignited, mixed with 2–3 p.c. of sal ammoniac and again ignited. While hot it is thrown into water, dried, and finely ground. Its value depends upon the amount of zinc sulphide present. For methods of analysis *v.* J. Soc. Chem. Ind. 1902, 1145; Austin and Keane, Analyst, 1912, 37, 238. The

following analyses of different samples are by Austin and Keane (*loc. cit.*):

	I. (German)	II. (English)	III.
$BaSO_4$ . . .	64·36	67·59	72·80
ZnS . . .	30·98	27·82	24·14
ZnO . . .	0·55	1·82	0·88
CaO, F_2O_3, $BaCO_3$, &c.	4·11	2·77	2·18
	100·00	100·00	100·00

Inferior qualities sometimes contain natural barytes which reduce the opacity and covering power and cause it to give a yellowish white tint when used in linoleum. The natural mineral may be detected by means of the microscope, the precipitated sulphate appearing as a fine powder composed of minute crystals of uniform size whereas the natural barytes consists of transparent irregular fragments of larger size (Stewart, J. Soc. Chem. Ind. 1920, 39, 188T.). For conditions determining the resistance of lithopone to change in sunlight in presence of moisture, due, it is surmised, to a dissociation of the illuminated surface with liberation of metallic zinc of a grey colour, see Steinau, Chem. Zeit. 1921, 45, 741.

LITMUS. *Tournesol en pain.* This colouring matter is well known to the chemist, since white paper impregnated with its solution in a slightly acid or alkaline condition has long been employed, under the name of red and blue litmus-paper, to indicate the presence, in any solution, of alkalis or acids respectively. Alkalis change the colour of red litmus-paper to blue, acids turn blue litmus-paper red. In alkalimetry litmus tincture was formerly the most generally adopted indicator. This use depends upon the fact that the free colouring matter of litmus is red, whereas its alkali salts are blue.

Commercial litmus has the form of small pale blue cubes, composed essentially of gypsum and chalk mixed with but comparatively little colouring matter, which is largely present in the form of a lake.

It is said to be prepared, chiefly in Holland, from various species of lichens, *e.g. Lecanora tartarea, Rocella tinctoria*, &c., the same, indeed, as are used in the manufacture of orchil (*q.v.*). Under the combined influence of ammonia and atmospheric oxygen the proximate principles contained in these lichens yield *orceïn*, the alkali salts of which are purple (orchil); but if potassium or sodium carbonate is present at the same time, the reaction proceeds further, and ultimately *azolitmin* (the colouring matter of litmus), the alkali salts of which are blue, is produced.

According to Gélis (J. Pharm. Chim. 24, 277; Revue Scient. 6, 50), litmus may be prepared as follows. Orchil-weed is ground and mixed with half its weight of potassium carbonate, and then repeatedly moistened with urine saturated with ammonium carbonate or with an aqueous solution of this salt; the mass soon acquires a brownish-red colour (3 days), which gradually becomes purple (20–25 days), and finally blue (30 days), yielding a litmus of the best quality in 40 days. The pulpy mass is mixed with chalk and gypsum, then moulded in the form of cubes, and dried in the shade.

By modifying the action of air and ammonia upon orcinol, through the addition of sodium carbonate, De Luynes also succeeded in obtaining the colouring matter of litmus (Compt. rend. 59, 49; Dingl. poly. J. 174, 61; Chem. Zentr. 1865, 127; J. 1864, 551). A mixture of 1 part orcinol, 25 parts cryst. sodium carbonate, 5 parts water, and 5 parts ammonia solution, was heated to 60°–80° for 4–5 days with frequent agitation. On diluting the blue solution thus obtained and acidifying slightly with hydrochloric acid, the colouring matter was precipitated. On washing and drying, it assumed a metallic lustre. It is sparingly soluble in water, but readily soluble in alcohol and in ether.

In making a litmus solution to be employed as indicator, the commercial litmus is extracted with boiling water, the filtered solution is slightly acidified with acetic acid, then carefully neutralised with ammonia, and boiled to expel any excess of the latter. Kept for any lengthened period in stoppered bottles, the solution becomes decolorised in consequence of a reductive fermentation; on exposure to air, however, the original colour is restored. This defect is prevented by saturating the solution with sodium chloride (Reichelt). Compare also Bellamy, J. Pharm. Chim. [v.] 18, 433.) A dry litmus-extract may be prepared according to Vogel in the following manner (*ibid.* 45, 64, 70; Chem. News, 1864, 205). Twenty grams powdered commercial litmus are twice digested, each time with 150 c.c. cold distilled water. The second solution, which is alone employed, is divided into two equal portions, one of which is slightly acidified with nitric acid and then mixed with the other. The purplish solution thus obtained is evaporated to dryness on the water-bath, and the granular amorphous mass is kept in a stoppered bottle ready for dissolving in water when required.

For the employment and characteristics of litmus as an indicator *v.* R. T. Thomson (J. Soc. Chem. Ind. 6, 198); also art. ACIDIMETRY, vol. i.; Marsh (Chem. News, 61, 2); Berthelot (Ann. Chim. Phys. [vii.] 25, 39); Rondo (Pharm. Zeit. 41, 736); Lescouer (Compt. rend. 123, 811); Lüttke (Zeitsch. anal. Chem. 31, 692); Foerster (*ibid.* 28, 428); Glaser (*ibid.* 38, 273).

Litmus exhibits a characteristic absorption spectrum. Ether extracts it from an acid solution, and forms a yellow liquid, which absorbs the more refrangible end of the spectrum to a point midway between D and E. If the solution is coloured blue by adding a drop of ammonia, an absorption-band is formed, commencing at D, where it is extremely black, and gradually diminishing to E. A blue aqueous commercial solution shows a well-marked absorption-band at D. Addition of acid changes the colour to red, the band at D disappears, and the spectrum now resembles that of œnolin, the colouring matter of red wine (A. H. Allen, Com. Org. Analysis, 325). (Compare also Vogel, Praktische Spectralanalyse, 1877, 269.)

Our knowledge of the chemistry of the colouring matters contained in litmus is very meagre. Gélis (J. Pharm. Chim. 27, 477) extracted from it several colouring matters in the following manner. After extracting commercial litmus with water, the insoluble residue is boiled with dilute caustic alkali and the filtered solution is precipitated with basic lead acetate. The blue

precipitate is washed by decantation until it begins to dissolve and colour the wash-water. It is then decomposed with hydrogen sulphide, exposed to air until free from excess of H_2S, collected on a filter and digested with dilute ammonia to extract the colouring matter. On adding acid to the filtered solution the main portion of the litmus colouring matters is thrown down as a red flocculent precipitate. The filtrate from this contains a very small quantity of colouring matter (α).

On extracting the dried red precipitate with ether and leaving the orange solution to spontaneous evaporation, it yields a bright-red residue (β) containing crystalline needles. This product is insoluble in water, but readily soluble in alcohol, also in alkalis with a violet colour. The portion insoluble in ether is dissolved in alcohol, and on allowing the blood-red solution to evaporate spontaneously it yields a large quantity of a reddish-purple product (γ) having a bronze lustre. This represents the colouring matter most abundant in litmus.

The residue, which is insoluble in water, in alcohol, and in ether, contains another product (δ) which is soluble in alkalis, from which it may be precipitated by acids. The three products β, γ, and δ, appear to contain nitrogen.

An examination of litmus was made in 1840 by Kane (Royal Soc. Trans. 1840, 298; Ann. Chim. Phys. [iii.] 2, 129; Annalen, 39, 57; J. Pharm. Chim. 1841, 569), who isolated from it the chief and characteristic colouring matters *azolitmin* and *erythrolitmin*, together with *erythroleïn* and *spaniolitmin*.

According to Kane, finely powdered commercial litmus is extracted with boiling water. Most of the colouring matter remains in the form of an insoluble lake in the residue, to which hydrochloric acid is added till effervescence ceases and the mixture is strongly acid. The insoluble matter mixed up with liberated colouring-matter is collected on a filter, washed free from acid, dried, and extracted with boiling alcohol. The alcoholic solution is filtered from an insoluble reddish-brown mass (impure azolitmin) and then evaporated to dryness, and the residue is digested with warm ether until it becomes no longer coloured. On distilling the filtered ethereal solution, *erythroleïn* is left as a purple semi-fluid oily substance. That portion of the alcoholic extract which is insoluble in ether consists of *erythrolitmin*.

The above-mentioned impure azolitmin is purified, either by dissolving it in a large quantity of boiling water and evaporating the solution to dryness, or by dissolving it in very dilute ammonia, evaporating the solution to dryness, neutralising any residual ammonia by dilute hydrochloric acid, and washing with alcohol until free from ammonium chloride and excess of hydrochloric acid. The residue represents purified *azolitmin*.

The colouring matter contained in the deeply coloured solution obtained in the first instance by boiling the commercial litmus with water and filtering, is isolated as follows. The solution is precipitated with neutral lead acetate, the purple precipitate thus obtained is well washed, suspended in water, and decomposed with hydrogen sulphide. The mixture of lead sulphide and liberated colouring matter thus obtained is well washed and digested with warm dilute ammonia; the filtered deep-blue solution is evaporated to dryness, the residue is moistened with hydrochloric acid, washed free from ammonium chloride and any excess of hydrochloric acid, with warm alcohol. The residual deep brownish-red powder consists usually of nearly pure azolitmin, more rarely of *spaniolitmin*, a substance very similar to azolitmin, but which does not contain nitrogen.

Since spaniolitmin occurs so rarely in litmus, and erythroleïn is coloured reddish-purple and not blue by alkalis, Kane considers azolitmin and erythrolitmin to be the essential colouring matters of litmus, in which they are combined with ammonia, potash, and lime, and mixed with a considerable quantity of chalk, gypsum, &c.

Azolitmin is a deep brownish-red amorphous powder, insoluble in alcohol and sparingly soluble in water, but readily soluble in alkaline solutions with a pure blue colour. Its ammoniacal solution gives with metallic salt solutions blue or purple precipitates according as they are more or less basic in character. Kane's formula for it is $C_9H_{10}NO_5$, but Gerhardt considers it is best represented by $C_7H_7NO_4$. It differs from all the other colouring matters isolated from litmus by containing nitrogen. Gerhardt considered it to be derived from orcinol, possibly in accordance with the following equation:

$$C_7H_6O_2 + NH_3 + 3O = C_7H_7NO_4 + H_2O$$

or from orceïn thus $C_7H_7NO_3 + O = C_7H_7NO_4$.

If the percentage composition assigned to this substance is correct, the explanation of the part played by the necessary alkaline carbonate in the manufacture of litmus may be that it facilitates and increases the oxidation of the orcinol, so that the orceïn at first formed is changed into azolitmin (Gerhardt, Ch. Org. 3, 816).

Scheitz (Zeitsch. anal. Chem. 1910, 49, 736) has isolated from litmus a blue colouring matter distinct from azolitmin in quantity equivalent to 1·5 p.c. of the weight of the purified material. It consists of a bright brown powder soluble in formic acid, pyridine, and ammonia, forming a bluish-violet solution with the last-named solvent. It absorbs ammonia gas with production of a dark blue ammonia compound, which dissolves in water to a reddish solution. This ammonia compound is a more delicate indicator than the corresponding derivative of azolitmin.

Erythrolitmin, which also constitutes one of the most important ingredients of litmus, is a bright-red powder, sparingly soluble in water and in ether. It is abundantly soluble in alcohol, from which it may be crystallised in the form of dark-red granular crystals. In strong caustic potash it dissolves with a blue colour. With ammonia it forms a blue compound which curiously enough is totally insoluble in water. With metallic salts it forms lakes of a fine purple colour. According to Kane its formula is $C_{13}H_{22}O_6$, and he considers it to be an oxidation product of his erythroleïc acid ($C_{13}H_{22}O_4$) obtained from orchil.

Erythroleïn forms a crimson semi-fluid mass, almost insoluble in water, soluble in ether and in alcohol with a red colour, and in ammonia with a purple colour. With metallic salts it

gives purple lakes. Kane gives its formula as $C_{13}H_{22}O_2$. Its general properties are very similar to those of the above-mentioned erythroleïc acid.

Spaniolitmin occurs but rarely in litmus, hence its name. It is a bright-red substance, insoluble in alcohol and in ether, and very sparingly soluble in water. It dissolves in alkalis with a blue colour and gives lakes very similar to those of azolitmin. Kane's formula for it is $C_9H_7O_8$.

Under the influence of hydrogen sulphide, the colouring matters of litmus are decolorised, Kane's idea being, that a colourless hydrogen sulphide compound is thus formed. (*V.* also Malaguti, Ann. Chim. Phys. [iii.] 37, 206; Vogel, J. pr. Chem. [ii.] 16, 311.) Nascent hydrogen, and other reducing agents such as ferrous and stannous oxide, &c., decolorise them by reduction in the ordinary manner. Azolitmin thus yields colourless *leucazolitmin*, which, however, rapidly oxidises and becomes coloured on exposure to air. If stannous chloride is added to an ammoniacal solution of azolitmin, purple-coloured stannous-azolitmin is precipitated; if this is boiled with slightly acidulated water there is formed the colourless compound of stannic oxide with leucazolitmin, which, if exposed to air, changes into the bright scarlet stannic-azolitmin.

Deoxidising agents such as sulphurous acid and sulphites do not decolorise the colouring-matters of litmus.

Azolitmin and erythrolitmin, suspended in water and submitted to the action of chlorine gas, are decolorised and give yellow chlorine derivatives, *chlorazolitmin* and *chlorerythrolitmin*, substances insoluble in water, but soluble in alcohol, ether, and in alkalis.

In his earliest memoir, Kane (Annalen, 36, 324) mentions that on heating the colouring matters of litmus mixed with chalk or gypsum, a red vapour is given off which condenses in the form of crystalline scales (atmérythrin) soluble in alcohol. When heated alone, this substance is not produced. Although Kane makes no subsequent mention of this body it is possible that it was indirubin or even indigotin, since at a later date, Wartha (Ber. 9, 217) states that he found some samples of litmus to contain indigotin, recognisable by the violet vapour given off on heating a few cubes of the commercial product in a test tube. Its presence may have been due to the use of urine containing indoxyl in the preparation of the litmus.

Wartha (*l.c.*) gives the following results of his examination of litmus. The commercial product is well shaken up with alcohol; the filtered purple solution thus obtained has a green fluorescence, and exhibits in the spectroscope a characteristic absorption band in the green with an almost total absorption of the violet end. The colouring matter (*a*) itself is obtained on evaporating the solution.

The litmus residue insoluble in alcohol is digested for 24 hours with distilled water, and the filtered deep-coloured solution is evaporated to dryness. The extract thus obtained is repeatedly treated with absolute alcohol containing a little glacial acetic acid and again evaporated, so that all traces of water may be removed, and there finally remains a brown powdery mass. On extracting this with absolute alcohol, a large quantity of a scarlet substance (*b*) is dissolved. It is similar to orceïn and dissolves in ammonia with a reddish-purple colour. That portion of the brown powder which is insoluble in the acidified alcohol is dissolved in water, the filtered solution is evaporated to dryness, and the residue is repeatedly washed with absolute alcohol and evaporated in order to expel all traces of acetic acid. The residual brown powder, which is very soluble in water, with a reddish-brown colour, but insoluble in alcohol and in ether, is the purified and extremely sensitive colouring matter of litmus (*c*). Its alkaline solution is blue, its aluminium and tin lakes are violet, and its calcium and barium lakes blue. It appears to be very similar to Kane's azolitmin, but it is said not to contain nitrogen. The yield of these various colouring matters is as follows: (*a*) 2·3 p.c., (*b*) 3·4 p.c., (*c*) 5·7 p.c. (Mitchell, Chem. News, 1876, 140).

An examination of the colouring matters of litmus was also made by Rochleder and Skraup (Wien. Anz. 1874, 118; Chem. Zentr. 1874, 424). Other references are Magner, J. Pharm. Chem. 12, 418; Desfosses, *ibid.* 14, 487; Peretti, *ibid.* 14, 539.

Of interest also in connection with this subject is the fact that when ethyl-amino-orsellinic acid is oxidised by air in alkaline solution it yields an orange-coloured dye possessing basic properties (Heinrich and Dorschky, Ber. 1904, 37, 1416).

A peculiar blue colouring matter similar to litmus, and called *tournesol en drapeaux*, has long been manufactured at Grand-Gallargues, Département du Gard, France, from the *Croton tinctorium* belonging to the *Euphorbiaceæ*. Coarse linen cloth is steeped in the deep bluish-green sap expressed from the berries and the tops of the plant, then dried quickly in the open air, and exposed for 1–1½ hours between layers of straw to the ammoniacal vapours of lant or horse-dung (*aluminadon*), care being taken not to submit them to this influence too long. The cloth thus acquires a deep-blue colour. It is then steeped in the sap a second time and dried in air till it acquires a purple or dull green. These blue cloths are used by the Dutch farmers for making an infusion with which to impart a red colour to the outside of their cheese, the blue being changed to red by the lactic and butyric acids of the cheese.

According to Joly (Ann. Chim. Phys. [iii.] 6, 111) the colouring matter pervades the entire plant and is readily extracted therefrom by water heated to 50°–60°. On being evaporated, an azure-blue resinous mass remains. Acids change the blue colour of its aqueous solution red, and this blue is not restored by alkalis, the colour becoming thereby rather greenish. It is, therefore, probably quite distinct from the colouring matter of litmus. Possibly it is identical with the blue colouring matter which can be extracted from another plant belonging to the *Euphorbiaceæ*, viz. *Mercurialis perennis*. A. G. P.

LIVER-BLENDE *v.* ZINC-BLENDE.

LIVER OF SULPHUR. *Hepar sulphuri; potassa sulphurata.* This compound consists of a mixture of salts of potassium, chiefly the higher sulphide, and is prepared by fusing in a clay crucible a quantity of potassium carbonate

with half its weight of flowers of sulphur. The fused mass is poured out on a greased flagstone and allowed to solidify, when it assumes a liver-brown colour; hence its name. It is alkaline, and acrid to the taste, and when quite dry is inodorous; but when moist it smells of sulphuretted hydrogen.

In medicine, it is given internally in cases of lepra and psoriasis; whilst externally it is used in the form of lotions, baths; as ointment in chronic skin-diseases, such as eczema, scabies, and pityriass. It is also largely used as a plant-spray.

LIXIVIATION. Lixiviation is the application of a liquid, generally water, to solid bodies for the purpose of extracting the soluble part. For instance, the preparation of pearl-ash by dissolving out the potassium carbonate from the wood ashes, and the preparation of sodium nitrate from the crude nitrate, of beet sugar by Schützenbach's process, are all applications of water to extract the soluble part. The extraction of gold from the tailings obtained from the stamp batteries, by means of dilute potassium cyanide solution in the presence of air, affords another example of the process of lixiviation.

In carrying out this process on a commercial scale, three things are sought to be attained: First, that the residue should be completely exhausted of soluble matter; second, that the solution obtained should be nearly saturated; and, thirdly, that the process should be continuous. A series of tanks is therefore provided, standing at the same level, and provided with false bottoms covered with a filtering bed, and with connecting tubes, pumps, and so on. Each of these tanks contains the substance to be lixiviated, and the water travels from tank to tank, increasing in saturation.

The process is so arranged that at any given moment a nearly saturated liquor is passing over a *fresh* supply of the substance, while clean water is running through the nearly exhausted residue. When the residue in any tank is completely exhausted it is removed, fresh stuff put in, and that tank made the last of the series. In some cases a pump is necessary between each tank to pump the liquid from beneath the false bottom into the next tank.

If the solution formed is of high sp.gr., so much pumping is not necessary. One detailed description will suffice. In the preparation of soda by the Leblanc process, the black ash (roughly speaking, soluble sodium carbonate and insoluble calcium sulphide) is lixiviated. For this purpose, four or more iron tanks are used, built side by side, each about 10 feet × 10 feet × 6 feet. Each tank has a false bottom of perforated iron plates, and a large cock in the bottom, by which all the liquor it contains can be run off. It has also an overflow pipe, rising from below the false bottom and communicating with the next tank, and a second overflow pipe which communicates with a trough outside. The first tank is connected with the last by a pipe. Any of these pipes can be closed by plugs or cocks. Suppose the process to be in full working order. Fresh black ash, broken in large lumps, has been placed in tank 4, on a bed of cinders laid over the false bottom. Tanks 3 and 2 contain partially exhausted black ash, and tank 1 completely exhausted black ash (tank waste). The overflow pipe between 3 and 4 is opened, and a pump connected with 1, which pumps the liquor over into 2. It flows from 2 to 3, from 3 to 4, until 4 is full. Tank 1 is now cut off, emptied, cleaned, and a fresh supply of black ash put in. While this is going on, fresh water is flowing into 2, and sufficiently saturated liquor flowing away from 4 by the outside overflow pipe. 4 is now connected with 1. The liquor is pumped out of 2 into 3, flows from 3 to 4, from 4 to 1. When 2 is empty of liquor it is in the same way cleaned out, and a fresh charge put in, and so the lixiviation is kept continuous, strong soda solution running off at one end, and exhausted tank waste being removed at the other.

LOADSTONE. A name applied to those specimens of the mineral magnetite (*q.v.*) which are magnetic with polarity, and are thus capable of orientating themselves when freely suspended. All specimens of magnetite are readily attracted by a magnet, but only few exhibit polarity in their natural state. Such specimens are found in exposed situations in mountainous districts, *e.g.* in the Ural and Harz Mountains, where they have no doubt been magnetised by the electric discharges of lightning. Such stones were at an early period mounted in iron frames and used as natural magnets. For historical details, *see* William Gilbert, De Magnete (1600; English edition with notes by S. P. Thompson, 1900). S. P. Thompson on Petrus Peregrinus's Epistola de Magnete (Proc. British Acad. 1907, vol. ii.).

LOBELACRIN *v.* LOBELIA.

LOBELIA, *Indian tobacco* (*Lobélie enflée*, Fr.; *Lobeliakraut*, Ger.). The official lobelia, *Lobelia inflata*, was described by Linnæus in 1741 (Acta Soc. Reg. Scient. Upsal. 1746) from specimens cultivated by himself, but he does not ascribe to it any medicinal properties. It is an annual herbaceous, somewhat pubescent plant, attaining a height of from 9 to 18 inches, with inconspicuous bluish racemose inflorescence. It is indigenous to the Eastern portions of N. America, and is cultivated in European gardens (Flück. a Hanb. 399; Bentl. a. Trim. 162). According to J. U. and C. G. Lloyd (Pharm. J. [iii.] 17, 566), the first to employ lobelia in medicine was Thomson, an American herbalist of some notoriety about the end of the eighteenth century. The Indians, although they made use of the great lobelia, *L. syphilitica* (Linn.), were not acquainted with the *L. inflata*, as has been commonly supposed, and as one of its names would imply. The drug only gradually came into favour as an article of *materia medica*, and it forms the ethereal tincture of the British Pharmacopœia (1914). The herb should be gathered when, after flowering, some of the capsules have become inflated. In physiological action, lobelia resembles tobacco. It is an acrid narcotic poison, but in small doses is expectorant or emetic and is employed in spasmodic asthma and diseases of the respiratory organs. The seed is more active than the herb, but the latter is almost exclusively employed in medicine.

The plant was investigated by Colhoun in 1834 (J. Pharm. Chim. [ii.] 20, 545), but the first definite results were obtained by Proctor (Amer. J. Pharm. 9, 98; 13, 1). The seed was exhausted with spirit containing a little acetic acid, the solution evaporated, and the residue

mixed with magnesia and extracted with ether. On evaporating the ether an acrid alkaloidal substance, *lobeline*, remained, which by conversion into acetate and treatment with animal charcoal, was obtained in a purer form. Lobelia was further studied by Pereira (Mal. Med. 2nd ed. 2, 584), Reinsch (Pharm. J. [i.] 3, 128), Bastick (*ibid.* [i.] 10, 217), F. F. Mayer (Amer. J. Pharm. 37, 209), Richardson (*ibid.* [iv.] 2, 203), Lewis (Pharm. J. [iii.] 8, 561), Dragendorff and Rosen (Chem. Zentr. 1886, 873), J. U. and C. G. Lloyd (Pharm. J. [iii.] 17, 566, 686, 1037; 18, 135), Dresser (Arch. exp. Path u. Pharm. 26, 237), Wieland (Ber. 1921, 54, 1784).

Lobeline, according to J. U. and C. G. Lloyd, is a colourless, odourless, amorphous powder, extremely active, a very small quantity of its solution applied to the tongue causing immediate vomiting. Soluble in alcohol, chloroform, ether, benzene, carbon disulphide; slightly soluble in water. Oxidised by permanganate, it yields benzoic acid (Pachkis and Smits, Monatsh. 11, 131). Salts of lobeline are soluble in water or alcohol, but, excepting the acetate, not in carbon disulphide. The aqueous solution is precipitated by alkalis and alkaloidal reagents. Its hydrochloride can be removed from its aqueous solution by repeated agitation with chloroform, and its final purification can be effected by crystallisation from alcohol, benzene, or ether. Gives a crystalline platinochloride.

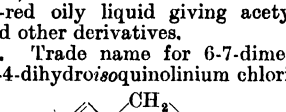
Lobeline, which, according to Dresser, is the only active constituent of lobelia, has the formula $C_{22}H_{29}O_2N$ (Wieland, *l.c.*). It crystallises in broad colourless needles, m.p. 130°–131°; $[\alpha]_D^{15} = -42{\cdot}85°$ in alcoholic solution. The sulphate, nitrate, bromide, and chloride are placed in order of increasing solubility in water; they are crystalline neutral salts. The base is monacidic. It is readily hydrolysed to acetophenone. Contains no ketonic or hydroxy groups; the lactone ring and methoxy group are absent. The nitrogen atom appears to be in the tertiary form.

Lobeline appears to occur in the plant in combination with *lobelic acid*. It is precipitated from an aqueous decoction of lobelia by copper sulphate, and may be separated by treatment with hydrogen sulphide and extraction with ether. Small acicular crystals, soluble in water, alcohol, or ether.

Lobelidine $C_{20}H_{25}O_2N$ is isolated from the final ethereal mother liquors obtained during the preparation of lobeline, in the form of small irregular prisms, m.p. 106°. Its hydrochloride has m.p. 165° (decomp.).

LOBINOL. A poisonous, unsaturated phenol, having two hydroxyl groups in the ortho position, isolated by McNair (J. Amer. Chem. Soc. 1921, 43, 159) from the bark of *Rhus diversiloba*. An amber-red oily liquid giving acetyl and benzoyl and other derivatives.

LODAL. Trade name for 6-7-dimethoxy-2-methyl-3-4-dihydro*iso*quinolinium chloride



Used in medicine as a pressor substance.

LOESS (Ger. *Löss*). A pale buff-yellow, porous, friable, fine-grained material occurring in certain regions as extensive deposits, which are probably in most cases of æolian (wind-borne) origin. It consists of minute angular grains of quartz and other rock-forming minerals, flakes of mica without definite orientation (in rocks of aqueous origin the flakes of mica lie parallel to the bedding planes), and clayey and calcareous material in varying proportions. It therefore varies between wide limits in chemical composition as illustrated in the following analyses: I and II, Loess from the Mississippi valley; on material dried at 100°, the H_2O includes H from the organic matter (T. C. Chamberlin and R. D. Salisbury, 6th Ann Rep. U.S. Geol. Survey, 1884–85). III, Adobe from Santa Fé, New Mexico; also Cl 0·34. IV, Adobe from Salt Lake City, Utah; also Cl 0·11 (III and IV by L. G. Eakins, quoted by I. C. Russell, Geol. Mag. 1899). V, Loess from Bonn on the Rhine (G. Bischof, Chem. Geol. 1855; stated as $CaCO_3$ 17·63, $MgCO_3$ 3·02, MgO 0·21). VI, 'Black-earth' (chernozem) from Russia (R. Phillips in R. I. Murchison, Geology of Russia, 1845; also Cl 1·7, traces of humic acid, SO_3).

When rubbed between the fingers the material is soft and friable with a harsh feeling; but, owing to its homogeneity and lack of bedding, it can stand up as vertical cliffs some hundreds of feet in height. Loess is of wide distribution in the Rhine valley, and extends through central Europe and Asia into China; in the latter country reaching its maximum development and forming in places deposits of over 1000 feet in thickness. Throughout the Mississippi valley it is also a common surface deposit; and a very similar material, known as *adobe*, is widely distributed in the arid regions of the south-western United States and Mexico. The material is much used for brick making, especially the sun-dried bricks of primitive peoples (hence the name adobe, which means in Spanish a sun-dried brick). The more calcareous varieties are used for mortars and cements. When containing much organic matter it forms a fertile soil, *e.g.* the well-known *black-earth* or *chernozem* (tchernozem) of south Russia.

For further analyses, *see* H. G. Schering, Chemische Untersuchungen über Löss und Lehm, Diss. Freiburg.-i.-Br. 1909; P. Werling, Chemische Untersuchungen über den Löss der Pampas-Formation Argentiniens, Diss. Freiburg-i.-Br. 1911. L. J. S.

LOGWOOD. Logwood or Campeachy wood is one of the most important dyestuffs, and at the present time is very largely employed. Although for a long time it has successfully competed with the artificial colouring matters, its supremacy as a cotton dye has been affected to a considerable extent by the introduction of the sulphide blacks.

Logwood appears to have been first imported into Europe by the Spaniards shortly after the discovery of America, and has been cultivated in Jamaica from the year 1715. In the time of Elizabeth its employment as a dye was prohibited by Act of Parliament, and large quantities of the wood were burned, because it was said to produce fugitive colours.

It is derived from the *Hæmatoxylon campechianum* (Linn.), a tree which belongs to the family *Cæsalpiniaceæ*, and is a native of the warmer part of South America and some of the West India Islands. It also grows in the island of Mauritius, and trials indicate that this wood is of good quality (private communication).

Logwood usually comes into the market in large blocks weighing about 400 lbs. These externally are of a deep brown colour, but internally have a much lighter tint. The best qualities come from Jamaica, Honduras, and St. Domingo, for the true Campeachy wood, at one time esteemed to be the best, is now practically exhausted.

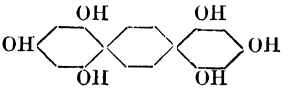
The colouring principle of logwood, *hæmatoxylin*, was first isolated in a crystalline condition by Chevreul (Ann. Chim. [ii.] 82, 53, 126), who obtained it by extracting the wood with ether, evaporating the extract, and digesting the residue with alcohol. After distilling off the alcohol the residue was allowed to stand in contact with water, when the hæmatoxylin separated in crystals. It may also be prepared by similarly treating commercial logwood extract which has been incorporated with a large quantity of sand (O. L. Erdmann, Annalen, 44, 292; J. pr. Chem. 26, 193; 36, 205; 75, 318). For this purpose ether containing water is preferable (Hesse, Annalen, 109, 332). It is, however, more easily obtained from the dark-coloured crusts which slowly separate when concentrated logwood liquor stands for some time in a cool place. The crude mass is ground to a fine powder, extracted repeatedly with ether, the ethereal solution evaporated, and the residue left in contact with water, when dark-coloured crystals separate, which by recrystallisation from water containing a small quantity of sodium bisulphite, may be obtained colourless (W. H. Perkin and Yates, Chem. Soc. Trans. 1902, 81, 236).

Pure hæmatoxylin crystallises in prisms with $3H_2O$, and is sparingly soluble in cold, readily so in hot, water. Its aqueous solution is coloured purple with alkalis, and this on exposure to air eventually assumes a brown tint. Hæmatoxylin is dextro-rotatory, a 1 p.c. aqueous solution having a rotation of 1·85 in a 200 mm. tube. It readily reduces salts of silver and gold, gives with alum a rose-red coloration, with iron alum a violet-black precipitate, and with neutral and basic lead acetate at first a colourless and then a blue deposit which darkens by air oxidation.

O. L. Erdmann (*l.c.*) was the first to submit hæmatoxylin to analysis, and proposed the formula $C_{40}H_{17}O_5$, which he subsequently altered to $C_{16}H_{14}O_6$. This latter formula was confirmed by Hesse (*l.c.*) and at the present day is accepted as correct.

By fusion with alkali, hæmatoxylin yields pyrogallol (Reim, Ber. 1871, 4, 331), and according to E. Erdmann and Schultz (Annalen, 216, 234) also formic acid. R. Meyer (Ber. 1879, 12, 1392) submitted hæmatoxylin to destructive distillation and considered that in this manner not only pyrogallol but also resorcinol is produced. According, however, to W. H. Perkin and Gilbody (Chem. Soc. Trans. 1902, 81, 245), no resorcinol is thus obtained.

Reim acetylated hæmatoxylin with acetyl chloride and prepared a substance which appeared to be the hexa-acetyl derivative $C_{16}H_8O_6(C_2H_3O)_6$, and as a result suggested the following constitution for this colouring principle:—



E. Erdmann and Schultz (Annalen, 1883, 216, 234) re-examined Reim's compound and showed that this was in reality a *penta-acetyl-hæmatoxylin* $C_{16}H_9O_6(C_2H_3O)_5$, m.p. 165°–166°, and that hæmatoxylin therefore contains five hydroxyl groups. This result was confirmed by the work of Herzig (Monatsh. 1894, 15, 143), who, by the action of sodium methoxide and methyl iodide on hæmatoxylin, obtained the *tetramethyl derivative* $C_{16}H_{10}O_2(OMe)_4$, m.p. 139°–140°, a substance which still contains a hydroxyl group, since on treatment with acetic anhydride it yields *acetyltetramethylhæmatoxylin* $C_{16}H_9O_2(OMe)_4(C_2H_3O)$, m.p. 178°–180°. It was thus shown that hæmatoxylin like brazilin contains an alcoholic hydroxyl group which is not methylated by means of methyl iodide and sodium methoxide under the usual conditions, and indeed it has long been considered probable that these two colouring matters are closely allied in constitution (Liebermann, Ber. 1876, 9, 1883; *cf.* also Hummel and A. G. Perkin, Chem. Soc. Trans. 1882, 41, 373).

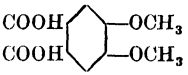
The following derivatives of hæmatoxylin have also been prepared: *Pentamethylhæmatoxylin* $C_{16}H_9O(OCH_3)_5$, plates, m.p. 144°–147° (Herzig); *dibromhæmatoxylin* $C_{16}H_{12}Br_2O_6$ (Dralle, Ber. 1884, 17, 373); *penta-acetylbromhæmatoxylin* $C_{16}H_8BrO_6(C_2H_3O)_5$, needles, m.p. 110° (Buchka, *ibid.* 1884, 17, 685); *penta-acetyltetrabromhæmatoxylin* $C_{16}H_5Br_4O_6(C_2H_3O)_5$ (Dralle); and *hæmatoxylinphthalein* $C_{40}H_{30}O_{14}$ (Letts, Ber. 1879, 12, 1652).

Our main knowledge of the chemistry of hæmatoxylin and the fact that it is in reality hydroxybrazilin is due to the elaborate researches of W. H. Perkin and his pupils, and their results have arisen mainly from a study of the oxidation products of hæmatoxylin tetramethyl ether.

According to this author (Chem. Soc. Trans. 1902, 81, 1059), tetramethylhæmatoxylin is most readily prepared by treating the solution of hæmatoxylin in alcoholic potash with methyl sulphate, a method which had previously been found serviceable by v. Kostanecki and Lampe

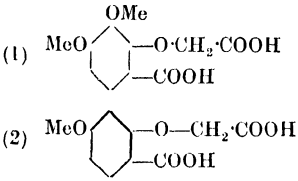
(Ber. 1902, 35, 1669) for the production of trimethylbrazilin from brazilin.

When tetramethylhæmatoxylin is oxidised with potassium permanganate (Perkin and Yates, *l.c.*), it yields *m-hemipinic acid*



an important result, because it is thus certain that hæmatoxylin like brazilin (Gilbody, Perkin and Yates, Chem. Soc. Trans. 1901, 79, 1400) contains a catechol nucleus. Consequently, whereas in the molecule of brazilin a resorcinol and a catechol nucleus occur, in hæmatoxylin pyrogallol and catechol groups are present.

In addition to *m*-hemipinic acid, large quantities of a second acid $C_{11}H_{12}O_7$, m.p. 215°, are produced. This is *2-carboxy-5 : 6-dimethoxyphenoxyacetic acid* (1)—



analogous to the *2-carboxy-5-methoxyphenoxyacetic acid* (2) which was obtained in a similar manner from brazilin trimethyl ether (*see* BRAZILWOOD).

Finally, from the product of the oxidation a third compound *hæmatoxylinic acid* $C_{20}H_{20}O_{10}$, m.p. 180°, was isolated. This on reduction with sodium amalgam is converted quantitatively into an acid $C_{20}H_{20}O_9$, which is a monobasic lactonic acid, and it is therefore evident that the latter is produced in two stages thus :—

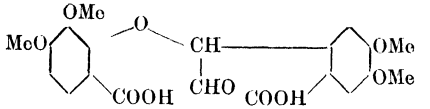
$$C_{20}H_{20}O_{10} + 2H = C_{20}H_{22}O_{10}$$

Hæmatoxylinic acid. Dihydrohæmatoxylinic acid.

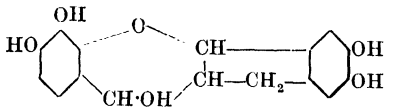
$$C_{20}H_{22}O_{10} - H_2O = C_{20}H_{20}O_9$$

Lactone of dihydrohæmatoxylinic acid.

The constitution at first assigned to hæmatoxylinic acid by these authors was as follows :—

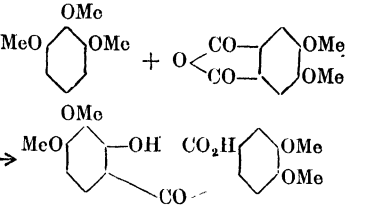


but this, and the corresponding hæmatoxylin formula—

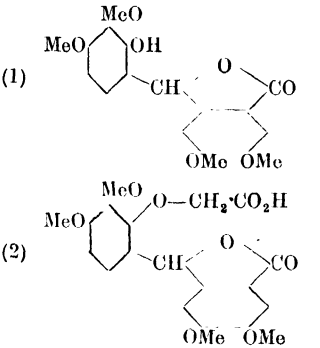


were subsequently modified, as the result of the synthesis of the lactone of dihydro-hæmatoxylinic acid referred to above (Perkin and Robinson, Chem. Soc. Trans. 1908, 93, 492).

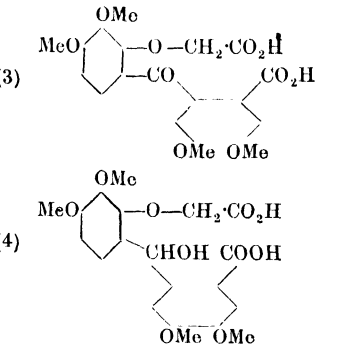
When aluminium chloride reacts with a mixture of pyrogallol trimethyl ether and *m*-hemipinic anhydride, *2′-hydroxy-3′ : 4′ : 4 : 5-tetramethoxybenzoylbenzoic acid* is produced :—



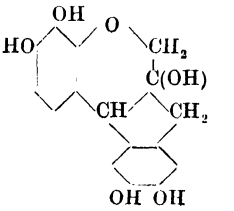
This ketonic acid is then converted by reduction with sodium amalgam into *2-m-mecomyl-5 : 6-methoxyphenol* (1), which by treatment with chloracetic acid and sodium hydroxide gives the lactone of dihydrohæmatoxylinic acid (2).



Consequently, the formulæ of hæmatoxylinic acid (3) and of dihydrohæmatoxylinic acid (4) are thus represented—



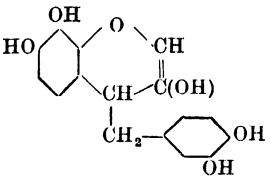
From these facts the constitution of hæmatoxylin itself naturally follows :—



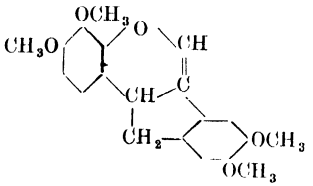
and this is identical with that which Pfeiffer (Chem. Zeit. 1904, 3, 380) from theoretical considerations suggested as possible.

Other constitutional formulæ have been

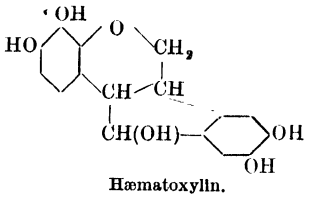
assigned to hæmatoxylin, of which that of Bollina, v. Kostanecki and Tambor (Ber. 1902, 35, 1678), analogous to the brazilin formula of Feuerstein and v. Kostanecki (Ber. 1899, 32, 1024), is of interest—



It was, however, evident that such an expression does not account for the production of *m*-hemipinic acid or 2-carboxy-5 : 6-dimethoxy phenoxyacetic acid by the oxidation of hæmatoxylin tetramethyl ether. On the other hand, v. Kostanecki and Lampe (Ber. 1902, 35, 1667) at first suggested that previous to the degradation of the methyl ether by oxidation with permanganate an internal linkage is produced, with production of the following compound :—

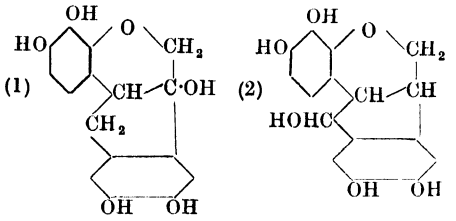


These authors ultimately considered, as W. H. Perkin contended, that a *m*-hemipinic residue is contained in hæmatoxylin tetramethyl ether, and as a result proposed the following modification of their formula for this colouring matter :—



Hæmatoxylin.

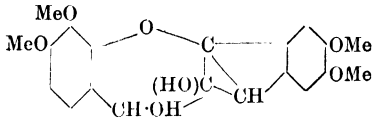
Again, Herzig and Pollak (Monatsh. 1906, 27, 743 ; Ber. 1906, 39, 267), in a criticism of the earlier formula of Gilbody, Perkin and Yates (*l.c.*), suggested, among others, two possible constitutions for brazilin, the second of which is identical with that of v. Kostanecki and Lampe (*see* above), and which applied to hæmatoxylin, are thus represented :—



These formulæ of v. Kostanecki and Lampe and Herzig and Pollak cannot, however, be correct, as they do not account for the formation of hæmatoxylinic acid by the oxidation of tetramethylhæmatoxylin with permanganate (Gilbody, Perkin and Yates, *l.c.*).

Herzig (Monatsh. 16, 906) submitted acetyltetramethylhæmatoxylin to oxidation with chromic acid and obtained a new product, which on hydrolysis gave *tetramethyldehydrohæmatoxylin* $C_{16}H_5O(OMe)_4OH$. This latter, on acetylation, yielded *acetyltetramethyldehydrohæmatoxylin* $C_{16}H_5O(OMe)_4(OC_2H_3O)$, and by methylation *pentamethyldehydrohæmatoxylin*.

W. H. Perkin (Chem. Soc. Trans. 1902, 81, 1057) oxidised tetramethylhæmatoxylin with chromic acid, and obtained a substance *tetramethylhæmatoxylone* $C_{16}H_6O(OMe)_4(OH)_2$, corresponding in all its reactions with trimethylbrazilone. For this, at that time, the formula

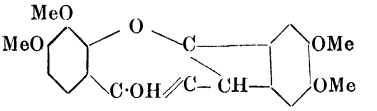


was proposed. In addition to this compound, 2-carboxy-5-6 dimethoxyphenoxyacetic acid and *m*-hemipinic acid were also produced during the oxidation. When digested with acetic anhydride, tetramethylhæmatoxylone gives *acetylanhydrotetramethylhæmatoxylone*

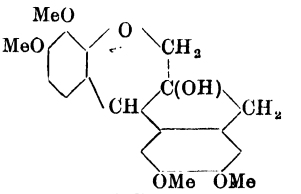
$$C_{16}H_5O(OMe)_4(OC_2H_3O)$$

evidently identical with Herzig's acetyltetramethyldehydrohæmatoxylin referred to above.

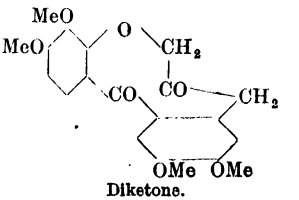
By hydrolysis this compound gave anhydrotetramethylhæmatoxylone $C_{16}H_5O(OMe)_4OH$—



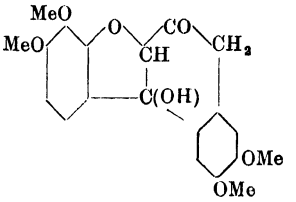
In a later paper Perkin and Robinson (Chem. Soc. Trans. 1908, 498) discarded these expressions and assigned to tetramethylhæmatoxylone the constitution given below. These authors consider that during the oxidation of tetramethylhæmatoxylin with chromic acid, a destruction of the central linkage occurs, and the unstable diketone which is thus formed undergoes aldol condensation with the production of tetramethylhæmatoxylone—



Tetramethylhæmatoxylin.



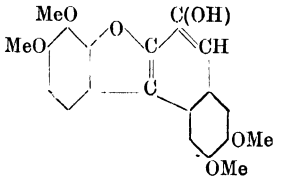
Diketone.



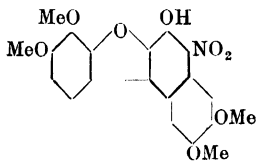
Tetramethylhæmatoxylone.

This formula indicates that tetramethylhæmatoxylone is a derivative both of coumaran and tetrahydronaphthalene.

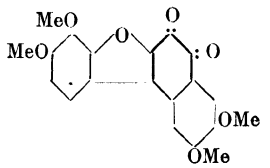
The formation of anhydrohæmatoxylone by means of acetic anhydride (*l.c.*) is due to the elimination of water from the aldol grouping in tetramethylhæmatoxylone, and the constitution thus given to this substance represents it as a derivative of β-naphthol, with which indeed it has many properties in common—



When acetylanhydrotetramethylhæmatoxylone is treated with nitric acid it readily reacts with the formation of the mononitro compound (Perkin and Robinson, *ibid.* 1909, 384)—



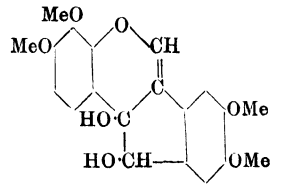
and from this substance by reduction with zinc-dust and hydrochloric acid the corresponding amino derivative is produced. This, when oxidised by ferric chloride, yields *tetramethoxy-a-brazanquinone* (*cf.* v. Kostanecki and Rost, *l.c.*)—



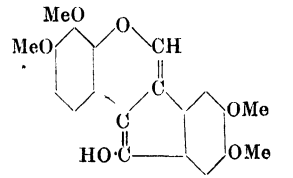
That this substance is an ortho-quinone is shown by its behaviour with *o*-tolylenediamine with which it condenses with formation of a characteristic quinoxaline. On reduction, the quinone is converted into the corresponding *dihydroxy* derivative.

v. Kostanecki and Rost (Ber. 1903, 36, 2202), on the other hand, proposed for the tetramethylhæmatoxylone (1) and anhydrotetramethylhæmatoxylone (2) of Perkin the following expressions which harmonised with their suggested constitution for hæmatoxylin (*l.c.*):—

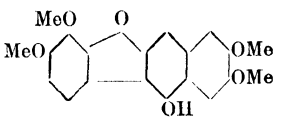
(1)



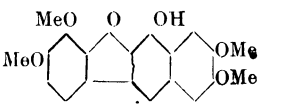
(2)



According to these authors, when tetramethylhæmatoxylone is treated with alcoholic sulphuric acid, a new compound (1′ or 4′) *hydroxy*-3 : 4 : 6′ : 7′-*tetramethoxybrazan* is formed, which is represented by one or other of the annexed formulæ :—

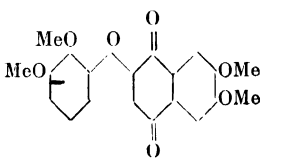


or

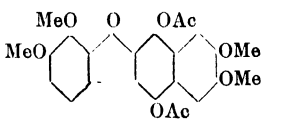


Oxidation with chromic acid converts this substance into 3 : 4 : 6′ : 7′-*tetramethoxybrazanquinone* (1), which by reduction and acetylation yields 3 : 4 : 6′ : 7′-tetramethoxy (1′ : 4′) diacetoxybrazan (2)—

(1)



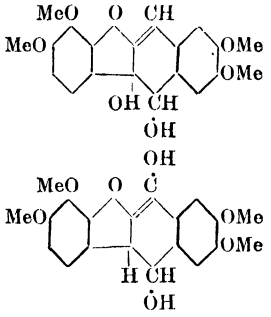
(2)



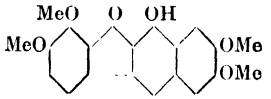
When distilled with zinc-dust, both hydroxytetramethoxybrazan and tetramethoxybrazanquinone yield *naphthalene*.

Herzig and Pollak (Ber. 1904, 37, 631) also found that cold concentrated sulphuric acid converts tetramethylhæmatoxylone into an isomeric compound *ψ-tetramethylhæmatoxylone*,

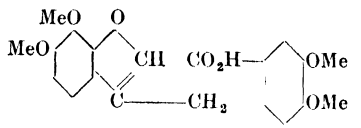
and suggested the following formulæ as applicable to this substance :—



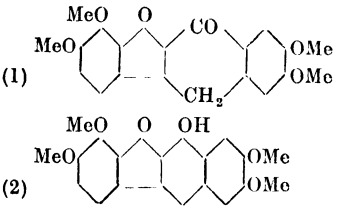
This by loss of water gives *β-anhydrotetramethylhæmatoxylone*, which is identical with v. Kostanecki and Rost's hydroxytetramethoxybrazan—



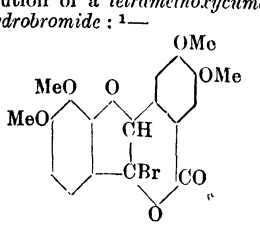
Perkin and Robinson (*l.c.*), as the result of a study of the work of Herzig and Pollak, have, however, shown that *ψ*-tetramethylhæmatoxylone is in reality a monobasic acid, and possesses the following constitution :—



This, by elimination of water, passes into the compound (1) and then by intramolecular change into hydroxytetramethoxybrazan (2) :—



When *ψ*-tetramethylhæmatoxylone is treated with potassium hypobromite a colourless precipitate soon separates. This crystallises in almost colourless prisms or needles, and possesses the constitution of a *tetramethoxycumarono-isocoumarinhydrobromide* : [1]—



For the theoretical considerations involved in the production of this interesting substance the original paper should be consulted.

Hæmatein.—When oxidised under suitable conditions, hæmatoxylin readily passes into the colouring matter hæmatein, according to the equation $C_{16}H_{14}O_6+O=C_{16}H_{12}O_6+H_2O$.

Hæmatein was first produced by O. L. Erdmann (*l.c.*) by passing air through an ammoniacal solution of hæmatoxylin, and subsequently acidifying with acetic acid.

Erdmann and Schultz (*l.c.*) who adopted a somewhat similar procedure, succeeded in isolating hæmatein in leaflets which possessed a metallic lustre. Reim, on the other hand (Ber. 1871, 4, 331), treated an ethereal solution of hæmatoxylin with a little concentrated nitric acid.

By extracting 'aged' logwood with ether, Halberstadt and Reis (Ber. 1881, 14, 611) obtained 1 p.c. of a very pure crystalline hæmatein.

Hummel and A. G. Perkin (Chem. Soc. Trans. 1882, 41, 373) exposed an ammoniacal solution of logwood extract to the air for two or three days. The precipitated ammonia compound of hæmatein was collected, dissolved in water, dilute acetic acid added, and the mixture digested on the water-bath to dissolve as much as possible of the suspended amorphous hæmatein. The clear liquid after partial evaporation deposited crystals of the colouring matter, possessing a yellowish-green iridescence, and having the composition $C_{16}H_{12}O_6$.

According to Mayer (Chem. Zentr. 1904, 1, 228), hæmatein may also be prepared by oxidising hæmatoxylin in aqueous solution with sodium iodate.

Engels, W. H. Perkin and Robinson (Chem. Soc. Trans. 1908, 93, 1140) passed air for 6 hours through a solution of 15 grams of hæmatoxylin, dissolved in a solution of 15 c.c. of concentrated ammonia in 150 c.c. of water. The product of the oxidation was added in a thin stream to dilute acetic acid (250 c.c. of 10 p.c.) heated on the water-bath, when hæmatein separated in crystals.

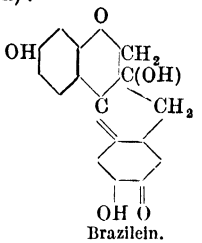
Hæmatein is very sparingly soluble in water and the usual solvents. Alkalis dissolve it readily; ammonia dissolves it with a brown-violet colour, whilst its strong alkaline solution has a rich purplish-blue colour. On exposure to air the colour of these alkaline solutions gradually becomes red and finally brown, the colouring matter being destroyed. By addition of potassium acetate to the boiling alcoholic solution of hæmatein, the monopotassium salt $C_{16}H_{11}O_6K$ is deposited (A. G. Perkin, Chem. Soc. Trans. 1899, 75, 443).

Sulphurous acid or sodium bisulphite solution converts hæmatein into a colourless addition product, readily soluble in water, but no reduction hereby appears to occur, as on boiling the solution or by addition of acid hæmatein is precipitated. With zinc and hydrochloric acid or with stannous chloride and caustic soda, a solution of hæmatein is decolorised, but on standing the liquid regains its former tint.

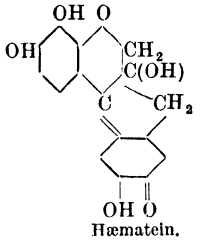
It has long been considered that hæmatein is hydroxybrazilein, and this has now been clearly proved by a study of the behaviour of both hæmatein and brazilein with reagents under similar circumstances. This relationship is at once evident from a comparison of the

[1] *ψ*-trimethylbrazilone behaves analogously.

following formulæ (Engels, Perkin, and Robinson) :—



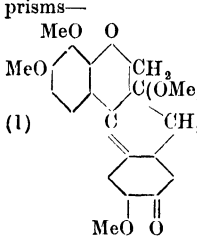
Brazilein.



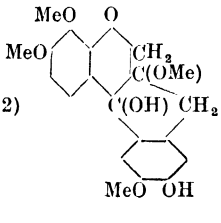
Hæmatein.

When hæmatein is methylated by means of alkali and methyl sulphate, the product consists essentially of tetramethylhæmatein and pentamethyldihydrohæmateinol.

Tetramethylhæmatein (1) crystallises in amber prisms, and when digested with dilute potassium hydroxide is converted by the addition of water into *tetramethyldihydrohæmateinol* (2), yellow prisms—

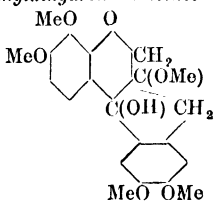


(1)



(2)

Pentamethyldihydrohæmateinol



the second product of the reaction, crystallises in yellow plates, and is also produced when tetramethyldihydrohæmateinol is methylated with methyl sulphate and alkali.

In the year 1882 Hummel and A. G. Perkin (Chem. Soc. Trans. 41, 367) observed that hæmatein and also brazilein are converted by the action of mineral acids into orange or red salts, from which the original colouring matters could not be regenerated.

When hæmatein is dissolved in cold sulphuric acid, a reddish-brown solution is produced from which, by cautious addition of acetic acid, minute orange-coloured prisms of *acid iso*hæ*mateinsulphate* $C_{16}H_{12}O_5SO_4$ are deposited. The reaction may be represented thus :

$$C_{16}H_{12}O_6+H_2SO_4=C_{16}H_{12}O_5SO_4+H_2O$$

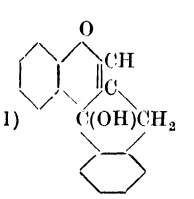
This substance, when left in contact with 80 p.c. alcohol, is gradually transformed, with loss of sulphuric acid, into a new compound crystallising in orange-red plates possessing a strong metallic lustre and to which the formula $(C_{16}H_{12}O_6)_2C_{16}H_{12}O_5SO_4$ was assigned. On the other hand, hydrochloric and hydrobromic acids in sealed tubes at 100° convert hæmatein respectively into *iso*hæ*matein chlorhydrin*

$$C_{16}H_{11}O_5\cdot Cl$$

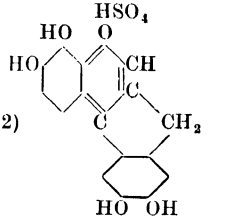
and *iso*hæ*matein bromhydrin* $C_{16}H_{11}O_5Br$, which crystallise in orange-red needles.

If to an aqueous solution of *iso*hæmatein chlorhydrin or bromhydrin silver hydroxide is added to remove the halogen, a solution of *iso*hæ*matein* is obtained, which on evaporation leaves this substance as an amorphous mass possessing a green metallic lustre. *Iso*hæmatein and its salts dissolve in solutions of the alkaline hydroxides with a red-violet colour which is easily distinguished from the corresponding blue-violet solution of hæmatein; moreover, the dyeing properties of these compounds and hæmatein differ considerably. Thus the *iso*hæmatein derivatives give, on cotton mordanted with alumina, a dull red inclining to chocolate, with strong iron a black, and with mixed alumina and iron a full chocolate. Again, the tinctorial power of these compounds is much greater than that of the original hæmatein, and the colours are much faster.

As the result of the investigation of a large number of pyranol salts (W. H. Perkin, Robinson, and Turner, Chem. Soc. Trans. 1908, 93, 1085), it seems certain that these hæmatein salts are derivatives of 4 : 3-*indenobenzopyranol* (1), and that *iso*hæmatein sulphate possesses the constitution (2)—

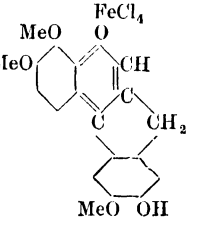


(1)

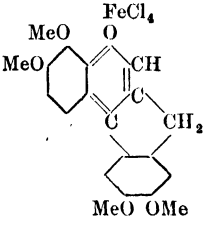


(2)

*Iso*hæmatein chlor- and bromhydrins are formulated similarly. Thus from tetramethylhæmatein, Engels, Perkin, and Robinson (*l.c.*) have prepared 5′-*hydroxy*-7 : 8 : 4′-*trimethoxy*-4 : 3-*indenobenzopyranol* (1 : 4) *anhydroferrichloride*—



which crystallises from acetic acid in well-defined elongated prisms. Pentamethyldihydrohæmateinol, on the other hand, gives 7 : 8 : 4′ : 5′-*tetramethoxy*-4 : 3-*indenobenzopyranol* (1 : 4) *anhydroferrichloride*—



Before being used by the dyer, logwood is reduced to chips or powder, and these products are known as 'chipped,' 'rasped,' or 'ground' wood. When first cut down the wood has a pale yellow colour and contains only hæmatoxylin, but during transport or storage this colour gradually deepens owing to a surface oxidation of the hæmatoxylin into hæmatein. Formerly, and even to some extent at the present time, it was the practice to submit the chipped or rasped logwood to what is known as the 'ageing' process, in order to facilitate the hæmatein formation. This consists in wetting the wood thoroughly with water, then forming it into heaps, 4 to 5 feet high, in large airy chambers. Very soon the mass begins to ferment, which is indicated by a rise of its internal temperature, the wood gradually darkens in colour, and during the operation the mixture is repeatedly turned over and remixed in order to avoid too vigorous a fermentation and to obtain an even result. Constant attention is necessary during this 'ageing' process, for if the reaction is allowed to proceed too far, a portion of the colouring matter is destroyed, and 'burnt' or 'over-aged' wood is produced. In order to expedite this operation, the use of various oxidising agents has been suggested; a sprinkling of the wood with ammonia has been said to exercise a beneficial result; but, on the other hand, such processes are best avoided, for it is difficult under these circumstances to control the reaction and prevent an over-oxidation.

Latterly this ageing operation has been less in vogue, not only on account of the increased employment of logwood extract, but because it is now recognised that where the mordant employed for dyeing purposes can exert an oxidising action, this preliminary treatment is unnecessary. Formerly, logwood blacks on wool were produced by means of an iron mordant, but this is now largely replaced by the use of potassium dichromate, which provides a mordant possessing the power of converting at least a portion of the hæmatoxylin into hæmatein.

Logwood extract is now prepared in enormous quantity not only in this country but also in Jamaica in the neighbourhood of the logwood plantations, and in the latter case an economy is naturally effected in the carriage of some varieties of the extract rather than that of the more bulky wood to this and other countries. Logwood extract is almost invariably prepared from the 'unaged' wood, because whereas hæmatoxylin is readily soluble in water, hæmatein is not. On this account, an aged wood is difficult to exhaust. For the manufacture on the large scale, two processes are in vogue known respectively as the 'American' and 'French' methods. These differ merely in the manner in which the wood is lixiviated, for this is carried out by the French process in open pans with warm or boiling water, whereas in the American process, closed vessels are used in which steam at from 15 to 30 lbs. pressure is employed. In both cases the liquid is afterwards concentrated, preferably in vacuum pans, and the product is sold at about 15°Tw. as *logwood liquor*, at 51°Tw. as *logwood extract*, or in the solid condition as *solid logwood extract*. As a rule, it is considered that the extract made at the lower temperature gives the brighter shade.

Certain processes are in use for the 'ageing' of 'logwood liquor,' that is, the conversion of the dissolved hæmatoxylin into hæmatein. For this purpose the following methods have been suggested: (*a*) treat the logwood liquor with bleaching powder solution; (*b*) half neutralise with alkali or ammonia and blow air or oxygen through the liquid; (*c*) employ air or oxygen for this purpose without the addition of alkali; (*d*) boil with manganese dioxide (Weldon mud) and filter. Interesting also in this respect is the patented process of Haak (Chem. Zentr. 1905, ii. 867), who treats the extract with sodium nitrite.

A very important product more recently introduced is the so-called crystalline *hæmatein paste*, which is a treacly extract containing in suspension minute crystals of hæmatein. The details of the preparation of this material, which appears to have been first introduced from Jamaica, although now also manufactured in this country, are kept secret. For experimental purposes, this paste may be employed as the source of a comparatively pure hæmatein, which can be isolated from it by dilution with glacial acetic acid and subsequent filtration (private communication).

Logwood and its extracts are enormously employed for the dyeing of blacks on silk, wool, and to a less extent with cotton, chiefly in conjunction with iron and chromium mordants. It also enters into the composition of numerous compound shades.

Bastard Logwood.—During the past few years the growers of logwood in Jamaica have been greatly disturbed by the apparent increase on their properties of an unmerchantable variety of the tree known as 'bastard' logwood. Bastard logwood is practically devoid of hæmatoxylin, but contains instead a yellowish-green pigment which, when admixed with the commercial extract, reduces its characteristic tinctorial properties. Chips of the bastard logwood present a yellow, pale pink, white, or even chocolate coloured surface instead of the dark red or purple-bronze tinted colour of the best Jamaican or Mexican logwoods of commerce.

So similar are the trees of the 'true' and the 'bastard' logwood, that it is frequently impossible to decide whether a tree is really a 'mulatto' or not. When first cut a bastard tree is frequently dark enough internally to indicate that it is a good red-wood tree, but instead of darkening with age, as all the best wood does, it remains the same colour or becomes lighter rather than darker.

Chemical tests readily distinguish between the red and bastard wood, for whereas alkaline solutions turn an extract of true logwood a purple colour, with a bastard extract the shade of yellow is merely deepened. Again, mineral acids turn aqueous extracts of true logwood orange to bright red, whereas a bastard extract is not thereby affected.

Dyeing trials, employing stripe mordanted calico, are also serviceable, because, in the case of the bastard variety, the aluminium mordant remains practically colourless.

Hæmatoxylon Africanum.

The genus hæmatoxylon has hitherto been represented by only one species, the *H. campeachianum*, and the recent discovery of a South African species is of particular interest. This, now termed the *H. africanum*, was found among the rocks at Holoog in Great Namaqualand by Dr. H. H. W. Pearson in February, 1909, during the Percy Sladen Memorial Expedition in South-West Africa, 1909. It consists of a shrub 1–1·5 metres tall, the flowers of which are yellow, and the leaves smaller than those of the *H. campeachianum* (Stephens, Trans. Roy. Soc. S. Africa, 1913, [iii.] 2, 255).

Stems of this plant sent to England for examination were covered with a thin brownish bark, and varied from ½–1¼ inches in diameter, and from 11–16 inches in length. Cut transversely they were seen to consist mainly of a reddish-brown core surrounded by an almost colourless layer of wood, and this core, as is the case with logwood itself, darkened somewhat on exposure to air and became of a richer colour. When ground, the ochre-coloured powder is of a much lighter tint than either ground logwood or Brazil-wood.

The aqueous extract of the ground wood gives in comparison with those obtained from logwood and Brazil-wood the following colour tests :—

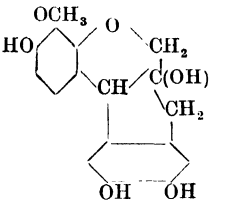
	H. africanum	Brazil-wood	Logwood
NaOH .	Pink	Crimson	Deep red-violet
$FeCl_3$.	Brown	Deep brown	Purplish-black
$Pb(Ac)_2$.	Pale pink almost colourless precipitate	Pink precipitate	Deep blue precipitate

The alkaline extract of the *H. africanum* on boiling deepens considerably in colour and possesses a faint greenish fluorescence, and this property is also exhibited by the corresponding extract of Brazil-wood.

Dyeing trials with both the *H. africanum* (170 p.c.) and Brazil-wood (40 p.c.) employing mordanted woollen cloth gave the following shades :—

	Cr	Al	Cu	Sn	Fe
H. africanum	Red-brown-violet	Dull bluish-red	Brown	Very pale brown	Dull purple
Brazil-wood	Red-violet	Bluish-red	Claret-brown	Red-brown very pale	Blue-violet

The *H. africanum*, therefore, differs from logwood in that the colouring principle it contains is not hæmatoxylin, but a substance which somewhat closely resembles brazilin in its general properties. It is a much poorer dyestuff than Brazil-wood, and on this account is of no technical importance, but should it eventually prove to contain brazilin, the matter is of special interest in view of the connection between this latter and hæmatoxylin which has been shown to exist by W. H. Perkin and his co-workers (*l.c.*). The slight difference in the properties of the *H. africanum* and Brazil-wood may be due to certain impurities in the former dyestuff not possessed by the latter, but on the other hand a methyl ether of hæmatoxylin of the type



will without doubt dye shades of an almost identical character with those given by brazilin itself (Perkin, J. Soc. Dyers, 1918, 34, 99).

LOKAO, a green dyestuff of Chinese origin, is, or rather was, since it has been supplanted by artificial colouring matters, met with in commerce in the form of thin laminæ of a dark bluish or bluish-green colour. Though formerly employed to some extent in Europe, it does not appear, owing to its extremely expensive nature, to have been extensively used. According to Crookes (Dyeing and Calico Printing, 429), lokao contains from 21·5 to 33 p.c. of ash, 9·3 p.c. of water, and 61·7 p.c. of colouring matter. It is insoluble in water, and the usual solvents, but dissolves in sulphuric acid with a red-brown coloration, and also in alkalis, but the solution thus obtained gradually acquires a brown tint.

According to Helot (Crookes, *l.c.*) and others, lokao requires for its preparation two distinct plants, the *Rhamnus dahurica* (Pall.) (hong. pi. lo. chou) and the *R. tinctoria* (Walldst. & Kit.) (pé. pi. lo. chou), the first of which is said to yield a deep and fast colour, whilst from the latter a weak but brilliant colour can be obtained. According to Rupe (Die Chemie der natürlichen Farbstoffe, 1900), the plant bark is extracted with hot water, the extract allowed to stand overnight, filtered, and then treated with potassium carbonate or milk of lime. Cotton yarn is immersed in this mixture, subsequently withdrawn and spread out in meadows overnight and a portion of the daytime, and the operation repeated ten or twenty times. The colouring matter is removed by rubbing the yarn with the hands in cold water, and the precipitate, which settles to the bottom of the receptacle, is washed by decantation, spread on paper and dried in the shade (*cp.* also Crookes, *l.c.*).

According to Cloez and Guignet (J. 1872, 1068) lokao or Chinese green is, in reality, a lake, and by treatment with ammonium carbonate is converted into the ammonium salt of the colouring matter *lokain* $NH_4 \cdot C_{28}H_{33}O_{17}$. By the action of dilute sulphuric acid lokain is hydrolysed with formation of *lokaetin* $C_{18}H_{16}O_{10}$, glucose (rhamnose ?), and a soluble compound which is precipitated by basic lead acetate.

Kayser (Ber. 1885, 18, 3417; *cf.* Rüdiger, Arch. Pharm. 1914, 252, 165) extracted finely powdered Chinese green with concentrated ammonium carbonate solution, added alcohol to the clear liquid, and thus obtained a precipitate of the crude ammonium salt of the colouring matter which he termed *lokaonic acid*. This was

collected, extracted with ammonium carbonate, the solution precipitated by alcohol, and the operation repeated several times, the product being finally dissolved in water and the liquid evaporated to crystallisation with the addition of a little ammonia. Thus prepared the *diammonium* salt of lokaonic acid $C_{42}H_{44}O_{25}(NH_4)_2$ (Rüdiger) consists of small crystals possessing a bronzy lustre, which at 40°C. commences to lose ammonia, and at 100° gives the mono-ammonium salt $C_{42}H_{47}O_{27}(NH_4)$. The *potassium* salt

$$C_{42}H_{44}O_{27}K_2$$

separates in the form of a blue amorphous powder, when a concentrated aqueous solution of the diammonium salt is treated with alcoholic potash; whereas the *barium* salt $C_{42}H_{44}O_{25}Ba$, obtained by means of barium chloride, has a similar appearance, the lead salt $C_{42}H_{44}O_{25}Pb$ is a dark brown powder.

Lokaonic acid $C_{42}H_{46}O_{25}$, prepared by the decomposition of the diammonium salt with oxalic acid, consists of a bluish-black powder, which, when rubbed, develops a metallic lustre. It is insoluble in the usual solvents, but dissolves in solution of the alkaline hydroxides and ammonia with a pure blue tint. Treatment with sulphuretted hydrogen changes this to a blood-red colour, which passes to green on exposing the liquid to air. Digested with dilute sulphuric acid on the water-bath lokaonic acid is hydrolysed with formation of *lokanic acid* and a sugar rhamnose (Rüdiger).

Lokanic acid $C_{36}H_{36}O_{21}$ is a violet-black crystalline powder insoluble in water, alcohol, ether, and chloroform, but soluble in alkaline solutions with a violet-blue coloration.

The *ammonium* salt $C_{36}H_{35}O_{21}NH_3$, the *barium* salt $C_{36}H_{34}O_{21}Ba$, and the *lead* salt $C_{36}H_{34}O_{21}Pb$, are described by Kayser.

Hot 5% p.c. potassium hydroxide solution converts lokanic acid into *phloroglucinol* and *delokanic acid* $C_{12}H_8O_5$, which consists of a brown powder dissolved by dilute alkalis, whereas nitric acid gives with lokanic acid *nitrophloroglucinol*.

The sugar to which Kayser gave the name of lokaose ($C_6H_{12}O_6$) is rhamnose $C_6H_{12}O_5$.

According to Persoz, cotton can be dyed in a weak alkaline solution of lokao, and it behaves also as a vat dyestuff, for which purpose it may be reduced by faintly acid or alkaline stannous chloride. The colour thus obtained is blue, and can be converted into green by the subsequent employment of a yellow dyestuff.

In order to dye cotton a green with lokao, Persoz recommends a bath prepared by adding the pigment to a solution of soap, whereas for silk Michel obtained excellent results by employing lokao and alum solution in the presence of lime salts. For Chinese and other methods of employing this dyestuff, *see* Crookes (*l.c.*), and Rupe (*l.c.*). A. G. P.

LÖLLINGITE or **LEUCOPYRITE.** Iron diarsenide $FeAs_2$ crystallised in the orthorhombic system, and isomorphous with marcasite (FeS_2) and mispickel (FeAsS). It contains on an average 67 p.c. of arsenic, with about 2 p.c. of sulphur; small amounts of cobalt (up to 6·4 p.c.), nickel, copper, silver, and gold are frequently present With increasing sulphur it passes into mispickel, which it closely resembles in colour—silver-white to steel-grey with brilliant metallic lustre; but there is a wide difference in density—sp.gr. 7·1–7·4 (for mispickel 6·1). An extensive deposit of arsenical iron, consisting mainly of löllingite, occurs in serpentine at Reichenstein in Silesia, and has been worked since 1699. The annual production amounts to 15,000 tons, from which white arsenic, arsenic sulphide, and arsenic are produced, as well as 50–60 kg. of gold. Deposits in mineral veins are also worked for arsenic at Breitenbrunn in Saxony, Schladming in Styria, Lölling in Carinthia, and in the Anniviers valley in Switzerland. L. J. S.

LOMATIOL. This colouring matter, which is closely related to lapachol, has been obtained from the seeds of the *Lomatia ilicifolia* and *Lomatia longifolia*, which occur in Australia (N.S.W. and Victoria).

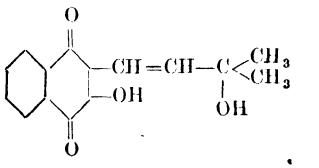
The colouring matter is obtained by extracting the seeds with boiling water acidified with acetic acid, and allowing the filtered extract to cool, when the product crystallises out. It is recrystallised from the same solvent.

Lomatiol $C_{15}H_{14}O_4$, yellow needles, m.p. 127°C., is easily soluble in alcohol or ether, in alkalis and alkali carbonates.

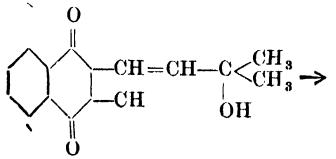
When heated with acetic anhydride and a trace of zinc chloride, it yields a *di-acetyl-derivative* $C_{15}H_{12}O_4(C_2H_3O)_2$, yellow needles, m.p. 82°.

The salts of lomatiol vary in colour from orange to brown; thus the silver salt, $C_{15}H_{13}O_4Ag,H_2O$ is brown, the calcium salt $(C_{15}H_{13}O_4)_2Ca$ is dark red, whilst the barium salt $(C_{15}H_{13}O_4)_2Ba,H_2O$ is orange.

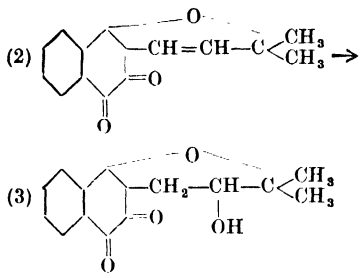
Rennie, who first examined this compound (Chem. Soc. Trans. 1895, 67, 784), was of the opinion that lomatiol was hydroxy-lapachol, but Hooker (Chem. Soc. Trans. 1896, 69, 1381), who continued Rennie's investigations, was able to show that it was *hydroxy*-iso-*lapachol*, and assigned to it the formula—



When lomatiol is dissolved in concentrated sulphuric acid, and left for some time, it passes into *hydroxy-β-lapachol* (3), red needles, m.p. 204°C., identical with that obtained from dihydroxy-hydro-lapachol by the action of the same reagent, whereas, if the reaction is stopped at an earlier stage, by pouring the solution of lomatiol in concentrated sulphuric acid into water almost as soon as solution is completed, an intermediate product, *dehydrolapachone*, is obtained to which Hooker gives the structure (2). The formation of these is shown thus :—



Lomatiol.



By careful oxidation of lomatiol, Rennie obtained acetic acid and phthalic acid.

A. G. P.

LONCHOCARPUS (*Lonchocarpus cyanescens*). The *Lonchocarpus cyanescens* (Benth.), a leguminous plant of the sub-order *Paplionaceæ*, is a woody climber from 10 to 14 feet long. The young leaves contain an indigo-yielding principle, and on this account the plant is employed by the tribes of Sierra Leone and the interior and those of Western Soudan as the source of a blue dye. In the former countries the young leaves are collected along with some more matured ones, roughly pounded and dried in the sun. In this state it is sent into the market as 'Gara,' and sold to the dyers. The natives of Western Soudan employ the young and tender buds, which are collected, pounded when quite raw, made into balls, and dried in the sun. For dyeing purposes the 'Gara' is covered with water, treated with potash and the bark of the *Morinda citrifolia* (Linn.), and left to ferment for some days. The cloth to be dyed is thrown into the vat, left there for some time, and dried in the sun. An examination of 'Gara' by Perkin indicated the presence of approximately 0·62 p.c. of indigotin (J. Soc. Chem. Ind. 1907, 389). Apparently also this plant is utilised in Northern Nigeria as a dyestuff in the form of a similar preparation to that described above, and for the manufacture of a crude indigo. A sample of this leaf product contained approximately 0·65 p.c. of indigotin, whereas in the indigo the presence of 21·47 p.c. of indigotin and 1·33 p.c. of indirubin was detected (Perkin, J. Soc. Chem. Ind. 1909, 353). The botanical examination of the former, and also of plant débris contained in the latter, by V. H. Blackman, indicated that they were derived from the *L. cyanescens*, or some closely related form. Rawson and Knecht (J. Soc. Dyers. 1888, 66) have described similar leaf and crude indigo products, which had been sent to this country by Sir T. Goldie, Governor of the Royal Niger Co., and these respectively contained 0·51 p.c. of indigotin, and 39·12 p.c. of indigotin, together with 4·75 p.c. of indirubin. A more recent examination of the leaf fragments in Rawson and Knecht's samples has shown that these possessed the same structure as those of the *L. cyanescens* (Perkin, *l.c.*), and it thus appears evident that in Western Africa this plant is extensively employed for dyeing and the preparation of indigo. There is reason to presume that the indigo-yielding principle present in the young leaves of the *L. cyanescens* gradually disappears when these reach maturity, as samples of the latter examined in this country were devoid of indigo-producing property. The *L. cyanescens* is probably identical with the 'Taroom akkar' described by Bancroft (Philosophy of Permanent Colours, 1813, i. 189 and 191). A. G. P.

LONDON WHITE. *Flake white* (*v.* PIGMENTS).

LONGIFOLENE. A tricyclic sesquiterpene found by Simonsen in Indian turpentine obtained from the oleo-resin of *Pinus longifolia* (Roxb.). A colourless, somewhat viscous oil with a faint odour; b.p. 254°–256°/706 mm.; 150°–151°/36 mm.; D_{30}^{30}; 0·9284; n_D^{30}; 1·495; M=64·15; $[a]_D$+42·73°. Does not yield a solid nitrose chloride, nitrosate, or nitrosite. Forms a hydrochloride as a crystalline solid, m.p. 59°–60°, $[a]_D$+7·1 (chloroform). The hydrobromide has m.p. 69°–70°, and the hydriodide m.p. 71° (Simonsen, Chem. Soc. Trans. 1920, 578).

LOPHOPHORINE *v.* MEZCALINE.

LORANDITE. Sulpharsenite of thallium $Tl_2S{\cdot}As_2S_3$, crystallised in the monoclinic system, and one of the few minerals containing thallium (Tl 59·4 p.c.) as an essential constituent. The crystals are rich in faces, transparent, and of a deep cochineal-red colour with a metallic-adamantine lustre; streak, dark cherry-red. They are soft (H. 2–2½) and can be bent like gypsum. Sp.gr. 5·53; soluble in nitric acid with separation of sulphur. The mineral occurs with realgar at Allchar in Macedonia (southern Serbia), and has been detected with realgar and orpiment in the Rambler mine near Encampment in Wyoming. L. J. S.

LORANSKITE. A rare-earth mineral containing Ta_2O_5 47, ZrO_2 20, Y_2O_3 10, Ce_2O_3 3, CaO 3·3, loss on ignition 8·15 p.c. It is black with a bright pitchy lustre and a greenish-grey streak. Sp.gr. 4·6, H. 5; optically isotropic. It is found as compact masses with other rare-earth minerals in pegmatite at Impilax in Finland. L. J. S.

LORETIN. Trade name for *m*-iodohydroxyquinoline sulphonic acid ($C_9NH_4I(OH)HSO_3$) used as a germicide in surgical dressings (*v.* SYNTHETIC DRUGS and IODOFORM).

LOSOPHAN *v.* SYNTHETIC DRUGS and IODOFORM.

LOTUS ARABICUS. The *Lotus arabicus* (Linn.) is a leguminous plant, indigenous to Egypt and Northern Africa, and in the young condition is extremely poisonous. The subject has been investigated by Dunstan and Henry (Phil. Trans. 1901, 194, 515).

Lotusin, the active principle, can be isolated by extracting the dried plant with methyl alcohol. The extract is evaporated, the residue treated with water to remove chlorophyll and resin, and from the aqueous solution tannin and other impurities are precipitated by means of lead acetate. The filtrate, on evaporation, leaves a syrupy residue, from which crystals of lotusin slowly separate. In the pure condition lotusin $C_{28}H_{31}O_{16}N$ forms yellow needles, and when hydrolysed by digestion with hydrochloric acid, or by means of an enzyme *lotase*, also found in the plant, yields dextrose, lotoflavin, and hydrocyanic acid, according to the following equation:

$$C_{28}H_{31}O_{16}N+2H_2O=2C_6H_{12}O_6+C_{15}H_{10}O_6+HCN$$

When warmed with alcoholic potash (20 p.c.) lotusin is gradually decomposed with production of ammonia and *lotusinic acid*:

$$C_{28}H_{31}O_{16}N+2H_2O=\underset{\text{Lotusinic acid.}}{C_{28}H_{32}O_{18}}+NH_3$$

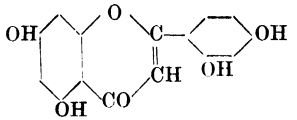
This compound is monobasic, gives yellow crystalline salts, and is hydrolysed by dilute hydrochloric acid with formation of *lotoflavin*, *dextrose* and *heptogluconic acid*:

$$C_{28}H_{32}O_{18}+2H_2O=C_{15}H_{10}O_6+C_6H_{12}O_6+C_7H_{14}O_8$$

Lotoflavin $C_{15}H_{10}O_6$ crystallises in yellow needles, soluble in alkaline solutions with a yellow colour. By fusion with alkali, *phloroglucinol* and *β-resorcylic acid* are produced.

With acetic anhydride lotoflavin gives a *tetraacetyl* compound $C_{15}H_6O_6(C_2H_3O)_4$, colourless needles, m.p. 176°–178°, and when methylated by means of methyl iodide the *trimethyl ether* $C_{15}H_7O_3(OCH_3)_3$ is obtained. This latter compound exists in two forms, viz. the α-form yellow rosettes, m.p. 125°, and the β-form glistening needles, m.p. 175°, which are mutually convertible. Both varieties give by means of acetic anhydride the same *monoacetyl lotoflavin trimethyl ether* $C_{15}H_6O_3(C_2H_3O)(OCH_3)_3$, yellow needles, m.p. 147°.

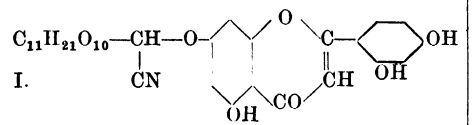
According to Dunstan and Henry, lotoflavin is probably a *tetrahydroxyflavone*, and possesses the formula:



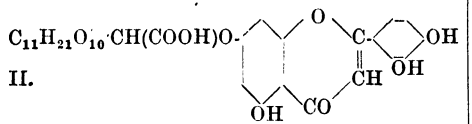
The hydrolysis of the cyanogenetic glucoside lotusin, with formation of maltose, lotoflavin and hydrocyanic acid, may also be expressed as follows:

$$C_{28}H_{31}NO_{16}+H_2O=C_{12}H_{22}O_{11}+C_{15}H_{10}O_6+HCN$$

The following constitutions are respectively assigned to lotusin (1) and lotusinic acid (2):



I.



II.

A. G. P.

LOTUSIN *v.* GLUCOSIDES; LOTUS ARABICUS.

LOXOPTERYGINE *v.* QUEBRACHO ALKALOIDS.

LUARGOL. A compound of salvarsan with silver bromide and antimony sulphate $(C_{12}H_{12}O_2N_2As_2)_2$, AgBr, $SbO(H_2SO_4)_2$. Used as a spirillocide Introduced in France by Danysz in 1913.

LUBAN MATI or **MEYETI** *v.* OLEO-RESINS.

LUBRICANTS. The purpose of lubricants is to reduce friction between surfaces which move one upon another.

As the value of a lubricant depends almost entirely upon the conditions of speed and pressure under which it is used, and the nature of the surfaces with which it is in contact, it is necessary to outline the theory of lubrication before describing the preparation and properties of lubricating oils and greases.

Static friction. If two clean surfaces of the same metal, say lead, are pressed together they will adhere firmly. In cases where metals work together without lubrication this '*seizing*' is only prevented by the existence of a '*contamination film*' on the surface of the metal. Thus the so-called 'solid friction' observed in such cases is really the friction of surfaces lubricated by an extremely thin film (*e.g.* of air).

Thurston, experimenting with sperm and lard oils, found that the friction rapidly increased with pressure up to about 70 lbs., and then increased less rapidly or remained constant.

With plastic substances, *e.g.* axle grease, under ordinary loads the frictional coefficient is least when at rest and gradually increases with increasing speed owing to the resistance of the grease to shear.

With liquids the reduction of static friction depends on the thickness of the film which remains on the bearing surfaces under the loads commonly used. Different liquids vary much in this respect, and the effect seems to depend less on the viscosity of the oil than on its 'oiliness' (*v. infra*).

(*Cf.* W. B. Hardy and J. K. Hardy, Phil. Mag. 1919, 38, 32; Rayleigh, *idem* 1918.)

Low-speed friction. In this case the film of oil is so thin that the irregularities of the surfaces engage one another, causing abrasion. This does not matter if the surfaces are of proper materials, but in some cases it may lead to seizing of considerable areas and so much distortion of the surface that at higher speeds the formation of the 'pressure film' may be prevented and serious over-heating of the bearing may result.

The friction of lubricated bearings at low speeds is really solid friction, *i.e.* it is (1) independent of velocity and area of bearing surface, (2) proportional to pressure, and (3) dependent on the nature of the surfaces, which should be made of dissimilar metals.

Where a complete oil film cannot form, the oiliness of the lubricant is very important, but as the speed increases the oil film thickens and the friction depends more on the viscosity of the oil and less on its oiliness.

Friction, especially at moderate speeds, depends very much on the manner in which the lubricant is applied to the bearing. The best results are obtained with bath lubrication, and the friction increases as the free supply of oil to the journal decreases.

The coefficient of friction at very low speeds —0·0005–0·01 feet per minute—is often greater than the static coefficient, but the change from one to the other is continuous. From about 6·0 feet per minute the coefficient of friction steadily decreases with increase of speed.

High-speed lubrication. At a speed depending on the nature of the lubricant and on the load the surfaces begin to separate, and a comparatively thick 'pressure film' forms between them, being carried into the bearing on the surface of the moving part.

The maintenance of a pressure film between two plane and parallel surfaces depends upon the *inertia* and the *viscosity* of the oil, but in the case of plane surfaces inclined to one another—and this is the case met with in practice—the liquid wedges itself between them and forces them apart.

To this action is due the great carrying power of cylindrical bearings, which in use always wear so that the radius of curvature of the brass is greater than that of the journal. The two surfaces are thus inclined to each other, and the journal, as it rotates, carries the lubricant into the space between the journal and the brass, where it is wedged under a pressure which increases to a maximum at the point where the two approach most nearly.

In the design of bearings great care has to be taken that oil-ways are not cut in this neighbourhood of maximum pressure, or the pressure of oil which should carry the load is released and serious friction results.

The theory of the pressure film has been worked out in great detail, mathematically, by Osborne Reynolds, but only his general results can be given here. At speeds sufficiently high to ensure the formation of the pressure film the following laws appear to be very nearly true :—

(1) The friction is independent of the load ;

(2) The friction varies directly as the area of the contact surfaces ; directly as the speed ; and as the viscosity of the lubricant.

These are the laws of ' fluid friction.'

Above speeds of 100 feet per minute low speed effects are not observed and the friction is nearly proportional to the square root of the speed. This is probably due to lessened viscosity of the lubricant brought about by rise of temperature. From 490 to 790 feet per minute the friction is proportional to the fifth root of the speed, and above 1970 feet per minute it is practically independent of the speed.

With alternating pressures, especially when the alternations are rapid, *e.g.* in the big ends of connecting rods, a given bearing will sustain much greater loads without seizing than it would if the pressure were continually in the same direction, because the oil is trapped between the surfaces at each reversal of the stress.

Friction in ball and **roller bearings** is practically independent of the presence of any lubricant, the chief function of the oil used being to prevent rusting of the polished surfaces.

A mineral oil of moderate specific gravity is therefore a suitable lubricant for such bearings.

Common Lubricants.

Lubricants are divisible into four classes :

(*a*) Fats and liquid waxes ;

(*b*) Mineral oils ;

(*c*) Blended oils ;

(*d*) Greases and solid lubricants.

(*a*) **Fats** and **liquid waxes.** These are comprised under the name of fixed oils (*v.* Oils, Fixed, and fats). The fixed oils principally used as lubricants are : tallow oil, lard oil, neat's foot oil, olive oil, rape oil, and castor oil. For delicate machinery, such as clocks and watches, hazel-nut oil, ben oil, porpoise oil, and dolphin oil (blackfish oil) are used.

Sperm oil and Arctic sperm oil are liquid waxes, and are excellent lubricants because of their oiliness, and because their viscosity is less affected by temperature than is that of other oils.

The fixed oils are seldom used alone as lubricants except for textile machinery, in which there is a risk of the oil being splashed on the fabric. Mineral oils are very liable to make stains which cannot be washed out subsequently without injury to the material.

(*b*) **Mineral oils** are derived from crude petroleum, shale and lignite, and consist of saturated, unsaturated, and closed-chain hydrocarbons of b.p. over 300°. Those of sp.gr. up to 0·900 are usually distillation products, while those of sp.gr. higher than 0·910 are either ' reduced oils ' or oils that have been distilled with steam *in vacuo*. Heavy oils that have been distilled under atmospheric pressure are unsuitable for use as lubricants because of the presence in them of products of ' cracking ' (*v.* Petroleum and Shale oil).

(*c*) **Blended oils.** Mineral oils are miscible with all fatty oils except castor oil, and mixtures containing 20–30 p.c. of good fixed oil, *e.g.* sperm oil, are the best lubricants available for ordinary loads and speeds. Blown oils (partially oxidised oils) are soluble in mineral oils, and are sometimes used to give body to the lighter grades, but such blended oils have a great tendency to gum, and, though cheap, are not to be recommended.

(*d*) **Greases** and **solid lubricants.** The chief solid lubricants are graphite, soapstone (talc, steatite, French chalk), mica, and asbestos. These are seldom used alone, but are usually incorporated in a grease, the advantage being that under ordinary conditions the frictional resistance is merely that due to the resistance to shear of the grease, while under excessive pressure, though the grease may melt and run off the bearing, the solid lubricant remains and prevents damage. Filling materials, such as barytes and chalk, are sometines added to greases, but they are not lubricants, and their addition is detrimental.

Anti-friction metals (*v.* Antimony) may be regarded as solid lubricants, but their chief purpose is to afford a material into which the shaft can bed itself quickly.

Greases may be natural fats, *e.g.* tallow, but are more commonly prepared by adding to mineral or fixed oils alkali metal soaps or, more often, aluminium, lime or lead soaps of fatty acids or resin acids. Such greases frequently contain a considerable quantity of water, but if this is thoroughly incorporated in the grease it has no bad effect upon its properties as a lubricant.

Boiled greases are prepared by dissolving lime soap in mineral oil ; they are very good for medium and heavy machinery.

' Set ' or **axle greases** are made by adding to a mixture of mineral oil (100 gallons) and good slaked lime (500 lbs.), called the *lime part*, a certain proportion of resin oil (2–25 p.c.), called the *set*. The mixture is run at once into the packages in which it is to be sold, and in a short time sets to a solid or semi-solid mass, according to the proportion of resin oil added (*v.* also Archbutt, J. Soc. Chem. Ind. 1901, 1193).

Cup greases are prepared by saponifying fat.

usually horse-fat, with freshly slaked lime in a large kettle heated by a steam jacket and provided with a mechanical stirrer. The usual proportions are 2000 lbs. fat, 200 lbs. lime, and 140 gallons of water. When saponification is complete and the excess of water has evaporated, a light-coloured mineral oil, sp.gr. 0·885-0·910 (about 100 gallons), is sprayed on the contents of the kettle until the right consistency is attained. The oil must previously be heated to 190°F.

Engine greases are made by incorporating cold mineral oil with hot soluble soda or potash soap. It is important that the soap should be neutral (Redwood).

Thickened mineral oils are often made by incorporating aluminium oleate with a light oil. The soap is made as follows: 112 lbs. oleic acid is mixed with 20 gallons hot water and a solution of 16½ lbs. 77 p.c. caustic soda in 10 gallons water, and boiled until the formation of sodium oleate is complete. 70 lbs. alum, dissolved in 20 gallons water, are then added to the solution, when aluminium oleate separates in greasy masses. It is freed from moisture by pressure (Hurst).

Railway waggon grease is usually composed of tallow, palm oil, soap, and water; and is prepared by heating the tallow and palm oil to 180°F., and running in a solution of sodium carbonate at 200°F. The whole is stirred well and run into tubs to set. It is usual to vary the composition of the grease according to the season of the year; the following are typical formulæ:

	Summer	Medium	Winter
Tallow . .	22	20	18
Palm oil . .	12	12	12
Sperm oil . .	1	1·5	2
Soda crystals .	5	5	5
Water . .	60	61·5	63
	100	100	100

The grease in use on the Midland Railway is prepared by dissolving 6 cwt. of palm oil in 12 cwt. of water and adding to the solution 6 cwt. of tallow and 2 cwt. of dark mineral oil.

Another English railway grease:—

	Summer	Winter
Tallow . .	504 parts	420 parts
Palm oil . .	280 ,,	280 ,,
Sperm oil .	22 ,,	35 ,,
Caustic soda .	120 ,,	126 ,,
Water . .	1370 ,,	1524 ,,

Other preparations are made of tallow with colza oil, soda, and water in various proportions; and, for fine machines, of tallow with castor oil, &c., &c.

Palm-oil lubricants. Although palm oil may be used alone, its melting-point is too low for most purposes; to correct this, tallow and other fats are added to the amount of one-third or one-half of the total weight of the lubricant. A small quantity of soda should form a part of these lubricants, as by its use the free fatty acids which are contained in palm-oil are saponified and their action on the metals with which they come in contact is destroyed. Soda also is the medium by which water is introduced into the mixture.

Lead-soap lubricants. Lead salts yield on saponification with fats solid combinations called lead-soaps; they are hard at low temperatures, viscous at ordinary temperatures, but sufficiently fluid on heating by friction The melting-point of lubricants prepared from these substances is high, and they are therefore less suited for high speeds. So-called 'anti-friction lubricants' are composed of lead-soaps A basic lead acetate (sugar of lead) is combined with the requisite quantity of fat in the following manner. The lead solution is thus prepared: Sugar of lead 10 parts, litharge 10 parts, and soft water 110 parts, are boiled with frequent stirring for an hour and a half or two hours. The mass is then allowed to rest, and the clear fluid drawn off and restored to 100 parts by the addition of water. It is then heated to from 145°F. to 165°F. and immediately mixed with ordinary fat (colza oil, lard, and sometimes neats-foot oil), as, *e.g.*, solution of sugar of lead. 100 parts, colza oil 80 parts, lard 80 parts. The preparation should show a uniform grey colour, and, after melting, congeal at from 100°F. to 122°F. (Brannt).

Soap lubricants. Ordinary soft soap, or fat combined with potash, is serviceable for some purposes, but is liable to have a part of the potash lye not fixed, by which damage is done to metals.

The following are from Brannt (Practical Treatise on Animal and Vegetable Fats and Oils):—

Caoutchouc lubricants for belts. Caoutchouc 20 parts, linseed oil 1000 parts. Melt the caoutchouc together with the same quantity of linseed oil, and as soon as the mixture commences to evolve vapours, stir in 20 parts of linseed oil and afterwards add the remainder of the oil by instalments of 100 parts.

Asphaltum waggon grease. Asphaltum 32 parts, black pitch 8 parts, petroleum 8 parts, litharge 8 parts, water 80 parts.

Naphthalene grease. Naphthalene 100 parts, colza oil 50–100 parts. Crude naphthalene is used.

Resin lubricant. Common resin 100 parts, resin oil 50 parts, lard 300 parts.

Graphite waggon grease. Tallow 36 parts, lard 9 parts, palm oil 9 parts, graphite 2 parts.

Graphite lubricants for quick-moving axles. Tallow 100 parts, graphite 100 parts; especially adapted for shafts revolving with great velocity without great load, as circular saws, ventilators, &c.

For this purpose natural graphite which frequently contains a large proportion of mineral matter is not so well suited as that produced by the Acheson process by heating anthracite at about 4000°C. This is reduced by machinery to a powder of such fineness that when suspended in liquids it exhibits the Brownian movement and cannot be separated by filtration, and when mixed with oil forms an emulsion, and does not subside on standing. It comes into commerce made into a paste with water (aquadag); fat (gredag); and oil (oildag). The first serves for the preparation of aqueous emulsions for cooling and lubricating boring and turning machinery, the second is used for cog-wheels and stuffing-boxes, and the third, when well mixed, to the extent of ½ p.c., with acid-free machine or

cylinder oil, can be used for the running parts of machinery.

Lubricant for cutting tools. This is usually a solution of soft soap and soda in water.

Physical Properties and Testing of Lubricants.

A. **Viscosity.** For methods of determining viscosity, *see* Petroleum. The methods there given are equally applicable to all lubricating oils.

The determination of the consistency of fats and greases is of importance, but the methods available are entirely empirical.

In *Kissling's apparatus* a pointed rod of glass or metal, weighted at the top, slides vertically through a hole in a fixed plate. The point of the rod presses on the surface of the grease contained in a small beaker, and the time taken for it to penetrate a definite distance into the fat is a measure of the stiffness of the latter.

Kunkler's apparatus consists of a metal cylinder having an orifice at the lower end through which the grease is squeezed by a weighted piston. The whole apparatus is surrounded by a water-jacket so that the temperature of the test can be regulated.

In any determination of the consistency of fats, great attention must be paid to the preliminary treatment they receive, as they are extremely sensitive to mechanical disturbance and to change of temperature. After the grease has been placed in position it is necessary to leave it for 24 hours before proceeding with the test.

B. **Specific gravity.** This property is used as an indication of the nature and purity of oils, and it forms the basis of the classification of the mineral oils. There is, however, no necessary connection between sp.gr. and lubricating power; *e.g.* it is well known that mineral oils commonly have less lubricating power than fatty oils of the same sp.gr. (*see* also Petroleum and Shale oil).

The sp.gr. of oils may be determined by the sp gr. bottle, by the Sprengel tube, or by the Westphal balance, but with viscous oils these methods are liable to be tedious, and hydrometers are commonly used for the purpose.

It is frequently necessary to know the density of an oil at a temperature at which it cannot conveniently be determined experimentally; it can then be calculated with sufficient accuracy (1 in 4000) from the following formula, if the density of the oil at 60°F. is known: $D=d-kt$, where d=the density of the oil at 60°F.

$$k=\begin{cases}0{\cdot}000368 \text{ for a fixed oil,}\\ 0{\cdot}000367 \text{ for a Scotch mineral oil,}\\ 0{\cdot}000345 \text{ for a Russian mineral oil,}\\ 0{\cdot}000350 \text{ for an American mineral oil,}\end{cases}$$

t=the number of degrees above 60°F., and D=the required density.

C. **Flash-point.** This is the temperature at which the oil gives off sufficient vapour to form an explosive mixture with air in the standard apparatus employed (for details *see* Petroleum). It is usually stated that only oils of flash-point over 350°–400°F. should be used as lubricants, but the loss on evaporation is at least as good a test.

D. **Volatility.** It is obviously desirable that lubricating oils should not evaporate to any considerable extent at the temperatures at which they are used. The fatty oils are satisfactory in this respect, but mineral oils frequently contain as much as 15 p.c. of hydrocarbons volatile at 100°C.

Archbutt's apparatus for the determination of this loss consists of a copper tube placed horizontally across an air-bath by which it can be kept at any desired temperature. The oil to be tested, usually 0·5 gram, is placed in a platinum tray within this tube and subjected to a current of air, previously heated to the temperature of the bath, passing at the rate of 2 litres per minute for exactly 1 hour.

In some cases the oil is tested in a current of steam, but the procedure is quite similar to that when air is used.

As an example of its use, an oil intended for cylinders working at 160 lbs. pressure is tested at 370°F. when it should not lose more than 0·5–1·0 p.c. of its weight. With machine oils and spindle oils, even at much lower temperatures, the permissible loss is much greater.

E. **Setting-point** (the *cold test*). With most oils this is taken as the temperature at which they cease to flow, but in the case of Scotch shale oils the setting-point is the temperature at which solid paraffin is first deposited.

The oil, contained in a corked tube, is cooled in water, or in ice and salt, until it ceases to flow on reversing the tube. It is necessary to maintain the temperature constant for about 20 minutes before observing the condition of the oil (*v.* Salkowsky, J. Soc. Chem. Ind. 1888, 37; and Holde, *ibid.* 1890, 112; 1896, 138, 160), and in Hofmeister's method this is attained by using solutions of various salts, of such concentrations that they are saturated at their freezing-points. The result is that freezing takes place with formation of a eutectic mixture, and the temperature remains constant till the whole is solidified.

Schultze's method, used in Germany, depends on finding the temperature at which the oil flows through a tube of 6 mm. diameter at a rate of 10 mm. per minute under a pressure equal to 50 mm. of water.

F. **Melting-point of fats and greases.** This is frequently of importance, as a grease loses its power of reducing friction under great pressure should it become liquefied. As in the case of determination of consistency, attention must be paid to the preliminary treatment of the grease, and it should, in most cases, be left undisturbed for 24 hours before the test is made.

Many methods are used, most of which depend on observing the temperature at which the grease begins to flow under its own weight (*v.* Bensemann, J. Soc. Chem. Ind. 1885, 535; Cook, Chem. Soc. Proc. 1897, 74).

G. **The colour of oils** is of some importance, and Redwood uses Lovibond's tintometer (*v.* art. Colorimeters) for making a numerical record of this characteristic. Most mineral oils exhibit a fluorescence, usually of a blue or green colour, but this is not of much importance as a test (*v.* Petroleum).

H. **Oiliness.** The most important property of oils and greases which are to be used under conditions of low speed and high pressure

(under 100 feet per minute and over 70 lbs. per square inch), is that called '*oiliness*' (*unctuosity, lubricity*). It depends on (1) interfacial action, which causes oils to spread themselves over metallic surfaces, and (2) on the power of the film to resist disruption.

It seems to be connected with the presence of unsaturated compounds which constitute 20–40 p.c. of most lubricating oils. It would appear that the unsaturated molecules of the lubricant enter into a firm physico-chemical union with the metallic surfaces, forming a friction surface which is a compound of oil and metal. Those oils which have the smallest coefficient of friction are found to be the best lubricants in practice (Deeley, Proc. Phys. Soc. 28, 11, 1919).

Oiliness may be defined as the power of a lubricant to maintain an unbroken film under a heavy load; it cannot be measured in any exact way, and information as to the extent to which any given oil possess this property may best be obtained by properly conducted tests on mechanisms resembling those on which it will be used. Oiliness would seem to depend upon the effect of the lubricant upon the surfaces with which it is in contact rather than on any particular physical property of the lubricant. This property is not necessarily connected with viscosity, being possessed in much greater degree by fixed oils than by mineral oils of the same viscosity. Moreover, different mineral lubricating oils of the same viscosity give very different frictional results. This is the reason that mineral oils must be blended with fatty oils to get the best lubricants for ordinary machinery. The amount of the admixed fatty oil need not be large. Stanton and Hyde found that a small proportion of rape oil had almost as marked effect upon the friction as a much larger percentage.

Oil-testing machines are made of many different designs, and may be used to investigate:

(1) Comparative oiliness or greasiness of lubricants;

(2) Frictional effects due to viscosity;

(3) Effects of temperature on friction;

(4) Effects of different loads;

(5) Effects due to varying speeds;

(6) Effects produced by different metals working in contact;

(7) Effects resulting from different methods of applying the lubricant.

Most of these effects, except (1), are amenable to calculation, or can be more easily determined in some other way; Nos. (6) and (7) are rather concerned with the design of bearings than with lubricants.

In most machines an experimental journal runs in brasses loaded in a manner which can be regulated by the operator, *e.g.* by a spring. The detailed description of such machines hardly falls within the scope of this article, and it is sufficient to say that Thurston's oil-testing machine is largely used (for a detailed description, *see* Archbutt and Deeley, Lubricants and Lubrication, 332; Hurst, Lubricating Oils, Fats, and Greases, 254 *et seq.*). Machines of similar type are those of R. H. Smith, A. Martins, Ingham and Stapfer, Stroudley, Goodman, and Lahmeyer (A. and D. chap. ix.).

These testing machines all suffer from the disadvantage that, at the speeds at which they are usually run, the frictional effects observed are due solely to the viscosity of the oil used, and therefore only give information as to that property; information which could better be obtained with a viscosimeter.

Machines of what is known as the *disc and collar* type are of much more use in investigating the 'oiliness' of lubricants. In them the oil is fed between a rotating disc and a stationary plate, a load is applied to force the two together, and low speeds are used. The best known machines of this class are MacNaught's, Woodbury's, Deprez and Napoli's, and Tower's.

Bailey's pendulum oil-tester is specially designed for use with oils intended for watches, clocks, and other small machines.

Chemical Properties of Lubricants.

The chemical methods used for the examination of lubricants are those used for oils in general (*v.* Petroleum; and Oils, Fixed, and Fats).

The chemical properties of oils which are of special importance with reference to their use as lubricants are: (1) corrosive action on metals, which is closely connected with the acidity of the oil; (2) their tendency to gum or resinify; and (3) their liability to decomposition under the conditions of use.

(1) Most fatty oils, even when freshly prepared, contain some fatty acid, the amount of which increases with time of storage of the unrefined oil. This cannot be avoided, and is one of the chief reasons that such oils have been largely superseded by mineral or blended oils. The addition of resin or resin oil to a lubricant will often increase the acidity owing to the resin acids present.

In the case of mineral oils consisting essentially of hydrocarbons it has been surmised that their lubricating value depends upon the presence of unsaturated molecules (Dunstan and Thole). Apparently the same is true in regard to fatty lubricants. It has been shown that free fatty acids, in limited amount, greatly improve the friction-reducing values of mineral oils and that the improvement in 'oiliness' or lubricating power of a mineral oil, by mixing with it a fixed oil, is mainly due to the small quantity of free fatty acid than to the neutral glyceride (Wells and Southcombe, J. Soc. Chem. Ind. 39 (1920), 53 R; Archbutt, *l.c.*).

Crude petroleum normally contains small amounts of organic acids, but refined mineral oils ought to be practically free from acidity. In many cases where they do not conform to this standard they are found to contain free sulphuric acid, which has been left in the oil owing to imperfect washing after refining with acid.

The extent of the corrosive action of an oil on metals is proportional to its acidity, but is conditioned by the access of air or water to the metal. In absence of air and water even a grease containing 70 p.c. of fatty acids has little or no action on metals (Burstyn, Dingl. poly. J. 217, 314; Redwood, J. Soc. Chem. Ind. 1886, 362; Fox, Analyst, 1883, 8, 116; Donath, J. Soc. Chem. Ind. 1895, 283). The acidity is usually determined by titration, and is expressed

in terms of alkali required to neutralise it, or as oleic acid.

(2) The *tendency to gum* in the case of fatty oils is closely associated with their drying properties. Such oils as linseed oil are impossible as lubricants. The semi-drying oils are not used as lubricants with the single exception of rape oil, the least oxidisable, which is largely used owing to its low cost.

A rough idea of the drying properties of oils can be obtained by coating them on pieces of clean glass and observing the length of time they take to set, or to arrive at the same consistency. Another way is to place drops of the oils at the upper end of an inclined steel plate, and observe the distances they travel before coming to rest. Care must be taken to distinguish those cases in which the thickening of an oil is due to its acidity, the corrosive action resulting in the formation of metallic soaps which dissolve in the oil.

Mineral lubricating oils can absorb small quantities of oxygen at a high temperature (Bach, J. Soc. Chem. Ind. 1889, 990; Ostrejko, J. Soc. Chem. Ind. 1896, 26, 345, and 645), but under ordinary conditions such oxidation is practically *nil*. Any tendency to gum in this case is due to evaporation of the lighter constituents with deposition of asphaltic and tarry matters (Holde, J. Soc. Chem. Ind. 1894, 668; 1895, 894). The amount of bituminous matter present can be determined by extraction with light petroleum (Bender, J. Soc. Chem. Ind. 1891, 354). Closely associated with the gumming tendencies of oils is their liability to cause spontaneous combustion of cotton waste, &c., with which they come in contact. For this reason mineral oils have entirely superseded fixed oils in many cotton mills.

(3) The danger of *decomposition* is present in those bearings which run at a high temperature, *e.g.* hot-neck rolls, but the commonest case where this has to be considered is that of cylinders of steam, gas, and oil engines. For these pure fixed oils should never be used, as in presence of steam they are hydrolysed to glycerol and fatty acids which rapidly corrode the cylinder and piston, forming large lumps of metallic soap. Steam cylinders are best lubricated with 'reduced' mineral oils of high viscosity, density, and flash-point, but very satisfactory results are obtained in practice by using lighter grades of mineral oils containing up to 30 p.c. of fixed oils or 'blown oils.'

For the lubrication of the cylinders of gas and oil engines a pure mineral oil should be used, preferably one which will evaporate without leaving any residue. The high temperature of the walls of such cylinders and the presence of flame cause such carbonisation of the oil and, unless care is used in its selection, this may cause serious trouble.

See OILS, FIXED, AND FATS; PETROLEUM; also Encyclop. Britt. 1910, arts. Lubricants and Lubrication; Archbutt and Deeley, Lubrication and Lubricants; Lewkowitsch, Chemical Technology of Oils, Fats, and Waxes; Redwood, Lubricants, Oils, and Greases; G. H. Hurst, Lubricating Oils, Fats, and Greases; Carpenter and Leask, Soap, Candles, Lubricants, and Glycerin, 258 *et seq.*; Discussion on Lubrication, Phy. Soc. of London, 1919, 32, 15; J. Soc. Chem. Ind. 1919, 38, 7T; Archbutt, J. Soc. Chem. Ind. 1921, 40, 287T; Report Lubrication Inquiry Committee, 1920 (Dept. of Scient. and Indust. Research).

LUCERNE or **ALFALFA.** *Medicago sativa* (Linn.). A leguminous plant bearing loose racemes of bluish-purple flowers. Its root penetrates very deeply into the soil and thus enables it to sustain drought. It is chiefly used as a fodder plant for horses, cattle and sheep, being generally cut and eaten green, though sometimes made into hay. It should be cut at or before the flowering period, or it tends to become woody and less digestible. The following shows the average composition of the plant in the freshly cut condition:—

	Water	Proteids	Amino compounds	Carbohydrates	Fat	Fibre	Ash
Very young	81·1	4·0	1·6	6·2	0·8	4·4	1·9
Before flowering	76·0	3·0	1·5	9·6	0·8	6·8	2·3
In full flower	76·0	2·7	1·2	9·3	0·8	7·8	2·2

While the hay from the plant has the composition:

Cut before flowering	16·0	12·2	4·0	31·1	2·4	27·0	7·3
Cut in flower	16·5	10·7	3·5	29·2	2·6	29·5	8·0

The ash is rich in lime. Lucerne hay has marked diuretic properties. The seed is small and kidney-shaped, and is borne in a spiral pod. For a study of the enzymes present in various parts of the plant, see Jacobson and Holmes (J. Amer. Chem. Soc. 1914, 36, 2170; J. Chem. Soc. Abst. 1913, 1, 151, ; 1914, 1, 1193). For lucerne-seed oil, *see* J. and H. (J. Amer. Chem. Soc. 1916, 38, 480).

The ash of lucerne contains:

K_2O	Na_2O	MgO	CaO	P_2O_5	SO_3	SiO_2	Cl
25·3	1·1	5·8	48·0	8·5	6·1	2·0	1·9

H. I.

LUCIDOL. Trade name for benzoyl peroxide used as an oxidising agent. Is a powerful antiseptic and may be employed as a drier towards linseed oil and other drying oils and for bleaching oils. Explodes on heating.

LUCIFERESCEINE. The fluorescent material present in certain luminous insects, particularly the fireflies (*Photinus pyralis*), (*P. corruscus*) and (*P. scintillans*). An alcoholic solution of the sticky fluid which the insects emit when irritated, has a bright blue fluorescence, yields a pale yellow amorphous substance, *luciferesceine*, giving a red coloration with concentrated sulphuric acid, and a dense cream-coloured precipitate with potassium ferrocyanide (Coblentz, Physikal. Zeitsch. 1909, 10, 955; McDermott, J. Amer. Chem. Soc. 1911, 33, 410).

LUDYL. Phenyl-disulphaminotetra-dioxy-diamino-arseno-benzene.

LUMINAL. Trade name for phenylethyl barbituric acid $C_6H_5{\cdot}C{\cdot}C_2H_5[CO{\cdot}NH]_2CO$ now officially termed 'phenylbarbital' in America (*v.* PYRIMIDINES AND SYNTHETIC DRUGS).

LUMINAL-SODIUM. The sodium salt of phenylethylbarbituric acid. A white hygroscopic powder, readily soluble in water and alcohol, sparingly soluble in ether and chloroform.

On boiling the solution, the salt is decomposed with evolution of carbon dioxide and formation of phenyl ethyl acetyl urea.

LUMINOUS PAINT *v.* BARIUM SULPHIDE.

LUMINOUS PAINTS, MANUFACTURE OF. Four methods for the manufacture of phosphorescent pigments are employed. The first utilises oyster shells as the raw material. The shells are first washed with hot water and then dried and calcined at a bright red heat. After cooling, the mass is crushed and freed from the *débris* of the external layers. The shell powder is then mixed with a small amount of powdered wood charcoal and transferred to a clay crucible, where it is arranged in alternate layers with powdered sulphur. The crucible, covered by a lid securely luted on, is strongly heated for about an hour, and after cooling the mass is extracted and pulverised. A phosphorescent colour prepared in this way from an impure calcium carbonate affords a more intense light than the colours made from pure carbonate of lime. In the second method the sulphates of calcium, barium, or strontium are used as the raw materials. These are intimately mixed with powdered wood charcoal, in the proportions of 1 part of carbon to 5 or 6 parts of sulphate. The mixture is then calcined as in the previous process. In the third method, when working with carbonates such as marble, witherite, or carbonate of strontium it is necessary to add, in addition to the wood charcoal, rather more than one chemical equivalent of sulphur, and then to proceed in the same manner as with the oyster shells. The second and third processes give masses with an orange, green, blue, or red phosphorescence. The sulphur is sometimes replaced by antimony sulphide or other similar sulphur compounds. More luminous but more expensive colours can be produced by starting with calcium oxide, barium carbonate, or carbonate or sulphate of strontium, either alone or mixed with calcium oxide or marble. The necessary carbon is obtained from starch, which is mixed with the above substances. The carbonates of rubidium and lithium, as well as bismuth nitrate, are equally of service. Sometimes sodium sulphate, or even lead acetate, is added, and the formulæ for the mixings vary with each individual factory. It may be taken as a general rule, however, that about 80 parts of the principal constituent require 12 parts of sulphur (or less if other sulphur compounds be present); 4 to 5 parts of starch, 2 to 4 parts of lithium carbonate, and 0·01 to 0·5 part of other metallic compounds. Those constituents, which are used only in very small amounts, are best added in alcoholic solution. The mixtures are heated in a closed crucible for three-quarters to one hour at a temperature of about 1200°C. Phosphorescent pigments are, when used, often mixed with barium sulphate, lakes of natural colouring matters, and often with mineral pigments of the same shade as the phosphorescent body itself. Thus, for example, realgar is used with red shades and orpiment with yellow shades (O. Prager, Chem. Tech. Fabrikant, through Chem. Trade Journ. August 6, 1921, 158).

LUNAR CAUSTIC. Silver nitrate fused and cast into rods or sticks.

LUPANINE $C_{15}H_{24}ON_2$ occurs in the *d*- and *dl*- form in the seeds of *Lupinus albus* (Linn.), and in the *d*- form in those of *L. angustifolius* (Linn.) and *L. perennis* (Linn.). The *dl*- form crystallises in needles, m.p. 99°, and furnishes crystalline salts. The *d*- form has m.p. 44°, and yields salts which are less soluble and crystallise more easily than those of the *dl*- form. The *l*- form, which may be separated from racemic lupanine, has m.p. 43°–44°, and crystallises less easily than the *d*- form. It has been suggested from time to time that lupanine is closely related to sparteine, but according to Beckel (Arch. Pharm. 1911, 249, 329; 1912, 250, 700), this is not the case. All the forms of lupanine are bitter and poisonous (Eichhorn, Nobbes Vers. St. 1867, 272; Siebert, Chem. Soc. Abstr. 1892, 62, 223; Soldaini, Boll. Chem. Farm. 1902, 41, 37; Arch. Pharm. 1902, 240, 260; Davis, Apoth. Zeit. 1896, 11, 94).

LUPEOL. A substance of the formula $C_{30}H_{50}O$ found associated with cinnamic acid in *Palaquium* [*Dichopsis*] *Treubii* (Burck.). Crystallises in fine needles, dextrorotatory $\alpha_D = +27·2°$ in chloroform, m.p. 190°–192° (Jungfleisch and Leroux, Compt. rend. 1907, 144, 1435; *cf.* Van. Romburgh, *ibid.* 1907, 926).

LUPINES. *Lupinus luteus* (Linn.); *L. angustifolius* (Linn.); *L. albus* (Linn.). The above three varieties, whose flowers are yellow, blue, and white respectively, are the chief species grown. They are often grown for green manure on account of their nitrogen-collecting powers, and are employed to enrich poor sandy soils in nitrogenous organic matter. They are only occasionally used as food either for men or animals, because of their bitter taste, but in times of famine they are sometimes used as an addition to rye-bread.

The following gives the mean composition of several varieties of the seed (König):—

	Water	Protein	Fat	N-free extract	Crude fibre	Ash
White lupines	15·9	28·8	6·8	33·6	11·9	3·0
Black ,, .	14·3	38·8	4·6	23·9	14·5	3·9
Blue ,, .	14·3	29·7	5·3	35·6	12·2	2·9
Yellow ,, .	14·7	37·8	4·3	25·5	14·2	3·5

The 'protein' of lupines contains a considerable proportion (10–20 p.c.) of non-albuminoids. A portion of the non-albuminoid nitrogen exists in the form of alkaloid-like substances. Blue and white lupines contain a substance *lupanin* $C_{15}H_{24}N_2O$, which can exist in two forms: a liquid which forms a hydrochloride $C_{15}H_{24}N_2O.HCl,2H_2O$, crystallising in prisms melting at 132°–133°; and a solid, crystallising in monoclinic crystals, which melt at 99°, and which forms a hydrochloride of the same composition as the other, but melting at 105°–106°. *Lupinin* $C_{21}H_{38}N_2(OH)_2$ occurs in yellow lupines; it forms crystals melting at 67°–68°. *Lupinidin*, another liquid alkaloid-like substance, consists of a solution of a crystalline hydrate $C_8H_{15}N+H_2O$ in the oily base $C_8H_{15}N$. The latter is a thick, oily liquid easily soluble in alcohol and ether, smells like hemlock and has an intensely bitter taste. It oxidises rapidly by exposure to air and acts as a weak poison.

These alkaloid-like substances are present both in the seeds and in the leaves and stems, and thus render the plant unpalatable to animals. The poisonous properties of lupines, often fatal

to sheep, were formerly ascribed to these alkaloids, but according to Kuhn and Liebscher, they are due to 'Ichtrogen,' a substance produced by the growth of a fungus which attacks lupines, and which can be extracted from diseased plants by treatment with water.

Lupines are sometimes deprived of their bitter taste before being given to animals. This can be done by an hour's steaming and washing with water; according to Kellner this treatment removes practically the whole of the alkaloids (95 p.c.), while it also removes about 3–4 p.c. of the nitrogenous substances, and 15–20 p.c. of the total dry matter. In spite of this loss the treated lupines are of greater feeding value than those untreated.

Of the proteids in lupines, conglutin is the largest constituent. The 'nitrogen-free extract' of lupines consists largely of gums and pectin bodies, together with starch and cane sugar. The blue lupine contains about 11 p.c. of *lupeose* (β-galactan); by heating with dilute sulphuric acid it splits up into *d*-fructose and galactose.

The following are analyses of the ash of lupines (König):—

	K_2O	Na_2O	CaO	MgO	Fe_2O_3	P_2O_5	SO_3	SiO_2	Cl
Yellow lupines	30·5	0·7	7·1	12·8	0·7	38·6	8·7	0·2	0·8
Blue „	30·9	1·0	10·6	9·7	0·6	37·1	7·8	1·0	0·4
White „	33·7	17·9	7·8	6·2	—	25·7	6·8	0·9	2·1

H. I.

LUPINIDINE (*Sparteine*) *v.* BROOM TOPS.

LUPININE $C_{10}H_{19}ON$, an alkaloid found with sparteine in the seeds of *Lupinus luteus* (Linn.) and *L. niger*. Rhombic crystals, m.p. 67°–68°. Distils without decomposition in hydrogen at 225°–257°; lævorotatory. It is bitter and slightly toxic. Is a tertiary, hydroxy base which furnishes crystalline salts (Baumert, Ber. 1881, 14, 1150; 1882, 15, 1951; Hagen, Annalen, 1885, 230, 370; Siebert, Arch. Pharm. 1891, 229, 531; Soldaini, *ibid.* 1892, 230, 16; Berend, *ibid.* 1897, 235, 262; Willstätter and Fourneau, Ber. 1902, 35, 1910).

LUPULIN *v.* OLEO-RESINS.

LUTECIENNE. A mixture of Fast Red A with Orange II. (β-naphthol orange), the sodium salt of *p*-sulphobenzene-azo-β-naphthol, comes into commerce under this name. Known also as French Red. The name is also given to the alkaline salts of dibromodinitro-fluoresceïn, prepared by simultaneous nitration and bromination of fluoresceïn in alcoholic solution or by nitration of dibromofluoresceïn in acetic acid or aqueous solution.

LUTECIUM. Sym. Lu. At.wt. 174 (175·0 Auer von Welsbach). The identification of this rare earth metal has resulted from the systematic examination of Marignac's ytterbia (Compt. rend. 1878, 87, 578), which is isolated from the least basic portions of the yttria earths derived from xenotime or ytterbite (gadolinite) (*v.* CERITE METALS). Prolonged fractionation in nitric acid of the crude ytterbium nitrate removed yttrium, erbium, and finally thulium, a trace of thorium being separated with hydrogen peroxide. The atomic weight of the elements present in the final fractions rose from 169·9 to 173·8. The most soluble fractions, which give the highest atomic weights, showed 34 characteristic lines in the spark spectrum and the band γ (λ517·5–λ513) in the absorption spectrum which are characteristic of lutecium (Urbain, Compt. rend. 1907, 145, 759; *cf.* Auer von Welsbach, Sitzungsber. Wien. Akad. 1907, 468). The commercially separated yttrium earths from ytterbite have been further fractionated as chromates to remove yttrium, and crystallised as nitrates, and as double nitrates with bismuth and magnesium to precipitate cerium and lanthanum. After removing the excess of bismuth and magnesium, the lutecium fraction was precipitated as oxalate, converted into nitrate, and fractionated to eliminate successively erbium, yttrium and neoytterbium. The most soluble lutecium fraction, converted into chloride with sulphur chloride (*v.* CERIUM), was heated till scandium and thorium chlorides were volatilised. *Lutecium chloride* is more volatile than neoytterbium chloride (Urbain, Bourion, and Maillard, Compt. rend. 1909, 149, 127). The xenotime earths were freed from cerium, gadolinium, terbium and dysprosium by fractionating the ethyl sulphates; the most soluble ytterbium fraction (containing yttrium, erbium, and thulium) was converted into nitrate, and decomposed fractionally in nitric acid when neoytterbium and lutecium were obtained in the most easily decomposable portions (*cf.* Auer von Welsbach, Monatsh. 1913, 34, 1713).

Lutecia (*lutecium oxide*) Lu_2O_3 is less basic than neoytterbia, and can be separated from it by fractional precipitation with caustic alkali; it is less paramagnetic than the latter oxide, the magnetic susceptibilities being in the ratio $Yb_2O_3 : Lu_2O_3 = 53 : 13$ (Urbain, Compt. rend. 1908, 146, 406).

The final uncrystallisable mother liquors obtained in the separation of lutecium from ytterbite (but not from xenotime) probably contain a new element *Celtium* indicated by a characteristic arc spectrum. The magnetic susceptibility of celtium oxide is three or four times less than that of lutecia, and in basic strength the former oxide is intermediate between the latter and scandia (Urbain, Compt. rend. 1911, 152, 141; Urbain and Blumenfeld, *ibid.* 1914, 159, 323) (*v.* CELTIUM). G. T. M.

LUTEOLIN. The sodium salt of *m*-xylidin-sulphonic-azo-diphenylamine. An orange-yellow dye discovered by Witt in 1883. No longer used. Also the colouring matter of weld (*q.v.*).

LUTES are used for packing joints, repairing fractures, and coating vessels externally to render them impervious to vapours, &c. For a lute to be effective it is important that the surfaces to which it is applied should be *clean*, and in the case of lutes that are applied in a molten or semi-fluid state it is preferable previously to heat the parts that are to be joined.

Of lutes for joints which are not to be subjected to high temperature may be mentioned: (1) Soaked bladder stretched and tied over a joint or employed to secure another lute on the joint. (2) India-rubber bands, or caoutchouc melted or dissolved in coal tar, naphtha, or other solvent. (3) A solution of 1 part caoutchouc in 2 parts hot linseed oil mixed with 3 parts pipeclay; this mixture remains soft and is very impervious. (4) Linseed or almond meal made into a paste with water, milk, glue, or lime-water. (5) A mixture of white lead and

oil spread upon strips of linen or bundles of tow. (6) Quicklime reduced to a dry powder by addition of a small quantity of water, and mixed with white of egg diluted with its own volume of water, is spread on linen strips and rapidly applied to the joint. This lute dries quickly and adheres strongly to glass. (7) *Lute d'âne*, a very strong cement prepared by mixing strong glue with recently slaked lime, with subsequent addition of white of egg. (8) Chalk and linseed oil (glazier's putty). (9) Plaster of Paris made into a paste with water, gum water, or glue, and coated when dry, if the joint is to be gas-tight, with melted paraffin or oil. (10) *Fat lute*, consisting of a mixture of clay and boiled linseed oil, is applied and retained by bladder or other substance, to hot joints or to prevent escape of corrosive vapours. (11) A mixture of clay with a solution of gelatin in pyroligneous acid.

For joints which are to resist considerable internal pressure, especially the joints of steam pipes, a mixture is applied consisting of equal parts of red lead and white lead made into a paste with linseed oil and mixed with tow. Other lutes for this purpose are: (1) 12 of Paris white, 5 of red ochre, 2½ of Venetian red, and ½ of plumbago, ground and mixed to a stiff paste with boiled linseed oil (Thompson, Eng. Pat. 27975, 1895). (2) Metallic zinc powder mixed with tow or whiting and made into a paste with linseed oil or wood oil (Boneville & Co. Fr. Pat. 332788). (3) 6 parts graphite, 3 parts slaked lime, 8 parts powdered barytes, and 7 parts of boiled linseed oil.

For making permanent joints and closing joints between metal and glass, &c., various compositions containing beeswax are used. Beeswax when melted with one-eighth its weight of turpentine becomes less brittle and, when the materials are melted in equal proportions, the product becomes pliant when held in the hand, melts easily, and is known as *soft cement*. *Cap cement* or *hard cement*, for closing the covers, &c., of scientific apparatus, is prepared by mixing and melting 1 part beeswax, 5 parts resin, and 1 part dried red ochre or other colouring matter. The mixture is heated to 100°C. until all frothing has ceased, and is cooled with frequent stirring to prevent settlement of the pigment.

Bottle lutes are used to cover the stoppers or corks of bottles. That most commonly employed is sealing wax; paraffin wax is also good. Wholesale dealers usually lute the stoppers of acid bottles with a paste of linseed meal and water.

Plumber's lute is made by adding 2 parts of fine brickdust to 1 part of melted black resin and stirring in thoroughly.

A *waterproof cement*, introduced by Edmund Davy, is prepared by melting together 2 parts by weight of common *pitch* and 1 part of *gutta percha*, with constant stirring. The resultant homogeneous fluid adheres with great tenacity to metal, stone, wood, &c., if applied to warm surfaces of those substances, and, although hard, is not brittle. It softens when heated and passes through various stages of viscosity until above 100°F. it forms a thin fluid. It appears to be absolutely unaffected by contact with water.

Mixtures of boiled linseed oil, clay, asbestos and red or white lead are waterproof, as is a mixture of flax seed meal and water. Portland cement mixed with water containing sodium silicate or glue makes a good lute.

Oil proof cements may be made from (*a*) glue, glycerol and water; (*b*) molasses and flour; (*c*) sodium silicate and whiting, or barium sulphate.

Two good *acid-proof* lutes are: (1) Pipe-clay made into a stiff paste with hot coal-tar; (2) equal parts of pitch and resin melted together and incorporated with 1 part of plaster of Paris; (3) equal weights of rubber (dissolved in CS_2) and boiled linseed oil.

A useful laboratory cement is obtained by mixing litharge to a stiff paste with glycerol. This quickly sets to a hard mass, impervious to water or gases.

This cement is employed for lining the digesters used in the manufacture of sulphite pulp. For its behaviour in setting, *see* Merwin, J. Ind. Eng. Chem. 1917, 9, 390. A suitable mixture for joints of silica ware (vitreosil) consists of 40 parts of asbestos, small, 8 parts asbestos fibre, 10 parts whiting, 2–3 parts tallow, boiled linseed oil 39–40 parts.

A *chlorine resistant cement* consists of powdered glass (1), Portland cement (1), sodium silicate (1).

Acetone collodion, a solution of collodion in acetone, is very useful as a lute in the laboratory. Painted on with a brush, it quickly dries to a hard film, which is proof against water and dilute acids, and is perfectly impervious to gases. It may be used to lute cork or rubber stoppers, to cover rubber tubing, to waterproof labels, &c., but it should not be subjected to a temperature above 150°C.

A lute acquiring a hardness equal to that of marble, and known as *oxychloride of zinc cement* (Sorel's cement), is prepared by dissolving 3 p.c. of borax in a solution of zinc chloride of 1·49–1·65 sp.gr. with addition of sufficient recently ignited zinc oxide to produce the proper consistency.

Magnesia cement is prepared by making a paste of powdered magnesite and 10–20 p.c. conc. hydrochloric acid, forming it into blocks, igniting, and finally grinding to powder. With water this yields a strong cement which quickly sets hard, but is not absolutely fireproof.

Bruyère's hydraulic cement is prepared by heating to bright redness for 3 hours a mixture of 3 parts clay and 1 part slaked lime, and powdering the product.

A cement employed for closing leaks in boilers, &c., is prepared by mixing 6 parts clay and 1 part iron filings to a paste with boiled linseed oil.

Iron cement, for permanently closing joints in iron, consists of a mixture of 100 parts iron filings, 3–20 parts flowers of sulphur, and 3–5 parts ammonium chloride, mixed with water to a paste and applied quickly. The larger proportion of sulphur is required when the iron filings are fine. The mixture soon becomes hot, with evolution of ammonia and sulphuretted hydrogen, and in a short time becomes almost as hard as iron. It is stated that the best iron lute consists of a mixture of 100 parts iron filings with only 1 or 2 parts of sal ammoniac and no sulphur. This lute, however, though stronger, requires a considerable time to set.

For coating earthenware, a paste is applied

consisting of a mixture of equal parts of zinc white and fine sand, made into a paste with a concentrated solution of zinc chloride. *Willis' lute* for the same purpose consists of a paste made with slaked lime and a solution of 2 oz. borax in 1 pint water. It is applied with a brush, and when dry is covered with a plastic mixture of slaked lime and linseed oil and is ready for use after a few days.

Among lutes for resisting high temperatures may be mentioned Stourbridge clay made into a paste with water, which withstands a higher temperature than any other lute in general use, and *Windsor loam*, a natural mixture of clay and sand. Both are used for coating vessels and for packing hot joints of metal vessels. With the addition of about one-tenth part of borax these clays are useful for glazing earthenware vessels. Leaks and fractures in furnace linings, &c., may be stopped with *ganister*, a highly silicious fireclay.

Gas retorts and similar vessels closed temporarily to withstand high temperatures are usually merely luted with mortar.

For luting crucibles, a paste of fireclay and powdered firebrick is useful, preferably with addition of a small proportion of borax to render the lute coherent.

A most valuable mixture for repairing broken furnaces, &c., consists of a paste of firebrick and liquid sodium silicate. Even considerable openings, if roughly filled with broken firebricks, may be sealed with this lute.

A fireproof cement for repairing retorts, &c., is made by taking 200 cwt. china clay, 100 cwt. barytes, 40 gall. sodium silicate (100°Tw.), 24 gall. water, and 28 lbs. borax, mixing well and adding magnesite to the extent of 25 p.c. of the mixture (Williams, Eng. Pat. 18064, 1903).

A lining for furnaces and crucibles may be made from 4 parts granular corundum, ground to a fine powder, mixed with 1 part powdered graphite and made into a paste with 10 p.c. of sodium silicate (Crowley and Payne, Eng. Pat. 8627, 1906; *v.* also Kilburn Scott, J. Soc. Chem. Ind. 1905, 501).

For other recipes *see* Sadtler, Chem. News, 1916, 113, 257; Analyst, 1916, 262.

LUTIDINES, LUTIDINIC ACID *v.* BONE-OIL.

LYCACONITINE *v.* ACONITINE.

LYCETOL. *See* Lysetol.

LYCIN (Acidol). Trade name for betaine hydrochloride.

LYCOPERDON GEMMATUM. According to Kotake and Naito (Zeitsch. physiol. Chem. 1914, 90, 254) the fungus *Lycoperdon gemmatum* on extraction with alcohol gives a crystalline brown dyestuff. This is a glucoside, and when hydrolysed gives dextrose and *gemmatein* $C_{17}H_{12}O_7$, brown needles. Fusion with alkali gives *p-hydroxyphenylacetic acid*, and when oxidised with hydrogen peroxide *homogentisic anhydride* is produced.

LYCOPODINE, $C_{32}H_{52}O_3N_2$, m.p. 114°–115°, is a crystalline alkaloid of bitter taste, occurring in *Lycopodium complanatum* (Boedeker, Annalen, 1881, 208, 363). In *Lycopodium Saururus* of tropical S. America there occurs *pillijanine* $C_{15}H_{24}ON_2$ crystals m.p. 64°–65°, with an odour of conine (Arata and Canzoneri, Gazz. 1892, 22, 1, 146). These two alkaloids, with those in ergot, are the only known alkaloids in Cryptogams. G. B

LYCORINE $C_{32}H_{32}O_8N_2$ occurs in the bulbs of *Lycoris radiata* (=*Nerine japonica*) and forms large crystals, m.p. 250° (Morishima, Arch. exp. Path. Pharm. 1897, 40, 221). It has an emetic action. The bulbs contain a second crystalline alkaloid *sekisanine* $C_{34}H_{36}O_9N_2$. G. B.

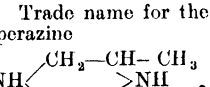
LYDDITE *v.* EXPLOSIVES.

LYDIAN STONE or **LYDITE** (*Lapis Lydius*, of Pliny, from Lydia, in Asia Minor). A black, jaspideous or cherty variety of quartz, which from its hardness and the closeness of its grain has been used as a touchstone for testing the quality of gold, whence its name *basanite*. The metal to be tested is rubbed on the polished surface of the stone, and the streak thus produced is compared with the streaks made by a series of alloys of known composition; the observer judging of the purity of the metal by the colour of the mark and by its behaviour when treated with a drop of acid. Lydite is also used as a hone-stone. Most Lydian stone has a schistose structure, and may be described as a hornstone-slate, or *Kieselschiefer*. The Lydian stone of Devon and east Cornwall is a fine-grained, indurated, carbonaceous shale, belonging to the Culm-measures. In Fifeshire it is represented by blocks of baked shale in the vents of ancient volcanoes. L. J. S.

LYDIN. A synonym for mauve or aniline purple.

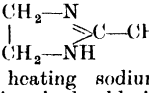
LYGOSIN. Trade name for di-hydroxydibenzalacetone.

LYSETOL. Trade name for the tartrate of of dimethylpiperazine



used as a uric acid solvent.

LYSIDIN. Ethylene-ethenyl-diamine



Prepared by heating sodium acetate and ethylene diamine hydrochloride. Used as a uric acid solvent.

LYSINE $NH_2[CH_2]_4CH(NH_2)CO_2H$, *αε-diaminohexoic acid*, was discovered by Dreschel (J. pr. Chem. 1889, [ii.] 39, 425; *see*, also, van Slyke, J. Biol. Chem. 1913–14, 16, 531; and Funk and McLeod, Biochem. J. 1914, 8, 109) among the products of hydrolysis of casein by hydrochloric acid and stannous chloride; it is produced by the hydrolysis of other proteins, conglutin, egg albumen, fibrin (Siegfried, Ber. 1891, 24, 418), and gelatin (Ernst Fischer, Arch. Anat. u. Physiol. 1891, 265; Osborne and Leavensworth, J. Biol. Chem. 1913, 14, 481; *cf.* van Slyke and Birchard, *ibid.* 1914, 16, 539); it occurs in antipeptone prepared from fibrin (Kutscher, Zeitsch. physiol. Chem. 1898, 25, 195); together with arginine it forms the chief product of hydrolysis of the protamines sturine, β-cyprinine, and crenilabrine (Kossel, Zeitsch. physiol. Chem. 1899, 26, 588; 1904, 40, 565; 1910, 69, 138; it also occurs among the hydrolytic products of the proteins of the seeds of various conifers, and the seedlings of *Lupinus luteus* (Linn.) (Schulze and Winterstein, Zeitsch. physiol. Chem. 1899, 28, 459, 465; 1901, 33

547), and has been found in *Shiokara*, Suzuki Yoneyama (J. Col. Agric. Tokyo, 1912, 5, 33), and in fungi (Reed, J. Biol. Chem. 1914, 19, 257); Omeliansky and Sieber (Zeitsch. physiol. Chem. 1913, 88, 445).

Dreschel (Chem. Zentr. 1891, ii. 712) showed that lysine is a diaminocaproic acid, and Ellinger (Ber. 1899, 32, 3542) proved that the two amino groups are in the $\alpha\epsilon$- positions, because on decomposition by putrefaction in an atmosphere of hydrogen, lysine is partially converted into cadaverine (pentamethylenediamine)

$$NH_2[CH_2]_4CH(NH_2)CO_2H = CO_2 + NH_2[CH_2]_5NH_2$$

cf. Ackermann (Zeitsch. physiol. Chem. 1910, 69, 273). The synthesis of *i*-lysine has been effected by Fischer and Weigert (Sitzungsber. K. Akad. Wiss. Berlin, 1902, 270) from ethyl γ-cyanopropylmalonate; when this compound is treated with ethyl nitrite it gives ethyl α-oximino-δ-cyanovalerate $CN[CH_2]_3C(NOH)CO_2Et$, which on reduction with sodium in alcoholic solution, yields $\alpha\epsilon$-diaminohexoic acid or *i*-lysine

$$NH_2[CH_2]_3CH(NH_2)CO_2H,$$

this is isolated by successive transformation into the phosphotungstate and picrate; the *picrate* forms thick needles that darken at 230°; the *hydrochloride* is crystalline and melts at 183°–186° (corr.); the *phenylcarbimide* forms colourless needles, m.p. 182°–185° (corr.); these derivatives differ from the corresponding derivatives of the naturally occurring *d*-lysine in being optically inactive and having slightly different melting-points. A further synthesis of *i*-lysine from ethyl cyanopropylphthaliminomalonate is described by Sörensen (Chem. Zentr. 1903, ii. 33); when this compound is reduced with sodium in alcoholic solution it yields the corresponding amino compound

$$C_6H_4:(CO)_2:NC(CO_2Et)_2[CH_2]_4NH_2,$$

which is transformed by the action of concentrated hydrochloric acid into *i*-$\alpha\epsilon$-diaminohexoic acid (*i*-lysine).

i-Lysine can also be obtained by a synthetic process from piperidine (Julius von Braun, Ber. 1909, 42, 839). The opening of the piperidine ring by phosphorus pentachloride affords among other products, benzoyl-ϵ-leucinenitrile $COPh{\cdot}NH[CH_2]_5CN$, which contains the skeleton of lysine, and yields on hydrolysis ϵ-benzoylaminohexoic acid $COPh{\cdot}NH[CH_2]_5CO_2H$; this on bromination forms the α-bromo derivative $COPh{\cdot}NH[CH_2]_4CHBr{\cdot}CO_2H$, which reacts with ammonia to give α-amino-ϵ-benzoylaminohexoic acid $COPh{\cdot}NH[CH_2]_4CH(NH_2)CO_2H$, from which *i*-lysine is obtained by hydrolysis.

Derivatives. *Salts.*—*d*-Lysine is a syrup (Winterstein, Zeitsch. physiol. Chem. 1905, 45, 77), it has $[\alpha]_D + 17{\cdot}5°$ in hydrochloric acid solution (Lawroff, *ibid.* 1899, 28, 388), and forms well-defined crystalline salts and double salts; the *monohydrochloride* is strongly acid, the *dihydrochloride* is a neutral substance (Dreschel, Arch. Physiol. 1891, 248); the *platinichloride* $C_6H_{14}O_2N_2{\cdot}H_2PtCl_6{\cdot}EtOH$ crystallises with 1 molecule of alcohol which it loses at 120°; *i-lysine platinichloride* has the composition $C_6H_{14}O_2N_2{\cdot}H_2PtCl_6$, it crystallises in prisms of a paler yellow colour than those of active lysine platinochloride. Siegfried (Zeitsch. physiol. Chem. 1912, 76, 234); the *aurichloride*

$$C_{12}H_{28}O_4N_4{\cdot}HCl{\cdot}3HAuCl_4,2H_2O$$

sinters at 120° and melts at 152°–155°; *i-lysine aurichloride* $C_{12}H_{28}O_4N_4{\cdot}4HAuCl_4,H_2O$ decomposes at 173°–176° (Siegfried, Zeitsch. physiol. Chem. 1905, 43, 363; Ackermann, *ibid.* 1908, 56, 305); the *picrate* $C_6H_{14}O_2N_2{\cdot}C_6H_3N_3O_7$ is sparingly soluble in alcohol (Kossel, Zeitsch. physiol. Chem. 1899, 26, 586), and advantage is taken of this fact in the quantitative separation of lysine from arginine and histidine (Kossel and Kutscher, *ibid.* 1900, 31, 165; Kossel and Weiss, *ibid.* 1910, 68, 165; Schreiner and Shorey, J. Biol. Chem. 1910, 8, 381). Lysine phosphotungstate crystallises in anhydrous needles, Drummond (Biochem. J. 1918, 12, 5); *see* Wechsler, Zeitsch. physiol. Chem. 1911, 73, 138, for the solubility of the phosphotungstate precipitate in a mixture of acetone and water.

Lysine readily yields an additive product with phenyl *iso*cyanate; this does not crystallise well, but on treatment with concentrated hydrochloric acid is converted into the *hydantoin*

$$NHPh{\cdot}CO{\cdot}NH[CH_2]_4CH\begin{cases}NH{\cdot}CO\\ \\ CO{\cdot}NPh\end{cases},$$ which is

crystalline and melts at 183°–184° (Herzog, Zeitsch. physiol. Chem. 1902, 34, 525); the corresponding derivative of *i*-lysine has m.p. 156° (von Braun, Ber. 1909, 42, 839).

Lysuric acid, the dibenzoyl derivative of lysine, has m.p. 144°–145°; the *acid barium salt*

$$2(C_6H_{12}Bz_2N_2O_2),(C_6H_{11}Bz_2N_2O_2)_2Ba,2H_2O$$

crystallises in beautiful needles, m.p. 144°–148°, at which temperature it becomes anhydrous; the *normal barium salt* $(C_{20}H_{21}N_2O_4)_2Ba,1\frac{1}{2}H_2O$ is a white crystalline powder, m.p. 168°; the *acid sodium salt* is white and crystalline, m.p. 108°–109°, and contains H_2O; the *acid strontium salt* contains $2H_2O$, crystallises in plates, and has m.p. 137°–138°; the *normal strontium salt* contains H_2O and is crystalline; the silver salt $C_{20}H_{21}N_2O_4Ag,1\frac{1}{2}H_2O$ is white and amorphous (Dreschel, Ber. 1895, 28, 3189: Willdenow, Zeitsch. physiol. Chem. 1898, 25, 523).

Methyl lysine hydrochloride prepared by the action of methyl alcohol and hydrogen chloride on *i*-lysine hydrochloride, has m.p. 218° (decomp.), *cf.* Engeland and Kutscher (Zeitsch. Biol. 1912, 59, 415); *lysine anhydride*, obtained by heating the methyl ester at 100°, forms the *picrate* $C_{12}H_{24}O_2N_4{\cdot}2C_6H_3O_7N_3$ yellow prisms or plates decomposing at 230° (corr.), and the *hydrochloride*, microscopic colourless needles decomposing at 270° (corr.) (Fischer and Suzuki, Sitzungsber. K. Akad. Wiss. Berlin, 1904, 1333). *d-Lysyl-lysine dipicrate*

$$C_{12}H_{26}O_3N_4,(C_6H_3O_7N_3)_2,$$

m.p. 238°–242° was isolated from the products of hydrolysis of pepsin extract (Hugounenq and Morel, Compt. rend. 1909, 148, 236); *i-lysyl-lysine* $C_{12}H_{26}O_3N_4$ forms a yellow crystalline *picrate*, m.p. 185° (corr.), and a *hydrochloride* crystallising in short twin prisms, m.p. 205° (corr.) (Fischer and Suzuki, Ber. 1905, 38, 4173).

Lysine yields carbamide when decomposed by barium hydroxide (Dreschel, Ber. 1890, 23,

3096); it is oxidised by barium permanganate, yielding glutaric acid as the chief product (Zickgraf, Ber. 1902, 35, 3401); and when the sulphate or hydrochloride is treated with barium or silver nitrite, $\alpha\epsilon$-dihydroxyhexoic acid, an aminohydroxyhexoic acid, m.p. 200°–201°, and a small amount of an alkaline yellow amorphous substance $C_8H_{13}O_3N$, m.p. 176°–178°, are produced (Szydlowski, Monatsh. 1906, 27, 821). Heated with nitrous acid above a temperature of 30° all the nitrogen is set free from lysine in ten minutes (Sure and Hart, J. Biol. Chem. 1917, 31, 527).

Experiments made by Buckner, Nollau and Kastle (Amer. J. Physiol. 1915, 39, 162) support the view that lysine is largely responsible for the stimulation of growth; Osborne and Mendel (J. Biol. Chem. 1916, 25, 1) point out the necessity of the presence of a certain proportion of lysine in order to form a nitrogen food suitable for producing satisfactory growth. *Cf.* Lewis and Root (J. Biol. Chem. 1920, 43, 79). *Cf.*, however, McCallum, Simmonds and Smith (J. Biol. Chem. 1917, 28, 483; Abderhalden (Zeitsch. physiol. Chem. 1915, 96, 1–147).

Lysine possesses germicidal properties (Wagner, Zentralblatt F. Baktr. u. Parasit. II, Abt. 42, 613). M. A. W.

LYSINE. This term is also used as a trade name for a preparation consisting of an acid solution of formalin containing inorganic salts and essences. Used as an antiseptic and bactericide.

LYSOCHLOR. Trade name for chloro-*m*-cresol.

LYSOL. Trade name for a preparation of crude carbolic acid. Used as a disinfectant.

M

M ACID. 1-amino-5-naphthol-7-sulphonic acid.

MACARITE. An explosive consisting of a mixture of trinitrotoluene (30 parts) and lead nitrate (70 parts).

MACE. *Description.*—Mace is the dried arillus or seed coat of the nutmeg, the latter being the fruit of *Myristica fragrans* (Houtt.) (or *Myristica argentea* (Warb.), *see* below).

The tree is a native of the Malay Archipelago, and is cultivated in both the East and West Indies.

The fruit (nutmeg) is surrounded by four coats: a thick pericarp on the outside, then the crimson arillus, then a thick tegument, and finally a thin membrane closely adherent to the kernel.

Many other species of *Myristica* are known in addition to *M. fragrans* (Banda or true mace), but only one yields aromatic seeds, viz. *M. argentea*, which furnishes the Papuan or Macassar mace.

The chief varieties of mace which appear on the British market are Penang, Singapore, Java, and West Indian, the first being the most highly esteemed. All these are derived from *Myristica fragrans*, but a small quantity of Macassar mace is also imported, and this variety has hitherto been sold as "mace" without any question being raised as to its genuineness. As it appears in commerce, mace has a yellow-brown colour, the lighter the better. The arillus, when unbroken, is about 1½ inch long and ¾ inch wide at the base. It is usually flattened, the tapering segments or blades being from ⅛ to ¼ inch wide. Macassar mace is of a dull brown colour and has much wider blades. Both varieties have a similar aromatic flavour, but that of Macassar mace is distinctly acrid (*v.* Holmes, Pharm. J. 1908, 652). The sole use of mace is as a flavouring agent and condiment.

Composition.—The chief constituents of mace are a volatile oil to which the flavour is mainly due, a fixed oil and a carbohydrate, amylodextrin, the granules of which are easily visible under the microscope and turn red on treatment with iodine. The following table shows the composition of Banda and Macassar mace, and also of false or Bombay mace (*see* below). (From Winton, Ogden and Mitchell, U.S. Dept. of Agric., Bul. 13 and 65, and other sources.)

		Ether extract					
			Volatile oil	Fixed oil	Amylo-dextrin	Crude fibre	Nitrogen
Mace (*Myristica fragrans*)	Water 5·67 to 12·04	Ash 1·62 to 4·10	4·04 to 10·80	21·20 to 29·08	22·60 to 31·60	2·90 to 8·90	0·73 to 1·12
Macassar mace	4·18	2·01	5·89	53·50	10·40	4·57	1·11
Bombay mace	0·32 to 7·04	1·36 to 1·98	0·00 to 0·67	56·70 to 59·80	16·20	3·21 to 8·17	0·81 to 0·79

More recent analyses by Parry ('Food and Drugs,' p. 236) yielded the following figures:

	True mace	Macassar mace	Bombay mace
Total ash	1·87–2·36	1·7–2·08	1·9–2·1
Do. soluble in water	1·08–1·27	1·1–1·25	1·0–1·2
Do. insoluble in HCl	0·07–0·20	0·6–0·75	0·07–0·08
Fixed ether extract	25·0–32·5	49·5–52·0	58·0–63·0
Alcoholic extract	22·0–25·0	28·0	45·8
Volatile oil	4·0–8·0	4·0–7·0	4·0–8·0
Fibre	5·0–9·0	4·0–8·0	3·0–8·0
Nitrogen	0·7–1·2	1·0–1·2	0·8–0·9
Ether extract after extracting with petroleum ether	2·0–3·5	similar to true mace	up to 33·0

Adulteration.—The only sophistication to which whole mace is liable is the addition of Bombay mace which is derived from *Myristica malabarica* (Lam.). The arillus of this species is about 2½ inches long by ⅝ inch wide, and the numerous blades are narrow and their vermiform ends are coiled in a tangled mass at the apex. It is of a deep red-brown colour, and almost devoid of aroma. As it is quite useless as a flavouring agent, and its price is about one-fourth that of genuine mace, its presence in the latter can only serve the purposes of fraud.

Bombay mace is also the chief adulterant of ground mace, but potato, arrowroot, the cereal starches, turmeric, and ground olive stones may possibly be found.

Detection of adulteration.—The presence of any of the above adulterants is best detected by means of the microscope. Banda and Macassar mace are practically indistinguishable from one another, but the presence of Bombay mace is at once revealed by the appearance of the dark orange-coloured oil cells, the contents of which when treated with alkali assume a blood-red tint. The oil cells in Banda and Papua mace are fewer in number, of a light yellow colour, and alter only slightly in appearance when treated with alkali. A further characteristic, which however can only be seen in transverse sections, is that the epidermal cells in Bombay mace are radially elongated whilst in the case of the other two varieties the elongation is tangential.

Chemical tests for the presence of Bombay mace are also available (Schneider, J. Pharmacol. 4, 57; Hefelmann, Pharm. Zeit. 1891, 128; Busse, Zeitsch. Nahr. u. Genussm. 1904, 590).

For the estimation of Bombay mace in the presence of Banda mace, provided that Macassar mace be absent, the determination of the fixed ether extract will afford a fair basis for calculation. Soltsien (Zeitsch. öffentl. Chem. 3, 253) recommends a preliminary extraction with light petroleum, the extract thus obtained being ten times greater from Bombay than from Banda mace, and Parry (see above table) confirms this.

The information thus obtained should be supplemented by comparison, under the microscope, of the sample with a mixture of Banda and Bombay maces in the proportions indicated. If there is a great discrepancy in the number of the characteristic orange-coloured oil cells the presence of Macassar mace may be suspected. The following test for this variety may also be applied (Griebel, Zeitsch. Nahr. Genussm. 1909, 202):—

Shake up 0·1 gram of the sample with 10 c.c. of light petroleum for 1 minute, filter and mix 2 c.c. of the filtrate with 2 c.c. of glacial acetic acid, and add concentrated sulphuric acid so as to form a layer under the acetic acid solution. In the presence of not less than about 20 p.c. of Macassar mace a red ring forms at the junction of the two layers, within two minutes. Banda mace similarly treated yields only a yellow ring within the same period, whilst Bombay mace produces no colour at all. Comparison experiments with samples of known authenticity should always be made.

Further confirmation of the presence of Bombay mace may be obtained by estimating the essential oil, preferably by Cripps' process (Analyst, 1909, 519), which consists in determining the moisture by heating the spice with calcium carbide, calculating the water from the acetylene involved, and deducting the figure thus obtained from the total loss on heating in a current of air to 135°C., the difference being taken as representing the essential oil. The figures he obtained were as follows:—

	Essential oil
Whole mace	6·1 -10·80 p.c.
Ground mace, unknown origin .	2·86- 7·15 „
Bombay mace	0- 0·67 „

The characters of the fixed oil may also be of use. These are shown in the following table (Spaeth, *ibid.* 1895, 200):—

RESULTS OF EXAMINATION OF THE FIXED OIL OF MACE.

	Melting point	Saponification number	Iodine number	Refraction index	Meissl number
True mace	25·0° to 26·0°	169·9-173·0	75·6-80·8	1·48-1·487	4·1-4·2
Macassar mace					—
Bombay mace	31·0° to 31·5°	189·4-191·4	50·4-53·5	1·463	1·0-1·1

Standards.—The standard fixed by the United States Department of Agriculture is as follows: Mace should contain not less than 20 nor more than 30 p.c. of fixed ether extract; not more than 3 p.c. of total ash; not more than 0·5 p.c. of ash insoluble in hydrochloric acid; and not more than 10 p.c. of fibre.

McGill (Bulletin No. 439, Canadian Inland Revenue Department) suggests the following: Ash not to exceed 3 p.c.; ash insoluble in hydrochloric acid not to exceed 0·5 p.c.; crude fibre not to exceed 7 p.c.; ether extract after previous extraction with petroleum ether not to exceed 5 p.c.; ether extract *plus* petroleum ether extract not to exceed 33 p.c. Both the U.S. Dept. of Agriculture and the Canadian Inland Revenue Dept. define true mace as being the Arillus of *Myristica Fragrans*.

Soltsien (Zeitsch. öffentl. Chem. 3, 253) suggests that the ether extract after removal of the fat by light petroleum should never exceed 5·5 p.c. C. H. C.

MACE OIL *v.* OILS, ESSENTIAL.

MACKENSITE *v.* THURINGITE.

MACKINTOSHITE. Silicate of thorium, uranium, &c., perhaps $UO_2{\cdot}3ThO_2{\cdot}3SiO_2{,}3H_2O$, crystallised in the tetragonal system in forms resembling zircon and thorite. It contains ThO_2 45, UO_2 22, PbO 4 p.c., together with small amounts of lanthanum, yttrium, iron, alkalis, &c. The water is probably due to alteration, and the original mineral probably had the composition $(Th,U)_4Si_3O_{14}$; by further alteration it gives rise to thorogummite. The prismatic crystals and nodular masses are black and opaque with a dull pitchy lustre. Sp.gr. 5·43; H. 5½. The mineral is gelatinised by sulphuric acid, and is readily soluble in a mixture of sulphuric and nitric acids. It is found associated with gadolinite and other rare-earth minerals in pegmatite at Barringer Hill near Bluffton in Llano Co., Texas. L. J. S.

MACLURIN. This substance occurs, together with morin, in the wood of the tropical tree *Chlorophora tinctoria* (Gaudich), which comes into commerce as 'Old Fustic.'

The colouring matters of old fustic were first investigated by Chevreul ('Leçons de chimie appliquée à la teinture,' ii. 150), who described two substances, one sparingly soluble in water, called *morin*, and a second somewhat more readily soluble. Wagner (Jour. f. pr. Chemie, (1), 51, 81) termed the latter *moritannic acid*, and considered that it had the same percentage composition as morin. Hlasiwetz and Pfaundler (Annalen, 127, 351), on the other hand, found that the so-called moritannic acid was not an acid, and as moreover its composition and properties were quite distinct from those of morin, they gave it the name 'Maclurin.'

When morin is precipitated from a hot aqueous extract of old fustic by means of lead

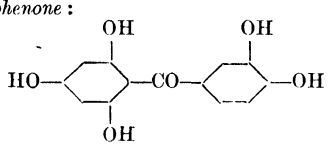
acetate the solution contains maclurin. After removal of lead in the usual manner, the liquid is partially evaporated and extracted with ethyl acetate, which dissolves the colouring matter. The crude product is crystallised from hot water or dilute acetic acid (Perkin and Cope, Chem. Soc. Trans. 1895, 67, 943). A crude maclurin is also obtained during the preparation of fustic extract, partly in the form of its calcium salt, and this product may be purified with dilute hydrochloric acid and crystallised from water. In order to decolorise the crystals, acetic acid is added to a hot aqueous solution and a little lead acetate in such quantity that no precipitate is formed, and the solution is then treated with sulphuretted hydrogen. The clear liquid thus obtained is much less strongly coloured, and after repeating the operation two or three times, the maclurin, which crystallises out on standing, possesses only a pale yellow tint.

Maclurin, to which the composition $C_{13}H_{10}O_6$ was assigned by Hlasiwetz and Pfaundler (Jahresber. 1864, 558), consists, when pure, of almost colourless needles, which contain one molecule of water of crystallisation; the anhydrous compound melts at 200°C. (Wagner, Jahresber. 1850, 529). The colouring matter is somewhat soluble in boiling water, is soluble in aqueous alkalis, forming pale yellow solutions, whilst with ferric chloride its aqueous solutions give a greenish-black coloration, and with aqueous lead acetate a yellow precipitate, which is soluble in acetic acid. When boiled with potassium hydroxide maclurin yields phloroglucinol and protocatechuic acid.

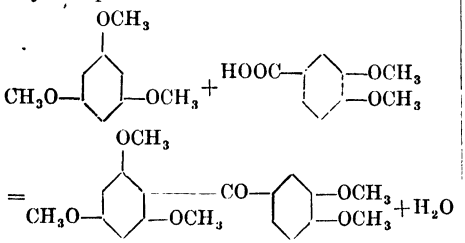
Pentabenzoyl-maclurin $C_{13}H_5O_6(C_7H_5O)_5$, which melts at 155°–156°C., was prepared by König and v. Kostanecki (Ber. 1894, 27, 1996), and *tribrom-maclurin* $C_{13}H_7Br_3O_6 \cdot H_2O$, colourless needles, by Benedikt.

Maclurin-pentamethyl-ether $C_{13}H_5O(OCH_3)_5$, forms colourless leaflets which melt at 157°C.

König and v. Kostanecki first assigned to maclurin the constitution of a *penta-hydroxy-benzophenone*:

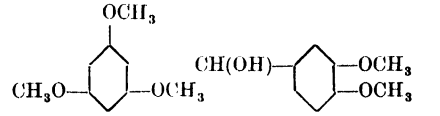


This is supported by the synthesis by W. H. Perkin and Robinson (Chem. Soc. Proc. 1906, 22, 305), and somewhat later by v. Kostanecki and Tambor (Ber. 1906, 39, 4022), of maclurin pentamethyl ether, by the interaction of veratric acid and phloroglucinol trimethyl ether in the presence of aluminium chloride. The reaction may be represented thus:



Maclurin-pentamethyl-ether.

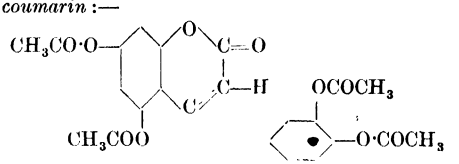
When maclurin pentamethyl ether is digested with alcoholic potash and zinc-dust, *leuco-maclurin-pentamethyl ether* (v. Kostanecki and Lampe, Ber. 1906, 39, 4014) is produced, prismatic needles,



m.p. 109°–110°C., and this on further reduction gives *penta-methoxy-diphenyl-methane*, m.p. 107°–108°C. On the other hand, if leucomaclurin-pentamethyl ether is oxidised in acetic acid solution, *veratric acid* and *dimethoxy-benzo-quinone* are formed.

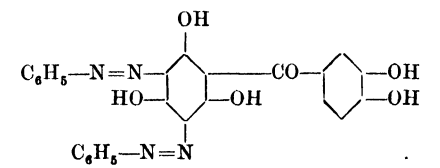
Maclurin itself has been synthesised by Hoesch & Zarzecki (Ber. 1917, 50, 462). Protocatechuonitrile is condensed with phloroglucinol in the presence of anhydrous $ZnCl_2$ and a stream of hydrogen chloride. The ketone-imide hydrochloride thus obtained on hydrolysis with boiling water yields maclurin.

By treatment of maclurin with acetic anhydride and sodium acetate, Ciamician and Silber (Ber. 27, 1628, and 28, 1393) obtained a crystalline product which has the composition of a penta-acetyl-maclurin less one molecule of water, viz. $C_{23}H_{18}O_{10}$, and to this compound the following constitutional formula has been ascribed, one of the acetyl groups having undergone condensation with the production of a coumarin derivative, *tetra-acetyl-tetrahydroxy-phenyl-coumarin*:—



Patent Fustin.—Under the name 'patent fustin' a colouring matter has been placed on the market, which consists chiefly of diazobenzene-maclurin (C. S. Bedford, 1887; Eng. Pat. 12667). To prepare this substance, old fustic is extracted with boiling water, the solution is decanted from the precipitate of morin and its calcium salt which separates on cooling, and is neutralised with the necessary quantity of sodium carbonate. Diazobenzene sulphate is then added until a precipitate no longer forms, and this is collected and washed with water. It is sold in the form of a paste, and dyes chrome mordanted wool an orange-brown shade.

Diazobenzene-maclurin (Bedford and Perkin, Chem. Soc. Trans. 1895, 67, 933; *ibid.* 1897, 71, 186), which crystallises in salmon-red prismatic needles, m.p. 270°C. (decomp.), has the following constitution:—



It dyes wool and silk direct from a weakly

acid bath, in shades of orange, and on mordants gives colours varying from orange-red on aluminium and orange-brown on chromium, to olive on iron. The dyeings are fairly fast to washing.

With acetic anhydride it yields a *tri-acetyl-derivative* only $C_{13}H_5O_5(C_6H_5N_2)_2\cdot(C_2H_3O)_3$, orange-red needles, m.p. 240°–243°C. (decomp.), which is in keeping with the fact that azobenzol-phloroglucinol yields only a mono-acetyl derivative when treated in like manner.

Dis-azo compounds of maclurin have also been prepared by coupling it with diazotised *o*- or *p*-toluidine, *p*-nitraniline, or sulphanilic acid, and the resulting compounds closely resemble the above described disazobenzene-maclurin.

Dyeing Properties of Maclurin.—With aluminium mordant maclurin gives a pale yellow, with chromium a yellow-green, and with iron a weak grey colour may be obtained.

A. G. P.

MADDER. Madder is the ground root of the *Rubia tinctorium* (Linn.), which has been cultivated for dyeing purposes from a remote antiquity, so remote indeed that one is unable to say with certainty in which countries it originated. It is known to have been employed by the ancient Egyptians, Persians, and Indians, probably by the last in the first instance, and more recently by the ancient Greeks and Romans. About the time of the Crusades the cultivation of madder was introduced into Italy and probably also into France. The Moors cultivated it in Spain, and during the sixteenth century it was brought to Holland. Colbert introduced it into Avignon in 1666, Frantzen into Alsace in 1729, but only towards 1760–1790 did it become important. During the wars of the Republic, its cultivation was largely abandoned, and only after 1815 did this again become regular.

Owing to the beauty and fastness of the tints it yields, and the range in colour that can be produced from it by a variation in the mordant, it was considered until recently as perhaps the most important of all dyestuffs. Although its commercial value has been greatly reduced through the introduction of artificial alizarin, it has still considerable scientific interest.

The plant is an herbaceous perennial belonging to the natural family of the *Rubiaceæ*, and its valuable portion is entirely the root, which is usually of considerable length but does not exceed an ordinary slate pencil in thickness. Old roots are richer in colour than young ones, and the plant is consequently left in the soil for at least 18 and sometimes for 28 months. When removed it is usually washed with water, allowed to dry in the sun or artificially by means of kilns, then finely ground and packed in casks. In certain districts it was stored in pits for several months before grinding, whereby its tinctorial power was said to be greatly enhanced; but these and other refinements of its preparation are now of so little importance as to be hardly worthy of mention. The root in many countries bears the name 'alizari' or 'lizari,' whence we have the name 'alizarin.' Madder was principally cultivated in Holland, France, and Turkey, and to a less extent in Belgium, Italy, and Germany, and North and South America, but the small quantity which enters this country is principally obtained from Holland. Perhaps no substance was submitted to so much examination by the older chemists as madder, and in many of the earlier works on dyeing much space is occupied by a description of these researches.

The isolation of the most important colouring matters of madder, alizarin, and purpurin occurred as far back as 1826 and 1828, and was due to the chemists Robiquet and Colin; but it is doubtful whether they were successful in obtaining these substances in a state of chemical purity. By many of the earlier workers it was considered that these colouring matters did not exist as such in madder, but were present in combination with sugar or some other substance. About 1823 Kuhlmann extracted a bitter-sweet yellow amorphous compound from the root and named it xanthin, and a similar yellow substance was also isolated by Runge and Watt. In 1848 Higgin observed that if a cold aqueous solution of madder, which has a deep yellow colour and an intensely bitter taste, was allowed to stand for some time or was heated to 50°, it lost these characteristics, and a gelatinous flocculent precipitate was formed in which all the tinctorial power of the original infusion resided. Higgin considered, therefore, that the xanthin of madder must, during this process, have been converted into alizarin, and that the change was probably brought about by the action of some ferment contained in the madder, and extracted along with the xanthin by cold water. Somewhat later (1851) Schunck isolated from madder a substance which he called rubian, as a dark brownish-yellow transparent, amorphous hard mass, which by hydrolysis with acids or by the action of the special madder ferment, which he termed 'erythrozym,' was converted into glucose, alizarin, and other substances.

The next important step was due to Rochleder, who prepared the alizarin glucoside in a crystalline condition and named it *ruberythric acid*. It appeared to possess the formula $C_{20}H_{22}O_{11}$, and its hydrolysis could be represented according to the following equation:—

$$\underset{\text{Ruberythric acid.}}{C_{20}H_{22}O_{11}} = H_2O + \underset{\text{Alizarin.}}{C_{14}H_8O_4} + \underset{\text{Sugar.}}{C_6H_{12}O_6}$$

Subsequently, Schunck prepared a crystalline compound, rubianic acid, which he regarded as an oxidation product of rubian, and which proved to be identical with the ruberythric acid of Rochleder.

Finally, this portion of the subject was exhaustively examined by Liebermann and Bergami, who assigned the formula $C_{26}H_{28}O_{14}$ to ruberythric acid, and proved that its hydrolysis with acid proceeds as follows:—

$$C_{26}H_{28}O_{14} + 2H_2O = C_{14}H_8O_4 + 2C_6H_{12}O_6$$

For the preparation of the glucoside, madder (1 kilo.) is extracted with boiling absolute alcohol (8–9 litres) for 2 to 4 hours, and the mixture filtered hot. The alcoholic extract is evaporated to about one-quarter its bulk, and on cooling a yellowish-brown crystalline precipitate of the impure glucoside separates. After filtering and evaporating the filtrate still further, crystals of cane sugar separate, and by

adding water to the remaining alcoholic solution impure alizarin is precipitated. In this way, according to Liebermann and Bergami, 1 kilo. of madder gave

Impure glucoside .	. 50–60 grams	(5–6 p.c.)
,, sugar .	. 15–30 ,,	(1·5–3 ,,)
,, colouring matter	30–40 ,,	(3–4 ,,)

The impure glucoside, which becomes resinous on drying, is dissolved in water, the solution is precipitated with lead acetate, filtered, and the filtrate treated with basic lead acetate. The pink-coloured precipitate is well washed, suspended in water, decomposed with sulphuretted hydrogen, and the lead sulphide, which contains also the liberated ruberythric acid, is collected and washed with cold water. The ruberythric acid is removed from the lead sulphide by means of boiling alcohol, the yellow extract is partially evaporated, water and some quantity of barium hydroxide solution are added, and, after filtering off a white precipitate, an excess of barium hydroxide is added to the filtrate. The dark cherry-red precipitate of barium ruberythrate is dissolved in acetic acid, the solution is filtered, barely neutralised with ammonia, and then treated with basic lead acetate. The resulting red precipitate is washed with alcohol, suspended in alcohol, and decomposed by hydrogen sulphide, and the liquid and precipitate together are heated to boiling and filtered hot. On cooling, the amber-coloured solution yields pale yellow needles of ruberythric acid which are recrystallised from hot water. The latter portion of this process, employed by Liebermann and Bergami, is due to Rochleder.

Ruberythric acid crystallises in silky needles of a pure yellow colour, melts at 258°–260°, and when strongly heated yields a sublimate of alizarin. It dissolves in caustic alkali solutions with a cherry-red colour, which on boiling changes to violet, and on acidification yields a precipitate of alizarin. With potassium carbonate solutions, dark red needles of potassium ruberythrate are produced. Ruberythric acid is not precipitated with lead acetate, but basic lead acetate gives a red flocculent precipitate. It possesses no dyeing power.

By the action of sodium acetate and acetic anhydride, Liebermann and Bergami obtained an *octoacetyl* derivative $C_{26}H_{20}O_6(C_2H_3O_2)_8$, which crystallises in yellow needles, melting at 230°.

Schunck and Marchlewski, by means of the method of Schotten and Baumann, obtained a *hexabenzoyl* and a *heptabenzoyl* compound. The fact that ruberythric acid gives an octoacetyl derivative renders two constitutions possible for this substance, viz. :—

(1) $C_{14}H_6O_2 < \begin{matrix} O{\cdot}C_6H_7O(OH)_4 \\ O{\cdot}C_6H_7O(OH)_4 \end{matrix}$

(2) $C_{14}H_6O_2 < \begin{matrix} O{\cdot}C_{12}H_{14}O_3(OH)_7 \\ OH \end{matrix}$

and of these the second is more probably correct, as an explanation is thus afforded of the well-characterised red-coloured salts which can be obtained from it.

Erythrozym, the madder enzyme, was obtained by Schunck by extracting madder with water at a low temperature (38°) and precipitating the solution with alcohol. When dried, it consisted of a brown amorphous mass. Under its influence, ruberythric acid is hydrolysed with formation of alizarin and glucose. This reaction no doubt takes place in the incompletely dried root on storing, and it is evidently due to this fact that madder was said to dye more readily after this treatment. In dyeing with madder, moreover, the presence of this enzyme will no doubt exercise a beneficial effect, because as it is frequently the practice to employ a cold dye-bath and then to gradually raise the temperature, hydrolysis of the glucoside, which is itself devoid of tinctorial property, will thereby occur with formation of the colouring matter.

Though purpurin is considered to exist in madder in the form of glucoside, such a compound has not yet been isolated, and some uncertainty exists on this point. During some experiments carried out by Perkin, it was found that an alcoholic extract of madder, on standing in cold weather, deposited a considerable quantity of cane sugar contaminated with a red precipitate. This latter was soluble in water, and on treating the solution with cold dilute acid, gave a precipitate of impure purpurin and appeared to consist of an acid calcium salt of this substance. On the other hand, it was not ascertained whether all varieties of madder behave similarly in this respect, and the matter requires further investigation. Presuming, however, that a purpurin glucoside is present in madder, it is evident that this compound is far less stable than ruberythric acid, and is hydrolysed by dilute acids at a temperature at which the latter is unaffected.

Kopp's Process for the Extraction of Madder.

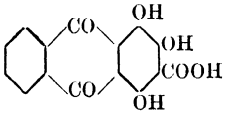
Based on this assumption, the commercial process of Kopp was devised, and this is specially interesting as it affords a fairly complete method for the isolation of the phenolic constituents of this dyestuff.

Ground madder is extracted with a cold aqueous solution of sulphurous acid, and the solution, after addition of 2–3 p.c. of hydrochloric acid (33 p.c.), is heated to 60°. A red flocculent precipitate of purpurin is thus thrown down which was collected, washed, dried, and sold under the name of 'commercial purpurine' or 'Kopp's purpurine.' This product was until recently prepared to a very small extent in France for the manufacture of a rose-red lake, and for this purpose gives results differing in some respects from those produced by the artificial dyestuff.

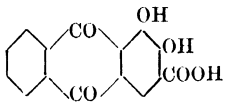
Kopp's purpurine, in fact, is not pure purpurin, but consists mainly of a mixture of this colouring matter with three other substances: *pseudo*-purpurine, purpuroxanthin, and purpuroxanthin carboxylic acid or munjistin.

Pseudo-purpurin was first isolated from Kopp's commercial product by Schützenberger and Schiffert, but the fact that it consists of a purpurin carboxylic acid is due to the investigation of Rosenstiehl. It consists of small red prismatic needles, and differs from purpurin in that it is more readily soluble in benzene. It melts at 218°–220° with evolution of carbon

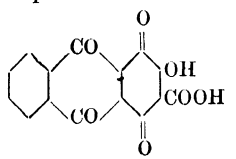
dioxide and formation of purpurin, and this decomposition is said to occur gradually at from 180°–195°. Purpurin is also produced by boiling *pseudo*-purpurin with dilute caustic alkali, or by long boiling with water or alcohol. The constitution of *pseudo*-purpurin is represented by the following formula :—



It may be prepared synthetically (D. R. P. 260765) by dissolving 1 : 2-dihydroxyanthraquinone-3-carboxylic acid—

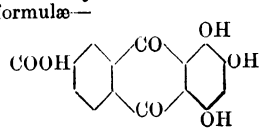


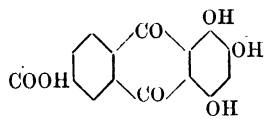
in 20 parts of sulphuric acid and slowly treating the solution at 15°–20° with 0·3–0·4 parts of manganese dioxide. In place of the 1 : 2-dihydroxy the 1 : 4 : 3-dihydroxycarboxylic acid may be employed (D. R. P. 272301), in which case the 2-hydroxyanthradiquinone carboxylic acid is the first product of the reaction—



This by means of sodium hydrogen sulphite solution is reduced to *pseudo*-purpurin.

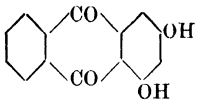
It is interesting to observe that an isomeric compound which is obtained by the oxidation of alizarin carboxylic acid, and for which also the two formulæ—





are possible, differs markedly from *pseudo*-purpurin, and is an exceedingly stable compound (Perkin and Cope).

Purpuroxanthin or xanthopurpurin, which forms glistening yellow needles, melting at 262°–263°, is a dihydroxyanthraquinone isomeric with alizarin, and was isolated from Kopp's purpurine by Schützenberger and Schiffert. These authors also found that purpuroxanthin can be produced by digesting purpurin with phosphorus iodide and water, or by the action on it of a boiling alkaline stannous chloride solution. The reverse action occurs, according to Rosenstiehl, when an alkaline solution of purpuroxanthin is boiled with excess of air, purpurin being thus produced. Purpuroxanthin was synthesised by Noah by heating 3 : 5-dihydroxybenzoic acid with benzoic acid in the presence of sulphuric acid, and possesses the following constitution :—



According to Plath, the dimethyl ether melts at 178°–180°, and the diacetyl derivative (Liebermann) at 183°–184°.

Purpuroxanthin dyes aluminium mordanted fabrics a yellow colour (Schützenberger and Schiffert).

Purpuroxanthin carboxylic acid (munjistin) was discovered by Schunck and Römer in the crude purpurin. It crystallises from acetic acid in golden yellow leaflets, melts at 231°, and dissolves in alkaline solutions and ammonia with a red coloration. By heating above its melting-point or by boiling with alkalis, it is converted into purpuroxanthin. It has not been prepared synthetically, but probably contains its carboxyl group in a similar position to that present in *pseudo*-purpurin. It is said to dye aluminium mordanted fabrics an orange-red colour, which is, however, not fast to the action either of soap or light.

Green alizarin.—The sulphurous acid liquid from which the purpurin precipitate has been removed is boiled for 2 hours, when the ruberythric acid and certain other glucosides present are hydrolysed and a deep green precipitate separates. This at one time was a commercial article, and was known under the name of 'green alizarin.'

Chlororubin.—The green tinge of this product arises from the presence in madder of a considerable quantity of a peculiar substance, possibly a glucoside, termed chlorogenin or rubichloric acid, but little or nothing is known of its chemical nature. It is also present in chay root, morinda root, in certain species of *galium* and in the *Gardenia grandiflora*. This compound, which has been obtained in the form of a colourless syrup and to which the formula $C_{14}H_8O_9$ has been assigned, on digestion with boiling dilute mineral acid, is converted into chlororubin and formic acid. Chlörorubin consists of a dark green amorphous powder which is insoluble in all the usual solvents, but dissolves in alkaline solutions with a blood-red colour.

Yellow alizarin.—In order to obtain this product, the dried and finely powdered 'green alizarin' was extracted at 150° with petroleum (toluene or coal-tar solvent naphtha is more suitable for laboratory purposes), by which means the alizarin and other phenolic constituents pass into solution, whereas the chlororubin remains undissolved. The petroleum extract after cooling is agitated with 10 p.c. caustic soda solution, and the dark violet-coloured alkaline liquid thus produced is removed and neutralised with acid. The bright yellow precipitate was collected, washed and dried, and sold under the name of 'yellow alizarin.'

The alizarin prepared in this manner is not completely pure, as it contains a small quantity of a mixture of non-tinctorial substances, which are derivatives of anthraquinone. To remove

these, an alkaline solution of the 'yellow alizarin' is treated with milk of lime, which precipitates the alizarin in the form of its calcium compound. This when collected, well washed, and decomposed with acid, gives a very pure alizarin which is best crystallised from solvent naphtha.

If the reddish-brown filtrate from the calcium alizarate is neutralised with acid, a small quantity of a dull yellow precipitate separates which is approximately equal to 0·02 p.c. of the madder employed. A preliminary examination of this product indicated that it consisted of at least four yellow crystalline substances, with no special properties that would permit of their ready separation.

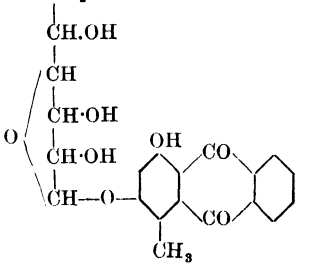
Schunck during his examination of madder obtained various yellow crystalline and amorphous products by the action of acids and alkalis on his rubian. The individuality of most of these substances, to which the names rubiretin, verantin, rubiadin, rubianin, rubiafin, rubiagin, rubiadipin, rubidehydran, rubihydran, and rubiacic acid were assigned, has been doubted by later writers, and but one of these—namely, rubiadin—has been characterised. On the other hand, it is quite possible that certain of these may exist in the mixture of yellow non-tinctorial substances previously referred to. For a description of his compounds, the original papers of Schunck should be referred to.

Rubiadin glucoside (Schunck and Marchlewski).—Madder is extracted with boiling water, the solution precipitated with lead acetate, and the filtrate treated with ammonia, by which means a second lead precipitate is formed. The latter is decomposed with sulphuric acid, the lead sulphate removed, and the clear liquid boiled with addition of hydrochloric acid. A dark green precipitate separates, only a portion of which dissolves in boiling alcohol. On treating the alcoholic extract with lead acetate, the alizarin present can be removed, and addition of baryta water now precipitates the barium salt of the rubiadin glucoside, which is decomposed by dilute hydrochloric acid. It crystallises from alcohol in citron-yellow needles, melts at 270° with decomposition, and when hydrolysed by acid gives rubiadin and glucose—

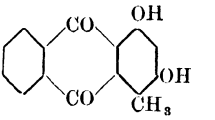
$$C_{21}H_{20}O_9+H_2O=C_{15}H_{10}O_4+C_6H_{12}O_6$$

Penta-acetylrubiadin glucoside, yellow needles, melts at 237°.

According to Marchlewski, the constitution of this glucoside is best expressed as follows :—



Rubiadin, prepared by the hydrolysis of the glucoside, forms yellow needles, melting about 290°, soluble in alkalis with a red coloration. By oxidation with chromic acid it gives phthalic acid. Rubiadin, according to Schunck and Marchlewski, is a methyl purpuroxanthin and possesses the following constitution :—



Rubiacin (Runge's madder orange) is a yellow crystalline substance obtained directly from the madder root, and is formed, according to Schunck, by the decomposition of a glucoside. It separates in small quantity from an infusion of madder made with only a little cold water, after it has become sour by 12 hours' standing. It crystallises in the form of plates and needles, having a strong reddish-green lustre. Alkalis dissolve it with a purple colour.

The following table illustrates the analysis of madder by the sulphurous acid extraction method :—

Madder is extracted with dilute sulphurous acid solution and the extract heated to 60°.

Precipitate consists of Purpurin, Pseudo-purpurin, Purpuroxanthin carboxylic acid, Purpuroxanthin.	Filtrate is digested with boiling dilute H_2SO_4, and the resulting precipitate of green alizarin extracted with boiling toluene or petroleum.
Chlororubin remains undissolved.	The toluene extract is agitated with caustic soda solution, and the alkaline liquid is treated with baryta water.
Precipitate consists of calcium alizarate, which when decomposed with acid gives alizarin.	Filtrate on acidification gives a precipitate of yellow non-tinctorial derivatives of anthraquinone.

Commercial Preparations of Madder.

The principal of these were: Garancine, Garanceux, Flowers of Madder, Commercial Alizarin or Pincoffin, and Madder extract.

Garancine.—The preparation of this product results from the observation in 1827 of Robiquet and Colin, that by treating ground madder with an equal weight of concentrated sulphuric acid, the various principles of the madder were destroyed with the exception of the colouring matter alizarin. We now know further that the glucoside of the root is decomposed by the action of the acid. This first product was termed *charbon sulphurique*, but soon the method of its preparation was slightly altered, and it then received the name *garancine*.

Garancine is made by mixing, in a wooden tank with false bottom, 100 kilos. ground madder, 1000 litres water, and 2 kilos. sulphuric acid, 168°Tw. (sp.gr. 1·84), stirring up and allowing the whole to macerate for about 12 hours. The liquid is then drawn off, the residue mixed with a little water and 30 kilos. strong sulphuric acid, and the whole boiled for 2–3 hours. After running off the acid liquor, the garancine remaining is washed with water till free from acid, drained, pressed, dried, and ground.

The colouring power of garancine is three to four times that of good madder, it dyes more readily, giving yellower-toned reds and pinks, and greyer lilacs. They are not quite so fast to soap as the madder colours, but since, in the case of printed calicoes, the unmordanted white parts are not so much soiled in the dye-bath, the operation of soaping can be omitted.

Garanceux or *Spent Garancine* was introduced in 1843 by L. Schwarz of Mulhouse. It was simply a low quality of garancine prepared in the above manner from the spent madder of the dye-baths, and made by each calico-printer for himself, by way of economy. Its colouring power is about one-fourth that of good garancine.

Flowers of Madder was first made in 1851 by Julian and Rogner of Sorgues. It can be prepared by macerating ground madder for several hours with cold water very slightly acidulated with sulphuric acid (1–2 p.c. on the weight of madder), then washing, draining, pressing, drying, and grinding. In this manner all soluble, mucilaginous, and sugary matter, &c., is removed, decomposition of the glucoside by fermentation occurs, and the residue has nearly double the colouring power of the original madder. The waste liquors were neutralised, allowed to ferment with the addition of yeast, and then distilled to gain the alcohol. 100 kilos. madder yielded 45–60 kilos. flowers of madder and 10 litres alcohol, suitable for making varnish, &c.

Commercial Alizarin or *Pincoffin* was introduced in 1852 by Schunck and Pincoff, who prepared it by submitting ordinary garancine to the action of high pressure and superheated (150°C.) steam. By this treatment the verantin and rubiretin present in the garancine were said to be destroyed, while the alizarin remained intact, and the product yielded in consequence more brilliant purples, and less soaping was required to clear the whites or unmordanted portions of printed calicoes.

Madder Extracts.—Already in 1826 attempts were made by Gaudin to apply mordants along with the colouring matter of madder directly to calico, in the form of an extract, *i.e.* as a steam-colour, instead of by dyeing, and in 1837 Gastard succeeded in doing this successfully on a large scale by means of a product named *colorine*. The expense, however, of this and other early madder extracts retarded their application, but their utility having been clearly demonstrated, the endeavours of numerous chemists were directed to their production in a reasonably cheap manner. Madder extracts consisted of variable mixtures of the two colouring matters of madder, alizarin and purpurin, or of each separately, in a more or less pure condition. By the introduction of artificial alizarin, just when their manufacture had been perfected, they lost all their importance. The following were the chief methods of production employed.

Schützenberger's process consisted in first extracting all the purpurin from ground madder by water heated to 55°C., and afterwards dissolving out the less soluble alizarin from the dried residual madder by means of wood-spirit. The aqueous solution was precipitated by lime, the washed calcium-purpurin lake was then decomposed with hydrochloric acid, the liberated purpurin collected and washed, when it was ready for use. The alcoholic solution of alizarin was merely precipitated by water, collected and washed. Alizarin and purpurin extracts were thus obtained.

Paraf's method (1868) consisted in extracting madder with superheated water, with or without the addition of a small quantity of alum or sulphuric acid, then collecting and washing the flocculent alizarin precipitate which separated out on cooling.

The modes of preparing Kopp's 'purpurine,' 'green alizarine,' and 'yellow alizarine' have already been given.

Pernod's madder-extract, once largely used, was prepared by extracting garancine with boiling water very slightly acidified with sulphuric acid, collecting and washing the precipitate thrown down on cooling, and extracting the dried precipitate with boiling alcohol. After recovering the major portion of the alcohol by distillation, the remaining solution was mixed with water, and the precipitated alizarin was collected and washed.

Use of Madder in Dyeing.

Previous to 1870 madder and its derivative garancine were the dyestuffs *par excellence* of the calico-printer and Turkey-red dyer.

By the former, it was used because of its characteristic property of yielding a variety of colours with the aluminium, tin, and iron mordants, viz. red and pink, orange, lilac, and black; also brown or chocolate, by employing a mixture of aluminium and iron mordants. Further, all these colours are fast to soap and light. To the calico-printer both the alizarin and the purpurin of the madder were of use, though undoubtedly the alizarin would, in most styles of work, be the essential colouring matter. The Turkey-red dyer employed madder, and afterwards garancine, because they yielded, by his peculiar process, the most brilliant and most permanent red on cotton which was known. In this case the alizarin was the all-important colouring matter, since the purpurin, although fixed on the fibre at first, was more or less removed during the operations of clearing. Alizarin, in conjunction with aluminium and iron mordants, gives a bluish-red and a comparatively bright lilac; purpurin, a yellowish-red and a greyish-lilac, respectively.

The method of applying madder in Turkey-red dyeing was similar to that now employed in the case of alizarin.

Another interesting feature in connection with the application of this dyestuff is that, if the madder was deficient in lime, it was necessary to add a certain proportion of chalk to the dye-bath; it now appears that calcium is a normal constituent of the madder colours, especially those obtained with aluminium and iron mordants.

Madder has also been used in the past, and is even now employed to a small extent, by the indigo dyer and the woollen dyer.

MADDER CAMPHOR *v.* CAMPHORS.

MADDER LAKE *v.* LAKES.

MAFOUREIRA NUT. A nut imported from Portuguese East Africa containing about 60 p.c. of fat, solid at ordinary temperatures and consisting mainly of palmitin and olein, together with some free fatty acids, chiefly oleic acid. Used in the manufacture of lubricants, soap, and candles. The supply is practically unlimited, the tree bearing the nut growing wild all over the country.

MAGDALA RED *v.* AZINES.

MAGENTA *v.* TRIPHENYLMETHANE COLOURING MATTERS.

MAGISTERY. The term magistery was employed by the older chemists to denote the white precipitates which form on the addition of water to strongly acidified solutions of certain metals.

MAGISTRAL. An old medical term signifying a sovereign remedy, employed by the Spanish smelters of Mexico and South America to the roasted and powdered copper pyrites, which is added to the stamped silver ores in the *torta* or magma, obtained in the *patio* process of decomposing horn silver (*v.* SILVER).

MAGMA. A pasty or semifluid mixture. Applied in medicine to the residuum obtained after expressing certain substances to extract the fluid parts of them, or after treating a substance with some menstruum; a thick ointment or confection (Dunglison). *See also* LAVA.

MAGNALIUM. An alloy of magnesium and aluminium (*v.* ALUMINIUM).

MAGNESIA ALBA. A hydrated basic magnesium carbonate (*v.* MAGNESIUM).

MAGNESIA NIGRA. An old name for native manganese dioxide (*v.* MANGANESE).

MAGNESITE (Fr. *Giobertite*). A mineral consisting of magnesium carbonate $MgCO_3$, and belonging to the calcite group of the rhombohedral carbonates. To French mineralogists it is known as giobertite or baudissérite, the name magnésite being applied by them to meerschaum. Crystals are of rare occurrence: they usually have the form of the primary rhombohedron, parallel to the faces of which are perfect cleavages. The angle between the faces of this rhombohedron is 72° 36′ (the corresponding angle in calcite being 74° 55′). Sp.gr. of crystals, 3·02; hardness, 4. Of the massive material there are two distinct varieties—crystalline and compact. The former consists of a spathose aggregate, showing bright cleavage surfaces, of varying degrees of coarseness, and sometimes so fine as to resemble a saccharoidal marble. The compact or cryptocrystalline variety, sometimes described as amorphous, is snow-white and has much the appearance of chalk or unglazed porcelain; this has sp.gr. 2·9 to 3·0. Analyses of massive material show 85 to 96 p.c. $MgCO_3$, with calcium and iron carbonates and often (especially in the compact variety) a little silica. A ferriferous variety of the spathose form, known as breunnerite or brown-spar, contains 5 to 30 p.c. $FeCO_3$ isomorphously replacing magnesium carbonate and forms a passage through mesitite (*q.v.*) to chalybite; here the sp.gr. ranges up to 3·2.

I. Compact magnesite from Eubœa (A. Christomanos, 1903).

II. Compact magnesite from Chalk Hills, Salem (H. H. Dains, 1909, also H_2O 0·60).

III. Compact magnesite from Alameda claim, Santa Clara Co., California (F. L. Hess, 1908).

IV. Crystalline, marble-like magnesite from Valley, Stevens Co., Washington (U.S. Geol. Survey, 1918).

V. Crystalline magnesite from St. Kathrein, Styria (C. v. John, 1907)

VI. Crystalline breunnerite from Veitsch, Styria (R. Banco, quoted by K. A. Redlich, 1914; also MnO 0·53).

The compact variety of magnesite occurs as an alteration product of serpentine rocks, in which it forms veins, interlacing networks, and large irregular masses Deposits of this kind are worked commercially on the island of Eubœa in the Grecian Archipelago, the 'Chalk Hills' near Salem in Madras, at several places in California, Transvaal, and in Piedmont; and several other localities are known. The spathose variety of the mineral occurs as beds and lenticular masses in metamorphosed sedimentary rocks, in association with limestone, dolomite, and spathic iron ores; and has probably originated by the action of solutions of magnesium salts on limestone. Deposits of this type are worked at Grenville in Quebec, Stevens Co. in Washington, and in Austria. The Austrian deposits extend from the Tyrol into northern Hungary with a maximum development in Styria. Here the predominating mineral is the breunnerite variety.

Magnesite is used for the preparation of Epsom-salts and other salts of magnesium, and for the production of carbon dioxide. Calcined magnesite is made into refractory bricks for lining basic steel furnaces and electric furnaces. For this purpose the ferriferous breunnerite

variety has the advantage that it sinters somewhat when calcined. The strong cement (oxychloride or Sorel cement) made by mixing partially calcined magnesite with magnesium chloride solution is employed for the construction of fireproof partitions, flooring, artificial stone, tiles, emery-wheels, grindstones, lithographic stone, &c. For this purpose the compact variety is best suited. Other applications of magnesite are in the manufacture of paper and paint, and as a non-conducting covering on boilers and steam-pipes.

MAGNESIUM. Sym. Mg. At.wt. 24·375. Magnesium appears to consist of three isotopes of masses 24, 25, and 26, which occur in the proportion 6 : 1 : 1 and give an average atomic weight of 24·375. The compounds of magnesium most widely occurring in nature are *magnesite* $MgCO_3$, *kieserite* $MgSO_4,H_2O$, *kainite*

$$MgSO_4 \cdot KCl,6H_2O \cdot$$

carnallite $MgCl_2 \cdot KCl,6H_2O$, and the many silicates, as *enstatite, talc, meerschaum, augite, olivine,* and *serpentine.* Together with calcium it frequently occurs in huge mountain masses as *dolomite* $(MgCa)CO_3$. The sulphate $MgSO_4,7H_2O$ is one of the principal saline constituents of many springs, and the chloride occurs in sea water.

Preparation of the metal.—Magnesium, in an impure state, was first obtained by Davy in 1808 by electrolysis, and also by reducing the oxide in a current of the vapour of potassium. In 1830, Bussy obtained it in larger quantity and in a purer form by heating anhydrous magnesium chloride to redness with potassium. On dissolving out the residual chlorides the metal was obtained as a powder which could be readily fused into globules. Bunsen subsequently prepared it by electrolysis of the fused chloride, using a battery of ten zinc-carbon cells. The operation was conducted in a porcelain crucible, of which the upper part was divided by a vertical partition, ground to the right size out of an ordinary crucible lid. The crucible was fitted with a tile cover, through which the poles of gas carbon were inserted, one on each side of the partition. The negative carbon pole was cut like a saw, in such a manner as to form overhanging ledges, under which the light magnesium collected, and was thus prevented from floating to the surface and burning at the high temperature employed.

As the anhydrous chloride is difficult to prepare, Matthiessen improved the process by substituting a mixture of three equivalents of potassium chloride with four of magnesium chloride. A little ammonium chloride is added, the mixture fused and electrolysed in Bunsen's apparatus; it is, however, unnecessary to cut the negative pole, as the magnesium is heavier than the fused mixture. In small quantities, the metal may be readily obtained by electrolysing this mixture in a clay tobacco pipe heated over a lamp, the negative pole being formed by an iron wire inserted down the stem, and the positive by a piece of gas-carbon just touching the surface of the fused mass.

Manufacture.—The first steps towards the preparation of magnesium on an industrial scale were taken by Deville and Caron, whose process essentially consisted in heating a mixture of anhydrous magnesium chloride, fluorspar, and sodium. In the earlier experiments 600 grams of the fused chloride, 480 grams of finely-powdered fluorspar, and 230 grams of sodium in small pieces were employed. The fused magnesium chloride is obtained by evaporating to dryness a mixed solution of magnesium and ammonium chlorides, and fusion of the residue. Magnesium chloride alone cannot be fused without decomposition, hence the use of the ammonium chloride, which prevents this.

The dry mixture, in the proportions mentioned, is then introduced into a red-hot earthen crucible and the cover pressed down by a weight while the violent reaction occurs. When all action ceases, the contents are stirred with an iron rod, which causes the minute globules of metal to coalesce. After being left to cool, all the magnesium may be collected as a ball upon the rod before the melt becomes solid. The metal is then hammered to free it from slag, and should amount to about three-fourths of the theoretical equivalent of the sodium used.

Wöhler subsequently showed that the troublesome preparation of the anhydrous chloride may be avoided by using instead a mixture of magnesium chloride with one-sixth of its weight of sodium chloride, or of a mixture of sodium and potassium chlorides.

Deville and Caron also showed that the metal may be distilled at nearly the same temperature as zinc, in carbon-lined vessels, in an atmosphere of hydrogen, and were thus enabled to obtain it in a very pure form, free from carbon, silicon, and nitrogen.

Sonstadt, in 1863, introduced a few improvements in the process of Deville and Caron. An iron crucible was substituted for the earthen one, and the mixture used consisted of magnesium and sodium chlorides with one-fifth its weight of sodium. The heating was continued for about half an hour after the whole crucible has been raised to full redness.

In a later patent, Sonstadt extended the whole process to a manufacturing scale, and adopted an enlargement of Deville and Caron's method of purification by distillation. The 'magnesium still' consisted of two wrought-iron vessels placed vertically over each other; the upper one served as the crucible, and was connected with the lower one, which actedas receiver,

by means of an iron condensing tube, which projected upwards into the crucible to within an inch of the lid. The whole apparatus could be rendered air-tight. The crucible filled with crude magnesium to the level of the top of the tube was fixed in a furnace and surrounded by fuel; the receiver was fitted into a recess of the fire grating, and projected below. Before commencing the distillation, the wrought-iron lid was screwed down, and the air displaced by a current of hydrogen or coal-gas. The receiver was cooled by external application of water. The crucible was maintained at an almost white heat until the operation was complete. The whole apparatus was then removed from the furnace and cooled; on taking to pieces, the magnesium was found as a solid mass in the receiver. This was then remelted and cast into ingots.

Magnesium was formerly prepared on a large scale in this country by the Magnesium Metal Company, at Patricroft, near Manchester.

Von Püttner (Eng. Pat. 1031, Jan. 24, 1885) prepared the metal by a process very like the reduction of zinc, which metal magnesium very closely resembles. The magnesium mineral is first treated so that the metal is present entirely as oxide. This is then intimately mixed with carbonaceous matter, to which may advantageously be added oxide of iron, and heated to whiteness in retorts. The vaporised metal is condensed and collected in receivers similar to those used in the zinc manufacture.

Matignon (C. R. 1913, 1157) obtained metallic magnesium by heating heavy magnesium oxide with aluminium powder in an exhausted steel tube at 1200°C. The reaction is almost complete, the magnesium being deposited in a crystalline state in the cooler part of the tube.

Gerhard and Smith (Eng. Pat. 16651, Dec. 19, 1884) describe a process for the electrolytic deposition of magnesium as follows. Magnesium ammonium sulphate is prepared by crystallising together 228 parts of magnesium sulphate and 132 parts of ammonium sulphate. This is dissolved in 35,000 parts of water, and the electrodeposition is effected in this solution at a temperature from 150° to 212°F. If a white metal is desired, a nickel anode is employed; for magnesium bronze, a copper anode. In the latter case the most suitable bath is formed by dissolving 360 parts of magnesium ammonium sulphate, 550 parts of potassium cyanide, and 550 parts of ammonium carbonate in 35,000 parts of water.

The electrolytic method has now superseded the chemical method. Briefly the details of the process, according to Borchers, are as follows. An anhydrous electrolyte consisting of chlorides having the composition corresponding to the formula $MgCl_2 \cdot KCl \cdot NaCl$ is prepared by heating the crystallised salts in an iron pan. Magnesium chloride cannot be used alone, as it decomposes on heating with the liberation of hydrochloric acid and the formation of oxychloride. This reaction takes place to a certain extent in spite of the presence of the alkaline chlorides; and if the oxide is not removed, as also any magnesium sulphate present, the globules of magnesium formed during electrolysis fail to unite to form a clean metal. The sulphate is therefore decomposed after fusion of the chlorides by stirring in some carbon or sawdust, when oxide is produced. The oxide is then converted to chloride by the addition of ammonium chloride, when a clear bath should result. The fused mass is then emptied into the electrolytic cells, which are usually of iron and form the cathode. The anode is a carbon rod surrounded by a porcelain cylinder and cap from which a tube passes for leading off the chlorine. The apparatus is kept in a furnace and the temperature is maintained somewhat above the melting-point of magnesium. The current density is about 1000 ampères per square metre with a pressure of 7 to 8 volts. The resulting metal and salts are poured into a mould, and after cooling the buttons of magnesium are separated and remelted with pure carnallite in an iron crucible, the temperature being raised until the magnesium floats on the flux, and is so liquated from impurities. The magnesium is ladled off, remelted, and poured into ingots.

According to U.S. Pat. 1258261 (Chem. and Met. Eng. 1919, 87) the chlorides of magnesium and potassium in a molten condition are electrolysed, using a carbon anode and a cathode of molten tin or copper. The magnesium separated from the electrolyte is alloyed with the molten cathode, which is removed when it contains sufficient magnesium for further treatment. In the second step the magnesium alloy is used as anode, the electrolyte is the same nature as before except with the addition of a heavy salt of an electro-positive metal such as barium chloride. In the second electrolysis magnesium enters into the solution from the impure anode and deposits in the cathode so arranged that the magnesium separated may float upon the electrolyte. In 1918 America produced 284,188 lbs. of magnesium valued at $615,217, about three-fifths of the total being sold as sticks and two-fifths as powder. Its purity varied from 99 to 99·9 p.c.

The Dow Chemical Co. uses magnesium chloride for the manufacture of the metal. This chloride is a by-product from its salt and bromine industry in the Saginaw Valley, Mich. The hydrated magnesium chloride, mixed with common salt in the proportion of 4 to 1, and with a small quantity of ammonium chloride, is heated in shallow vats over a slow coal fire to remove its combined water. About 50 p.c. of the water is driven off in this way. The partly dehydrated mixture is removed from the vats, cooled, and then completely dehydrated in a second furnace at a higher temperature. The metal is then produced by electrolysis of the fused magnesium chloride in a bath of sodium chloride and ammonium chloride. The electrodes used are graphitised carbon, and electrolysis takes place in cylindrical sheet-iron cells, which serve as cathodes.

The American Magnesium Corporation uses magnesite mined on the Pacific Coast, and calcined before shipment to the plant at Niagara Falls, N.Y. The electrolyte or bath is a mixture of fused fluorides, the oxide going into solution and being decomposed by the electric current. The slag is removed and the metal drawn from the furnaces at hourly periods and poured into small ingot moulds. The metal is refined by remelting the ingots in small retorts. Most of the magnesium now used is employed in

foundries as a deoxidiser or scavenger in brass, bronze, copper, nickel, and aluminium. It was for a time used chiefly in the production of flares, tracer bullets, and special explosives, and as a flashlight in photography; it is also used in a small way in making alloys with other metals (R. W. Stone, U.S. Geol. Survey Report, through Chem. Trade Journ. October 8, 1921, 434).

Properties.—Magnesium is a brilliant white metal resembling silver. When heated *in vacuô* to the temperature of the softening of porcelain it sublimes, and deposits itself upon the cooler parts of the vessel in beautiful silver-white crystals (Dumas, Compt. rend. 90, 1027). During the heating it gives off about one and a half times its volume of gas; 20 grams of the metal yielded 12·3 c.c. of hydrogen and 4·1 c.c. of carbon monoxide. The faces of the crystals are often curved and the edges rounded; the usual form is a regular hexagonal prism, the basal planes being less brilliant than the prism faces. The angle of the corresponding rhombohedron is 80° 3′, and is intermediate between those of zinc and arsenic (Des Cloizeaux, Compt. rend. 90, 1101). Its sp.gr. is 1·74-1·75. It melts at 651°, and the boiling-point is a little higher than that of zinc. It preserves its silvery lustre in dry air, but soon tarnishes in moist air owing to the formation of a film of hydrated oxide. It is readily malleable, but only ductile at high temperatures. Average coefficient of expansion between 0° and 100°, 0·0000259. On the large scale it is usually pressed into wire while in a state of semi-fluidity, and is then frequently flattened into ribbon. It burns when heated in a flame in air with an intense white light, very rich in the chemically active violet rays; hence its use in photography. According to Roscoe, a burning magnesium wire of 0·297 mm. thickness evolves as much light as 74 stearin candles of which five go to the pound. The light of burning magnesium is also employed in signalling and pyrotechny. For the production of the so-called 'Bengal lights,' the following mixtures are recommended. For white fire, 1 part shellac is fused with 6 parts barium nitrate, the fused mixture ground and mixed with 2·5 p.c. of powdered magnesium. For red fire, 1 part shellac is fused with 5 parts strontium nitrate, and the ground mass mixed with 2·5 p.c. of magnesium. These mixtures may either be made into ribbons about a finger's breadth or may be charged into thin zinc tubes so as to serve as torches. On burning, the zinc case burns along with the mixture. Star shells are made of a mixture of magnesium powder with barium nitrate and potassium nitrate, or the magnesium powder may first be mixed with a certain proportion of aluminium powder.

The strength of magnesium has been determined at the mechanical experimental station at Charlottenburg, and shown to be very considerable. Its breaking coefficient for tensile strain per square mm. is 23·2 kilos.; specific resistance to compression, 27·2 kilos. per square mm.; bending strength, 17·4 kilos. At a temperature of 450° it can be rolled, pressed, worked, and brought into complicated forms. Screws and threads of magnesium are considerably sharper and more exact than those of aluminium (J. Soc. Chem. Ind. 6, 730). It is quite as resistant to corrosion as aluminium, whilst it is superior to it in heat conductivity, and equal to it in electrical conductivity. The metal is barely attacked by a mixture of strong sulphuric and fuming nitric acids.

Magnesium has no action on pure water, but in presence of a trace of platinum chloride it decomposes water rather quickly, evolving hydrogen and forming magnesium hydroxide. Powdered magnesium reacts with water of crystallisation, being most active with halogen salts. $SnCl_2.2H_2O$ and $Fe_2Cl_6.6H_2O$ show the greatest activity. Hydroxides of lead, calcium, and aluminium which contain no water of crystallisation do not react even at 200°. Platinised magnesium constitutes a good deoxidising agent; it reduces nitrobenzene, for instance, completely to aniline (Ballo, Ber. 16, 694). Dilute acids rapidly dissolve it with violent evolution of hydrogen; with dilute hydrochloric acid it inflames when first thrown in. Strong sulphuric acid acts slowly, and a mixture of this acid with fuming nitric acid has no action upon it at ordinary temperatures. Solutions of caustic alkalis have no action upon it, but, heated with solutions of ammonium salts, it evolves hydrogen and dissolves, forming a double salt of ammonium and magnesium. Aqueous solutions, however, of acid sodium or potassium carbonates, as well as solutions of carbonic acid, dissolve the metal with evolution of hydrogen (Ballo, Ber. 15, 3003). Magnesium burns when heated in chlorine gas or bromine vapour, and especially brilliantly in the vapours of sulphur and iodine. It combines at determinate temperatures, when in a finely divided state, with sulphur, phosphorus, and arsenic, and at a red heat decomposes oxides of carbon, sulphur dioxide, and many hydrocarbons. Silica and boric acid are readily reduced by it. It combines directly with nitrogen, forming a crystalline nitride Mg_3N_2. It precipitates nearly all the metals from their neutral solutions in the metallic state; aluminium, uranium, and chromium as oxides.

Magnesium may be advantageously employed in place of zinc in toxicological investigations, owing to its freedom from arsenic. It may likewise be used instead of zinc in voltaic batteries, owing to its higher electromotive force (Roussin, J. Pharm. Chim. [iv.] 3, 413).

Alloys.—Magnesium forms malleable alloys with potassium and sodium, which decompose water at ordinary temperatures. 15 parts of magnesium form with 85 parts of tin a brittle lavender-coloured alloy, which also decomposes water. An alloy with 5 p.c. of thallium is stable and more malleable than pure magnesium. With mercury, it does not appear to form an amalgam at ordinary temperatures. Alloys with aluminium, zinc, cadmium, lead, bismuth, antimony, silver, gold, and platinum have also been prepared (Parkinson, Chem. Soc. Trans. 1867, 125) by fusing the metals together in a current of hydrogen, or by fusion in an earthen crucible under a flux of equal parts fluorspar and cryolite, or one part fluorspar with two parts of common salt. The magnesium is attached to the end of an iron rod and well stirred among the other metal, otherwise, being so light, it would float to the top. Triple alloys are also obtained with bismuth and copper, copper and gold, and with

copper and nickel. Most of these alloys are brittle, and of little use in the arts.

Magnesium and zinc form a single compound $MgZn_2$ and no solid solution (Compt. rend. 1910, 904). Broniewski, from his investigations of alloys of aluminium and magnesium, comes to the conclusion that two definite compounds, AlMg and Al_2Mg_3, exist. These form a continuous series of solid solutions. 'Duralumin' is aluminium alloyed with a small percentage of magnesium and copper. It has the property of hardening, like steel, on heating and quenching. Magnesium alloyed with small amounts of zinc gives a strong alloy which can be wrought and rolled, and presents the fracture of fine steel. It resists the action of air and water and can be cast and turned like brass and copper. 'Electron' contains 95 p.c. Mg, 4·5 p.c. Zn, and 0·5 p.c. Cu. Sp.gr. 1·78. The mechanical properties of the alloy are: Yield point 12·0, maximum load 16·1–18·4, crushing load 23·0 tons per sq. in., elongation 13–19 p.c.

Alloys of magnesium and lead containing from 5 to 50 p.c. of magnesium and 95 to 50 p.c. of lead when exposed to moist air rapidly absorb oxygen, and crumble to a black powder consisting of magnesium hydroxide $Mg(OH)_2$ and hydrated lead suboxide, $Pb_2(OH)_2$. It has been suggested that these alloys might be used for removing oxygen in gaseous mixtures as in the case of hydrogen for aircraft purposes (Ashcroft, Trans. Faraday Soc. 1919, 14, 271).

Magnesium oxide. *Magnesia.* MgO. This is the product of the combustion of magnesium in air or oxygen. It is also formed when the carbonate or nitrate is heated in the air. As thus obtained, it is a white amorphous powder, but may be obtained crystallised in cubes and octahedra by heating the amorphous form in a current of hydrogen chloride. If ferric oxide be mixed with the magnesia, brilliant black octahedra of magnoferrite $MgO{\cdot}F_2O_3$ are formed, together with octahedra of MgO, slightly yellow in colour, due to oxide of iron, and identical with those of *periclase*, a mineral found at Monte Somma, near Vesuvius. Moissan obtained transparent crystals of magnesia, sp.gr. 3·654, by distillation of the oxide in the electric furnace. Ordinary magnesia is known in commerce as *magnesia usta* or calcined magnesia, and is much used for medicinal purposes. It is a fine bulky powder of sp.gr. 3·07 to 3·2. The sp.gr. is increased to 3·61 by heating in a pottery furnace.

It melts at 2800° (Kanolt, J. Franklin Inst. 1913, 176, 587), and on solidifying forms a hard enamel, which scratches glass. It is alkaline to litmus, but is not caustic. It is almost insoluble in water; according to Fresenius, it requires 55,368 parts of either cold or boiling water to effect solution. This solution has an alkaline reaction. Magnesia containing 0·1 p.c. of chromic oxide becomes slightly fluorescent after ignition.

Manufacture.—Magnesia is generally obtained commercially by gentle but prolonged heating of the carbonate or by heating the hydroxide. Since the discovery, however, of the immense stores of carnallite, the double chloride of potassium and magnesium, in the saline deposits of Stassfurt, several processes have been patented for utilising the waste magnesium chloride liquor obtained as by-product in the manufacture of potassium chloride.

Schlœsing, in 1881 (Compt. rend. 93, 156, 215), describes the following process for obtaining cheap magnesia. A paste of slaked lime and water containing 34–36 p.c. of calcium oxide is allowed to run through perforations in a metallic plate into a solution of magnesium chloride containing 60–95 grams per litre. As soon as the lime paste reaches the solution it becomes coated with a layer of magnesium hydroxide, which acts like a shell, causing it to form long threads, which are entirely converted into magnesium hydroxide in about 6 days. The hydroxide thus obtained may be washed by diffusion, and, when triturated with water and dried, gives a compact, friable powder, which can of course be converted into calcined magnesia by heating in a suitable furnace. Presence of common salt has no effect on the process, but if soluble sulphates are present, they must be removed by adding some of the calcium chloride solution from a previous operation, allowing to settle, and decanting from the more insoluble calcium sulphate.

Ramdohr, Blumenthal, & Co., in 1881, patented the following process (D. R. P. 19259, Sept. 1881). A solution of magnesium chloride is evaporated until it consists approximately of $MgCl_2{,}6H_2O$. About 4–10 p.c. of magnesite is added, and the mixture heated to redness in a current of air until the evolution of hydrogen chloride ceases. Magnesium oxychloride is left, which, on heating with water, splits up into magnesium hydroxide and chloride.

The United Chemical Works Joint Stock Co., Leopoldshall, in 1882, patented the following process (D. R. P. 20277, Feb. 1882). Burnt lime is treated with a solution of calcium chloride. After removal of the clear liquid, the paste is washed with a fresh solution of calcium chloride, whilst the clear solution in turn is repeatedly digested with fresh lime. A small portion of this solution is then mixed with the magnesium chloride solution in order to precipitate all the iron and sulphuric acid which it contains. The purified magnesium solution is then added to the bulk of the clear calcium solution, which contains calcium oxychloride $3CaO{\cdot}CaCl_2{,}16H_2O$, when pure hydrated magnesium oxide separates out.

According to Meunier (Bull. Soc. Chim. 1919, 25, 560) magnesia may be freed from lime by igniting at a red heat and after cooling extracting with successive portions of a 10 p.c. solution of sucrose until the extract gives no turbidity with ammonium oxalate.

On account of its infusibility, magnesia is now extensively used in the manufacture of firebricks, especially for use in the basic Bessemer steel process. The bricks are made of crushed dead-burnt magnesite mixed with sufficient gently calcined magnesite to give plasticity to the paste formed by mixing the materials with water to permit of moulding. The bricks are fired at a red heat before use.

A kiln described before the Ceramic Society, 1918, for the dead burning of magnesite shows a considerable advance on the older types, both for fuel economy and increased output. The kiln consists of one vertical chamber without contraction at the hot zone. The hottest zone

is lined with magnesite bricks and other parts with best firebrick; the whole having a backing of secondary firebricks. The material is raised by an electric lift and dropped into a charging bell. It gradually descends through the dead burning zone to the cooling region, at the bottom of which it is automatically pushed out into a discharging hopper. The whole process takes about 40 hours, including 3 hours in the dead burning zone. Air for combustion is supplied by a fan through six damper-controlled openings at the bottom, and passes upward through the burnt material, becoming very hot by the time it reaches the level of the gas inlets. A secondary system of air flues constructed in the brickwork (which heat the air) conveys air about two-thirds up the kiln and then downwards again to enter through slits just above the gas ports; these are only used as necessity arises. The gas is generated in a gas producer, and is heated by passing through three flues before it enters through the six ports. With good English coal a temperature of 1700° is attained. The ascending gases leave the kiln at 150°, a suction fan being used to exhaust the gases. The mechanical arrangements of the draughts and process of calcination give complete control. A special feature of the kiln is the rotating bottom, consisting of a conical cast-steel head with ribs on the upper surface carried on a vertical shaft. Its rotation moves the finished material towards the opening and tends to grind any lumps in the calcined product,

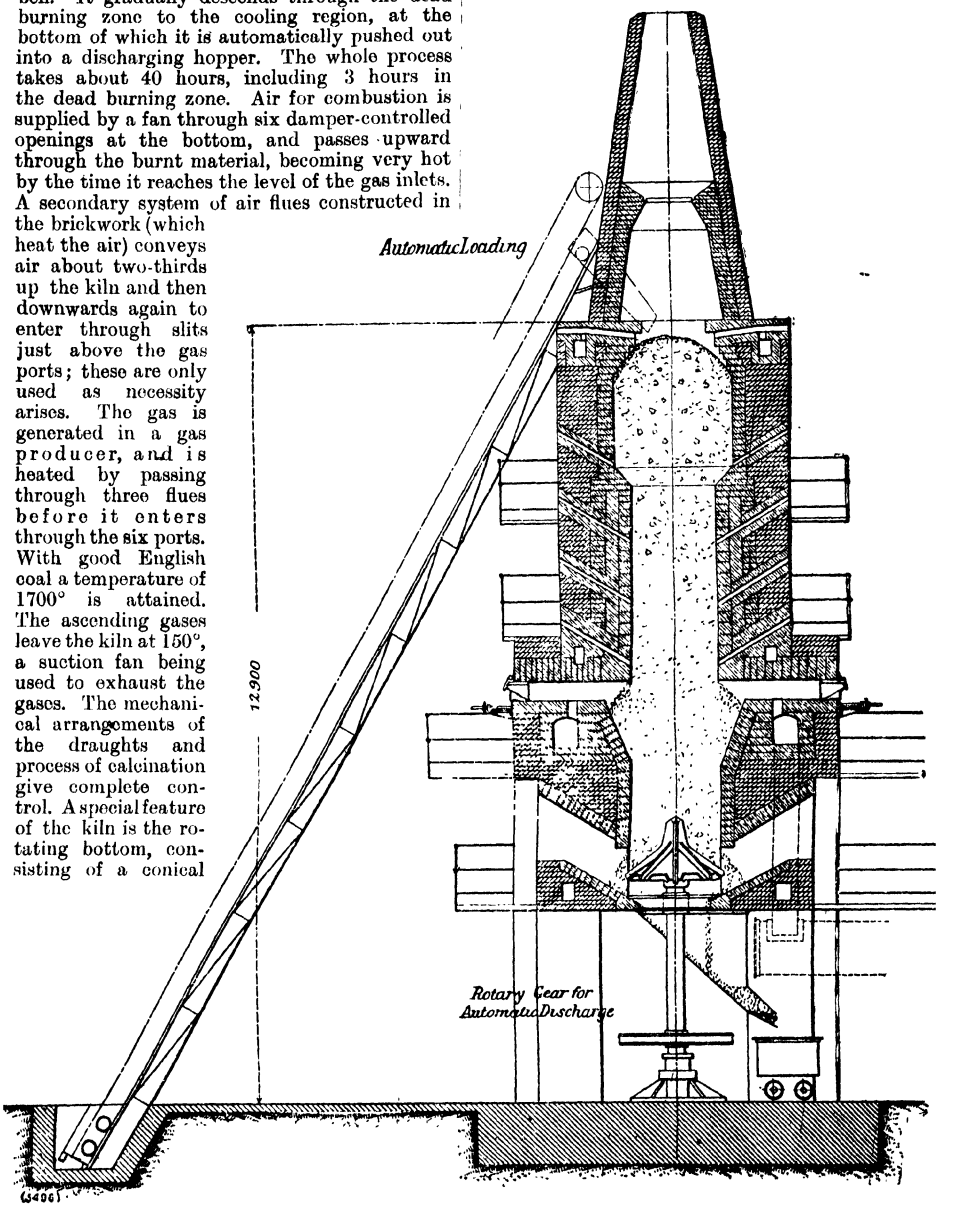

FIG. 1.

(*From* 'Engineering.')

also, by keeping the column in constant motion, it causes the material to descend gradually. The shaft rotates once in 40 minutes and the wear is very slight (Engineering, 1918, p. 619).

Magnesia bricks with high magnesia content, tested by resistance to crushing with increasing temperature, showed a sudden fall between 1500° and 1600°; less pure varieties showed a fall between 1300° and 1400° as compared with 1100° for ferro-chrome brick (Compt. rend. 1917, 165, 488).

Dolomite has also been extensively used for

the preparation of magnesia for refractories. Closson's plan was to mix calcined dolomite with a solution of magnesium chloride, when calcium chloride and magnesia are formed; the calcium chloride can then be washed out. Magnesia may be obtained from dolomite by calcination at 900° and treatment of the solution obtained by lixiviation by ammonium and sodium chlorides, the ammonia being recovered and magnesium hydroxide precipitated by calcined dolomite (U.S. Pat. 1156662, 1915). Many other wet methods for the recovery of magnesia have been employed, but, according to Wedding, magnesia prepared in the wet way, though obtained from cheap waste materials or by-products, is too expensive for the manufacture of bricks.

Magnesia, in combination with lime, also finds an extended use for mortar making in districts where only magnesium limestone is available. The dolomitic limestone is burnt at a lower temperature than ordinary limestone, otherwise its hydrating properties and consequently the quality of the mortar are impaired.

Magnesium suboxide. A substance of this nature appears to be formed when a solution of sodium or ammonium chlorides is electrolysed, using poles of magnesium wire, the positive pole becoming covered with a black deposit (Beetz, J. 1866, 172). The same substance is also obtained when magnesium is immersed in solutions of chlorides of the alkalis and alkaline earths, common salt giving the largest deposit. In a few days it disappears, being replaced by the ordinary white oxide. It turns white when heated just below redness. It dissolves in nitric acid with partial reduction of the acid. It readily dissolves in hydrochloric and sulphuric acids with effervescence, forming the ordinary chloride and sulphate (Gore, Chem. News, 50, 157).

It is also obtained as a dark brown substance when chlorides of magnesium and potassium are electrolysed. It is without action on a solution of nickel chloride in absolute alcohol (metallic magnesium precipitates nickel). It decomposes water evolving hydrogen. It is not formed if oxygen is completely excluded from the electrolyte (Trans. Amer. Electrochem. Soc. 27, 209).

Magnesium hydroxide $Mg(OH)_2$ occurs native as the mineral *brucite*, crystallising in the rhombohedral section of the hexagonal system. The hydroxide is precipitated as a white powder when the hydroxide of potassium or sodium is added to the solution of a magnesium salt. De Schulten (Compt. rend. 101, 72) obtained it in the form of flattened hexagonal prisms, of sp.gr. 2·36 at 15°, by heating a mixture of 12 grams crystallised magnesium chloride $MgCl_2,6H_2O$, 340 grams of potash, and 60 c.c. of water, at 210°–220°. The solid residue, after washing away the alkali, consisted of these small crystals of the hydroxide. They were readily soluble in acids and in a warm solution of ammonium chloride.

Magnesium hydroxide slowly absorbs carbon dioxide from the air. At a low red heat it loses its water, becoming converted into the oxide. This calcined magnesia is again capable of taking up water, with evolution of heat, to reform the hydroxide, provided that it has not been too strongly heated Magnesium oxide obtained by igniting magnesite at 1450° was only hydrated to the extent of 70 p.c. in 6 years.

Magnesium hydroxide is much used upon the Continent for extracting sugar from molasses; it forms an insoluble granular crystalline magnesium saccharate, which when decomposed by carbon dioxide yields pure sugar.

In order to meet this demand, the Consolidated Alkali Company of Stassfurt manufacture large quantities of magnesium hydroxide by the following process. The 3 p.c. of sulphates contained in the last mother liquor from the extraction of potassium chloride from carnallite are first removed by means of a solution of calcium chloride. A quantity of milk of lime is then added rather less than sufficient to decompose the whole of the magnesium chloride; the precipitated magnesia is allowed to settle and then passed through filter presses, in which it is thoroughly washed. The magnesium hydroxide thus obtained contains only 0 1 p.c. of calcium sulphate, and is eminently suitable for the purpose of the sugar refiner (Hake, J. Soc. Chem. Ind. 2, 149).

Magnesia prepared by heating the nitrate is converted by prolonged immersion in water into a form of the hydroxide having the density of marble, but harder and more translucent. A similar form, but contaminated with oxide of iron and aluminium, magnesium carbonate and sand, is also obtained by action of water upon the product of the ignition of commercial magnesium chloride. This singular property of hardening is only possessed by magnesia prepared by ignition of the nitrate or chloride at a moderate red heat. After heating to whiteness it appears to lose it. Ignition of native magnesite at the lowest possible temperature also yields a product possessing the same hydraulic property, but the basic carbonates of commerce yield a perfectly soft hydroxide. The paste prepared from calcined magnesite and water hardens in about half a day, and afterwards not only withstands the action of water, but actually acquires in contact with it the hardness of the best Portland cement.

A mixture of magnesia with a concentrated solution of magnesium chloride of sp gr. 1·16–1·26 hardens in a short time to a compact mass of basic chloride, which resists the action of water. The pasty mixture is very plastic, and is capable of binding more than twenty times its weight of sand.

Magnesium chloride $MgCl_2$ is one of the salts present in sea-water and in the water of many springs. It also occurs combined with potassium chloride in large quantities as the mineral *carnallite* $MgCl_2{\cdot}KCl,6H_2O$ in the Stassfurt deposits. It is formed when magnesium burns in chlorine, or when a stream of chlorine is passed over a heated mixture of magnesia and carbon. It is also produced by dissolving the metal, oxide, or carbonate, in hydrochloric acid. On concentration of the solution monoclinic crystals of the composition $MgCl_2,6H_2O$ separate out. Crystals of this composition have also been discovered, associated with carnallite and rock salt, at Stassfurt, and named *bischofite*. On attempting to obtain the anhydrous chloride by ignition of these crystals, hydrochloric acid is evolved in addition to water, and a portion of the chloride becomes

converted to oxide. If, however, the crystals be heated in a current of hydrogen chloride, the anhydrous chloride is obtained without the formation of any basic salt (Hempel, Ber. 21, 897). Another method of obtaining the anhydrous chloride is to add ammonium chloride to the solution, evaporate to dryness, and ignite in a platinum dish The magnesium ammonium chloride thus formed loses its water without any decomposition of the magnesium chloride, and the ammonium chloride can then be sublimed out, leaving the anhydrous magnesium chloride as a clear fused mass, which on cooling solidifies to a crystalline solid. Magnesium chloride is a solvent for the crystallisation of metallic oxides. Octahedral crystals of 'magnesia-red' can be obtained by heating $MgCl_2$ with cobalt sulphate. By a similar process, nickel sulphate gives rise to octahedral crystals of 'magnesia green.' The crystals are a mixture of the two oxides. 100 parts of water at 0° dissolve 52·2 parts of the anhydrous chloride, with considerable evolution of heat, forming a solution of sp.gr. 1·3619 at 15° (Engel, Bull. Soc. chim. [ii.] 47, 318). At the ordinary temperature 100 parts of water dissolve about 130 parts, and at 100° about 366 parts. This solution on cooling again deposits the crystals. Magnesium chloride solution possesses a bitter taste. The solid, either anhydrous or crystals, is very deliquescent. It combines directly, with evolution of heat, with methyl and ethyl alcohols, the solutions yielding, on cooling with ice, crystals of $MgCl_2,6CH_3OH$ and $MgCl_2,6C_2H_2OH$, respectively.

Commercial preparation.—The last mother liquor obtained in the process of preparing potassium chloride from the carnallite at Stassfurt supplies as by-product large quantities of magnesium chloride. The liquor has a sp.gr. of 1·32, and contains no less than 35 p.c. of the chloride. It is first evaporated to sp.gr. 1·34, when potassium and sodium chlorides and magnesium sulphate separate out. The hot concentrated liquor is then run into casks, where on cooling it solidifies to a white translucent mass containing 50 p.c. of magnesium chloride. In this state it is largely exported to this country, being used by cotton-spinners as a thread lubricator (Hake, J. Soc. Chem. Ind. 2, 149).

Lanquetin, in 1881, patented (D. R. P. 20396) a process for preparing magnesium chloride by introducing burnt magnesite or dolomite into a solution of waste calcium chloride, and driving carbon dioxide through the mixture, when calcium carbonate separates out and magnesium chloride remains in solution.

Cochrane and Bramley, of Middlesbrough (Eng. Pat. 15498, Nov. 1886), charge hydrated magnesium carbonate into a series of closed vessels through which a solution of calcium chloride is circulated, carbon dioxide being at the same time injected. Magnesium chloride is in this case gradually formed in solution and calcium carbonate precipitated.

Magnesium chloride may also be extracted from the mother liquor of the potassium chlorate manufacture (Muspratt and Eschellmann, Widnes, Eng. Pat. 1900, Feb. 1885).

Magnesium chloride unites with the alkaline chlorides to form crystalline double salts.

Magnesium chloride solution is preferable to brine as a refrigerating medium. As it is more viscous than brine it is less liable to spray or splash, and its freezing point is lower than brine of the same concentration.

Magnesium potassium chloride

$MgCl_2 \cdot KCl,6H_2O$

the carnallite of Stassfurt, crystallises in colourless deliquescent rhombic prisms. On heating, the water is driven off without loss of chlorine, the anhydrous mixture fusing at a red heat. The native carnallite used at Stassfurt for the extraction of potassium and magnesium chlorides has the following average composition (Hake, J. Soc. Chem. Ind. 2, 149):

KCl	16·2	$CaCl_2$	0·2
$MgCl_2$	24·3	Clay and $CaCO_3$	2·1
$MgSO_4$	9·7	H_2O	28·8
NaCl	18·7		

Magnesium ammonium chloride

$MgCl_2 \cdot NH_4Cl,6H_2O$

is deposited from mixed solutions of magnesium and ammonium chlorides in small rhombic crystals.

The corresponding sodium salt appears to contain only one molecule of water (Poggiale, Compt. rend. 20, 1130).

Magnesium calcium chloride, *Tachydrite*, $2MgCl_2 \cdot CaCl_2,12H_2O$, is also found at Stassfurt in deliquescent yellowish masses.

Magnesium oxychlorides. When highly calcined magnesia is treated with a strong solution of magnesium chloride, it dries in a few hours to a hard mass of oxychloride, capable of receiving a polish. A sample prepared in this manner, and hardened by 6 months' exposure in the air, was found to consist of a mixture of $MgCO_3$ with a compound,

$MgCl_2 \cdot 5MgO,17H_2O$

On heating to 180° it was converted into $MgCl_2 \cdot 5MgO,6H_2O$. By prolonged treatment with water the whole of the magnesium chloride was extracted, and the compound $2MgO \cdot 3H_2O$ left. This residual hydrate is a compact solid as hard as sandstone, possessing a brilliant surface, and taking a high polish; its cohesive power is not impaired by either cold or hot water (Bender, Annalen, 159, 341).

Magnesium oxychloride is the essential constituent in Sorel cement, usually made by adding a solution of magnesium chloride to finely ground calcined magnesite; when mixed with various filling materials, such as wood flour, cork, talc, silica, asbestos, clay, marble dust, or sand, it is frequently used in the construction of 'sanitary flooring.' It was stated that magnesia cement was used by the Germans for gun emplacements, as it sets quickly, produces a smooth, even floor, which may be laid in large areas without cracking, and attains great strength sooner than Portland cement.

The crystalline deposit frequently found in bottles containing magnesia mixture (magnesium sulphate or chloride, ammonia and ammonium chloride) consists of a hydrated oxychloride $MgCl_2 \cdot 5MgO,13H_2O$. On washing the crystals with a large quantity of water the whole of the chloride may be removed, the residue consisting of hydrated oxide (Davis, Chem. News, 25, 258).

By mixing freshly calcined magnesia with a

solution of magnesium chloride in a flask well corked and nearly filled with the liquid, and heating on a water-bath with frequent agitation, needle-shaped crystals of an oxychloride are formed. When washed and dried at 110° they consist of $MgCl_2 \cdot 10MgO.14H_2O$. The dry crystals are not attacked by carbon dioxide, but when moist are decomposed (Krause, Annalen, 165, 38).

When 20 grams of calcined magnesia are boiled with a solution of 400 grams magnesium chloride in 500 grams of water and the solution filtered, the filtrate deposits needles of $MgCl_2 \cdot MgO,16H_2O$. When dried *in vacuô* they are converted into $MgCl_2 \cdot MgO,6H_2O$. Both salts are decomposed by water and alcohol (André, Compt. rend. 94, 444).

When crystallised magnesium chloride is heated in air, an oxychloride of variable composition appears to be left, a portion of the chlorine passing away in the form of hydrochloric acid. If the chloride be heated to a sufficiently high temperature in a current of air a certain amount of free chlorine is evolved; and if a mixture of hydrogen chloride and air is passed over the heated chloride, especially in presence of a little free magnesia, a larger quantity of chlorine is obtained in the free state. This reaction forms the basis of the Weldon-Pechiney process of manufacturing chlorine, as worked at Salindres (Weldon, Eng. Pat. 9307, June, 1884; 11036, Aug. 1884). A solution of magnesium chloride is first evaporated down until it consists approximately of $MgCl_2,6H_2O$. This is then converted to oxychloride by addition of $1\frac{1}{2}$ equivalents of calcined magnesia. This oxychloride is crushed and sifted, solid pieces free from dust being eventually chosen not larger than the size of a walnut. It is next heated to remove a portion of its water, and finally decomposed by heating to a high temperature in a current of air. The furnace employed for the latter process is constructed upon the principle of a baker's oven. It consists of a series of vertical chambers, the thickness of the dividing walls of which is greater than the width of the spaces between them. Before charging these spaces with the small lumps of oxychloride, products of combustion are passed through them until the dividing walls are raised to a high temperature. After charging, the oxychloride becomes heated by contact with the walls, and a mixture of chlorine, nitrogen, excess of air, and hydrogen chloride is evolved. The hydrochloric acid is condensed in ordinary towers, and the remaining gases pass on to the bleaching powder chambers. The magnesium remains as oxide, the oxygen being furnished by a regulated supply of air, and is afterwards partly dissolved in the condensed hydrochloric acid for preparation of more oxychloride (Weldon, J. Soc. Chem. Ind. 4, 175). The reactions occurring in the process are probably as follows:

(1) $H_2O+MgCl_2=MgO+2HCl$.
(2) $2HCl+O=H_2O+Cl_2$.
(3) $MgCl_2+O=MgO+Cl_2$.

(Kingzett, J. Soc. Chem. Ind. 7, 286).

Nithack (D. R. P. May 29, 1884) decomposes magnesium chloride for the preparation of chlorine by injecting a fine spray of the solution into heated chambers, when the same reactions occur.

Mond (Brit. Assoc. 1896, 741) modified the process for recovering both ammonia and chlorine from the ammonium chloride produced in the ammonia soda process. Magnesia is mixed with a little china clay and potassium chloride to facilitate the production of a perfectly anhydrous chloride. The mixture is made into pills and placed in towers. These are heated from a previous operation to 300°; the ammonium chloride vapour is passed through, producing ammonia and magnesium chloride. Air at 600° is then circulated, when free chlorine is liberated and magnesia reformed. Hence the process becomes continuous.

Hermite (J. Soc. Chem. Ind. 7, 726, 737) prepares chlorine for bleaching purposes by the electrolysis of a solution of magnesium chloride.

Magnesium bromide $MgBr_2$ (m.p. 711°) occurs in sea-water and many salt springs. It resembles the chloride, being deposited from a solution of magnesia in hydrobromic acid in needles of $MgBr_2,6H_2O$, which behave like the chloride on heating.

Magnesium iodide MgI_2 also occurs in sea-water and saline springs, and may be obtained by dissolving magnesia in hydriodic acid, when deliquescent crystals separate, which readily evolve iodine on warming.

Magnesium fluoride MgF_2 occurs native in the mineral *sellaïte* in colourless quadratic crystals, and may be prepared in an amorphous form by evaporating magnesia with excess of hydrofluoric acid. When the amorphous form is fused with sodium chloride and gradually cooled, it is obtained, after washing with water, in crystals resembling those of sellaïte.

Feldmann (Eng. Pat. 15295, Nov. 1887) patented a process for an industrial preparation of this salt. Magnesium chloride is treated with calcium fluoride in either the dry or the wet way. In the former the fluorspar is mixed with the anhydrous chloride in excess, and the mixture fused at a red heat, when $CaCl_2$ and MgF_2 are formed. After cooling, the mass is lixiviated, when the magnesium fluoride remains behind. In the wet method powdered fluorspar is suspended in a concentrated solution of magnesium chloride and heated till double decomposition occurs, water being added to make up the loss by evaporation. It is then allowed to cool, when the mass solidifies and is lixiviated as before. Any undecomposed calcium fluoride may be removed by elutriation from the specifically lighter magnesium fluoride.

A double fluoride of magnesium and sodium $MgF_2 \cdot NaF$ is obtained in insoluble cubical crystals by fusing magnesium chloride with a large excess of sodium fluoride and chloride and allowing to cool slowly. Also in the amorphous state by boiling a solution of sodium fluoride with magnesia.

Magnesium carbide has not been isolated in the pure state. It is obtained mixed with carbon by heating magnesium powder to redness in the vapour of benzene (Parkinson) or acetylene (Berthelot). According to Moissan, it is completely decomposed in the electric furnace, which explains why magnesia can be fused in a carbon crucible without reaction (Ann. Chim. Phys. [vii.] 16, 151).

Novák (Zeitsch. physikal Chem. 73, 513) obtained the carbide by heating magnesium in a tube at a definite constant temperature and passing over it a definite volume of a gaseous hydrocarbon. He obtained two carbides, MgC_2 and Mg_2C_3, and their decomposition with water proceeds according to the equations

$$MgC_2+2H_2O=Mg(OH)_2+C_2H_2$$
$$Mg_2C_3+4H_2O=2Mg(OH)_2+C_3H_4$$

The formation of MgC_2 by acetylene commences at 400°C. At 460° the presence of Mg_2C_3 in the product can be proved and the proportion increases up to 545°.

Magnesium carbonate $MgCO_3$ occurs native as *magnesite* in rhombohedral crystals isomorphous with those of calcite. It is also found in large compact or granular masses, and, associated with calcium carbonate, as *dolomite* $(MgCa)CO_3$, in immense quantities all over the world. The amorphous precipitate formed when an alkaline carbonate is added to a solution of a magnesium salt has the composition

$$MgCO_3,2H_2O$$

but after standing an hour or two at a temperature below 16°, it becomes converted into tabular crystals of $MgCO_3,5H_2O$. If the temperature exceeds 22° it beomes converted into prismatic crystals of $MgCO_3,3H_2O$. Between 16° and 22° both these hydrates are formed. The amorphous precipitate is decomposed by water into a basic carbonate of the composition

$$5MgO\cdot4CO_2,11H_2O$$

or $5(MgCO_3,2H_2O)$, in which one molecule of $MgCO_3$ has been converted into $Mg(OH)_2$. This basic carbonate absorbs carbon dioxide from the air, and becomes $MgCO_3,2H_2O$ again (Engel, Compt. rend. 100, 911). According to Marignac, normal magnesium carbonate is also formed by the action of magnesium chloride on calcium carbonate.

When the precipitated carbonate is suspended in water and dissolved by the passage of a current of carbon dioxide, on evaporation of the solution the anhydrous carbonate is precipitated in minute crystals isomorphous with aragonite, the rhombic form of calcium carbonate. On the other hand, when mixed solutions of a soluble magnesium salt and an alkaline bicarbonate supersaturated with carbon dioxide are inclosed in a strong vessel closed by a cork, through which the carbon dioxide is slowly allowed to escape, microscopic rhombohedrons of the anhydrous carbonate resembling those of native magnesite and calcite are deposited.

Both the natural and artificial varieties of magnesium carbonate give an alkaline reaction with litmus solution. They dissolve slowly in acids with but little effervescence.

Magnesium carbonate dissolves in water saturated with carbon dioxide. According to Engel (Compt. rend. 100, 444, 1224) the solubility at constant temperature is proportional to the cube-root of the pressure of the carbon dioxide. The results of a large number of experiments agreed with those calculated from the general formula $x^{0\cdot333}=ky$ or $y=\frac{1}{k}\sqrt[3]{x}$, where x represents the pressure of carbon dioxide, y the quantity dissolved, and k a constant $=0\cdot03814$. At different temperatures under atmospheric pressure the amount of magnesium carbonate dissolved is proportional to the coefficient of solubility of carbon dioxide at the particular temperature. The following table is given by Engel and Ville (Compt. rend. 93, 340) showing the solubility first at constant temperature and second at constant pressure :

Atmospheres pressure	Temperature	$MgCO_3$ dissolved in a litre of water
	°	
1·0	19·5	25·79
2·1	19·5	33·11
3·2	19·7	37·30
4·7	19·0	43·50
5·6	19·2	46·20
6·2	19·2	48·51
7·5	19·5	51·20
9·0	18·7	56·59
mm. pressure		
751	13·4	28·45
763	19·5	25·79
762	29·3	21·94
764	46·0	15·70
764	62·0	10·35
765	70·0	8·10
765	82·0	4·90
765	90·0	2·40
765	100·0	0·00

When the solution in carbonic acid is left to evaporate spontaneously, or kept in a partially closed flask for some time at 50°, it deposits small hexagonal prisms of $MgCO_3,3H_2O$, which effloresce in air, becoming opaque. At a winter temperature the same solution deposits monoclinic prisms of $MgCO_3,5H_2O$. Warmed with water at 50°, they are converted into the trihydrate, whilst on boiling with water they lose carbonic acid and become converted eventually into the basic carbonate

$$2MgCO_3\cdot Mg(OH)_2,2H_2O.$$

Saturated solutions of magnesium hydrogen carbonate deposit between 65° and the boiling point a basic carbonate, $4MgO,3CO_2,6H_2O$, in the form of slender needles. Between 65° and 55°, the basic carbonate separates, mixed with the trihydrate, $MgCO_3,3H_2O$, below 55°, the trihydrate alone is formed down to about 6°, and at 2° the unstable pentahydrate is formed (Leitmeier, Z. Kryst. Min. 1909, 47, 104).

Basic carbonates. A basic carbonate of the composition $3MgCO_3\cdot Mg(OH)_2,3H_2O$ occurs native as *hydromagnesite* in small white monoclinic crystals of sp.gr. 2·14–2·18. A salt of the same composition is also obtained by mixing magnesium sulphate with excess of a hot solution of potassium carbonate and boiling the precipitate with fresh quantities of water so long as acid carbonate dissolves out. Also by boiling a saturated solution of the acid carbonate, and twice boiling the precipitate produced with fresh quantities of water. When dried at 100° in the air it absorbs carbon dioxide, and is converted into $5MgO\cdot4CO_2,5H_2O$.

Another basic carbonate of the composition $2MgCO_3\cdot Mg(OH)_2,2H_2O$ is obtained as above from the solution of the normal carbonate in carbonic acid. Also, according to Fritzsche (Pogg. Ann. 37, 310), by precipitating magnesium sulphate with a very large excess of sodium

carbonate and boiling till granular, then washing rapidly three times with fresh boiling water.

Commercial carbonates. The commercial preparation known as *magnesia alba* is a basic carbonate of slightly varying composition, according to the conditions of production. It is usually prepared by precipitation of either the commercial sulphate or chloride of magnesium with sodium carbonate. As thus obtained it is a very light bulky powder, and is distinguished as *magnesia alba levis*. If the precipitation is carried on at a higher temperature by the addition of one volume of a cold saturated solution of sodium carbonate to a boiling mixture of one volume of a saturated solution of magnesium sulphate with thirty volumes of water, the precipitate washed with hot water and dried at 100°, a denser form is obtained known as *magnesia alba ponderosa*. The composition of the light variety is generally given as the same as that of hydromagnesite

$$5MgCO_3 \cdot Mg(OH)_2, 3H_2O$$

Beckurts (Arch. Pharm. [iii.] 18, 429; 19, 13), however, deduces the formula

$$5MgCO_3 \cdot 2Mg(OH)_2, 7H_2O$$

but also found several specimens of the hydromagnesite formula, but containing $4H_2O$. Kraut (Arch. Pharm. [iii.] 20, 180) gives

$$4MgCO_3 \cdot Mg(OH)_2$$

as the correct formula. Hence it appears likely that different samples vary somewhat in composition. As representing the composition of the heavy variety, Beckurts (*l.c.*) gives the formula $3MgCO_3 \cdot Mg(OH)_2, 4H_2O$, which only differs from that of hydromagnesite by one molecule of water.

Magnesia alba levis and *ponderosa* yield upon calcination corresponding light and heavy varieties of the oxide, known in commerce as *magnesia usta levis* and *magnesia usta ponderosa*.

Another method of preparing *magnesia alba* was patented by Pattinson. This consists in treating slightly ignited dolomite with water and carbon dioxide under a pressure of 5–6 atmospheres. So long as any magnesium carbonate remains undissolved, the calcium carbonate is unattacked, the acid magnesium carbonate being much more readily formed. This solution of hydrogen magnesium carbonate is decanted from the calcium carbonate and heated by injection of steam, when *magnesia alba* is precipitated as a white bulky powder of loose texture. Unignited dolomite does not yield any acid carbonate with carbonic acid.

Bramley and Cochrane, of Middlesbrough, patented a process (Eng. Pat. 13762, Oct. 1886) in which magnesia is added to the solution of an alkaline bicarbonate or sesquicarbonate and the mixture heated and agitated. The alkaline carbonate is converted to a normal carbonate, and hydrated magnesium carbonate formed. The operation is performed in closed vessels to prevent loss of carbon dioxide.

Magnesia alba can also be profitably prepared from sea-water (Gutzkow, Dingl. poly. J. 270, 30). The mother-liquor (bittern) obtained after extraction of common salt (bay-salt) is treated with milk of lime; the precipitated magnesium hydroxide is allowed to settle, the supernatant liquid removed by decantation, and the precipitate stirred up with water through which a stream of carbon dioxide is passed. The hydroxide is dissolved as acid carbonate. The clear solution is then heated rapidly to 70°, and afterwards more gradually to the boiling-point. The precipitated *magnesia alba* is filtered off and dried on plates heated by steam. If necessary, the original mother-liquor may first be freed from organic matter by treatment with alum.

Magnesia alba is almost insoluble in water, but dissolves readily in solutions of ammonium salts owing to the formation of soluble double salts of magnesium and ammonium and ammonium carbonate.

Magnesium ammonium carbonate

$$MgCO_3 \cdot (NH_4)_2CO_3, 4H_2O$$

separates in rhombohedral crystals from a mixture of cold aqueous solutions of magnesium sulphate or chloride and excess of ammonium carbonate and free ammonia.

Magnesium potassium carbonate

$$MgCO_3 \cdot K_2CO_3, 4H_2O$$

is obtained in small rhombic prisms when *magnesia alba* is digested with a solution of acid potassium carbonate for 15 hours at 60°–70°.

A salt of the composition

$$MgCO_3 \cdot HKCO_3, 4H_2O$$

is obtained in large crystals from a cold aqueous mixture of magnesium chloride or nitrate with excess of acid potassium carbonate. Engel (Compt. rend. 100, 1224) obtained the same salt by decomposing a solution of the acid magnesium carbonate with potassium bicarbonate, and also by direct action of the potassium bicarbonate upon normal magnesium carbonate.

Magnesium sodium carbonate $MgCO_3 \cdot Na_2CO_3$ is similarly obtained in small anhydrous crystals by digesting *magnesia alba* with sodium bicarbonate.

Magnesium nitride Mg_3N_2. Magnesium combines directly with nitrogen when heated to redness. It is also one of the products of the incomplete combustion of magnesium in air. Matignon (Compt. rend. 1912, 154, 63) states that oxygen is absorbed at a temperature of 600° and nitrogen at 670°. At the latter temperature and atmospheric pressure, oxygen is absorbed at least 1000 times more rapidly than nitrogen. The nitride is conveniently obtained by the interaction of finely divided magnesium and ammonia. From the heat developed when the nitride is decomposed by dilute sulphuric acid the heat of formation is calculated to be +119·7 cals. It is a greenish-yellow amorphous body which decomposes slowly in humid air, yielding ammonia and magnesia, rapidly in contact with water with elevation of temperature. Hydrochloric and nitric acids decompose it yielding ammonia and the magnesium salt. With sulphuric acid it yields sulphur dioxide and magnesium sulphate. Argon does not combine with magnesium.

Magnesium amide. Anhydrous liquid ammonia dissolves magnesium to a slight extent, producing a blue solution which decomposes gradually with the formation of the amide and the liberation of hydrogen.

Mixtures of liquid ammonia and acetylene react with metallic magnesium at the ordinary temperature, and on evaporation of the solution

the crystalline compound $MgC_2,C_2H_2,5NH_3$ is obtained together with ethylene and a small quantity of ethane. At atmospheric pressure this compound loses a portion of its ammonia when the temperature reaches 2° and is converted into the compound $2MgC_2,2C_2H_2,7NH_3$ which is stable up to 60° at which temperature acetylene and ammonia are given off, leaving a residue consisting of magnesium amide and nitride, together with a little carbide (J. Phys. Chem. 18, 85). Potassium ammono-magnesiate is obtained by the action of potassamide on magnesium amide in liquid ammonia solution (J. Amer. Chem. Soc. 37, 2295).

Magnesium nitrate $(Mg(NO_3)_2$ occurs in the mother-liquors of the saltpetre manufacture, and also frequently in well-water. It may readily be prepared by dissolving *magnesia alba* in nitric acid and evaporating to small bulk, when monoclinic prisms and needles of the hydrated salt $Mg(NO_3)_2,6H_2O$ separate out. These are soluble in half their weight of cold water, and also in nine times their weight of alcohol of sp.gr. 0·84, with which magnesium nitrate forms an alcoholate of the composition $Mg(NO_3)_2,6C_2H_6O$. When dried over sulphuric acid the hydrated salt loses four molecules of its water, and at the temperature of melting lead another molecule is evolved, leaving the salt $Mg(NO_3)_2,H_2O$. When this latter salt is heated to a still higher temperature the last molecule of water is given off, together with part of the nitric acid, and a tri-magnesium nitrate $Mg_3(NO_4)_2$, analogous to the tri-orthophosphate, is left.

Magnesium borate. When magnesium oxide in slight excess is heated with a mixture of boric anhydride and potassium hydrogen fluoride in molecular proportions, the borate $3MgO,B_2O_3$ is obtained in transparent acicular crystals which are soluble in inorganic acids but not in acetic acid or water.

Magnesium phosphide Mg_3P_2 may be obtained by heating magnesium filings with red phosphorus (Parkinson) or by passing phosphorus vapour over magnesium filings, heated to redness, in a current of carbon dioxide. Gautier obtained it crystalline by heating red phosphorus and magnesium in a graphite boat, then driving off the excess of phosphorus in a current of hydrogen (Compt. rend. 128, 1167). It decomposes water, yielding phosphoretted hydrogen and magnesium hydroxide.

Tri-magnesium orthophosphate $Mg_3(PO_4)_2$ is found in the ashes of plants and animals and combined with fluorine occurs in nature as *wagnerite* $Mg(MgF)PO_4$. It may be prepared by adding magnesium sulphate in excess to a solution of trisodium phosphate and boiling. It is a white amorphous powder containing $5H_2O$, which on calcining loses water and becomes phosphorescent.

Di-magnesium orthophosphate $Mg_2H_2(PO_4)_2$ is formed by precipitating a solution of a magnesium salt with normal sodium phosphate. If the solution is dilute it separates in hexagonal needles containing seven molecules of water. It occurs in the fæces of man (*cf.* Balareff, Zeitsch. anorg. Chem. 1918, 102, 241).

Ammonium magnesium phosphate

$$MgNH_4PO_4,6H_2O$$

is formed as a crystalline precipitate when sodium phosphate is added to an ammoniacal solution of a magnesium salt. The precipitate is almost insoluble in water and still less so in ammonia. It serves for the quantitative estimation of both magnesia and phosphoric acid. The compound occurs in nature in well-formed crystals known under the name of *struvite*.

Magnesium pyrophosphate $Mg_2P_2O_7$ is obtained by igniting either ammonium magnesium phosphate or the acid phosphate.

Magnesium sulphide MgS is formed by heating magnesium filings in the vapour of sulphur or sulphuretted hydrogen. So obtained it is a grey amorphous material which is difficultly fusible even in the electric furnace (Mourlot, Compt. rend. 127, 180). Tiede (Ber. 1916, 49, 1745) states that the sulphide prepared by the method of Mourlot contains only 8 p.c. of sulphur. Reichels' process of heating magnesium in a current of hydrogen followed by hydrogen mixed with sulphur gave a product containing 30 to 50 p.c. sulphur. This was purified by heating it in a highly evacuated quartz tube to 600°–700° for two hours, when the excess of metal volatilised. It was also obtained by boiling the crude sulphide (10 grams) with fresh absolute ether (100 c.c.), ethyl iodide (19 grams), and a crystal of iodine for three hours, moisture being rigorously excluded. The metal dissolves in the alkyl iodide whilst the sulphide is unaffected. The purified sulphide was washed with ether and dried in a vacuum.

It is an amorphous powder of reddish-white colour and feebly luminescent after exposure to daylight or the arc light. Luminosity is best excited by rays of long wave length. Radium, X-, and ultra-violet rays did not excite it. When exposed to cathode rays magnesium sulphide shows a bright blue and red fluorescence with a feeble after-glow. Magnesium sulphide containing bismuth exhibits an intensely blue phosphorescence which is excited by daylight or arc or mercury-vapour light. Specimens containing antimony have a delicate yellow colour and a persistent, intensely yellow-green phosphorescence after excitation by daylight or particularly by exposure to cathode rays. It is decomposed by cold water with the formation of magnesium hydrogen sulphide. In warm water it is said to form polysulphides, and on boiling, hydrogen sulphide is evolved leaving only hydrated magnesia.

Magnesium sulphite $MgSO_3$. When water containing magnesium hydroxide in suspension is saturated with sulphur dioxide, the solution concentrated *in vacuo* at a temperature below 100° and then allowed to cool, rhombohedral crystals of $MgSO_3,6H_2O$ are deposited (Hartog, Compt. rend. 104, 1793).

A basic magnesium sulphite of the composition $MgSO_3{\cdot}2Mg(OH)_2$, similarly prepared by passing sulphur dioxide into water holding magnesia in suspension, is used in sugar factories (Bergreen and Licht, Bied. Centr. 1884, 201). The bisulphite is prepared by passing sulphur dioxide into a solution of the sulphite or by the action of sulphurous acid solution on magnesite. Solution of the bisulphite mixed with sulphide are used for extracting cellulose from material containing lignin and pectic substances. Magnesium bisulphite is said to

have more solvent action on the free resins of wood than lime. It is more stable than calcium bisulphite and dissolves the non-cellulose matter more completely.

Magnesium sulphate (*Epsom salts*) $MgSO_4$ occurs in the mineral *kieserite* $MgSO_4,H_2O$, in the Stassfurt salt beds; and as *epsomite*

$$MgSO_4,7H_2O$$

in the gypsum quarries of Montmartre, in Spain, Chile, and in the Mammoth Cave, Kentucky. Kieserite is occasionally found in rhombic prisms, but more generally occurs in granular masses. Epsomite is found both in the massive state and in silky fibrous crystals. Natural crystals of epsomite more than a centimetre long have also been found coating the walls of a gypsum quarry in the Department of Hérault, France. The sulphate was in a constant state of exudation, and as it solidified formed a lustrous coating of crystals upon the surface of the gypsum (De Rouville, Compt. rend. 87, 703).

Magnesium sulphate forms the purgative principle of bitter spring waters (hence its name of Bitter salt) such as those of Bath, and Seidlitz, Saidschütz, and Püllna in Bohemia. At the three latter places it is obtained by digging pits into which the bitter water runs, and allowing the solution thus collected to evaporate in shallow pans.

The magnesium sulphate of commerce is now chiefly obtained from the kieserite of Stassfurt.

The crude kieserite obtained from the upper layers (Abraumsalz) of the Stassfurt beds is first freed from magnesium and sodium chlorides by being placed in large sieves, standing in tanks of water. The two salts mentioned dissolve out, whilst the kieserite, which is very sparingly soluble in water, falls through the meshes of the sieves in a state of fine powder. Any gangue or other impurities such as anhydrite or larger lumps of rock salt remain behind in the sieves. The kieserite powder is then packed into conical wooden moulds, where it sets to a compact solid, owing to its combining with six more molecules of water to form epsomite. This solid 'stone' is then dried and afterwards powdered. In this condition it contains from 80 to 90 p.c. of $MgSO_4$ and about 1 to 2 p.c. of sodium chloride. A large quantity is brought into the market in this form. The rest is crystallised from water and brought into commerce as Epsom salts

Another mode of manufacturing magnesium sulphate, which was almost universally employed before the working of the Stassfurt beds, consists in decomposing dolomite, magnesium limestone $(CaMg)CO_3$, with oil of vitriol. As calcium sulphate is only sparingly, while magnesium sulphate is readily soluble, the separation offers no difficulty.

The dolomite is first calcined, when on treating the hot mass with a small quantity of water it is readily broken up into powder. This powder is then suspended in water in large digesters constructed of wood lined inside with lead and Yorkshire flags. For a digester 6 feet square and 7 feet deep, about 3 tons of dolomite would form a convenient charge. Into this emulsion are then poured the contents of twelve carboys of sulphuric acid, and water added until the sp.gr. becomes 1·125 to 1·150. At the end of an hour, when the contents begin to cool down, steam is injected by a leaden pipe which completes the action. Excess of acid must be carefully avoided, as it causes loss in crystallising. The liquor is then run off into a settler made of lead or flags, but not of iron; after settling the clear solution is siphoned over into an iron evaporating pan, where it is evaporated down to 66° of Twaddell's hydrometer. The clear concentrated liquor stands for an hour or two to allow any suspended matter to settle, after which it is conveyed to the coolers, which are made of wood, flags, or, best of all, slate, where it is agitated so as to cause the salt to fall in small crystals. The crystals are then drained and finally dried on shelves in a stove room at a temperature not exceeding 80°F.

Magnesium sulphate is largely used in the Lancashire cotton trade in the process of warp-sizing; it is also employed for medicinal and agricultural purposes and for dyeing with the aniline colours.

The crystals have the composition of epsomite $MgSO_4,7H_2O$, and form right rhombic prisms, resembling those of the sulphates of zinc and nickel. They have a sp.gr. of 1·676 (Thorpe and Watts, Chem. Soc. Trans. 37, 106). On heating, they melt in their water of crystallisation, lose 6 molecules of water at 150° and the seventh at 200°.

A salt also having the composition $MgSO_4,7H_2O$ is occasionally deposited from cold supersaturated solutions in monoclinic prisms isomorphous with those of ferrous sulphate $FeSO_4,7H_2O$. By crystallisation of the ordinary salt above 40° monoclinic prisms of a hydrate $MgSO_4,6H_2O$, of sp.gr. 1·734, are obtained. By drying the heptahydrate over oil of vitriol to constant weight, $MgSO_4,5H_2O$, of sp.gr. 1·869 is obtained. A salt of the composition $MgSO_4,2H_2O$, sp.gr. 2·373, may also be prepared by boiling finely powdered Epsom salts with absolute alcohol. The sp.gr. of the monohydrate $MgSO_4,H_2O$ is 2·445 and that of the anhydrous salt 2·709 (Thorpe and Watts, *l.c.*).

An octahydrate is capable of existence in solutions containing 32 p.c. of sodium sulphate at 30°, but changes to the heptahydrate if the amount of sodium sulphate exceeds 32 p.c. (Shirô Takegami, J. Chem. Soc. Japan, 1921, 42, 441).

Magnesium sulphate is readily soluble in water. According to Gay-Lussac 100 parts of water dissolve 25·76 parts of the anhydrous salt at 0° and 0·47816 part for every degree beyond. One part of Epsom salts dissolves in 0·79 part of water at 18·75°, forming a liquid of sp.gr. 1·2932.

The table on page 194, due to Schiff (Annalen, 108, 336), shows the amounts of the sulphate in solutions of different specific gravities.

Magnesium sulphate also dissolves in dilute alcohol, but is insoluble in absolute alcohol.

Magnesium hydrogen sulphate $MgH_2(SO_4)_2$. If 2 parts of anhydrous magnesium sulphate are dissolved in 100 parts of boiling sulphuric acid of sp.gr. 1·7 and the solution evaporated at the boiling-point, $MgH_2(SO_4)_2$ is deposited in prisms. On cooling, an acid salt of the composition $MgSO_4·3H_2SO_4$ crystallises out in small shining tables which fuse and decompose when heated.

Magnesium sulphate forms an isomorphous

series of double salts with the sulphates of the alkali metals, of the general formula

$$MgSO_4{\cdot}M_2SO_4,6H_2O,$$

which crystallise in monoclinic prisms.

Magnesium potassium sulphate

$$MgK_2(SO_4)_2,6H_2O$$

is found in the Stassfurt salt deposits and is known as *schönite*; also as a volcanic product (*pieronerite*). It is prepared by dissolving the salts in molecular proportions and crystallising. It forms monoclinic prisms.

Magnesium ammonium sulphate

$$Mg(NH_4)_2(SO_4)_2,6H_2O$$

is found in the fumeroles of Tuscany and is known as *cerbolite*. Prepared artificially it crystallises in monoclinic prisms and is isomorphous with the potassium double salt.

Magnesium silicide (Compt. rend. 154, 116) is readily prepared in quantity by ramming an intimate mixture of dried quartz powder (200 parts) with magnesium powder (100 parts), igniting with a little magnesium on the surface and covering to exclude air. A bluish-black mass of magnesium silicide is so obtained. Treatment with hydrochloric acid evolves a gas containing 6–7 p.c. of silicon hydrides.

Magnesium silicates occur abundantly in nature and some of them have been prepared artificially. The main features of the binary system $MgO-SiO_2$ as investigated by the American Geo. physical School are: magnesia has a melting-point of about 2800°; fosterite crystallises at 1890° and forms a eutectic at 1850° with magnesia. There is no eutectic between fosterite and clino-enstatite, but the latter and cristobalite (m.p. 1625°) form an eutectic at 1543°. The introduction of lime-alumina-silicate into the system not only gives rise to anorthite but magnesium aluminate (spinel) $MgAl_2O_4$ may result. The more important silicates are the following:—

Forsterite Mg_2SiO_4 occurs in crystals in the volcanic ejections of Monte Somma. Ebelmen (Ann. Chim. Phys. [iii.] 33, 58) obtained the mineral artificially by fusing silica and magnesia in proper proportions with boric acid. The crystals obtained were similar to those from Vesuvius. Forsterite forms with the corresponding calcium orthosilicate (*monticellite*) an isodimorphous group of mixed crystals (V. Poschl, Tsch. Min. Mitt. 26, 413).

Olivine $n Mg_2SiO_4+Fe_2SiO_4$ is a constituent of many basic rocks. It crystallises in the rhombic system. The olive-green and bottle-green crystals are used as gemstones under the name of peridote. Magnesium silicate forms isomorphous mixtures with iron orthosilicate, but there is a gap in the series (V. Poschl, *loc. cit.*).

Enstatite $MgSiO_3$ the metasilicate, occurs in nature crystallised in the rhombic system. Ebelmen (*loc. cit.*) obtained it by fusing magnesia and silica with boric acid in proportions corresponding with the metasilicate; Poschl (*loc. cit.*) has shown that it forms with diopside ($CaMgSi_2O_6$) an isodimorphous series similar to that given by magnesium sulphate and ferrous sulphate.

Sepiolite $2MgO3SiO_22H_2O$ is a compact, earthy hydrated silicate, sometimes known as meerschaum.

Talc $H_2Mg_3(SiO_3)_4$ occurs as foliated masses, compact as steatite; the soft variety is known as soapstone or French chalk.

Serpentine $H_4Mg_3Si_2O_4$ forms large rock masses and usually contains ferrous oxide. The fibrous variety is known as *chrysotile* and comes into commerce under the general name of asbestos.

Magnesium titanate $MgTiO_3$ occurs in nature as *geikielite*.

Magnesium citrate $Mg_3(C_6H_5O_7)_2,14H_2O$ is obtained as a crystalline crust when magnesia is dissolved in slightly more than an equivalent quantity of a solution of citric acid, and the solution evaporated at about 50°. It is very soluble in water, and is often preferred to Epsom salts as a mild purgative on account of its pleasanter taste.

The citrate of magnesia of the shops, so popular as an effervescent salt, may be prepared by mixing 16 parts of sodium bicarbonate, 10½ of tartaric acid, 4 of citric acid, about 12 of sugar, ½ part of Epsom salts, and 2 parts of crystallised sodium bisulphate, and heating on an enamelled iron plate until it becomes spongy from the escape of carbon dioxide. The cooled mass is then put through sieves of four to six meshes per square inch. In this granular form it is again heated until quite dry. The solution of the granules in water, after the liberation of the carbon dioxide, contains principally citrate and tartrate of soda and sugar.

It may also be prepared by making a mixture of magnesium citrate, prepared by dissolving magnesia in citric acid solution and crystallising, with sodium bicarbonate, citric acid and sugar, and rendering granular by moistening with alcohol and drying.

The magnesia preparation called *sinodor*, used for removing unpleasant odours and for disinfecting and preserving purposes, is obtained by heating neutral magnesium acetate with magnesium oxide until the mass assumes a pasty consistency. It consists of basic magnesium acetate containing excess of magnesium hydroxide (Kubel, Pat. 18090, Nov. 1881).

Magnesium is usually estimated quantitatively by precipitating an ammoniacal solution with sodium or ammonium phosphate. The precipitate is washed with ammonia water, ignited and weighed as pyrophosphate. This occasionally turns grey on ignition, especially in contact with fibres of filter paper or other form of organic matter. By moistening the ignited mass with a few drops of ammonium nitrate solution and reheating the colour is removed.

Volumetric methods employed for limestones and dolomites depend upon (1) determination of total CaO+MgO by acid and alkali titration less the amount of CaO separately estimated. (2) Solution in standard HCl and titration with NaOH cold for CaO with phenolphthalein as indicator and further titration in boiling solution depending upon the complete precipitation of magnesia hydroxide as indicated by a permanent pink colour. G. S. B.

MAGNESIUM-PERHYDROL. *Biogen.* A combination of hydrogen peroxide (perhydrol) and magnesia and magnesium peroxide. Used as an internal antiseptic.

MAGNETIC IRON ORE *v.* MAGNETITE; IRON.

MAGNETIC PYRITES *v.* PYRRHOTITE.

MAGNETITE, or Magnetic iron ore. A mineral of the spinel group, consisting of magnetic oxide of iron, Fe_3O_4 or $FeO{\cdot}Fe_2O_3$; an important ore of iron (Fe 72·4 p.c.). Sharply developed crystals with bright faces are not uncommon; these belong to the cubic system and usually have the form of the regular octahedron or the rhombic-dodecahedron. Granular to compact masses are, however, more abundant. The colour is iron-black with a dull, sub-metallic lustre and a black streak. Sp.gr. 5·18; hardness 6. The mineral may be always readily recognised by its strong magnetic character: small fragments are picked up by a magnetised knife-blade. Only occasionally are specimens magnetic with polarity (*v.* LOADSTONE) For the magnetic properties of varieties of magnetite, *see* Wilson and Herroun (Proc. Phys. Soc. London, 1919, 31, 299). The titaniferous magnetites, which are also of frequent occurrence, consist of an intimate intergrowth of magnetite with ilmenite or rutile (*v.* J. T. Singewald, The Titaniferous Iron Ores in the United States, their Composition and Economic Value, U.S. Bureau of Mines, 1913, Bull. 64).

As small grains and crystals, magnetite is of wide distribution in many kinds of igneous rocks, especially the darker coloured with a low silica percentage. In such rocks it sometimes forms rich segregations available for mining; as in the Ural Mountains, and at Kirunavara and Gellivara in Swedish Lapland. Other important deposits, *e.g.* some of those in southern Sweden and Norway, have been formed by the metamorphism of pre-existing iron-ores, where these have been subjected to the baking action of intrusive masses of igneous rock. Extensive deposits of magnetite are also mined in the crystalline Archæan rocks of the Adirondack region of New York and in Canada (H. Ries, Economic Geology, New York, 1916).

L. J. S.

MAGNOFERRITE *v.* IRON.

MAHUA or **MAHWA FLOWERS.** The flowers of *Bassia longifolia* and *B. latifolia*. May be used as a source of alcohol. They contain dextrose, levulose, maltose, sucrose, pentoses, the total sugar being greatest when the flowers are ready to fall, when it amounts to 60–70 p.c. The development of the various sugars at different stages of growth has been studied by Fowler and coadjutors (J. Indian Inst. Sci. 1920, 3, 81). Yields of alcohol up to 90 p.c. of the theoretical were obtained by fermentation of a mash of the flowers with cultures of the natural yeast present in the flower with the addition of sulphuric acid and ammonium phosphate. *Cf.* BASSIA *or* MAHWA FLOWERS, Vol. I.

MAILLECHORT *v.* NICKEL.

MAIZE. *Zea Mays* (Linn.). **'Indian corn'** or **'mealies.'** This plant was grown by the aborigines of America; it was introduced into Europe in the sixteenth century, and is now extensively grown in almost all countries possessing sufficiently warm climates. It grows to a height of from 5 to 12 or even 15 feet.

Many varieties of maize are known, differing greatly in size, shape, colour, and composition of the grain and in the arrangement of the grain around the cob.

The average composition of all varieties of maize has been given under CEREALS.

South African, American, and Australian grown maizes contain distinctly less moisture than European samples. White and yellow are the commonest colours of the maize grain, but orange, red, blue, violet, and even black grains are known, as well as striped ones.

The separate parts of white American horse-tooth maize have been analysed by Plagge and Lebbin in 1897 (quoted by König). They obtained the following results:—

	P.c. of whole grain	In the dry matter, p.c.			
		Water	Protein	Fat	Carbohydrates	Ash
Germ	11·78	6·70	13·75	29·36	46·99	7·23
Husks	9·35	8·66	8·32	7·94	82·81	1·63
Horny part of starch	49·79	12·16	8·04	0·64	91·11	0·21
Mealy ,, ,,	29·08	9·68	6·46	0·93	92·97	0·34
Whole grain		11·38	8·09	5·79	84·61	1·51

Hopkins, Smith and East (J. Amer. Chem. Soc. 1903, 25, 1166) determined the distribution of the proteids in maize grains of (*a*) low (9·89 p.c.), (*b*) medium (11·33 p.c.), and (*c*) high (12·64 p.c.) protein content. Their results were—

	(*a*)	(*b*)	(*c*)
Germ	19·31	20·14	18·45
Husks	2·75	2·07	1·85
Horny portion	53·07	59·03	64·88
Mealy portion	23·98	17·63	14·22
Tip caps	0·89	1·14	0·59

They found that the germ contained almost all the oil and about ten times the percentage of ash of the other parts of the grain. Hopkins, indeed (Bull. 55, Illinois Agric. Stat. 1899, 310), finds it possible to classify samples of maize according to their richness in protein or fat by mechanical examination only, the fat being

mainly dependent upon the proportion of germ in the grain and the nitrogenous matter being largely determined by the proportion of horny or glutinous matter.

For proteids and oil of maize, *v.* CEREALS.

The injurious effect of a diet consisting largely of maize upon animals has been ascribed to the absence of tryptophan among the products of hydrolysis of *zein*, the characteristic protein of maize (Willcock and Hopkins, J. Phys. Chem. 1906, 35, 88); also to the presence of much phenylalanine and tyrosine among such products, and the ease with which they split off phenolic compounds, thus producing phenolic poisoning (Baglioni, Atti. R. Accad. Lincei. 1908, 17, i. 109).

According to McCallum, Simmonds and Pitz (J. Biol. Chem. 1916, 28, 153) the proteins of maize contain all the amino-acids essential for growth and also the accessory factors 'fat-soluble A' and 'water-soluble B,' the former, however, being present in insufficient quantity to allow of maximum growth. The addition of butter effects a marked improvement in the growth of animals whose sole source of protein is maize. The inorganic content of maize is not suitable for the needs of normal growth.

The 'non-nitrogenous extract' of maize consists mainly of starch and cellulose, but includes also cane sugar, dextrin, and gum.

As the average of several determinations of the soluble carbohydrates in various types of maize, König gives the following numbers:

Maize from	Number of determinations	In the original substance, p.c. Sugar	Dextrin and gum	Starch, etc.
South-eastern Europe	8	1·76	2·83	61·20
Italy . . .	22	2·22	1·09	64·41
America (Flint corn)	23	2·29	2·30	64·04
America (Dent corn)	11	2·64	3·62	62·39
America (Sweet corn)	10	4·64	14·47	43·47

Stone (Bull. 34, O. Exp. St. 14) extracted 0·25 p.c. cane sugar from ordinary and 3·5 p.c. from sweet maize, but could not detect invert sugar in the former. Tollens and Washburn (J. Landw. 1889, 37, 503) found 9 p.c. of glucose and 7·8 p.c. of sucrose and dextrin in sweet maize, but only a trace of glucose and 1·78 p.c. of sucrose and dextrin in ordinary maize. Stone found about 5 p.c., Tollens 7·08 p.c. of pentosans in maize grain.

For ash of maize grain, *v.* CEREALS.

An objection to the use of large quantities of maize as a cattle food is the effect which it has of lowering the melting-point of the fat produced by the animal (*e.g.* bacon in the case of the pig, butter in the case of dairy cows). Maize is too rich in fat and carbohydrates and too poor in ash constituents, especially lime, to form the sole diet of an animal.

Maize cob—the central portion of the ear—consists largely of cellulose and xylan (25 p.c. of the latter). American analyses show it to contain—

Water	Protein	Fat	N-free extract	Crude fibre	Ash
10·7	2·4	0·5	54·9	30·1	1·4

It is sometimes ground along with the grain, and the product, 'corn and cob meal,' is used as a cattle food.

Maize is also employed as a fodder plant, being cut green and either eaten fresh, or, in some cases, made into hay or ensilage. Though immature maize plants contain a cyanogenetic glucoside (Brünnich, Chem. Soc. Trans. 1903, 788), the quantity of hydrocyanic acid present—not exceeding 0·5 grain per 1 lb. of green material—is so small, that there is little or no danger of poisoning the animals fed upon them.

The following table gives the average composition of certain products from maize:

	Water	Protein	Fat	N-free extract	Crude fibre	Ash
Green fodder .	79·3	1·8	0·5	12·2	5·0	1·2
Silage . .	79·1	1·7	0·8	11·0	6·0	1·4
Straw . .	15·0	5·0	1·5	34·5	39·2	4·8
Bran . .	12·5	9·9	3·6	61·5	9·5	3·0
Maize germ cake	11·0	21·0	9·0	43·8	9·1	6·1
Corn & cob meal	15·1	8·5	3·5	64·8	6·6	1·5
Gluten meal .	9·6	29·4	6·8	52·4	1·6	0·7

H. I.

MAIZE OIL (Corn oil) is obtained from the germs of the maize plant, *Zea Mais*, L. The germs are recovered, in the process of manufacturing starch, by sifting and winnowing them from the starch granules in which they are imbedded. The oil is therefore a by-product of starch and glucose works using maize (corn) as their raw material.

Formerly maize oil was obtained as a by-product in alcohol distilleries. When the malted and crushed grain was allowed to ferment, the oil was laid bare and rose to the top in the fermentation vats. Before distilling off the alcohol, the oil was ladled off and purified in a crude fashion by washing, filtering, and 'settling.' Since, however, the presence of the germ imparts an unpleasant flavour to the spirit obtained by fermentation, and the oil so recovered was very impure, and had a different character from the oil expressed from the germs, the older process of fermenting the crushed grain has been abandoned. Nowadays, the corn is first malted, beaten up with water to a fine pulp, and the germs are separated from the starch by sieving. At present, maize oil is manufactured on a very large scale from the isolated germs by expression in hydraulic presses. In a dry condition, the germs contain 53 p.c. of oil, and yield in practice about 40 p.c. The whole grain contains about 4 to 5 p.c. of oil.

In the process patented by Leuders and Bauer (U.S. Pat. 1225664 of 1917) maize is steeped in a solution of sulphurous or other acid, and then crushed and separated from the germs. The latter are washed in water containing sufficient alkali to neutralise the acid left from the steeping, and are then dried and the oil expressed.

Maize oil, if properly prepared, is clear in colour, and does not require refining for commercial purposes. If, however, the oil is badly prepared and allowed to stand in contact with albuminoid matter, it undergoes a process of fermentation, whereby considerable quantities of free fatty acids are produced, and acquires a dark colour which renders it unsuitable for light-coloured soaps. Such oil is therefore bleached in soap works in the same manner as linseed oil.

By distilling the freshly expressed oil with

steam for several hours lower esters are dissociated, and the residual oil, when washed and dried, is lighter in colour and less acid, and is more suitable for food.

The freshly prepared maize oil is of a pale yellow or golden-yellow colour, and has a distinctive odour; its taste is pleasant at first, and is most characteristic in that it resembles that of newly ground corn-meal. It is therefore possible to identify the oil by its taste alone.

Maize oil is characterised by its high amount of unsaponifiable matter, amounting to as much as 1·55 and even 2 32 p.c. The unsaponifiable matter consists of lecithin, and of an alcohol which appears to be identical with sitosterol (phytosterol). The sp gr. of maize oil is 0·9215 to 0·927 at 15·5°. The saponification value is 190 to 192, and the iodine value varies between 120 and 130.

The saturated fatty acids in maize oil amount to about 5 p.c. and appear to consist of palmitic, stearic, and arachidic acids. As to liquid fatty acids, linolenic acid is absent, but the oil contains considerable amounts of linolic acid in addition to oleic acid. Baugham and Jamieson (J. Amer. Chem. Soc., 1921, 43, 2696) found maize oil to consist of glycerides of the following fatty acids: oleic, 45·4; linolic, 40·9; palmitic, 7·7; stearic, 3·5; arachidic, 0·4; and liquoceric, 0·2 p.c. No hypogæic acid was present. The oil has somewhat better drying powers than cotton-seed oil, but differs from the latter in that it is not oxidised with equal energy when finely subdivided on cotton waste.

Well-refined maize oil is used for edible purposes ('salad oil'). Since its 'grainy' taste is objectionable, the edible quality is frequently a mixture of maize oil with edible cotton oil and other edible oils. Maize oil is also used in the manufacture of margarine ('oleomargarine' of the United States), as also in the manufacture of compound lard (replacing cotton seed oil). Such maize oil as cannot be employed for edible purposes is used chiefly in the manufacture of soft soap, for which it is eminently suitable. A cotton 'softener' largely used in the United States contains maize oil soft soap. Maize oil is not suitable for hard soaps of acceptable quality.

J. L.

MALACHITE. An ore of copper, crystallising in the monoclinic system, but usually occurring as mamillated and botryoidal forms, or as fibrous, compact, or earthy masses of a bright green colour. It is a basic copper carbonate $H_2Cu_2CO_5$ (or $CuCO_3+CuO_2H_2$), having a sp.gr. of 3·9 to 4·0, and hardness 3½ to 4. Heated in a tube, it evolves water and turns black, while on charcoal it yields metallic copper. Malachite is frequently found as an alteration-product of other copper ores, and occurs as a pseudomorph after cuprite, &c. If derived from copper pyrites it is generally accompanied by limonite. Malachite is not only important as an ore of copper (Cu, 57·4 p.c.), but is valued as an ornamental stone, since it takes a good polish and is prettily marked with light and dark green bands of colour. It is chiefly used for vases and small boxes, but its comparative softness stands in the way of its extensive use in jewellery. Large slabs are not generally attainable, but small pieces are skilfully joined together, the interstices being filled in with powdered malachite, and the whole polished; in this way it becomes easy to employ it for inlaid and encrusted furniture, especially for table-tops of considerable size. Malachite is also used to a limited extent as a green pigment, but the term 'malachite green' has been extended to certain organic dyestuffs. Malachite is widely distributed as a mineral, being found in greater or less quantity in most copper deposits, but the finest examples occur near Nizhni-Tagilsk and Gumeshevsk in the Ural Mountains, at Burra-Burra and Wallaroo in South Australia, Namaqualand in South Africa, and Bwana Mkubwa in Northern Rhodesia.

L. J. S.

MALACHITE GREEN, VICTORIA GREEN, BENZAL GREEN *v.* TRIPHENYLMETHANE COLOURING MATTERS.

MALACON. One of the several names that have at different times been applied to altered and hydrated forms of zircon (*q.v.*). This name (from *μαλακός*, soft) was originally given by T. Scheerer, in 1844, to bluish-white tetragonal crystals occurring in granite-pegmatite at Hitterö in Norway, which differed from the accompanying zircon in containing 3 p.c. of water, and in their lower degree of hardness (H. about 6, instead of 7½ as for zircon). The material is optically isotropic, has sp.gr. about 3·9, and is often somewhat radioactive. When heated, it suddenly glows brightly, and gives off water and gas; it then has the properties of ordinary zircon. The gas given off consists largely of carbon dioxide, together with some hydrogen, nitrogen, helium, and argon (C. F. Hogley, Phil. Mag. 1909, 18, 672). Similar altered zircon, referred to 'malacon,' has been described from Chanteloube in France, the Ilmen Mountains in the Urals, and several other localities. That from Madagascar contains 9·5 p.c. water (A. Lacroix, Minéralogie de Madagascar, 1922, 239).

L. J. S.

MALAKIN *v.* SYNTHETIC DRUGS.

MALARIN. Trade name for the citrate of acetophenone-phenetidide, prepared by heating equivalent proportions of acetophenone and *p*-phenetidine either alone or with addition of dehydrating agents. Crystallises in yellow needles, m.p. 88°, readily soluble in hot alcohol, ether, or glacial acetic acid.

MALAYAN CAMPHOR *v.* CAMPHORS.

MALE FERN *v.* FILIX-MAS.

MALEIC ACID *v.* FUMARIC ACID.

MALIC ACID, *Hydroxysuccinic acid* (*Acide malique*, Fr.; *Aepfel-säure*, Ger.)

$$\begin{array}{l} CH_2COOH \\ | \\ CH(OH)COOH. \end{array}$$

This acid contains an asymmetric carbon atom and hence can occur in three modifications, viz. a dextrorotatory form, a lævo-rotatory form, and an inactive variety. The lævo-rotatory variety occurs free or in the form of salts in many plant juices and hence is frequently termed *ordinary* malic acid. *l*-Malic acid was discovered by Scheele in 1785 in sour apples, and Liebig in 1832 ascertained its composition. The inactive acid was first obtained by Pasteur in 1852 from inactive aspartic acid, and by Kekulé in 1861 from bromosuccinic acid. The *d*-acid was firs

obtained by Bremer in the reduction of *d*-tartaric acid.

Preparation.—l-Malic acid occurs free in unripe grapes (Ordonneau, Bull. Soc. chim. 1891, 261); in apples, gooseberries, strawberries, cherries, tomatoes (Albahary, Compt. rend. 145, 131), mountain ash berries (*Pyrus Aucuparia*) (Liebig, Ann. 5, 141); in the berries of *Hippophaë rhamnoides* (Erdmann, Ber. 1899, 3351); and of *Berberis vulgaris*; in honey (Hilger, Zeitsch. Nahr. Genussm. 8, 110, Farnsteiner, *ibid.* 1908, 598); in fruit juices (Kunz and Adam, Chem. Zentr. 1906, i. 1849); in ferns (Regnault, Ann. Chim. Phys. 1836, 208); in tamarind (Adam, Chem. Zentr. 1905, ii. 1042); in baobab fruits (Franck and Marckwald, Chem. Zeit. 1914, 587), &c. Suint contains potassium malate to the extent of 2½ p.c. of the solid residue and it is a product of excretion (A. and P. Buisine, Compt. rend. 106, 1426); *l*-malic acid is also found in the calcium precipitate formed in the treatment of beetroot (Lippmann, Ber. 1891, 3299). It can be prepared from the unripe berries of *Pyrus Aucuparia* (Ehrh.) (Hagen, Annalen, 38, 257), or of *Berberis vulgaris* (Linn.) (Lennsen, Ber. 1870, 966) in the following manner. The expressed juice is evaporated, filtered, heated to boiling, and saturated with milk of lime. The calcium malate which separates is dissolved in hot dilute nitric acid (1 : 10); on cooling, the solution deposits the acid malate, which is purified by recrystallisation from water. In order to obtain malic acid from it, its solution is precipitated with lead acetate and the lead salt is decomposed with sulphuretted hydrogen (Brœksmit, Pharm. Weekbad. 42, 637). The precipitate known as 'sand' which is formed during the evaporation of maple sap contains 60–80 p.c. of calcium malate and constitutes a readily available source of malic acid. The annual production of 'sand' in America and Canada is estimated to be 100–330 tons, corresponding to 50–165 tons of calcium malate. Malic acid may be obtained from the juice of cherries or grapes by means of the cinchonine salt, which is very insoluble, the cinchonine salts of the other acids remaining in solution (Lindet, Bull. Soc. chim. 1896, 15, 1160). Castoro recommends separating malic acid from the expressed juice of the rhubarb, in which it occurs as the acid potassium salt, by means of its strontium salt (Chem. Soc. Abstr. 1902, i. 259). Sahasrabuddhe (Agric. Rep. Inst. Pusa, 1914) describes its preparation from *Cicer arietinum;* the acid secretion of this plant contains 19 parts of malic to 1 part oxalic acid, it is washed off the plant every 6 days, and furnishes considerable quantities of malic acid.

l-Malic acid can be obtained from *l*-chloro- or *l*-bromosuccinic acid through the action of moist silver oxide, mercuric oxide, &c., or from *d*-chloro- or *d*-bromosuccinic acid by the action of potassium hydroxide, or hydroxides of the other alkali metals (Walden, Ber. 1896, 135; 1897, 2795, 3148; 1899, 1833, 1853). It can also be obtained by the action of nitrous acid on *l*-asparagine or *l*-aspartic acid (Walden, *l.c.*); and by the action of *Bac. aerogenes* on succinic acid (Ber. 1899, 1915). By heating the ammonium salt of inactive malic acid to 80°, the active salt crystallises out from the solution of the inactive salt (Kenrick, Ber. 1897, 1749; Van 't Hoff and Dawson, *ibid.* 1898, 528).

d-Malic acid occurs naturally in *Crassulaceæ* (Aberson, Ber. 1898, 1432; Walden, *ibid.* 1899, 2706). It can be obtained synthetically by methods similar to those for obtaining *l*-malic acid (Walden, *l.c.*; Piutti, Ber. 1886, 1693; Bremer, *l.c.*). Racemic acid can be reduced to inactive malic acid, which can be resolved into *d*- and *l*-malic acids by cinchonine (Bremer, Ber. 1880, 351; Rec. trav. chim. 4, 180).

Inactive malic acid can be prepared by methods similar to those above (Tanatar, J. Russ. Phys. Chem. Soc. 1891, i. 339; Annalen, 273, 37; Van 't Hoff, Ber. 1885, 2170, 2173). It is also obtained by heating fumaric or maleic acids with caustic soda to 100° (Van't Hoff, *l.c.*; Lloyd, Annalen, 192, 80; Bremer, *l.c.*; Skraup, Monatsh. 12, 113); by heating chloral and malonic acid with acetic acid and treating the γ-trichloro-β-hydroxybutyric acid thus formed with potassium hydroxide (Garzarolli-Thurnbackh. Monatsh. 12, 556); and by reducing oxalacetic acid with sodium amalgam in acid solution (Wislicenus, Ber. 1891, 3416; 1892, 2448).

Properties.—Inactive malic acid. Melts at 130°–131°; sp.gr. 20°/4° 1·611. Affinity constant (Walden, Ber. 1896, 1698). The diethyl ester is obtained by reducing ethyloxalacetate with aluminium amalgam (Wislicenus, J. pr. Chem. 1896, [ii.] 59, 18). Dielectric constant *v.* Drude, Zeitsch. physikal. Chem. 23, 310).

d-Malic acid. Physical properties, *v. l-malic acid.*

l-Malic acid. Crystallises in colourless needles, m.p. 100°. Very soluble in water or alcohol. Rotation of acid (*v.* Nasini and Gemari, Gazz. chim. ital. 25, i. 422; Zeitsch. physikal. Chem. 1896, 19, 113; Winther, Chem. Zentr. 1896, ii. 22; Woringer, Zeitsch. physikal. Chem. 1901, 36, 336; Stubbs, Trans. Chem. Soc. 1911, 2265). Thermal constants, *v.* Massol. Compt. rend. 113, 800. Dissociation constants, *v.* Smith and Jones, Amer. Chem. J. 50, 1. The esters are prepared by adding dry silver malate in small quantities at a time to an excess of alkyl iodide and completing the reaction by heating on the water-bath; or by treating malic acid and an alcohol with hydrochloric acid or sulphuric acid. When the former method is used, a small quantity of a more active substance is always present, *e.g.* in the preparation of ethyl malate, ethyl ethoxysuccinate is also produced (Purdie and Lander, Chem. Soc. Trans. 1898, 293; Purdie and Pitkeathly, *ibid.* 1899, 154). The dimethyl ester boils at 129° (16 mm.) and has sp.gr. 1·2301 at 20°/4°; the diethyl ester boils at 138° (25 mm.) and has sp.gr. 1·1340 at 20/4° (Purdie, *l.c.*; Walden, Zeitsch. physikal. Chem. 1895, 17, 245; Frankland and Wharton, Chem. Soc. Trans. 1899, 338). Rotation, *v.* also Anschutz and Reitter, Zeitsch. physikal. Chem. 1895, 16, 493; Clough Trans. Chem. Soc. 1915, 96. Dielectric constant, v. Walden, *ibid.* 46, 103. According to H. Traube (Zeitsch. Kryst. Min. 1899, 31, 160), the best method for the preparation of the salts of malic acid is by the interaction of strontium hydrogen malate with the sulphate of the metal. A detailed account of the composition and crystallographic properties of the salts is given.

On heating malic acid to 100° for 24 hours, there results malomalic acid $C_5H_7O_3(CO_2H)_3$, and on heating *in vacuô* at 180° there is formed an anhydride, *malide* $C_8H_8O_8$ and small quantities of fumaric acid and maleic anhydride (Walden, Ber. 1899, 2716). Prolonged heating at 140°–150° yields fumaric acid as the main product, and at 180°, fumaric acid, maleic anhydride, and water are formed. Oxidation with hydrogen peroxide in the presence of a ferrous salt yields oxalacetic acid (Fenton and Jones, Chem. Soc. Trans. 1900, 77); with hydrogen peroxide in a sealed tube at 120°, tartaric acid (Zinno, Mon. Scient. 16, ii. 493); with potassium permanganate, oxalacetic acid (Deniges, Compt. rend. 130, 32); with nitric acid, oxalic acid; with potassium dichromate, malonic acid. Reduction with hydriodic acid yields succinic acid. By heating malic acid with sulphuric acid, the half aldehydes of malonic acid and formic acid are produced, the former of which is changed into coumalic and trimesic acids (Von Pechmann, Annalen, 264, 261): heating with glycerol gives rise to carbon dioxide and acrolein (de Coninck and Raynaud, Compt. rend. 135, 1351). Heating with excess of alcoholic potash results in racemisation (McKenzie and Thompson, Trans. Chem. Soc. 1905, 1004). Carbon dioxide, acetaldehyde, and crotonic aldehyde are formed by the electrolysis of a concentrated aqueous solution of the sodium salt (Miller and Hafer, Ber. 1891, 470). The coumarins are produced when malic acid is heated with phenols and sulphuric acid (Pechmann, Ber. 1884, 929, 1646). Benzaldehyde and malic acid in piperidine at 150°–160° react to form β-benzoyl propionic acid (Mayrhofer and Nemeth, Monatsh. 1903, 24, 80). Heated with hydrobromic acid, malic acid yields bromosuccinic acid and with phosphorus pentachloride chlorosuccinic acid. A concentrated solution of an alkaline malate gives with calcium chloride on boiling a precipitate of calcium malate. Ammonium salts prevent the precipitation; addition of alcohol aids it. Piñuera (Compt. rend. 1897, 124, 291) uses as a reagent a solution containing 0·02 gram β-naphthol per c.c. strong sulphuric acid. If 0·05 gram of dry substance is added to 15 drops of the reagent in a porcelain dish and malic acid is present, a yellow-green coloration is produced, changing to light yellow on heating and orange on dilution. De Coninck (Bull. Soc. chim. 1914, 93) states that a red colour is given on adding calcium salicylate, less stable than that produced by succinic acid. Details as to estimation *v.* Clowes, J. Amer. Chem. Soc. 1908, 30, 1285; Pozzio-Escot, Bull. Soc. chim. Belg. 1908, 22, 413. Photo-chemical decomposition of solutions of malic acid gives formaldehyde, acetaldehyde and formic, acetic, glycollic, and oxalic acids (Spoehr, Biochem. Zeitsch. 57, 95).

Malic acid is present in wines (Mayer, Zeitsch. öffentl. Chem. 1909, 15). When fermentation is carried out with pure yeast on sterile musts, no decomposition of malic acid occurs until the wines become contaminated with micro-organisms in the ordinary cellar operations. Then gradual fermentation sets in and this liberates the carbon dioxide necessary to prevent premature decay (Rosenstiehl, Compt. rend. 1908, 147, 150; *cf.* Mestregat, *ibid.* 1907, 145, 260; Emmerling, Ber. 1899, 1915). Lebedew showed, however, that solutions containing 2 p.c. malic acid are fermented by certain yeasts, higher concentrations being more feebly attacked; the products are lactic acid and CO_2 (J. Soc. Chem. Ind. 1917, 300). Seiffert (Chem. Zentr. 1903, ii. 257) has shown that malic acid is gradually converted into lactic acid by an anærobic micrococcus (*Micrococcus malolacticus*); this is also brought about by *Bacillus lactis aërogens* (Emmerling, *l.c.*). *Bacillus cloacæ* in the presence of oxygen gives acetic, succinic, and carbonic acids (Thompson, Proc. Roy. Soc. B, 84. 500).

Detection and estimation in wines and fruit juices, v. Schneider (J. Soc. Chem. Ind. 1890, 1068); Micko (Zeitsch. anal. Chem. 31, 465; 32, 481; Chem. News. 68, 286); Hilger (Chem. Zentr. 1900, ii. 597; Zeitsch. Nahr. Genussm. 1903, 6, 721); Kunz (Apoth. Zeit. 1905, 20, 677); Mestzerat (Compt. rend. 1906, 143, 185; Ann. Chim. anal. 1907, 173; 12, 194); Jörgensen (Zeitsch. Nahr. Genussm. 13, 241); Heide and Steiner, *ibid.* 1909, 17, 307); Dutoit and Duboux (Bull. Soc. Chim. [4], 13, 832). *In tobacco*, Kissling (Chem. Zeit. 1898, 22, 1; 1899, 23, 2). *In cider vinegar*, Leach and Lythgoe (J. Amer. Chem. Soc. 1904, 25, 375).

Ammonium malate is prepared by leading dry NH_3 into an ethereal solution of the acid (McMaster, Amer. Chem. J. 49, 294).

Copper malate $C_4H_4O_5Cu$ hard rhombic crystals insoluble in water. A soluble cuprimalate is also described (Pickering, Trans. Chem. Soc. 1913, 1354).

For malates of heavy metals *v.* Pickering Trans. Chem. Soc. 1916, 235.

iso*Malic acid.* Methyltartronic acid, *v.* TARTRONIC ACID.

β-iso*Malic acid.* *β-Hydroxyisosuccinic acid* $CH_2(OH)CH(CO_2H)_2$. The ethyl ester is obtained by treating formaldehyde with hydrogen chloride and adding to the solution ethylsodiomalonate; the produot is hydrolysed with potash and the acid so obtained is a syrup decomposing into acrylic acid on heating (Coops, Rec. trav. chim. 1901, 20, 430; Chem. Weekbad. 1, 535; *cf.* Tanatar, Annalen, 273, 44).

Citramalic acid, α-Methylmalic acid

$$CO_2H{\cdot}CH_2(CH_3)C(OH)CO_2H$$

Prepared from acetoacetic ester by means of hydrocyanic acid and hydrochloric acid (Michael, J. pr. Chem. [ii.] 46, 287; Demarcy, Bull. Soc. chim. [ii.] 27, 120; Morris, Chem. Soc. Trans. 1880, 6); by the reduction of chlorocitramalic acid, which is formed from citraconic acid (Carius, Annalen, 129, 160; Morawski, J. 1878, 721); by the action of N_2O_3 on methylaspartic acid (Piutti, Ber. 1893, 2046); by the action of caustic soda on β-bromopyrotartaric acid (Ssemenoff, J. Russ. Phys. Chem. Soc. 31, 289). Melts at 115°–117° and on heating to 200° decomposes into water and citraconic anhydride (Wislicenus, Ber. 1892, 196).

β-Methylmalic acid

$$CO_2H{\cdot}CH(OH)CH(CH_3)CO_2H$$

Prepared by heating the ester of methyloxalacetic acid with sodium amalgam in aqueous solution (Wislicenus, Ber. 1892, 199). Colourless syrup.

MALLEABLE CAST IRON *v.* IRON

MALLEBREIN. Trade name for aluminium chlorate.

MALLET BARK. The bark of *Eucalyptus occidentalis* (Endl.), found in Queensland. Employed in tanning; contains from 30 to 50 p.c. of tanning substance. The commercial extract has a density of 22°–24°B. and contains 30–36 p.c. of tanning substance.

MALLOTOXIN *v.* RESINS.

MALONAL, MALOUREA. Syns. for Veronal (*q.v.*).

MALONIC ACID $CH_2(COOH)_2$, the second member of the oxalic acid series, was first prepared by Dessaignes by oxidising malic acid with potassium dichromate (Annalen, 1858, 107, 251), and was found by Lippmann among the calcium salts formed in beet-sugar manufacture (Ber. 1881, 14, 1183). Calcium malonate has been found in a fermented solution of sucrose containing lime-water (von Lippmann, Ber. 1920, 53 [B] 2069). Malonic acid can be obtained by oxidising crude sarcolactic acid with potassium dichromate (Dossois, Zeitsch. Chem. 1866, 449); or allylene or propylene with potassium permanganate (Berthelot, Annalen (Supl.) 1867, 5, 97); by the action of fuming nitric acid on hexabromomethylethyl ketone (Demole, Ber. 1878, 11, 1714); or of boiling baryta water on ethyl chloroacrylate (Pinner, *ibid.* 1875, 8, 963); or of silver oxide at 125° on ethyl dichloroacrylate (Wallach, Annalen, 1878, 193, 25); by boiling bromomucic acid with baryta water (Jackson and Hill, Ber. 1878, 11, 289); or by boiling barbituric acid with alkali (Baeyer, Annalen, 1864, 130, 143). Malonic acid is best prepared by the hydrolysis of cyanacetic acid (Conrad, Ber. 1879, 12, 749; Bourgoin, Compt. rend. 1880, 90, 1289). Endemann (D. R. P. 183328, 1907) has devised a method for preparing malonic acid from abietic acid and the accompanying resins, by hydrolysing the resin or abietic acid with sodium hydroxide, oxidising the product with permanganate at 0°, and separating the malonic acid from the mixture of acids by means of its sparingly soluble calcium salt. Malonic acid also occurs among the decomposition products obtained by hydrolysing cellulose nitrate with concentrated alkali solution (Berl and Fodor, Chem. Zentr. 1911, ii. 1039).

Properties and reactions. Malonic acid crystallises in large triclinic plates, m.p. 133°–134°, decomposing at a higher temperature into carbon dioxide and acetic acid (for its rate of decomposition, *see* Hinshelwood, Chem Soc. Trans. 1920, 117, 156); when heated under a pressure of 8–10 mm. it sublimes unchanged (Krafft and Noerdlinger, Ber. 1889, 22, 816). For its solubility in alcohol and in ether *v.* Lamouroux, Compt. rend. 1899, 128, 999; Klobbie, Zeitsch. physikal. Chem. 1897, 24, 615.

Malonic acid dissolves in hot acetic anhydride to give a yellowish-red solution with a strong yellowish-green fluorescence, intensified by the addition of glacial acetic acid: the reaction is sensitive, being produced by a milligram of the acid (Kleemann, Ber. 1886, 19, 2030). For its absorption of ultra-violet light *v.* Bielecki and Henri (Ber. 1913, 46, 2596).

When malonic acid or its sodium salt is administered internally it passes only in small quantity into the urine, and leads to an increase of urinary carbonates and to the formation of barbituric acid (Marjori, Chem. Zentr. 1896), ii. 106).

Detection and Estimation.—Malonic acid, or its esters, mixed with anhydrous methyl or ethyl alcohol, containing hydrogen chloride, heated for a few minutes and then neutralised yields on addition of an alcoholic solution of bromomethyl furfuraldehyde and rendering slightly alkaline with alcoholic potassium hydroxide an intense blue fluorescence, Fenton (Pro. Camb. Phil. Soc. 1914, 17, 477). Bougault (J. Pharm. Chem. 1913, [vii.] 8, 289) suggests the formation of cinnamylidene malonic acid as a means for detecting malonic acid. Malonic acid or its salts may be estimated by oxidation with permanganate at 80°–90° first in acid and then in alkaline solution, and titrating the excess of permanganate (Durand, Ann. Chim. anal. 1903, 8, 330; Cameron and McEwan, Chem. Soc. Proc. 1910, 26, 144).

The malonic acid contained in maple products is estimated by precipitation with normal lead acetate and converting the washed precipitate into lead sulphate by evaporation with nitric and sulphuric acids (Albert P. Sy, Chem. Zentr. 1906, ii. 714).

Salts. Malonic acid is a strong dibasic acid forming both acid and normal salts, and the following salts are described: ammonium, barium, cadmium, calcium, cerium, chromium, cobalt, copper, iron, lead, lithium, magnesium, manganese, nickel, potassium, silver, sodium, strontium, uranium, zinc, brucine, pyridine (Massol, Ann. Chim. Phys. 1894, [vii.], 1, 184; Finkelstein, Annalen, 133, 338; Miczynski, Monatsh. 7, 260; Rimbach, Kilian, Annalen, 1909, 368, 110; Howe, J. Amer. Chem. Soc. 1903, 25, 444; Werner, Chem. Soc. Trans. 1904, 144; Lord, J. Phys. Chem. 1907, 11, 173; Motooki Malsui, J. Coll. Sci. Tōkyō, 1908, 25, ii. 1; Heintzel, Annalen, 139, 129; Mulder, Bull. Soc. chim. [ii.] 29, 532; Fay, Amer. Chem. J. 18, 281; Hilditch, Chem. Soc. Trans. 1909, 1580; Keiser and McMaster (Amer. Chem. J. 1913, 49, 84; Flack, Zeitsch. anorg. Chem. 1913, 82, 173; Mazzucchelli and d'Alceo, Atti. R. Accad. Lincei, 1912, [v.] 21, 11, 620; Traube and Goodson, Ber. 1916, 49, 1679; Werner, Annalen, 1911, 386, 1; Pfeiffer, Ber. 1914, 47, 1580).

For toluidine hydrogen malonates, *see* Grünwald (J. pr. Chem. 1913, [ii.] 88, 176).

For the absorption spectra of salts of malonic acid *v.* Wright (Chem. Soc. Trans. 1913, 103, 528).

For the dissociation constant of the neutral sodium salt *v.* Datta and Dhar, Chem. Soc. Trans. 1915, 107, 826).

Esters. The *ethyl ester* $CH_2(CO_2Et)_2$, can be prepared from malonic acid by the ordinary processes of esterification (Finkelstein, Annalen, 1864, 133, 338; Conrad, Ber. 1879, 12, 749; Phelps and Tillotson, Amer. J. Sci. 1908, [iv.] 26, 243); but it is more usually prepared by heating cyanoacetic acid with absolute alcohol in the presence of sulphuric acid or in a current of hydrogen chloride (Venable and Claisen, Annalen, 1883, 218, 131; Noyes, J. Amer. Chem. Soc. 1896, 18, 1105; Phelps and Tillotson, *l.c.*), and commonly contains small quantities of ethyl cyanoacetate (Crossley and Gilling, Chem. Soc. Trans. 1909, 95, 27 *f.n.*).

Diethyl malonate is a colourless liquid, b.p. 197·7°–198·2° (corr.), sp.gr. 1·06104 at 15°, 1·05284 at 25° (Perkin, *ibid.* 1884, 45, 508), 1·07607 at 0° (Wiens, Annalen, 1889, 253, 298); m.p. −49·8° (von Schneider, Zeitsch. physikal. Chem. 22, 233. *Diethyl malonate tin tetrachloride* $CH_2(CO_2Et)_2,SnCl_4$ has m.p. 115°–117°, Pfeiffer and Halperin (Zeitsch. anorg. Chem. 1914, 87, 335). For derivatives of iodo- and bronoanils of the type $C_6X_2[CH(COOEt)_2]_2O_2$ (where X is Br or I) and their reduction products and bromine derivatives, *see* Jackson and Bolton (J. Amer. Chem. Soc. 1914, 36, 1481). The viscosity of the ester and its relationship to other physical properties are described by Hilditch and Dunstan (Zeitsch. Elektro Chem. 1912, 18, 881), and the desmotropy by Meyer (Ber. 1912, 45, 2864). *Ethyl hydrogen malonate* $HO_2C{\cdot}CH_2{\cdot}CO_2Et$ (Hoff, Ber. 1874, 7, 1572), has sp.gr. 1·201 at 0° n_D 1·337 at 22° (Massol, Ann. Chim. Phys. 1894, [vii.] 1, 184); b.p. 147°/21 mm., sp.gr. 1·1759 at 19°/19°, n_D 1·4275 at 19° (Marguery, Bull. Soc. chim. 1905, [iii.] 33, 541).—*Dimethyl malonate* $CH_2(CO_2Me)_2$, a colourless liquid, b.p. 181·5° (corr.), sp.gr. 1·16028 at 15°; 1·15110 at 25° (Perkin, Chem. Soc. Trans. 1884, 45, 509); b.p. 180 7° (corr.), sp.gr. 1·1753 at 0° (Wiens, Annalen, 1889, 253, 297); solidifies to a vitreous mass at −80° (von Schneider, Zeitsch. physikal. Chem. 22, 233). Mercuri salts of possible therapeutic value are obtained by shaking mercuric oxide (1 mol.) and methyl malonate (2½ mols.) in water at 37°; when the *monomercuri-dimalonic ester* $Hg[CH(CO_2Me)_2]_2$ thus formed is hydrolysed the acid loses CO_2 and forms the *anhydride* of *oxymercuri-acetic acid* $\begin{matrix}CH_2{\cdot}Hg\\|\quad|\\CO{-}O\end{matrix}$. The methyl esters of methyl, ethyl, propyl and allyl malonic acid, or the alkali salts of the acid yield similar compounds (Schoeller and Schrauth, D.R.P. 208634, 1909; 213371, 1909; Bülmann and Hoff, Rec. trav. chim. 1917, 36, 306). *Methyl β-benzoyl-α-phenylethyl-malonate* $C_6H_5CO{\cdot}CH_2{\cdot}CHPh{\cdot}CH(CO_2Me)_2$ crystallises in large colourless needles, m.p. 107° (Kohler, Heritage, and McLeod, Amer. Chem. J. 1911, 46, 234). *Ethyl propyl malonate*

$$(CO_2Et)CH_2{\cdot}CO_2Pr$$

b.p. 211° (corr.), sp.gr. 1·04977 at 0° (Wiens, *l.c.*).—*Dipropyl malonate* $CH_2(CO_2Pr)_2$, b.p. 228°–229° at 770·3 mm. or 228·3° (corr.); sp.gr. 1·02705 at 0° (Wiens, *l.c.*). *Dibutyl malonate* $CH_2(COOC_4H_9)_2$, b.p. 251·5° (corr.), sp.gr. 1·0049 at 0° (Wiens, *l.c.*). *Di-l-amyl malonate* $CH_2(COOC_5H_{11})$, has $[M]_D$ 8·09° (Walden, Chem. Zentr. 1899, i. 327). *Diphenyl malonate* $CH_2(CO_2Ph)_2$, has m.p. 50°, b.p. 210°/15 mm. *Dibenzyl malonate* $CH_2(CO{\cdot}OCH_2Ph)_2$, b.p. 234·5°/14 mm. (Bischoff and Hendenström, Ber. 1902, 35, 3452; Auger and Billy, Compt. rend. 1903, 136, 555). *Dimenthyl malonate* $CH_2(CO{\cdot}OC_{10}H_{19})_2$, m.p. 62°, $[\alpha]_D$ 79·24° (Hilditch, Chem. Soc. Trans. 1909, 95, 1579). *tert-Butyl hydrogen malonate* $CO_2H{\cdot}CH_2{\cdot}CO_2{\cdot}C_4H_9$ has m.p. 102°–103°, gem.-*Trichloro-tert-butyl hydrogen malonate* has m.p. 116° and the *malonate* m.p. 102°–103° (Wolffenstein, Loewy, Bachstez, Ber. 1915, 48, 2035).

Amides and substituted amides. *Ethyl malonamate* $EtO{\cdot}OC{\cdot}CH_2{\cdot}CONH_2$, m.p. 50°, (Pinner, Ber. 1895, 28, 473); *malonamide* $CH_2(CONH_2)_2$, m.p. 170°, soluble in 12 parts of water at 8° (Henry, Compt. rend. 1885, 100, 943).

Malonylmalonamide

$$CH_2\begin{matrix}<CO{\cdot}NH{\cdot}CO\\CO{\cdot}NH{\cdot}CO\end{matrix}>CH_2$$

m.p. 252°–253°, prepared by condensing malonamide and ethyl malonate, and the alkyl substituted derivatives in which one or more of the methylene hydrogen atoms are replaced by alkyl groups, have no hypnotic properties (Remfry, Chem. Soc. Trans. 1911, 99, 610).

Malondimethylamide $CH_2(CONHMe)_2$, m.p. 135° (Whiteley, Chem. Soc. Trans. 1903, 83, 24). *Malondiethylamide* $CH_2(CONHEt)_2$, m.p. 149° (Wallach and Kamenski, Ber. 1881, 14, 170; Backes, West and Whiteley, Chem. Soc. Trans. 1921, 119, 366). *Malondi-n-propylamide* $CH_2(CO{\cdot}NHPr^n)_2$, m.p. 139°; *malondi-n-butylamide* $CH_2(CO{\cdot}NH{\cdot}C_4H_9)_2$, m.p. 132·5°. *Malondiisobutylamide* $CH_2(CONH{\cdot}C_4H_9)_2$, m.p. 126°–127°; *malondibenzylamide*

$$CH_2(CO{\cdot}NH{\cdot}CH_2Ph)_2$$

m.p. 142° (Backes, West and Whiteley, *l.c.*) *Malonanilic acid* $HOOC{\cdot}CH_2{\cdot}CONHPh$, m.p 132° with decomposition (Rügheimer, Ber. 1884, 17, 235; Seifert, Ber. 1885, 18, 1358); for its halogen derivatives *see* Chattaway and Clemo (Chem. Soc. Trans. 1916, 109, 101); *methyl malonanilate*, m.p. 42°–43° (Staudinger and Becker, Ber. 1917, 50, 1016); *ethyl malonanilate* m.p. 38°–39° (Rügheimer and Hoffmann, *ibid* 1884, 17, 739); the p-*iodo derivative* melts at 120° (Chattaway and Constable, Chem. Soc. Trans. 1914, 105, 130); the p-*nitro derivative* melts at 92°–95° (Jacobs and Heidelberger, J. Amer. Chem. Soc. 1917, 39, 1454); *malonmonophenylamide* $PhHN{\cdot}CO{\cdot}CH_2{\cdot}CONH_2,\frac{1}{2}H_2O$ m.p. 153°–154° (Whiteley, Chem. Soc. Proc. 1904, 93); the p-*nitro* derivative melts at 218°–220°, the p-*amino* derivative crystallises with 1 H_2O and melts at 200°–210° (Jacobs and Heidelberger, *l.c.*); *malonanilide* $CH_2(CONHPh)_2$, m.p. 225° (Whiteley, Chem. Soc. Trans. 1903, 83, 24); m-*nitromalonanilide*, m.p. (after melting at 173°–177° and resolidifying) 198°–200° (corr.); p-*nitromalonanilide*, m.p. 241°–242°; m-*aminomalonanilide*, m.p. 180°–185° (corr.). (Jacobs and Heidelberger, *l.c.*); *dithiomalonanilide*

$$CH_2(CSNHPh)_2$$

m.p. 149° (Reissert and Moré, Ber. 1906, 39, 3298). *o-*, *m-* and *p-Malonamidobenzoic acids*

$$CH_2(CONH{\cdot}C_6H_4{\cdot}CO_2H)_2$$

melt and decompose at 242°, 258°–259° and 270° respectively (von Pollack, Monatsh. 1905, 26, 327); the *ethyl ester* of *p-malonamidobenzoic acid*, $CO_2Et{\cdot}CH_2{\cdot}CONH{\cdot}C_6H_4{\cdot}CO_2H$, has m.p. 172°–173° (Schiff, Annalen, 1886, 232, 129; Gazz. chim. ital. 1885, 15, 534); *malonyldiphenetidide*

$$CH_2(CONH{\cdot}C_6H_4{\cdot}OEt)_2$$

has m.p. 226° (Bischoff, Ber. 1898, 31, 3248). The chloro and bromo substituted derivatives of malonanilide and malonanilic acid are described by Chattaway and Mason (Chem. Soc. Trans. 1910, 97, 340). Certain of the salts and ethyl esters of the three isomeric *malontoluidic*

acids $CO_2H{\cdot}CH_2{\cdot}CONHC_7H_7$, were prepared by Rügheimer and Hoffmann (Ber. 1885, 18, 2971). The *o*-, *m*- and *p*- acids melt at 138°–143°, 99°–101°, and 156° respectively; compare also Chattaway and Olmsted (*l.c.* 938). *Malondi-p-tolylamide* $CH_2(CONH{\cdot}C_7H_7)_2$, has m.p. 250° *malonmono-p-tolylamide* has m.p. 144°; *malondi-o-tolylamide* has m.p. 193° (Whiteley, *l.c.*); *dithiomalondi-o-toluidide* $CH_2(CSNHC_7H_7)_2$, and the corresponding *p*- isomeride melt at 122°–123° and 145° respectively (Reissert and Moré, Ber. 1906, 39, 3298). *Malondi-α-naphthylamide* $CH_2(CONH{\cdot}C_{10}H_7)_2$, melts at 225°; the β-isomeride melts at 235° (Whiteley, *l.c.*). *α-Malonnaphthil* $C_{10}H_7N{<}\overset{CO}{CO}{>}CH_2$, has m.p. above 300° (Meyer, Annalen, 1906, 347, 17). *Malondimethylanilide* $CH_2(CONMePh)_2$, m.p. 109° (Freund, Ber. 1884, 17, 133); *malontetraphenylamide* $CH_2(CO{\cdot}NPh_2)_2$, m.p. 219°–220° with decomposition; *malonmonomethylanilide*

$$NHPhCO{\cdot}CH_2{\cdot}CONMePh$$

m.p. 112° (Whiteley, Chem. Soc. Proc. 1904, 93). *Malonylmonobenzanilide* $C_{16}H_{13}O_4N$, m.p. 100°–101° (with decomp.) (Mumm, Hesse and Volquartz, Ber. 1915, 48, 379).

Malonyldiurethane $CH_2(CONH{\cdot}CO_2Et)_2$, m.p. 124° (Conrad and Schulze, Ber. 1909, 42, 729). *Malonylpiperidide* $C_{13}H_{22}O_2N_2$, m.p. 57° (Franchimont, van Rijn and Friedmann, Rec. trav. chim. 1907, 26, 228). *Malonylazoimide* $CH_2(CO{\cdot}N_3)_2$, an explosive oil, is converted into methylenediurethane, $CH_2(NHCO_2Et)_2$, on treatment with alcohol (Curtius, J. pr. Chem. 1895, [ii.] 52, 210).

Ethylenemalonamide $CH_2{<}\overset{CO{\cdot}NH}{CO{\cdot}NH}{>}C_2H_4$, from ethylenediamine and malonamide at 170°–180° (Freund, *l.c.*); *o-phenylenemalonamide* and *o-tolylenemalonamide* melt above 300° (Meyer, Annalen, 1906, 347, 17).

Malonylcarbamide, barbituric acid (2 : 4 : 6-di-ketohexahydropyrimidine), *v.* PYRIMIDINES.

Hydrazides. *Malonhydrazide*

$$CH_2(CONH{\cdot}NH_2)_2$$

crystallises in needles, m.p. 154°; for condensation products with aldehydes and alkyl acetoacetates, *see* Curtius, Schöfer and Schwan (J. pr. Chem. 1895, [ii.] 51, 180); Ruhemann (Ber. 1894, 27, 1658); Bülow and Bozenhardt, (Ber. 1909, 42, 4784; 43, 234; 551). *Potassium hydrazino-malonate*, m.p. 174°; *benzylidene-hydrazino-malonic acid*

$$CO_2H{\cdot}CH_2\,CO{\cdot}NH{\cdot}N{:}CHPh$$

m.p. 162° (Curtius and Sieber, Ber. 1921, 54 [B], 1430). *Malonphenylhydrazide*

$$CH_2(CONH{\cdot}NHPh)_2,$$

m.p. 187° (Goldsmith, *ibid.* 1888, 21, 1240; Asher, *ibid.* 1897, 30, 1018). The phenylhydrazine salt of *phenylhydrazidemalonic acid*

$$PhNH{\cdot}NH_2{\cdot}HO_2C{\cdot}CH_2{\cdot}CONH{\cdot}NHPh$$

melts at 141°–143°, and yields the *acid*

$$CO_2H{\cdot}CH_2{\cdot}CONH{\cdot}NHPh$$

m.p. 154° on treatment with acid, and *malonylphenylhydrazide*, $CH_2{<}\overset{CO}{CO}{>}N_2HPh$, m.p. 128°, when heated at 200° (Fischer and Passmore, Ber. 1889, 22, 2728).

Malondihydroxamic acid $CH_2(C(OH){:}NOH)_2$, m.p. 160°, *ammonium malonylhydroxamate*

$$(NH_4)O_2C{\cdot}CH_2{\cdot}C(OH){:}NOH$$

m.p. 181° (Hantzsch, Schatzmann, and Urbahn, Ber. 1894, 27, 804; Pickard, Allen, Bowdler and Carter, Chem. Soc. Trans. 1902, 81, 1572).

Nitriles of malonic acid. The *seminitrile* or *cyanacetic acid* $CN{\cdot}CH_2{\cdot}CO_2H$, prepared by the action of potassium cyanide on chloroacetic acid (Fiquet, Ann. Chim. Phys. 1893, [vi.] 29, 438; Phelps and Tillotson, Amer. J. Sci 1908, iv. 26, 267, 278), forms well-defined large prisms, m.p. 69°–70°. The salts of cyanacetic acid are either amorphous or crystallise with difficulty (Engel, Bull. Soc. chim. [ii.] 44, 225; Meves, Annalen, 1867, 143, 201).

Ethyl cyanacetate $CN{\cdot}CH_2{\cdot}CO_2Et$, b.p. 207° (Phelps and Tillotson, *l.c* 264, 257); condenses with carbamide to form the ester,

$$CO{<}\overset{NH}{NH}{>}C{\cdot}CH_2{\cdot}CO_2Et$$

m.p. 162° (decomp.), soluble in 8333 parts of water at 24°. It gives *m*-toluidine, strychnine, bromine and metallic derivatives. The corresponding *methyl ester* crystallises with $1\frac{1}{2}$ H_2O, m.p. 116° (anhydrous has m.p. 128°) and gives similar derivatives to the ethyl ester (Frerichs and Hartwig, J. pr. Chem. 1905, [ii.] 72, 489; *ibid.* 1906, [ii.] 73, 21).

The *sodium* compound of ethyl cyanacetate, $CN{\cdot}CHNa{\cdot}CO_2Et$ or $CN{\cdot}CH:C{<}\overset{ONa}{OEt}$, forms a neutral solution in water which is not decomposed by hydrochloric acid in the cold. It absorbs iodine rapidly, forming the compound $C_5H_6O_2NI$, and also ethyl dicyanosuccinate, m.p. 120°, as the result of a secondary reaction (Thorpe, Chem. Soc. Trans. 1900, 77, 923).

Methyl cyanacetate $CN{\cdot}CH_2{\cdot}CO_2Me$ is a colourless liquid, b.p. 177° (Fenton, Chem. Soc. Trans. 1900, 1297). *Menthyl cyanacetate*

$$CN{\cdot}CH_2{\cdot}CO_2{\cdot}C_{10}H_{19}$$

flattened needles, m.p. 83°–84°, $[\alpha]_D$ −81·12° (2 p.c. solution in benzene); the monobrom derivative has m.p. 134°–135° (Bowack and Tapworth, Chem. Soc. Proc. 1903, 22). *o-Tolylcyanacetate* $CN{\cdot}CH_2{\cdot}CO_2{\cdot}C_6H_4Me$, prisms, m.p. 70·4° (Haller, Compt. rend. 1889, 108, 1116).

Cyanacetamide $CN{\cdot}CH_2\,CONH_2$ forms hexagonal tablets, m.p. 120° (Hesse, Amer. Chem. J. 18, 724; Errera, Gazz. chim. ital. 27, ii. 412; Sachs, Ber. 1900, 33, 964; Fiquet, *l.c.*). *Cyanacetanilide*, $CN{\cdot}CH_2{\cdot}CONH{\cdot}C_6H_5$, m.p. 198·5°–200° (Quenda, Atti R. Accad. Sci. Torino, 27). The fluorine derivative

$$CN{\cdot}CH_2{\cdot}CONH{\cdot}C_6H_4F$$

has m.p. 150°–151° (Wallach and Heusler, Annalen, 1888, 243, 223). *Cyanacetdiphenylamide* $CN{\cdot}CH_2{\cdot}CO{\cdot}N(C_6H_5)_2$, has m.p. 153°–154° (Guareschi, Atti R. Accad. Sci. Torino, 27). *Cyanacet-p-tolylamide*, $CN{\cdot}CH_2{\cdot}CONH{\cdot}C_7H_7$, m.p 180° (Grothe, Arch. Pharm. 823, 608).

Cyanacetxylylamide

$$CN{\cdot}CH_2{\cdot}CONH{\cdot}C_6H_3(CH_3)_2$$

has m.p. 167°.

Cyanacetpiperidide, $CN{\cdot}CH_2{\cdot}CONC_5H_{10}$, forms large prisms, m.p. 88°–89° (Guareschi, *l.c.*).

Cyanacetphenocoll

$OEt{\cdot}C_6H_4{\cdot}NH{\cdot}CO{\cdot}CH_2{\cdot}NHCO{\cdot}CH_2{\cdot}CN$

white crystals, m.p. 28°.

Cyanacetylanisidine

$OMe{\cdot}C_6H_4{\cdot}NH{\cdot}CO{\cdot}CH_2{\cdot}CN$

m.p. 136°, and *Cyanacetyl-p-aminophenetole* $OEt{\cdot}C_6H_4{\cdot}NH{\cdot}CO{\cdot}CH_2{\cdot}CN$, m.p. 180°–181°, yield the corresponding oxamic acid on oxidation (Nicola, Ann. Chim. Farm. 18, 353).

Cyanoacetylhydrazine $CN{\cdot}CH_2{\cdot}CO{\cdot}NH{\cdot}NH_2$, m.p. 114·5°–115°. With aldehydes it yields the compounds $CN{\cdot}CH_2{\cdot}CONH{\cdot}N:CHR$, with ketones, the compounds $CN{\cdot}CH_2{\cdot}CONHN:CRR'$.

Cyanacetylacetylhydrazine,

$CN{\cdot}CH_2{\cdot}CONH{\cdot}NH{\cdot}CO{\cdot}CH_3$

has m.p. 172°.

Cyanacetyl phenylsulphonylhydrazine

$CN{\cdot}CH_2{\cdot}CONH{\cdot}NH{\cdot}SO_2C_6H_5$

is formed by the action of benzenesulphonic chloride on cyanacetylhydrazine (Rothenberg, Ber. 1894, 27, 1894).

Cyanacetylcyanamide $CN{\cdot}CH_2{\cdot}CO{\cdot}NH{\cdot}CN$, m.p. 93° (D. R. P. 167138, Chem. Zentr. 1906, i. 797).

Cyanacetylcarbamide $CN{\cdot}CH_2{\cdot}CONH{\cdot}CO{\cdot}NH_2$, m.p. 212° (decomp.). The *methyl carbamide*, m.p. 206°, the *phenyl*, m.p. 216°, and other alkyl derivatives are described (D. R. P. 175415; Chem. Zentr. 1906, ii. 1590; Baum, Ber. 1908, 41, 532; Conrad and Schulze, Ber. 1909, 42, 735). They are employed technically in the production of the purine bases.

Cyanacetylurethane

$CN{\cdot}CH_2{\cdot}CO{\cdot}NH{\cdot}CO_2Et$

m.p. 167°–168° (Conrad and Schulze, *l.c.*).

Malonodinitrile $CH_2(CN)_2$ (Henry, Compt. rend. 1886, 102, 1394; Hesse, Amer. Chem. J. 1896, 18, 726) is a colourless crystalline compound, m.p. 29°–30°, b.p. 218°–219°/760 mm. (Henry); b.p. 99°/11 mm. or 109°/20 mm., soluble in 7·5 parts water, 2·5 parts alcohol, 5 parts ether, 10 parts chloroform, or 15 parts benzene (Hesse); forms the mono- and di- silver salts $CHAg(CN)_2$ and $CAg_2(CN)_2$ (Hesse), and reacts with hydroxylamine (1 mol.) to form *cyanethenylamidoxime*

$CN{\cdot}CH_2{\cdot}C(NH_2):NOH$

m.p. 124°–127° with decomposition, and yields an *acetyl* and *benzoyl* derivative, m.p. 142° and 184°–192° respectively; *malonodiamidoxime* $CH_2[C(NH_2):NOH]_2$ melts and decomposes at 163°–167°, and yields a *diacetyl* and *dibenzoyl* derivative, m.p. 153°–159° and 183°–185° respectively (Schidtmann, Ber. 1896, 29, 1168). For the action of nitrous acid on malononitrile *see* Diels and Borgwardt (Ber. 1921, 54 [B], 1334).

Aldehydes of malonic acid. The *semialdehyde*, $CHO{\cdot}CH_2{\cdot}CO_2H$, obtained by Wohl and Emmerlich (Ber. 1900, 33, 2760) from β-chloropropionacetal $CH_2Cl{\cdot}CH_2{\cdot}CH(CO_2Et)_2$ is not stable and its physical constants have not been determined. The *amide* $(CHO{\cdot}CH_2{\cdot}CONH_2)$ obtained by Langheld (Ber. 1909, 42, 2360) by the action of sodium hypochlorite on asparagine, is not a stable compound but yields a *phenylhydrazone* $C_9H_{11}ON_3$, m.p. 239°–240°. The *nitrile* or *cyanacetaldehyde* $CN{\cdot}CH_2{\cdot}CHO$ is a colourless, limpid, volatile inflammable liquid of b.p. 71·5° (Chautard, Ann. Chim. Phys. 1889, [vi] 16, 176).

The dialdehyde and semialdehyde of malonic acid are stated to be among the products formed when the ozonide peroxides of α- or β-linolenic acids are decomposed by boiling with water (Erdmann, Bedford and Raspe, Ber. 1909, 42, 1334).

Malonic acid halides. *Malonic semichloride* $CO_2H{\cdot}CH_2{\cdot}COCl$, m.p. 65° with decomposition, obtained by the action of thionyl chloride on an ethereal solution of malonic acid, is unstable (Staudinger and Ott, Ber. 1908, 41, 2208); the *methyl ester* has b.p. 57°–59° (Staudinger and Becker, Ber. 1917, 50, 1016); the *ethyl ester* $COCl{\cdot}CH_2{\cdot}CO_2Et$, has b.p. 170°–180°, (Van 't Hoff, Ber. 1874, 7, 1572), or 68°–70°/13 mm., loses HCl at 125°–130°, and yields the *compound* $C_{13}H_{12}O_8$, yellow prisms, m.p. 170°–180° (corr.) (Marguery, Bull. Soc. chim. 1900, [3] 33, 541; Leuchs, Ber. 1906, 39, 2641). The *nitrile* or *cyanacetylchloride* $CN{\cdot}CH_2{\cdot}COCl$, was prepared by Mulder (Bull. Soc. chim. [ii.] 29, 533). *Malonyl chloride* $CH_2(COCl)_2$, obtained when malonic acid is mixed with an excess of thionyl chloride and distilled under reduced pressure (Staudinger and Bereza, Ber. 1908, 41, 4461), and yields carbon suboxide (*q.v.*) when treated with silver or lead oxide (Staudinger and Bereza, *l.c.*), is a colourless liquid, b.p. 58°/27 mm. (Auger, Ann. Chim. Phys. 1891, [vi.] 22, 325). For the constitution of the chloride *v.* Auwers and Schmidt (Ber. 1913, 46, 457). *Malonyl bromide* $CH_2(COBr)_2$, b.p. 55°–57°/11 mm. (Fleischer, Hittel and Wolff, Ber. 1920, 53 [B], 1847.

The *seminitrile* of *malonyl bromide*, *cyanacetylbromide*, crystallises in the monoclinic system, and has m.p. 77°–79° (Hübner, Annalen, 1864, 131, 66).

Substituted Malonic Acids and Derivatives.

Alkyl malonic acids. The hydrogen atoms of the methylene group in ethyl malonate can be replaced by sodium (Conrad, Annalen, 1880, 204, 129; Ballo, Ber. 1881, 335); ethyl sodiomalonate, $CO_2Et{\cdot}CH{<}^{ONa}_{OEt}$ (Meyer, Ber. 1912, 45, 2864), is a colourless crystalline compound; it does not undergo dissociation in alcoholic solution (Vorländer and Schilling, *ibid.* 1899, 32, 1876); is not stable in the presence of water, and yields no colour with ferric chloride (Vorländer, *ibid.* 1903, 36, 268). It condenses with alkyl and aryl halides to form the alkyl or aryl substituted malonic ester, the sodio-derivative of which yields on similar treatment the di-substituted ester (Bischoff, *ibid.* 1895, 28, 2616). For the mechanism of these reactions *see* Jackson and Whitmore (J. Amer. Chem. Soc. 1915, 37, 1522, 1915). The corresponding substituted malonic acids can be obtained by hydrolysis of the esters, and these lose carbon dioxide when heated above their melting-point with the formation of the corresponding acid of the acetic series:

$$CH_2(CO_2Et)_2 \rightarrow CHR(CO_2Et)_2 \rightarrow CRR'(CO_2Et)_2 \rightarrow CRR(COOH)_2 \rightarrow CHRR'{\cdot}COOH$$

With the exception of diethylmalonic acid, which is employed in the synthetic preparation of certain pyrimidines of therapeutic value, a description of the numerous alkyl malonic acids

does not come within the scope of this article. For the identification of the acids by means of their *p*-nitrobenzylesters, *v.* Lyman and Reid (J. Amer. Chem. Soc. 1917, 39, 701).

Diethylmalonic acid $CEt_2(CO_2H)_2$, m.p. 112°; the *anhydride* $[CEt_2<\begin{matrix}CO\\CO\end{matrix}>O]_n$, has m.p. 95°–97° (Staudinger and Ott, Ber. 1908, 41, 3829); the *quadrimolecular anhydride* has m.p. 220° (Einhorn and Diesbach, Ber. 1906, 39, 1222), and a liquid *anhydride* is described by Ott (Ann. 1913, 401, 159); the *ethyl ester* has b.p. 228·5°–229·5° (corr.) (Michael, J. pr. Chem. 1905, [ii.] 72, 537), for its absorption spectra *v.* Brannigan, Macbeth, Stewart (Chem. Soc. Trans. 1913, 103, 406); *methyl ester* has b.p. 204°–205° (Meyer, Ber. 1906, 39, 198); *p-nitrobenzyl ester*, m.p. 91·2° (Layman and Reid, J. Amer. Chem. Soc. 1917, 39, 701); *diethylmalonate of glycollamide* $CEt_2(CO{\cdot}O{\cdot}CH_2{\cdot}CO{\cdot}NH_2)_2$, has m.p. 126°; *diethylaminoethyl diethylmalonate*

$$CEt_2(CO{\cdot}OCH_2{\cdot}CH_2{\cdot}NEt_2)_2$$

(Einhorn, Annalen, 1908, 359, 145); *ethyl diethylmalonamate*, has m.p. 79°. b.p. 263° (D. R. P. 182045); *trichlorbutyl hydrogen diethylmalonate* has m.p. 100° (D. R. P. 289001); *diethylmalonamic acid*, m.p. 146°, *diethylmalondiethylamic acid* $NEt_2CO{\cdot}CEt_2{\cdot}CO_2H$, m.p. 88°–90° (Einhorn and Diesbach, Ber. 1906, 39, 1222); *diethylmalonamide*, m.p. 224° (corr.) (Fischer and Dilthey, *l.c.*), forms a crystalline compound, $CEt_2(CONH_2)_2{\cdot}CCl_3{\cdot}CHO$, m.p. 178° with chloral hydrate (Burrows and Keane, Chem. Soc. Trans. 1907, 91, 269). *Diethylmalonylmalonamide* has m.p. 175°–176°, *diethylmalonylmethylmalonamide* has m.p. 118°–119°; *diethylmalonylethylmalonamide*, m.p. 88°–89°; *diethylmalonylbenzidine*, m.p. 224° (Remfry, *l.c.*). *Diethylmalonylmonophanylamide* $NH_2{\cdot}CO{\cdot}CEt_2{\cdot}CO{\cdot}NHPh$, m.p. 132° the *sulphanilide* $NH_2{\cdot}CO{\cdot}CEt_2{\cdot}CO{\cdot}NH{\cdot}C_6H_4{\cdot}SO_3H$, has a strong acid reaction and decomposes carbonates, *diethylmalonanilic acid*

$$NHPh{\cdot}CO{\cdot}CEt_2{\cdot}CO_2H$$

m.p. 105° (Conrad and Zart, Annalen, 1905, 340, 335). *Diethylmalonyl-p-phenetidine*

$$CEt_2(CO{\cdot}NH{\cdot}C_6H_4{\cdot}OEt)_2$$

m.p. 143°, has antipyretic properties and exerts a soporific action (D. R. P. 165311). *Diethylmalonyldiurethane* $CEt_2(CO{\cdot}NH{\cdot}CO_2Et)_2$, a thick oil (Traube, D. R. P. 179946); *ureide of diethylmalonic acid* $CO_2H{\cdot}CEt_2{\cdot}CO{\cdot}NH{\cdot}CO{\cdot}NH_2$, m.p. 162° (corr.) (Fischer and Dilthey, Annalen, 335, 334); *ethyl diethylmalonylureide*

$$CO_2Et{\cdot}CEt_2{\cdot}CO{\cdot}NH{\cdot}CO{\cdot}NH_2$$

m.p. 85°; *methyl diethylmalonylureide*, m.p. 115° (Boehringer and Söhne, D. R. P. 193447); *diethylmalonyluramide*

$$NH_2{\cdot}CO{\cdot}CEt_2{\cdot}CO{\cdot}NH{\cdot}CO{\cdot}NH_2$$

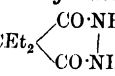
m.p. 199° (Conrad and Zart, *l.c.*); *diethylmalonyltetramethyldicarbamide*

$$CEt_2(CO{\cdot}NH{\cdot}CO{\cdot}NMe_2)_2$$

m.p. 158°; *diethylmalonyltetraethyldicarbamide*, m.p. 123°–126° (Einhorn, D. R. P. 193446). *Diethylmalonylanthranilamide*

$$CEt_2(CO{\cdot}NH{\cdot}C_6H_4{\cdot}CONH_2)_6$$

m.p. 215°. *Cyclo Diethylmalonylhydrazide*



m.p. 256° (Einhorn, Annalen, 1908, 359, 145). *Diethylmalonodinitrile* $CEt_2(CN)_2$, m.p. 44°, b.p. 195°–195·5° (Hesse, Amer. Chem. J. 1896, 18, 723; Errera and Berté, Gazz. chim. ital. 1896, 26, ii. 220). The *seminitrile of diethylmalonic acid* (*diethylcyanacetic acid*)

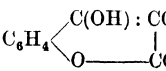
$$CN{\cdot}CEt_2{\cdot}CO_2H$$

has m.p. 57°, b.p. 162°–164°/18 mm., the *ethyl ester*, b.p. 215°–216°, 100°–101°/14 mm. (Hesse, Amer. Chem. J. 1896, 18, 723; Hessler, *l.c.* 171). *Diethylcyanacetamide* $CN{\cdot}CEt_2{\cdot}CONH_2$, colourless plates, m.p. 120° (Hesse). *Diethylmalonic semichloride* is an oil (Staudinger and Ott, Ber. 1908, 41, 2208); *diethylmalonyl chloride* $CEt_2(COCl)_2$, has b.p. 196·5°–197·5° (Fischer and Dilthey, Ber. 1902, 38, 844).

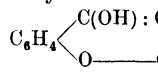
Acyl malonic esters. The acyl derivatives of malonic esters are prepared by the condensation of the sodiomalonic ester with the acyl chloride; the corresponding acids are not known. For the constitution of the esters *see* von Auwers and Auffenberg (Ber. 1917, 50, 929).

The acetyl, diacetyl, phenacetyl, diphenacetyl, propionyl, butyryl, benzoyl, nitrobenzoyl, succinyl, adipyl, phthalyl, and camphoryl malonic esters and derivatives have been prepared, *see* Michael, Amer. Chem. J. 1892, 14, 481; Schott, Ber. 1896, 29, 1985; Guinchant, Bull. Soc. chim. 1895, [iii.] 13, 1029; Held, Compt. rend. 116, 720; Lang, Ber. 1887, 20, 1326; Knoevenagel and Faber, Ber. 1898, 31, 2771; Claisen, Annalen, 1896, 291, 72; Bischoff and Rach, Ber. 1884, 17, 2793; Haller, Bull. Soc. chim. [ii.] 45, 271; Barthe, *ibid.* [ii.] 21, 529; Scheiber, Ber. 1909, 42, 1318; Wislicenus, Annalen, 1887, 242, 23; Wislicenus and Winzer, Annalen, 1890, 257, 298; Baeyer, Ber. 1892, 25, 1039; Ingle, Ber. 1894, 27, 2526.

Ethyl sodiomalonate condenses with acetyl salicylyl chloride or ortho substituted salicylylchlorides to form ethyl β-hydroxycoumarin-α-carboxylate



or the corresponding ortho-substituted derivatives; the acids obtained from these compounds by hydrolysis lose carbon dioxide and yield the β-hydroxycoumarin



or an ortho-substituted derivative, substances of potential therapeutic value.

Ethyl β-hydroxycoumarin-α-carboxylate has m.p. 93°; *β-hydroxycoumarin* has m.p. 206°; *ethyl 3 : 5-dichloro-β-hydroxycoumarin-α-carboxylate* has m.p. 135°, and *3 : 5-dichloro-β-hydroxycoumarin* has m.p. 275° (Aktien Gesellschaft für Anilinfabrikation, D. R. P. 102096. 1899; *cf.* Anschütz, Ber. 1903, 36, 463).

Chloro, bromo, and iodo malonic acids. Malonic acid, its esters, amides and substituted amides react readily with chlorine or bromine, forming under suitable conditions the mono- and di-halogen derivatives. The halogen in

certain of these compounds is highly reactive and liberates iodine from hydrogen iodide with the regeneration of the malonic compound according to the equation

$$(CONH_2)_2CBr_2+4HI = (CONH_2)_2CH_2+2HBr+2I_2$$

The reaction is in most cases quantitative and affords a rapid means of estimating the halogen in the compound (Whiteley, Chem. Soc. Proc. 1908, 24, 278; and Backes, West and Whiteley, Chem. Soc. Trans. 1921, 119, 359).

Chloromalonic acid $CHCl(CO_2H)_2$, m.p. 133° (Conrad and Guthzeit, Ber. 1882, 15, 605), the *ethyl ester*, b.p. 137°–139°/50 mm., sp.gr. 1·1776 at 20°/4°, n_D 1·4327 at 20° (Brühl, J. pr. Chem. [ii.] 50, 140); b.p. 91°/2 mm. (Forster and Müller, Chem. Soc. Trans. 1910, 97, 126); the *seminitrile* or *ethyl chlorocyanacetate*

$$CN{\cdot}CHCl{\cdot}CO_2Et$$

b.p. 190° (Henry, Compt. rend. 1887, 104, 1618). *Chloromalonamide* $CHCl(CONH_2)_2$, m.p. 170° (Conrad and Bischoff, Annalen, 209, 231); *chloromalondimethylanilide* $CHCl(CONMePh)_2$, m.p. 184°, and *chloromalontetraphenylamide* $CHCl(CONPh_2)_2$, m.p. 213° (Whiteley). *Chloromalonaldehyde* $OH{\cdot}CH:CCl{\cdot}CHO$, m.p. 144°, gives with aniline, the *monoanilide*

$$NHPh{\cdot}CH:CCl{\cdot}CHO$$

m.p. 193° (Dieckmann and Platz, Ber. 1904, 37, 4638).

Dichloromalonic acid $CCl_2(CO_2H)_2$ (Dootson, Chem. Soc. Trans. 1899, 169); the *aniline salt* has m.p. 105° (Conrad and Reinbach, Ber. 1902, 35, 1813); the *ethyl ester*, b.p. 231°–234°, sp.gr. 1·268 at 17°/15° (Conrad and Brückner, *ibid.* 24, 2993); the *methyl ester*, b.p. 110°–120°/20 mm., (Zincke, Kegel, *ibid.* 1890, 23, 244). *Dichloromalonamide*, m.p. 204° (Conrad and Brückner, *l.c.*; Zincke and Kegel, *l.c.*).

Bromomalonic acid $CHBr(CO_2H)_2$ (Petrieff, Ber. 1878, 11, 414; Conrad and Reinbach, Ber. 1902, 35, 1813; Lutz, Ber. 1902, 35, 2549; Biilmann and Madsen, Annalen, 1914, 402, 331) crystallises in plates, m.p. 113°; the *barium salt*, and the *silver salts* are crystalline. *Methyl bromomalonyl chloride*, b.p. 90°–91°/10 mm. (Staudinger and Becker, Ber. 1917, 50, 1016). *Methyl brommalonate* $CHBr(CO_2Me)_2$ is a colourless mobile liquid, b.p. 145°/22 mm. (Kohler, Heritage, McLeod, Amer. Chem. J. 1911, 46, 234). *Ethyl bromomalonate* $CHBr(CO_2Et)_2$, b.p. 223°-235° with slight decomposition (Knoevenagel, Ber. 1888, 21, 1356), 118°–119°/11 mm. (private communication); 150°–152°/25 mm. (Bischoff, Ber. 1907, 40, 3134); sp.gr. 1·426 at 15° (Conrad and Brückner, Ber. 1891, 24, 2997); *methyl bromomalonate* $CHBr(CO_2Me)_2$, b.p. 112·5°–113°/15 mm. (Bischoff, *l.c.*) *Bromomalonamide* $CHBr(CONH_2)$, m.p. 181° *Bromomalondiurethane* $CHBr(CO{\cdot}NH{\cdot}CO_2Et)$, m.p. 148° (Backes, West and Whiteley, *l.c.*).

For the *bromomalon*-alkyl-*amides*, and the *bromomalon*-aryl-*amides* and their brominated derivatives, *see* Backes, West and Whiteley (*l.c.*).

Methyl bromomalonanilate, m.p. 113°–114° (Staudinger and Becker, *l.c.*).

The *seminitrile* or *bromocyanacetic acid* $CN{\cdot}CHBr{\cdot}CO_2H$ (Petrieff, J. Russ. Phys. Chem. Soc. 10, 160). *Ethyl bromcyanacetate*, b.p. 116°/25 mm. (Nef, Annalen, 1897, 298, 202).

Bromomalonitrile $CHBr(CN)_2$, has m.p. 65°-66° (Hesse, Amer. Chem. J. 1896, 18, 723).

Bromomalonaldehyde $OH{\cdot}CH:CBr{\cdot}CHO$, m.p. 140°; the *anilide* $NHPh{\cdot}CH:CBr{\cdot}CHO$, has m.p. 184°; the *dianilide hydrobromide*

$$NHPh{\cdot}CH:CBr{\cdot}CH:NHPh,HBr$$

crystallises with EtOH and has m.p. 217° (Lespieau, Compt. rend. 1901, 133, 538).

Dibromomalonic acid $CBr_2(CO_2H)_2$ (Petrieff, Ber. 1874, 7, 400; Willstätter, Ber. 1902, 35, 1374; Conrad and Reinbach, Ber. 1902, 35, 1813) has m.p. 130°–131° (Willstätter), or 147° (Conrad and Reinbach); the heat of solution is +2·02 cal. *Potassium hydrogen dibromomalonate* forms brilliant anhydrous crystals, heat of dissolution −5·60 cal.; the *potassium salt* becomes anhydrous at 100°, decomposes at 200°, and has heat of dissolution −9·94 cal. (Massol, Compt. rend. 1892, 114, 1200); the crystalline *aniline* salt melts at 113° (Conrad and Reinbach, *l.c.*). *Methyl dibromomalonate* $CBr_2(CO_2Me)_2$, m.p. 63°–65°; *ethyl dibromomalonate* has b.p. 145°–155°/25 mm. (Conrad and Brückner, Ber. 1891, 24, 3001), b.p. 126°–131°/14 mm. (Reitter and Weindel, *ibid.* 1907, 40, 3358); 135°–137°/13 mm. (Ruhemann and Orton, Chem. Soc. Trans. 1895, 67, 1003); b.p. 134°/12 mm. (private communication). *Dibromomalonamide*

$$CBr_2(CONH_2)_2$$

m.p. 203° (Backes, West and Whiteley, *l.c.*), *dibromomalondimethylamide*

$$CBr_2(CONHMe)_2$$

m.p. 162° (Freund, Ber. 1884, 17, 780); *dibromomalonanilide* $CBr_2(CONHPh)_2$, m.p. 147° (Staudinger and Bereza, Ber. 1908, 41, 4465; Backes, West and Whiteley, *l.c.*).

For other *dibromomalon*-alkyl-*amides*, and *dibromomalon*-aryl-*amides* and their brominated derivatives, *see* Backes, West and Whiteley, *l.c.*

Dibromomalonitrile $CBr_2(CN)_2$, m.p. 123·5°–124° (Hesse, Amer. Chem. J. 1896, 18, 723). *Dibromomalonylchloride* $CBr_2(COCl)_2$, has b.p 75°–77°/15 mm., and solidifies at the ordinary temperature (Staudinger and Bereza, Ber. 1908, 41, 4461); *dibromomalonylbromide*

$$CBr_2(COBr)_2$$

has b.p. 91°–92°/13 mm. (Staudinger and Klever, *ibid.* 1908, 41, 906)

Iodomalondimethylanilide

$$CHI(CONMePh)_2$$

has m.p 164° (Vorländer and Herrmann, Ber. 1898, 31, 1826).

Di-iodomalonic acid $CI_2(CO_2H)_2$, is very unstable; it crystallises in pale yellow leaflets, m.p. 119°–120°. The *methyl ester* crystallises in pale yellow needles, m.p. 79°–80° (Willstätter, Ber. 1902, 35, 1374).

Ethyl chlorobromomalonate $CClBr(CO_2Et)$, has b.p. 136°–139°/35 mm., sp.gr. 1·467 at 16°/15° (Conrad and Brückner, Ber. 1891, 24, 2993); the *methyl ester* is crystalline, m.p. 40°–42° (Bischoff, Ber. 1907, 40, 3150).

Derivatives of cyanomalonic acid. *Ethyl cyanomalonate* $CN{\cdot}CH(CO_2Et)_2$, is a colourless oil, b.p 120°–130°/25 mm., with a pungent smell and acid reaction, and forms crystalline soluble salts. *Methyl cyanomalonate* also yields crystalline metallic derivatives (Haller, Compt. rend. 1882, 95, 142; Ann. Chim. 1889, [vi.] 16,

403). The *ethyl ester* of the *seminitrile* (*ethyl dicyanacetate*) $(CN)_2CH{\cdot}CO_2Et$ is crystalline, and forms crystalline sodium, silver and copper salts. The methyl ester is also known (Haller, Compt. rend. 1890, 111, 53).

Ethyl dicyanomalonate or *ethyl cyaniminoisosuccinate* $NH{:}C(CN){\cdot}CH(CO_2Et)_2$, colourless needles, m.p. 93°.

Derivatives of triazomalonic acid. *Ethyl methyltriazomalonate* $CH_3{\cdot}CN_3(CO_2Et)_2$, is a colourless liquid, b.p. 69°/0·6 mm., sp.gr. 1·11695 at 16°/16°; *methyltriazomalonamide* $CH_3{\cdot}CN_3(CONH_2)_2$, m.p. 137·5°; *methyltriazomalonic acid* $CH_3{\cdot}CN_3(CO_2H)_2$, m.p. 87·5°; *ethyl triazomalonic acid* $C_2H_5{\cdot}CN_3(CO_2H)_2$, melts and decomposes at 105°–107°; the *ethyl ester* has b.p. 83·5°/0·7 mm., sp.gr. 1·1161 at 16°/10°; the *amide* has m.p. 167°.

Phenyltriazomalonic acid $C_6H_5{\cdot}CN_3(CO_2H)_2$, m.p. 99°; the *ethyl ester* decomposes on attempted distillation, the *amide* has m.p. 189°. *Ethyl bistriazomalonate* $C(N_3)_2(CO_2Et)_2$, has b.p. 115°–115·5°/0·81 mm., sp.gr. 1·2136 at 20°, and is decomposed violently by sulphuric acid; the *amide* melts at 162° with vigorous decomposition (Forster and Müller, Chem. Soc. Trans. 1910, 97, 126).

Aminomalonic acid and derivatives. *Aminomalonic acid* $H_2N{\cdot}CH(CO_2H)_2,H_2O$, m.p. 109° (Baeyer, Annalen, 131, 291; Ruhemann and Orton, Chem. Soc. Trans. 1895, 67, 1007; Lutz, Ber. 1902, 35, 2549); *ethyl aminomalonate hydrochloride* $H_2N{\cdot}CH(CO_2Et)_2,HCl$, forms colourless needles, m.p. 162° (decomp.). The hydrochloride of the *methyl ester* melts and decomposes at 159°. *Aminomalonamide* $H_2N{\cdot}CH(CONH_2)_2$, m.p. 192° (Conrad and Guthzeit, Ber. 1882, 15, 605; Piloty and Neresheimer, *ibid.* 1906, 39, 514). *Aminomalonanilide* $(CO\cdot NHPh)_2CH{\cdot}NH_2$, m.p 141°–142°; *aminomalondimethylanilide* $(CONMePh)_2CH{\cdot}NH_2$, m.p. 108°; *aminomalontetraphenylamide* $(CONPh_2)_2CH{\cdot}NH_2$, m.p 200°–201°, are obtained by reducing the corresponding *iso*nitroso derivatives (Whiteley, Chem. Soc. Proc. 1904, 92).

Methyl formylaminomalonate

$$CHO{\cdot}NH{\cdot}CH(CO_2Me)_2$$

m.p. 85°, b.p. 250° (decomp.); the *ethyl ester* has m.p. 48°; the *amide* has m.p. 206° (decomp.) (Conrad and Schulze, Ber. 1909, 42, 729).

Diaminomalonamide $C(NH_2)_2(CO{\cdot}NH_2)_2$ (Conrad and Brückner, Ber. 1891, 24, 2993; Ruhemann and Orton, Chem. Soc. Trans. 1895, 67, 1002) loses ammonia and yields *iminomalonamide* $NH{:}C(CO{\cdot}NH_2)_2$ when carefully heated at 90°–100°. *Methyl tetramethyldiaminomalonate* $C(NMe_2)_2(CO_2Me)_2$, has m.p 83°–85°, and yields on hydrolysis *tetramethyldiaminomalonic acid*, m.p. 133° (Willstätter, Ber. 1902, 35, 1378).

Iminodimalonamide

$$(H_2N{\cdot}OC)_2CH{\cdot}NH{\cdot}CH(CONH_2)_2$$

decomposes without fusion (Conrad and Guthzeit, Ber. 1882, 15, 605).

Anilinomalonic acid $NHPh{\cdot}CH(CO_2H)_2$, m.p. 118°–119° (Reissert, Ber. 1898, 31, 382; Conrad and Reinbach, *ibid.* 1902, 35, 511). *Ethyl anilinomalonate* $NHPh{\cdot}CH(CO_2Et)_2$, m.p. 44°–45° (Curtiss, Amer. Chem. J. 1897, 19, 691), yields indoxylic acid when heated (Blank, Ber. 1898, 31, 1812).

Methyl anilinomalonate, m.p. 68°: the *hydrochloride* has m.p. 133°–135°; the *amide*, m.p. 156°.

Ethyl p-*toluidinomalonate* and *ethyl* β-*naphthylaminomalonate* melt at 55° and 88° respectively and yield indoxylic acid derivatives when heated (Blank, Ber. 1898, 31, 1812).

Anilinomalonanilic acid

$$NHPh{\cdot}CH(CO_2H)(CO{\cdot}NHPh)$$

melts and decomposes at 157° (Reissert, *l.c.*). *Anilinomalonanilide*, m.p. 246°–247° (Wislicenus and Münzesheimer, Ber. 1898, 31, 551).

Ethyl dianilinomalonate $(NHPh)_2C(CO_2Et)_2$, m.p. 117°–118° (Curtiss, Amer. Chem. J. 1897, 19, 691); *methyl dianilinomalonate*, m.p. 124°–125° (Conrad and Reinbach, Ber. 1902, 35, 511).

Aniline dianilinomalonate melts and decomposes at 120° (Conrad and Reinbach, Ber. 1902, 35, 1813).

Methyl phenyliminomalonate

$$PhN{:}C(CO_2Me)_2$$

is a thick yellow oil, reacting vigorously with water, alcohols, ammonia, amines and acids to form substituted anilinomalonates (Curtiss and Spencer, J. Amer. Chem. Soc. 1911, 33, 985).

Alkyl- and aryl-oxy-malonic acids. *Ethyl ethoxymalonate* $CH(OEt)(CO_2Et)_2$ has b.p. 228° and yields on hydrolysis *ethyl ethoxymalonic acid*, m.p. 123°–125°.

Ethyl diethoxymalonate $C(OEt)_2(CO_2Et)_2$, m.p. 43°–44°, b.p. 228° (Bischoff, Ber. 1897, 30, 487; Curtiss, Amer. Chem. J. 1897, 19, 691).

Ethyl diphenoxymalonate $C(OPh)_2(CO_2Et)_2$, b.p. 250°–260°/60 mm.; the *acid* has m.p. 173°.

Nitrophenoxymalonates. Sodium *o*-, *m*- and *p*-nitrophenoxides react with bromo-malonic esters in benzene or xylene solution according to the equation

$$NO_2{\cdot}C_6H_4{\cdot}ONa+CXBr(CO_2Y)_2 = NaBr+NO_2{\cdot}C_6H_4{\cdot}O{\cdot}CX(CO_2Y)_2$$

where X = H, Me, Et; Y = Me, Et; and sodium nitrophenoxides condense with methyl and ethyl dibromomalonates yielding bisnitrophenoxymalonic esters $(COOR)_2C(O{\cdot}C_6H_4{\cdot}NO_2)_2$ (Bischoff, Ber. 1907, 40, 3134, 3150).

Nitromalonic esters and derivatives. *Ethyl nitromalonate* $NO_2{\cdot}CH(CO_2Et)_2$ is a colourless liquid, b.p. 127°/10 mm., sp.gr. 1·1988 at 20°, 1·220 at 0°; the alkali salts are bright yellow, and probably have the *iso*nitro structure $(CO_2Et)_2C{:}NO{\cdot}OR$ (Wahl, Compt rend. 1901, 132, 1050; *cf.* Franchimont and Klobbie, Rec. trav. chim. 1889, 8, 283; Hantzsch, Ber. 1907, 40, 1523; Curtiss and Kostalek, J. Amer. Chem. Soc. 1911, 33, 962); *methyl nitromalonate* $NO_2{\cdot}CH(CO_2Me)_2$ forms a crystalline ammonium salt, m.p. 166° (Franchimont and Klobbie, *l.c.*). *Ethyl bromonitromalonate*

$$NO_2{\cdot}CBr(CO_2Et)_2$$

is a neutral oil, b.p. 136°–137°/11 mm.; the *methyl ester* has b.p. 133°/16 mm. (Willstätter and Hottenroth, Ber. 1904, 37, 1775).

Nitromalonamide $NO_2{\cdot}CH(CO{\cdot}NH_2)_2$, forms six-sided colourless prisms, m.p. 172° (with decomposition). The *potassium* salt is colourless, but yields yellow solutions (Ruhemann and Orton, Chem. Soc. Trans. 1895, 67, 1002). *Bromonitromalonamide* $NO_2{\cdot}CBr(CONH_2)_2$, has m.p. 131°–132° and decomposes on boiling with water yielding bromonitromethane (Ratz, Monatsh. 1904, 25, 687).

Nitromalonanilide $NO_2{\cdot}CH(CO{\cdot}NHPh)_2$ (Michael, Ber. 1905, 38, 22; Whiteley, Chem. Soc. Proc. 1904, 93) forms pale yellow leaflets, m.p. 141°–142°.

Nitromalonic aldehyde $CHO{\cdot}CH(NO_2){\cdot}CHO$ has m.p. 50°–51°. For its condensation products with amines, hydrazines, and hydroxylamines, *v.* Hill and Torrey, Amer. Chem. J. 1899, 22, 89; Hill and Hale, Amer. Chem. J. 1903, 29, 253.

Ethyl ester of the seminitrile of nitromalonic acid or *ethyl nitrocyanacetate*, $CN{\cdot}CH(NO_2)CO_2Et$, yields a potassium salt, m.p. 240° (Conrad and Schulze, Ber. 1909, 42, 735). *Nitrocyanacetamide* (fulminuric acid, *q.v.*) $(CN)CH(NO_2)CONH_2$ has m.p. 145° (decomp.) *ibid.* 739.

Nitrocyanacetyl carbamide

$$CN{\cdot}CH(NO_2)CO{\cdot}NH{\cdot}CONH_2$$

is obtained as its potassium salt by the oxidation of the corresponding nitroso compound.

***iso*Nitrosomalonic acid and derivatives.** *iso*-*Nitrosomalonic acid* $(CO_2H)_2C{:}NOH$, m.p. 120°, first obtained by Baeyer by hydrolysis of violuric acid (Baeyer, Annalen, 1864, 131, 292; Conrad and Bischoff, Ber. 1880, 13, 595), is identical with the oxime of mesoxalic acid prepared from mesoxalic acid and hydroxylamine (Meyer and Müller, *ibid.* 1883, 16, 608). *Ethyl* *iso**nitrosomalonate* $(CO_2Et)_2C{:}NOH$ (Conrad and Bischoff, Ber. 1880, 13, 595), is a colourless viscid liquid, b.p. 172°/12 mm., sp.gr. 1·206 at 4°/0° (Bouveault and Wahl, Compt. rend. 1903, 137, 196); or 1·149 at 15° (Conrad and Bischoff, *l.c.*). *Methyl* *iso**nitrosomalonate*, b.p. 168°/13 mm, m.p. 67° (Bouveault and Wahl, *l.c.*). For *oximinomalonamic acid*

$$COOH{\cdot}C(:NOH){\cdot}CONH_2$$

m.p. 137° (decomp.), and *oximinomalonamidine* $CO_2H{\cdot}C(:NOH){\cdot}C(:NH){\cdot}NH_2$ (decomposes at 283°), and allied compounds, *v.* Wieland and Baumann, Annalen, 1912, 392, 196.

The *iso*nitroso derivatives of malonamide and the substituted amides of malonic acid are obtained by the action of nitrosyl chloride at 0° on the amide dissolved or suspended in dry chloroform, and the yield is usually quantitative.

*iso*Nitrosomalonamide and the alkyl substituted derivatives are colourless, the aryl substituted derivatives are yellow, or exist in two forms one yellow and one colourless, exhibiting dynamic isomerism; all the *iso*nitroso derivatives form crystalline yellow alkali and silver salts, and deep violet or blue ferrous salts. It is probable that the yellow *iso*nitroso derivatives and the salts possess the true oximino structure

$$(CONHR)_2C{:}NOH\ ;\ (CONHR)_2C{:}NOK$$

whilst the colourless *iso*nitroso derivatives are

*iso*oximes $(CONHR)_2C\langle{}^{NH}_{O}\rangle$.

iso*Nitrosomalonamide* $(CONH_2)_2C\langle{}^{NH}_{O}\rangle$ colourless, m.p. 187° (decomp.); the *acetyl* derivative is colourless, m.p. 190°; *ethyl* derivative, pale yellow, m.p. 150°–151°; the silver salt $(CONH_2)_2C{:}N{\cdot}OAg,2NH_3$, deep yellow prismatic crystals; *potassium* salt

$$(CO{\cdot}NH_2)_2C{:}N{\cdot}OK$$

is yellow, and forms with ferrous sulphate the *ferrous potassium salt*

$$(CONH_2)_2{\cdot}C{:}N{\cdot}OK,[(CONH_2)_2C{:}N{\cdot}O]_2Fe$$

which crystallises in well-defined purple prisms with a bronze or green reflex. The *yellow* variety of *iso*nitrosomalonamide

$$(CONH_2)_2C{:}NOH$$

differs from the colourless form only in colour.

iso*Nitrosomalondimethylamide*

$$(CO{\cdot}NHMe)_2C\langle{}^{NH}_{O}\rangle$$

m.p. 157°; the *potassium* salt

$$(CONHMe)_2C{:}N{\cdot}OK$$

is bright yellow; the *ferrous* salt

$$[(CONHMe)_2C{:}NO]_2Fe$$

is purple.

iso*Nitrosomalonanilide*. The *colourless* variety becomes yellow at 138°–140° and melts at 141°; the *yellow* variety becomes white at 120°–122° and melts at 141°; the equilibrium mixture of the two isomerides melts at 124°.

iso*Nitrosomalonmonophenylamide*

$$NHPh{\cdot}CO{\cdot}C(CO{\cdot}NH_2)\langle{}^{NH}_{O}\rangle$$

has m.p. 180°–181° (decomp.).

iso*Nitrosomalondi-*p*-tolylamide*

$$(CONH{\cdot}C_7H_7)_2C{:}N{\cdot}OH$$

is pale yellow, m.p. 170°–171°; the *colourless* isomeride becomes yellow at 150° and melts at 170°–171°.

iso*Nitrosomalonmono-*p*-tolylamide*

$$C_7H_7{\cdot}HN{\cdot}CO{\cdot}C(CO{\cdot}NH_2){:}NOH$$

is lemon yellow, m.p. 183°.

iso*Nitrosomalondi-*o*-tolylamide*

$$(CONH{\cdot}C_7H_7)_2C{:}NOH$$

is yellow, m.p. 111°; the *colourless* isomeride changes to yellow at 75° and melts at 111°

Ethyl iso*nitrosomalon-*o*-tolylamate*

$$C_7H_7{\cdot}HN{\cdot}CO{\cdot}C(CO_2Et){:}NOH$$

is pale yellow, m.p. 140°–141°.

iso*Nitrosomalondi-*α*-naphthylamide*

$$(CONH{\cdot}C_{10}H_7)_2C{:}NOH$$

is orange coloured, m.p. 184°.

iso*Nitrosomalondi-*β*-naphthylamide* is pale yellow, m.p. 221°; the *acetyl* derivative is colourless, m.p. 179° (decomp.).

iso*Nitrosomalondimethylanilide* crystallises with 1 mol. methyl alcohol.

$$(CO{\cdot}NMePh)_2C\langle{}^{NH}_{O}\rangle,\ MeOH$$

is colourless and has m.p. 109°; the *acetyl* derivative has m.p. 130°, the *benzoyl* derivative m.p. 157°–158°, and the *ethyl ether* m.p. 138°.

iso*Nitrosomalontetraphenylamide*

$$(CONPh_2)_2C{:}NOH$$

forms pale yellow prisms, m.p. 237°–238°

(decomp.); the *acetyl* derivative is pale yellow, m.p. 190°; the *benzoyl* derivative is colourless, m.p. 175°, the *ethyl ether* has m.p. 164°–165°, (Whiteley, Chem. Soc. Trans. 1900, 77, 1040; 1903, 83, 18, 24; Chem. Soc. Proc. 1904, 93).

iso*Nitrosomalondiurethane*

$(CONH{\cdot}CO_2Et)_2C{:}NOH$

m.p. 203°–204° (Conrad and Schulze, Ber. 1909, 42, 735). The *ammonium* salt forms bright orange prisms, m.p. 174°. The *potassium* salt $(CO{\cdot}NH{\cdot}CO_2Et)_2C{:}N{\cdot}OK$, is bright orange-red (Whiteley).

Derivatives of the seminitrile of isonitrosomalonic acid. *Ethyl isonitrosocyanacetate*

$HON{:}C(CN)CO_2Et$

m.p. 133°, yields metallic derivatives (Conrad and Schulze, Ber. 1909, 42, 735).

The *methyl ester* has m.p. 123°. The *ethers*

$EtON{:}C(CN)CO_2Et$

b.p. 125°–127° 1/22–24 mm. and

$EtON{:}C(CN)CO_2Me$

b.p. 121°–124°/23–25 mm. and the corresponding benzoyl derivative, m.p. 131°–132°, are described by Müller (Ann. Chim. Phys. [vii.] 1, 463).

Isonitrosocyanacetamide (Desoxyfulminuric acid) $CN{\cdot}C{:}NOH{\cdot}CONH_2$, m.p. 184° (*ibid.* 738).

Isonitrosocyanacetyl carbamide

$HON{:}C(CN)CO{\cdot}NH{\cdot}CONH_2$

m.p. 220° (decomp.) (*ibid.* 741).

Isonitrosocyanacetyl urethane

$HON{:}C(CN)CO{\cdot}NH{\cdot}CO_2Et$

forms white crystals, m.p. 201° (decomp.) (*ibid.* 742).

Condensation of malonic acid with aldehydes. Malonic acid condenses with aldehydes according to the equation

$$(CO_2H)_2CH_2+OHC{\cdot}R=(CO_2H)_2C{:}CHR+H_2O$$

The methylene malonic acids thus produced yield the corresponding alkyl or aryl malonic acids $CH_2R{\cdot}CH(CO_2H)_2$ on reduction; and lose carbon dioxide on heating to form the substituted acrylic acid $CHR{:}CH{\cdot}CO_2H$.

The *bis*malonic acid $CHR[CH{\cdot}CO_2H)_2]_2$ is sometimes obtained when the aldehyde and malonic acid are taken in the proportion of 1 mol. of the former to 2 mols. of the latter.

For the condensation products with formaldehyde, *see* Haworth and Perkin, Chem. Soc. Trans. 1898, 73, 339; Bottomley and Perkin, *ibid.* 1900, 77, 294. For the *ethylidene*, iso*butylidene*, iso*amylidene*, *œnanthylidene*, *valerylidene*, *citrylidene*, *furfurylidene*, *crotonylidene*, *benzylidene*, and *cinnamylidene*, *anisylidene*, *methylsalicylidene*, *piperonylidene* and *phenylpropionylidene* malonic acids and derivatives, *see* Kommenos, Annalen, 1883, 218, 145; Knoevenagel, Ber. 1898, 31, 2585; Braun, Monatsh. 1896, 17, 207; Riedel and Straube, Annalen, 1909, 367, 40; Knoevenagel, D. R. PP. 161171, 156560, 164296, 97735; Verley, Bull. Soc. chim. 1899, [iii.] 21, 414; Dakin, J. Biol. Chem. 1909, 7, 49; Röhmer, Ber. 1898, 31, 281; Riedel, Annalen, 1908, 361, 89; Stuart, Chem. Soc. Trans. 1883, 43, 403; 1885, 47, 155; 1886, 49, 360; Claisen and Crismer, Annalen, 218, 129; Einhorn and Gehrenbeck, Annalen, 1889, 253, 374; Claisen, Ber. 1903, 86, 3664). For condensation with *αβ-di-bromopropaldehyde*, *v.* Lespieaw (Compt. rend. 1910, 151, 1359).

M. A. W.

MALONYLCARBAMIDE, *Barbituric acid, v* PYRIMIDINE.

MALT *v.* BREWING.

MALTASE is the enzyme which hydrolyses maltose to two molecules of dextrose. It is present in most, though not in all, species of yeasts; those yeasts (*e.g. Saccharomyces marxianus*, *S. exiguus* (Rees), *S. ludwigii*, *S. saturnus*, *S. anomalus*) which do not contain maltase are unable to ferment maltose. Maltase is found in *Aspergillus niger*, *Penicillium glaucum*, and other mould fungi; a maltose splitting enzyme is present in the intestine (Brown and Heron, Proc. Roy. Soc. 1880, 30, 393) and in numerous other animal tissues (Tebb, J. Physiol. 1894, 15, 421). According to Compton (Biochem. J. 1921, 15, 681) it is present in the blood serum of the dog, pig, goat, horse, and ox, and is absent in that of the cat, guinea-pig, rabbit, and man. Maltase is present in the solid residue left after repeatedly extracting maize, millet, or buckwheat with water until the diastase has been removed. The dry powder has far more powerful enzymatic properties than aqueous extracts, and in this respect resembles the powders from dried leaves containing emulsin, &c., investigated by Armstrong (Proc. Roy. Soc. 1912, 85, B, 363). The maltase so obtained is stated by Wierchowski (Biochem. Zeitsch. 1913, 56, 209, 57, 125) to hydrolyse starch to dextrose and soluble starch, no dextrins being formed as intermediate products. Maltase is more difficult to extract than invertase; active extracts can only be obtained from yeast after the cells have been destroyed, or, better, after a preliminary drying in a thin layer at a low temperature. The enzyme is not liberated on shaking yeast with toluene water. Yeast juice made by Buchner's method of compression contains maltase. Brown and Heron found aqueous extract of pig's intestine to have no action on maltose, but after drying at 35° fine shreds of the intestine were active. Using similar methods Tebb found most maltase in the mucous membrane of the small intestine; it was also present in the spleen, lymphatic gland, liver, kidney, and in the pancreatic and salivary glands, and least of all in muscle. When the tissue is finely minced and sufficient time (several days) is allowed for adequate extraction, active maltase may be obtained from fresh tissues. Malt does not contain maltase.

In preparing maltase solutions for practical work it is always advisable to devote some attention to ascertaining the exact conditions necessary to get a preparation of maximum activity. The yeast should be dried quickly and in thin layers at about 25°, the extract should be prepared with suitable distilled water in hard glass vessels at 35° or less, maceration being continued for not too long a period. The extract should be filtered quickly and used at once. Toluene is by far the best antiseptic to employ.

Maltase is destroyed by precipitation of the aqueous extract with alcohol, so that it has not been possible to purify it.

Maltase also hydrolyses α-methylglucoside and other synthetical α-glucosides, although it is

without action on the isomeric β-glucosides. Amygdalin is hydrolysed by an enzyme akin to maltase, present in some yeasts, to dextrose and amygdonitrileglucoside (Fischer, Ber. 1895, 28, 1508). This action is due, however, not to maltase, but to amygdalase (Caldwell and Courtauld, Proc. Roy. Soc. 1907, B, 79, 350). Maltase is able to cause synthetic as well as analytic changes (Croft Hill, Chem. Soc. Trans. 1898, 73, 634; 1903, 83, 578; *see* also Bayliss, The Nature of Enzyme Action, Longmans, 1911).

The optimum temperature of maltase is 35°–40°.

Maltase is destroyed by excess of alkali, and also by acids of any marked strength, a nucleoprotein-like substance being precipitated. The optimum activity as measured towards maltase or α-methyl glucoside takes place in solutions which are just acid, viz. between p_H=6·1 and p_H=6·8, and in this respect it differs markedly from invertase (optimal point p_H=4·5). At this point maltase is inactive and even destroyed. Maltase differs from invertase also in that it is precipitated at its isoelectric point and is adsorbed by kaolin, whereas invertase is not (*cf.* Michaelis and Rona, Biochem. Zeitsch. 1913, 57, 70). The activity of maltase solutions is as a rule increased by dialysis, and in such dialysed solutions the optimum activity generally occurs in a solution of lower acid concentration. E. F. A.

MALTHA. A variety of 'mineral tallow' or wax, sp.gr. 0·77, soluble in alcohol, naphtha, and oil of turpentine, said to be originally found on the coast of Finland. It is white, brittle, and stains paper like oil, melts at a moderate heat, and burns with a smoky flame. A similar hydrocarbon is met with in the oil-fields of California.

MALTODEXTRIN *v.* DEXTRIN.

MALTOSE *v.* CARBOHYDRATES (*cf.* Haworth and Leitch, Chem. Soc. Trans. 1919, 115, 809).

MALVIDIN, MALVIN *v.* ANTHOCYANINS.

MAMMIN *v.* SYNTHETIC DRUGS.

MANACCANITE. A variety of titaniferous magnetic oxide of iron found in grains and small angular fragments at Manaccan near Helstone, and other places in Cornwall, *v.* ILMENITE; TITANIUM.

MANCHESTER YELLOW. *Dinitronaphthol v.* NAPHTHALENE. Dinitronaphthol-yellow has been used to artificially colour natural saffron. To detect the adulteration, an infusion of the matter is prepared, to which some tartaric acid is added. A hank of wool is then dipped in the boiling solution. The wool thus dyed is washed in very dilute sulphuric acid, and the acid afterwards neutralised with ammonia. If saffron contained any dinitronaphthol, the wool or the solution will be coloured yellow, whereas wool dyed with a decoction of genuine saffron and treated in the same manner becomes colourless (Cazeneuve and G. Ginnossier, J. Soc. Chem. Ind. 5, 437).

MANDELIC ACID (*Phenylglycollic acid*; *α-phenylhydroxyacetic acid*) $C_6H_5{\cdot}CH(OH)CO_2H$. Discovered by Winkler in 1852 in the emulsion of bitter almonds. It may be obtained by warming ω-dibromoacetophenone with dilute alkali (Engler and Wöhrle, Ber. 1887, 2202); by oxidising ω-hydroxyacetophenone with copper sulphate (Breuer and Zincke, *ibid.* 1880, 635); by boiling phenylchloracetic acid with alkali (Spiegel, *ibid.* 1881, 239); and by warming benzoylformaldehyde with alkali (Pechmann, *ibid.* 1887, 2905; Müller and Pechmann, *ibid.* 1889, 2558). It is best prepared by shaking commercial benzaldehyde with a concentrated solution of sodium bisulphite, filtering off and drying the bisulphite compound. This is then made into a paste with water, and the calculated quantity of potassium cyanide solution added with stirring. The oily mandelonitrile soon separates, and is hydrolysed by boiling with three times the theoretical quantity of hydrochloric acid (Pape, Chem. Zeit. 1896, 20, 90; Chem. Fab. vor. Hofmann and Schoetensack, Eng. Pat. 14886; J. Soc. Chem. Ind. 1896, 614; *cf.* Müller, Arch. Pharm. [iii.] 2, 385, 389; Ber. 1872, 980; Wallach, Annalen, 193, 38; Luginin, *ibid.* 139, 299; Winckler, *ibid.* 18, 310).

Forms colourless rhombic prisms; m.p. 118° (Claisen, Ber. 1877, 847); sp.gr. 1·361 at 4°/4° (Schröder, *ibid.* 1889, 1612); readily soluble in alcohol and ether. On heating the acid at 200°, benzaldehyde and an amorphous mass is obtained; benzaldehyde, water and diphenylmaleic anhydride are formed when it is heated in a current of air under reduced pressure (Bischoff and Walden, Annalen, 279, 118; Liebig, *ibid.* 18, 312). For the anhydride of mandelic acid $C_{32}H_{26}O_9$, *v.* Stutz, Ber. 1911, 44, 3485. (It is possible that this so-called anhydride is the lactide $C_8H_6O_3$.) *Cf* Denham and Woodhouse, Chem. Soc. Trans. 1913, 1870. Fuming nitric acids yields *o*- and *p*-nitrophenylglycollic acids (Pratesi, Gazz. chim. ital. 21, ii. 402). Electrolysis of an aqueous solution of the potassium salt results in the production of hydrobenzoin and a small quantity of *iso*hydrobenzoin (Walker, Chem. Soc. Trans. 1896, 1279); but according to Miller and Hofer (Ber. 1894, 469) benzaldehyde, carbon dioxide, and carbon monoxide are the products. By passing carbonyl chloride into an ice-cold solution of the acid in pyridine the bimolecular anhydride, m.p. 240°, is formed (Einhorn and Pfeiffer, Ber. 1901, 2951). Hydrogen iodide and phosphorus convert mandelic acid into phenylacetic acid, and fuming hydrochloric acid at 140° yields phenylchloracetic acid. Mandelic acid condenses with phenols in the presence of 73 p.c. sulphuric acid to *o*-hydroxydiarylacetic acid, lactones and *p*-dihydroxydiarylacetic acids (Bistrzycki and Flatau, Ber. 1895, 989; 1897, 124); *v.* also Simonis (Ber. 1898, 2821) for condensation with β-naphthol, resorcinol, and orcinol. The nitrile prepared as above, is a yellow oil, solidifying at −10°. The amide has m.p. 190°, the anilide 151°–152°, and the phenylhydrazide 182° (Tiemann and Friedländer, Ber. 1881, 635; Reissert and Kayser Ber. 1890, 3701; Biedermann, *ibid.* 1891, 4083; Bischoff and Walden, Annalen, 279, 118). The methyl ester has m.p. 52° (Zincke and Brewer, Ber. 1880, 636; Ruhe, *ibid.* 1895, 259), and the ethyl ester has m.p. 34°, b.p. 253°–255° (Michael and Jeanprêtre, Ber. 1892, 1684; Beyer, J. pr. Chem. [ii.] 31, 389); m.p. 37° (McKenzie, Chem. Soc. Trans. 1899, 755).

Mandelic acid contains an asymmetric carbon atom, and hence can be split into two

optically active isomerides. Lewkowitsch (Ber. 1882, 1505; 1883, 1565, 2722) obtained *l*-mandelic acid by treating the inactive acid with *Saccharomyces ellipsoideus* (Rees) and *d*-mandelic acid by using various microzoa, such as *Penicillium glaucum*, &c. Partial resolution of the inactive acid has also been effected by means of the fractional crystallisation of salts with alkaloids, such as quinine and morphine, and with active amines such as methylhydrindamine; and by esterification with active alcohols, such as menthol and borneol (McKenzie, Chem. Soc. Trans. 1899, 968; 1904, 378; McKenzie and Thompson, *ibid.* 1905, 1004; Marckwald and Paul, Ber. 1906, 3654; Kipping, Chem. Soc. Trans. 1909, 416; Findlay and Hickman, *ibid.* 1909, 1386). Racemisation is found to take place on boiling the active acid with alkali (Holleman, Rec. trav. chim. 1898, 17, 323; McKenzie and Müller, Chem. Soc. Trans. 1907, 1814). Asymmetric syntheses have been conducted by McKenzie and Humphries (*ibid.* 1909, 1106) from *l*-menthylbenzoylformate, and by Rosenthaler (Biochem. Zeitsch. 1908, 14, 238) from *d*-benzaldehydecyanhydrin. *d*- and *l*-Mandelic acids can also be prepared by the hydrolysis of amygdalinic acid (Dakin, Chem. Soc. Trans. 1904, 1512; *cf.* Wöhler, Annalen, 66, 238; Walker, Chem. Soc. Trans. 1903, 83, 472; Tutin, *ibid.* 1909, 663; Feist, Arch. Pharm. 248, 101; Rosenthaler, *ibid.* 105). Incomplete hydrolysis of the ethyl ester by *lipase* yields the *d*-acid, whilst the ester remaining is lævorotatory (Dakin, Chem. Soc. Proc. 1903, 161; J. Physiol. 1903, 30, 253).

l-Mandelic acid has m.p. 132·8°, and $[\alpha]_D$ −153·1° in water (Walden, Zeitsch. physikal. Chem. 1895, 17, 705; *cf.* Lewkowitsch, *l.c.*; Rimbach, Zeitsch. physikal. Chem. 1899, 28, 251; Ber. 1899, 2385). *d*-Mandelic acid has m.p. 132·8°, and $[\alpha]_D$ +156° (Kipping, Chem. Soc. Trans. 1909, 416). For experiments on the *Walden Inversion* with mandelic and phenylchloracetic acids, *v.* McKenzie and Clough, Chem. Soc. Trans. 1909, 777.

MANDRAGORA ROOT. In 1889 Ahrens (Annalen, 251, 312) extracted from *Mandragora* root an alkaloid possessing similar physiological properties to atropine, and which he named *mandragorin*. Thoms and Wentzel (Ber. 1898, 31, 2031) showed that the *mandragorin* of Ahrens was a mixture of bases, the chief of which was *hyoscyamine*, and subsequently isolated another base, which they named *scopolamine* (Ber. 1901, 31, 2031). Hesse (J. pr. Chem. 1901, 64, 274) further investigated the subject and found that *mandragora* root contains 0·36 p.c. *hyoscyamine*, 0·04 p.c. *hyoscine* (*scopolamine* of Thoms and Wentzel), 0·01 p.c. *ψ-hyoscyamine*, and a still smaller quantity of a new base *mandragorine*. To obtain these alkaloids, the roots are powdered, moistened with a solution of caustic soda, and extracted with ether under a reflux apparatus. The ethereal solution is repeatedly extracted with dilute sulphuric acid, the acid solution being made alkaline with sodium bicarbonate and extracted with chloroform. This operation is then repeated, whereby the hyoscyamine remains in the aqueous solution. The bases from the chloroform extract are neutralised with hydrobromic acid, and the filtered solution allowed to crystallise. The hydrobromides of the bases are then extracted with acetone, which leaves the pure hydrobromide of hyoscine $C_{17}H_{21}NO_4$ (m.p. 194°). The free base is decomposed by baryta into tropic acid and oscine $C_8H_{13}NO_2$. The mother liquors of the hyoscinehydrobromide yield *ψ*-hyoscyamine on addition of sodium bicarbonate and extraction with chloroform. On adding sodium carbonate to the residual solution, the alkaloid *mandragorine*, forming a gold double salt $C_{15}H_{19}NO_2HAuCl_4$ is obtained. The free base is decomposed by baryta into atropic acid, and a base resembling tropine.

MANGANATES *v.* MANGANESE.

MANGANESE. Sym. Mn. At.wt. 54·95. (Fr. *Manganèse*; Ger. *Mangan.*) Manganese is not found in the metallic state. In combination, especially as oxide, it is widely distributed. The most important ores are those corresponding with the dioxide MnO_2, *pyrolusite*. It is also found as the oxides *braunite* Mn_2O_3, *hausmannite* Mn_3O_4, as hydrated oxide Mn_2O_3,H_2O in *manganite*, and associated with barium oxide in *psilomelane*. As sulphide it occurs as *alabandite* MnS and *hauerite* MnS_2; as carbonate in *rhodocrosite* or *dialogite* $MnCO_3$; as silicate in *rhodonite* $MnSiO_3$; and *tephroite* Mn_2SiO_4. The former is of a beautiful red colour, found largely in the Ural Mountains, and used as an ornamental stone. It is often present to a small extent in other silicates, and confers on them its colour. The chief sources of the manganese ores are Russia, the Caucasus, Brazil, and India. Smaller quantities are mined in Germany, Austria, Spain, Turkey, Japan, Greece, and Hungary. Deposits of manganiferous iron ores occur in California and in the Eastern States of America, Vancouver Island, and Nova Scotia. Manganese deposits are also worked in Cuba. Manganese is present in soils, and frequently in mineral, particularly chalybeate, waters. It occurs in many plants, especially in tea and tobacco, and is, in fact, widely distributed throughout the vegetable kingdom.

Preparation.—Metallic manganese is not used in the arts except when alloyed with other metals. It may be prepared by reduction of the oxide with carbon, but the temperature necessary for the reduction is so high (1105°C., Greenwood, Chem. Soc. Trans. 1908, 1491) that it is only obtained with difficulty in ordinary furnaces. The original method of preparation described by John (Gehlen's Jour. für Chem. Phys. 3, 452) consisted in making an intimate mixture of finely divided manganous oxide and carbon by mixing with oil and heating, and exposing it to as high a temperature as possible in a crucible lined with charcoal. The impure manganese so obtained was purified by fusing under salt and nitre.

Brunner (Annalen, 102, 330) prepared the metal by heating a mixture of sodium and manganese chloride or fluoride in a blast furnace for 15 minutes. It may also be obtained by the reduction of the chloride by magnesium.

Deville obtained the metal by the reduction of the pure red oxide Mn_3O_4 by means of sugar charcoal present in insufficient quantity to reduce the whole (Ann. Chim. Phys. 1856, 46, 182).

Valenciennes (Compt. rend. 70, 907) produced it by reduction of the pure oxide with carbon in a magnesia-lined crucible as a hard and brittle mass, quickly oxidised by exposure to air.

Oxides of manganese are reduced to the protoxide but not to metal by ignition in hydrogen. Hugo Tamm (Chem. News, 26, 111) recommends the following process for the preparation on the large scale. Two fluxes are prepared. (1) A fusible 'white' flux of ground glass (free from lead) 63, quicklime 18½, and fluorspar 18½. (2) Flux No. 1 34 parts, lampblack 5½, native manganese dioxide of good quality 60½.

The crucibles used should be very refractory, lined with a mixture of 3 parts plumbago and 1 part fireclay, made into a paste with water. This casing resists the action of the flux for a considerable time. In such a crucible flux No. 2 is ignited at the highest temperature of a wind furnace with the production of 17½ parts of 'Cort manganese' and a green slag saturated with manganous oxide. Of this slag 635 parts are thoroughly mixed with 91 parts of lampblack (charcoal cannot be used), and then with 1000 parts of rich manganese ore. The whole is made into a paste with oil, pressed into the crucible, covered with a piece of wood to prevent oxidation, and luted down, leaving an aperture for the escape of gases.

The crucible is next heated in a blast furnace, at first gently, until fumes cease to escape, and finally to whiteness, for several hours. On cooling, the manganese is found as a coherent mass. The green slag may be used several times with the addition of a little white flux to increase the fluidity, provided too much gangue be not present in the ore.

Operating with an ore containing 79·5 p.c. manganese dioxide, 6·5 p.c. ferric oxide, and 10·5 p.c. gangue, the manganese obtained showed the following composition: Mn 96·9, Fe 1·05, Al 0·10, Ca 0·05, P 0·05, S 0·05, Si 0·85, C 0·95. This metal, when fused with one-eighth part of manganous carbonate, contained Mn 99·91, Fe 0·05, Si 0·015, C 0·025.

The metal is now almost entirely prepared either by reduction by aluminium by the Goldschmidt method or by means of the electric furnace. In the latter method pure manganous oxide is intimately mixed with carbon and heated in an electric furnace, a current of 300 ampères at 60 volts giving a yield of 100–120 grams of manganese in 5 or 6 minutes, or a current of 100 ampères at 60 volts giving the same amount in 10–15 minutes. Care has to be taken to avoid prolonged heating, as the metal readily volatilises in the electric furnace, and hence considerable loss may result. As carbon readily dissolves in manganese the metal so prepared usually contains from 5 to 14 p.c. carbon, which, if the manganese is volatilised, remains as graphite. By again fusing with oxide it may be obtained almost quite free from carbon and silicon (*v.* Moissan, The Electric Furance).

The principal use of manganese in the arts is in the manufacture of steel (*q.v.*), where its alloys are employed as a deoxidiser for carburising the finished steel by means of the large percentage of carbon contained, the manganese also conferring improved qualities on the steel. Both spiegeleisen and ferromanganese are smelted in blast furnaces similar to those used for making pig-iron. More basic slags and a higher temperature are, however, employed, involving a larger consumption of fuel and shorter life for the furnace lining; consequently, the boshes are usually completely water-jacketed. Spiegeleisen is manufactured containing 10–20 p.c. of manganese and 4–5 p.c. carbon, according to the demands of the steel-maker. As a considerable proportion of manganese passes into the slag (up to 6 and 7 p.c. in spiegeleisen) allowance has to be made for this in making up the charge. Ferromanganese containing 80 p.c. manganese and more with 6 p.c. carbon is manufactured and largely used in open hearth steels.

Properties.—Pure manganese is soft and does not scratch glass; if it contains but little carbon it may be kept in open vessels. As the percentage of carbon increases it becomes more readily decomposed by the moisture in the air and small fragments exposed to the air become oxidised in 24 hours with the production of hydrogen and hydrocarbons. It appears to form a definite carbide Mn_3C, which is hard and brittle, and rapidly oxidises in air, and by moisture is decomposed according to the equation

$$Mn_3C+6H_2O=3Mn(OH)_2+CH_4+H_2$$

equal volumes of methane and hydrogen being evolved. This carbide is probably present in solid solution in the impure manganese, on which it confers its hardness (*cf.* Ruff and Gersten, Ber. 1913, 46, 400).

The metal has been obtained crystalline by distillation in the electric furnace, and as a pyrophoric powder by gentle ignition of its amalgam in a current of hydrogen (Prelinger, Monatsh. 14, 353). If the temperature of ignition is too high it is no longer pyrophoric, and although paramagnetic at ordinary temperatures becomes ferromagnetic on heating.

The metal dissolves in dilute acids, and with hot sulphuric acid liberates sulphur dioxide; when used as an anode in electrolysis it behaves normally in acid and neutral electrolytes but becomes *passive* in alkaline sulphate or phosphate baths (Müller, Zeitsch. Elektrochem. 11, 755). Its sp.gr. is about 8.

The melting-point of a 99 p.c. manganese was found by Heraeus to be 1245° (Zeitsch. Elektrochem. 1902, 8, 185). According to Tiede the melting-point of manganese is 1290°. Other authorities give 1210° to 1230°. When heated in nitrogen or ammonia a nitride is formed, possessing marked magnetic properties (Shukoff, J. Russ. Phys. Chem. Soc. 40, 457); nitrides of composition Mn_3N_2, Mn_5N_2, and Mn_7N_2 are stated to exist (Wedekind and Weit, Ber. 41, 3769). From the lowering of the freezing-point by phosphorus the value 27·5 has been calculated for the latent heat of fusion (Schemtschuschny and Efremoff, J. Russ. Phys. Chem. Soc. 39, 777). At 1000° the metal is oxidised by carbon monoxide with formation of manganous oxide and carbon (Charpy, Compt. rend. 148, 560).

Detection.—All compounds of manganese, if strongly ignited, impart an amethyst-red colour to the borax bead in the oxidising flame; the

bead can be rendered colourless by careful heating in the reducing flame. When heated with soda and a little nitre on platinum foil a very small quantity of manganese produces a green colour.

A very delicate test, in the absence of chlorides, consists in heating the substance or solution with dilute nitric acid and a little lead peroxide. The manganese is thus oxidised and imparts to the solution the pink colour of permanganic acid (Crum).

Minute quantities in soils, minerals, vegetables, &c., may be detected by incinerating, heating the ash with nitric acid, evaporating to dryness, taking up with water and adding to the filtrate some 40 p.c. ammonium persulphate and a drop of a 2 p.c. solution of cobalt nitrate, when a pink colour is developed on boiling.

Tetraphenyldiaminodiphenylmethane is stated to be a very delicate test for manganese (in the absence of copper). The substance to be tested is warmed with sodium hydroxide, incinerated and the ashes moistened with acetic acid. On warming with the reagent a blue colour is developed. The same colour is also produced with lead.

Manganese may be detected in N/10000 solution of manganous salts by the red colour produced by the addition of a few drops of a N/10 solution of potassium periodate (Benedict, Amer. Chem. J. 34, 381).

It may also be detected and estimated by adding to 5 c.c. of the solution, 3 c c. of glycerol, and 1 c.c. of a 50 p.c. solution of sodium hydroxide, and then drawing a current of air through the liquid. A fine ruby colour is developed, the intensity of which is proportional to the manganese present, so that the test may be used for colorimetric estimation (Tarugi, Gazz. chim. ital. 36, 332).

When manganese is present in its usual form, as a protosalt, sulphuretted hydrogen produces a flesh-coloured precipitate from alkaline, but not from acid or neutral solutions. If ammonium hydrogen sulphide is added to a solution made alkaline with ammonia green manganese sulphide is precipitated. If the precipitation takes place at 100°, a dense green sulphide is obtained, which can be easily collected and washed. For conditions of its formation, *see* Fischer, J. Russ. Phys. Chem. Soc. 1914, 46, 1481.

Potassium and sodium hydroxides precipitate white hydrated manganous oxide which rapidly becomes brown from absorption of oxygen. Ammonia produces the same precipitate, which is soluble in excess, especially in presence of ammonium chloride, but slowly forms a precipitate of the brown oxide.

Where the manganese exists as the acid oxide, as in manganates and permanganates, the reactions are different. Alkaline manganates produce green solutions which slowly become red on exposure to air, more rapidly on addition of an acid, from production of the permanganate. Both these compounds are rapidly reduced and rendered colourless by the addition of sulphurous acid, ferrous salts, or other reducing agent. The manganese then exists as a base and shows the usual reactions. All manganates and permanganates oxidise hydrochloric acid, especially when heated, with evolution of chlorine.

Estimation.—Manganese is usually precipitated as carbonate. To the nearly boiling solution, sodium carbonate is added drop by drop, until precipitation is complete, and the solution boiled for a few minutes and the precipitate allowed to subside. It is washed by decantation three times and finally well washed on the filter. The dried precipitate is strongly ignited in a platinum crucible and weighed as Mn_3O_4, which contains 72·05 p.c. of manganese. The ignited mass should show no alkaline reaction with test paper. The precipitate of carbonate may also be converted into, and weighed as, sulphate.

A very delicate method of estimating small quantities of manganese, as in limestones, &c., has been devised by Chatard. The process, as modified by Thorpe and Hambly (Chem. Soc. Trans. 1888, 182), is as follows: The solution should be free from chlorides, should contain between 0·004 and 0·008 gram of manganese, and should occupy about 25 c.c. To it is added 5 c.c. concentrated nitric acid, 2 or 3 grams of lead peroxide, and 10–20 c.c. dilute sulphuric acid (1 acid to 2 water), and the solution gently boiled for 4 minutes. The sides of the flask are washed down to destroy any organic matter, and the liquid boiled for half a minute longer. The lead sulphate and excess of lead peroxide are allowed to settle and the solution is at once filtered (with the aid of a filter pump if possible) through a plug of asbestos recently ignited and washed with dilute sulphuric acid. The filtrate is heated to 60° and titrated with a weak solution of ammonium oxalate, freshly standardised by a standard solution of permanganate. It may also be titrated if desired with sodium arsenite, or hydrogen peroxide.

The separation from other metals is not difficult. From the alkaline earths it may be separated by addition of hydrated ammonium sulphide to the nearly neutral solution; the sulphide so precipitated is washed well, redissolved in hydrochloric acid, and precipitated as above with sodium carbonate.

From iron, chromium, uranium, and aluminium, it may be separated by digesting the dilute solution with freshly precipitated barium carbonate. These metals are thus deposited as hydroxides. The barium is removed from the solution by the addition of sulphuric acid, and the manganese precipitated as usual.

When manganese occurs together with a large proportion of iron, as in iron ores, iron, steel, &c., the following separation is useful. The nearly boiling solution of the substance in hydrochloric acid or *aqua regia*, which must be absolutely free from organic matter, is treated with ammonia, with constant stirring, until it becomes much darkened; weaker ammonia is then cautiously added until the liquid has become of a mahogany colour, but still without any permanent precipitate. A hot solution of ammonium acetate is then added. The precipitate of basic ferric acetate should be brick-red; if it be dark red, more ammonium acetate must be added. The solution is boiled for a few minutes only, and the granular precipitate filtered through a large filter paper. The filter with the precipitate is replaced in the beaker which still contains the remaining portions of the precipitate and is redissolved in

hydrochloric acid, reprecipitated as before and filtered into the beaker containing the first filtrate. In this way the small portion of manganese contained in the first iron precipitate is separated. A portion of the second ferric acetate precipitate should, in important cases, be boiled with lead peroxide and nitric acid, when, if a trace of manganese be present, the liquid will acquire a pink colour.

The liquid containing the manganese may be concentrated by evaporation, filtered if necessary, and cooled. Sufficient bromine is added, with frequent shaking, to render it brown, and the whole rendered alkaline by ammonia. The manganese is thus precipitated as black hydrated peroxide.

The liquid is heated to boiling, filtered, and the precipitate washed and ignited as usual to Mn_3O_4. If a trace of organic matter be present in the solution, a portion of the iron will not be precipitated as acetate and will come down with the manganese. If this is the case the ignited oxide is redissolved and the iron precipitated as acetate, ignited, and weighed as Fe_2O_3 and its weight deducted from that of the manganese oxide obtained. In ores containing lime a second precipitation of the manganese is necessary and where present cobalt and barium are usually carried down in small amounts and should be looked for after weighing the precipitate.

A convenient method for the volumetric determination of manganese in ores or alloys is due to Volhard, many modifications of which have been described. The method is based on the fact that manganese salts in the presence of zinc oxide are quantitatively oxidised to zinc manganite by means of potassium permanganate ($3MnO + Mn_2O_7 = 5MnO_2$). The modification of Fischer (Zeitsch. anal. Chem. 1909, 48, 751; *cf.* Cahen & Little, Analyst, 1911, 36, 52) is as follows. One gram of the ore or alloy is dissolved in *aqua regia*, and the solution evaporated nearly to dryness with excess of hydrochloric acid. The residue is dissolved in 300 c.c. of water, mixed with a sufficiency of an emulsion of zinc oxide and made up to 1 litre. 100 c.c. of the clear solution are diluted to 500 c.c. and heated to boiling after adding 10 grms. of zinc sulphate. One gram of freshly ignited zinc oxide is added, and the liquid titrated with N/10 permanganate, boiling and shaking frequently until the supernatant liquid is red; 1 c.c. of pure glacial acetic acid is then added, when the red colour disappears, and the titration is slowly finished with permanganate in the hot but not boiling liquid.

The value of pyrolusite in generating chlorine is related to its content of available oxygen, and this may readily be ascertained as follows: The well-mixed sample is ground so as to pass through a 200-mesh sieve, and dried at 105° to constant weight. 0·5 gram heated with 50 c.c. of standard ferrous sulphate solution (90 grams in 200 c.c. sulphuric acid of sp.gr 1·84, and 900 c.c. of water) until dissolved, the solution diluted to about 150 c.c. and the excess of ferrous iron titrated with standard permanganate solution.

Solutions of manganous sulphate are completely precipitated as manganese dioxide, which may be subsequently estimated, when boiled with excess of ammonium persulphate. Sodium bismuthate in cold nitric acid solution oxidises manganous salts to permanganate, which may then be titrated (*v.* Analysis).

Alloys.—**Iron** alloys with manganese in all proportions (*see* Iron).

Copper and **manganese** yield a continuous freezing-point curve with a minimum of 866° at 65 p.c. copper. The form of the curve and the microscopic examination of the alloys indicate that a continuous series of mixed crystals exists, and that no compounds are formed. The alloys are only homogeneous if heated for some time below the melting-point. In appearance the alloys resemble bronzes, and are generally hard and malleable. A bronze—known as 'manganese bronze'—is made by adding a copper manganese alloy to the molten bronze and usually contains from 1 to 4 p.c. manganese, and from 80 to 90 p.c. copper. It forms a useful, workable alloy, possessing very great tenacity, and is used for stay bolts on some of the Continental railways. Alloys resembling German silver are also obtained from copper, zinc, and manganese.

Brunck describes an alloy with **aluminium** of composition Mn_2Al_7, which forms in white crystals soluble in hydrochloric acid (Ber. 25, 777). According to Hindricks (Zeitsch. anorg. Chem. 59, 414) two compounds exist, Mn_3Al and $MnAl_3$, both of which form mixed crystals. Alloys containing between 57 and 86 p.c. aluminium separate into two liquid layers.

Alloys with **Boron** may be produced in the electric furnace and exhibit magnetic properties due to the compound MnB. A second compound MnB_2 probably exists, but is not magnetic (Jassoneix, Compt. rend. 142, 1336).

Antimonides may be produced by the 'thermit' method. By removal of excess of manganese by means of dilute acid and of antimony by chlorine, alloys regarded as MnSb and $MnSb_2$ have been obtained. Both are magnetic (Wedekind, Zeitsch. physikal. Chem. 66, 614).

With **Tungsten** alloys containing from 12 to 60 p.c. tungsten have been obtained by the 'thermit' method as hard, brittle, steel-grey ingots, from which dilute acids dissolve the manganese.

By the same method hard brittle homogeneous alloys containing from 12 to 29·6 p.c. **molybdenum** are obtained (Arrivant, Compt. rend. 143, 464, 94).

Nickel and manganese give a continuous freezing-point curve with a minimum of 1030° at 56 p.c. manganese. The addition of manganese decreases the magnetic susceptibility of nickel.

Manganese and **cobalt** form a continuous series of solid solutions, the freezing-point curve passing through a flat minimum at about 30 p.c. cobalt, and 1150°. The crystals obtained are not homogeneous, but become more nearly so after annealing in magnesia at 1000° for five hours.

Manganese and **zinc**, according to Parravano (Gazz. chim. ital. 45, 1, 1), form two alloys $MnZn_7$ and $MnZn_3$ which are hard and brittle.

With **silver** between 30 and 90 p.c. manganese, two liquids are formed, and no solid solutions (Hindricks).

With **tin** compounds $SnMn_3$ and SnMn are

indicated by potential measurements. Alloys with below 40 atomic p.c. Mn are white and soft, above they become hard and brittle (Puschin, J. Russ. Phys. Chem. Soc. 38, 869).

Silicides are obtainable in the electric furnace, compounds Mn_2Si, MnSi, and $MnSi_2$ having been described. Of these the first forms lustrous prisms, which scratch glass, and the second can scratch topaz; the sp.grs. are 6·4, 5·9, and 5·2. The existence of these compounds is also indicated by the MnSi freezing-point curve (Doernickel, Zeitsch. anorg. Chem. 50, 117). Gin describes also a compound Mn_3Si_2 (Compt. rend. 143, 1229).

Phosphides are obtained by heating manganous chloride and phosphorus in a current of hydrogen. Compounds Mn_5P_2 and Mn_3P_2 are described, both of them magnetic. The latter is probably, however, an eutectic mixture (Schemschuschzy and Efremoff, *l.c.*, *supra*. Hilbert and Dieckmann (Ber. 44, 2831) have prepared the phosphide MnP as a black powder. On heating it loses its magnetic properties at 18° and regains them on cooling at 26°.

Manganese arsenides. Arsenic combines with manganese at 200° with incandescence. The arsenide Mn_2As (stable at high temperature) is grey and non-magnetic. At 700°–800° in a current of hydrogen the arsenide obtained has the composition Mn_3As_2 and is highly magnetic. The highest arsenide MnAs is stable only between 400° and 450°, and may also be obtained by the action of arsenic chloride on manganese, combination taking place with incandescence at 500°. It is highly magnetic (Arrivant, 7th Inter. Congr. App. Chem.). Hilbert and Dieckmann (Ber. 44, 2378) find that the best way of preparing pure arsenides is to heat the finely powdered metal with the vapour of arsenic under pressure. The materials are introduced into a bomb-tube of Jena glass and heated for several hours at 700°–750°. MnAs could only be obtained pure by using manganese prepared from the amalgam. It is a greyish-black powder D 6·2. The freezing-point curve of a manganese arsenide and manganese indicate the existence of three arsenides, Mn_2As, MnAs, Mn_3As_2 (Metallurgie, 8, 739). MnAs loses its magnetic properties on heating at 40° and regains them on cooling at 45°.

Manganese carbides. Trimanganese carbide was prepared by Troost and Hautefeuille and re-examined by Moissan, who obtained it by heating a mixture of trimanganese tetroxide with one quarter its weight of sugar carbon, in a carbon tube closed at one end, in an electric furnace with a current of 350 amperes and 50 volts. The reaction is complete in a few minutes; sp.gr. at 17° 6·89. $Mn_3+C(\text{diamond}) = Mn_3C$ develops +10·4 cal. $Mn_3C+3O_2 = Mn_3O_4+CO_2$ develops +412·4 cal. (Le Chatelier). Water decomposes Mn_3C with evolution of methane and hydrogen in equal volumes; dilute acids attack it with formation of liquid hydrocarbons. Ruff and Borman (Zeitsch. anorg. Chem. 1914, 88, 365) have investigated the solubility of carbon in manganese in the carbon-resistance vacuum furnace, using a thermo-couple or Wanner pyrometer for measuring the temperatures. The solubility increases from 1360° to 1525°, the b.p. of the solution under 30 mm. pressure. At the latter temperature manganese saturated with carbon contains 7·12 p.c., and the vapour 1·94 p.c., carbon. Pure manganese boils at 1510°. The whole of the carbon in rapidly cooled alloys is in the combined state. The residue, after distilling the manganese, contains graphite. A carbide richer in carbon than Mn_3C is indicated. Ruff and Gersten also prepared the trimangano carbide in a similar furnace by heating a mixture of manganese and carbon at 1600° for 20 minutes under 20 mm. pressure. The manganese used was prepared by the thermit process, and had the composition Mn 98·68, Fe 0·43, Al 0·55, Insoluble 0·25, m.p. 1239°–1242°. The regulus obtained contained nests of crystals which, after separating admixed carbon by acetylene tetrabromide, were found to have the composition corresponding to Mn_3C. Molecular heat of formation from manganese and graphite 12·9±2·14 cal. (Le Chatelier, value 9·34 cal.) (Ber. 46, 400). Both carbides of iron and manganese are soft, so that the hardness of alloys cannot be due to their existence as such, but is probably due to their solid solutions. When finely powdered manganese is treated with methane or with a mixture of methane and hydrogen at 600°–900°, carbides are formed. In pure methane, carbides containing over 20 p.c. carbon are obtained. When carbides containing 8 p.c. or less of carbon are treated with dilute acids, nearly all the carbon is evolved as methane, very little ethylene and no acetylene being formed; with more than 8 p.c. carbon fatty substances and spongy carbon is produced. Manganese carbides therefore are not simple derivatives of hydrocarbons like those of calcium and aluminium (Ber. 1913, 46, 3429).

Manganese oxides. The compounds of manganese with oxygen are numerous. The lower or manganous oxide MnO is powerfully basic; the sequioxide Mn_2O_3 is less basic, the tetroxide Mn_3O_4 and the dioxide MnO_2 are practically neutral; the dioxide occasionally reacts as a basic oxide, but at other times as an acidic oxide forming *manganites* of the type M_2MnO_3, *i.e.* it belongs to the class of amphoteric oxides. The higher oxides, however, MnO_3 and Mn_2O_7, have decided acid-forming properties and produce well-marked series of salts.

Manganous oxide MnO is prepared by ignition of any other manganese oxide, or of the carbonate, in a current of hydrogen. It is of an olive-green colour and absorbs oxygen from the air with formation of a brown oxide. Heated in sulphur dioxide it is ultimately converted into manganous sulphate. In solution in acids it forms manganous salts.

Manganese sesquioxide Mn_2O_3 occurs in nature as *braunite* in brownish-black, anhydrous, acute octahedra frequently containing silica. In the hydrated form it occurs as *manganite* in brilliant, black or steel-grey, rhombic prisms.

It may be prepared hydrated, by passing chlorine, not to saturation, through water in which manganous carbonate is suspended, and removing the excess of carbonate by dilute nitric acid. It is slowly acted on by dilute acids yielding either manganic salts of tervalent manganese, isomorphous with the salts of aluminium and ferric iron, or a mixture of manganous salts and manganese dioxide. The

colour of the amethyst is attributed to the presence of this oxide.

Manganese tetroxide. Red oxide of manganese Mn_3O_4 occurs as *hausmannite* in brownish-black octahedra, and in massive forms. It is produced by heating any oxide of manganese in the air. By the action of acids it yields a mixture of manganous and manganic salts or a manganous salt and manganese dioxide. It was formerly used as a pigment under the name of *manganese brown*.

Manganese dioxide. Peroxide or black oxide of manganese, frequently known as 'manganese,' MnO_2.

This important oxide occurs as *pyrolusite* in very pure iron-black or steel-grey, rectangular rhombic prisms of sp.gr. 4·8–5, and frequently massive or reniform, in radiating fibrous masses, usually brittle. Its hardness varies within wide limits, and it seldom occurs pure, but usually associated with other manganese ores.

A hydrated variety occurs largely as *psilomelane* in amorphous, massive, stalactitic, and frequently in botryoidal masses, but never in crystals. Its composition is very variable. It is usually found in the same localities as pyrolusite, frequently in alternate layers with that mineral. *Varvicite* and *newkirkite* are also hydrated varieties of pyrolusite.

Wad is an important earthy variety produced by the decomposition of other manganese minerals. It occurs, generally, in low-lying districts, in amorphous, earthy, dull black or brownish pieces of very variable composition and hardness. It frequently contains oxide of cobalt; one variety known as *asbolane* or *earthy cobalt* sometimes contains as much as 32 p.c. of cobalt. Another variety, *lampadite*, contains 18 p.c. of copper oxide. In addition to its employment as a chlorine producer, wad is used as an 'umber' paint.

Of these oxides pyrolusite is the purest and contains the highest percentage of oxygen; it has therefore the greatest commercial value. At a red heat it evolves one-third of its oxygen, leaving the red tetroxide.

When heated with concentrated sulphuric acid, it dissolves with formation of manganous sulphate and evolution of half its oxygen. If organic matter be present the oxygen decomposes it with evolution of carbon dioxide.

Its action on hydrochloric acid is of great importance. The hydrogen of this acid is oxidised, a portion of the chlorine thus liberated combines with the manganese, while the remainder is set free;

$$MnO_2+4HCl=MnCl_2+2H_2O+Cl_2$$

On this account it is very largely used for the production of chlorine and of bleaching powder (*q.v.*).

Nitric acid has but slight action upon it. When finely divided, sulphur dioxide, at a low red heat, ultimately converts it into manganous sulphate. Pyrolusite is a good conductor of electricity and is strongly electronegative: it is used as the depolariser in the Leclanché battery. In the electric furnace it melts and evolves oxygen forming the monoxide. It is used in conjunction with other oxides for producing warmer shades in coloured glass and to destroy the injurious tint produced in colourless glass and white enamels by the presence of ferrous compounds. The oxygen converts the greenish salt into the nearly colourless ferric salt, whilst the slight pink tint imparted by the manganese still further counteracts the bluish colour. It seems probable that the effect is due principally to the latter cause, as red lead and other oxidising agents have not this decolorising power.

Pyrolusite is also used in the preparation of dark violet, black, and metallic-like enamels for pottery and enamel iron ware. It is also added to cheapen blue enamel by intensifying the colour of cobalt, to which, however, it imparts a violet tint. It has been used as a pigment under the name of *manganese black*. It is used as a *drier* for oils, *i.e.* a substance added to confer drying properties to the oils. It is one of the most powerful driers known, and is added in the proportion of about ¼ lb. to 1 cwt. of oil. The 'tackiness' of rubber is augmented by small quantities of manganese oxide.

Manganese dioxide may be prepared artificially by moderately igniting the nitrate, boiling the residue with nitric acid, washing and gently heating (Berthier). The hydrated oxide has been used for the removal of iron from aluminium sulphate.

According to Fremy (Compt. rend. 82, 1231) it forms a definite sulphate on solution in sulphuric acid, and a solution containing this under the name of manganese peroxide sulphate, produced by the electrolysis of a sulphuric acid solution of manganous sulphate is used as a mild oxidiser in aniline dye manufacture. Double salts containing $MnCl_4$ also exist.

Colloidal manganese dioxide may be obtained by the action of potassium permanganate on a solution of dextrose, lævulose or galactose in dilute solution of alkali hydroxide: it first passes into a viscous or gel stage, and subsequently into a limpid, colloidal solution. The colloid is best formed at low temperatures, and the concentrated colloid is readily coagulated on warming (Witzemann, J. Amer. Chem. Soc. 1915. 37, 1079; *cf.* Bredig and Marck, Chem. Zentr. 1911, 1, 1190). A convenient method of preparing it consists in adding strong ammonia solution at the rate of one drop every 3 minutes to a boiling N/20 solution of potassium permanganate until it has become deep coffee-coloured and has lost the characteristic colour of permanganate (Cuy, J. Phys. Chem. 1921, 25, 415). Chronic manganese poisoning has been observed to occur in workers handling or grinding manganese dioxide, or working in dust containing manganese as oxides or silicates (Chem. Abstr. Amer. Chem. Soc. 1919, 13, 3243).

Manganese trioxide. Franke (J. pr. chem. 1887, 14) has described a trioxide MnO_3; its existence has been confirmed by Thorpe and Hambly (Chem. Soc. Trans. 1888, 177). This oxide appears to form a sulphate $(MnO_3)_2SO_4$

Manganese heptoxide Mn_2O_7 is a highly hygroscopic, non-volatile, reddish-brown liquid, which gradually decomposes on exposure to the air. Its composition was determined by Aschoff (Pogg. Ann. 3, 217). These two oxides are of interest, as they form the acid radicles of manganates and permanganates; thus, $MnO_3{\cdot}K_2O$, $Mn_2O_7{\cdot}K_2O$.

Salts of Manganese.

Of the salts corresponding to these various oxides, only two series are of practical importance, manganous salts, corresponding to the monoxide, and manganates and permanganates, in which manganese acts as an acid corresponding to the tri- and hept-oxides.

Manganous chloride $MnCl_2$ is produced by the action of chlorine gas on metallic manganese, or of hydrochloric acid gas on the heated carbonate. In solution, it is obtained by dissolving the oxide or carbonate in hydrochloric acid.

On the large scale it is usually produced from the residual solutions from the chlorine manufactures. This is first evaporated to remove excess of hydrochloric acid, and one-fourth of the solution is removed and precipitated by sodium carbonate. The precipitate, which contains manganous carbonate and ferric hydrate, is washed and boiled with the remainder of the solution. The iron in solution is thus precipitated as hydrate, being replaced by an equivalent quantity of manganese from the carbonate. Copper, if present, is precipitated by the addition of sulphuretted hydrogen, leaving in solution manganese, and usually calcium and other alkaline earthy metals. Cobalt and nickel may be removed by the addition of freshly precipitated manganous sulphide, as long as it becomes darkened; those metals are then precipitated as sulphides.

The manganese is precipitated by means of ammonium sulphide, washed, dissolved in hydrochloric acid, evaporated, and crystallised.

It may be obtained pure by evaporating the crude solution of the ore in acid to dryness, igniting gently in a crucible, exhausting the residue with water, concentrating and crystallising. It forms pink deliquescent crystals, containing 4 molecules of water, soluble in two-thirds their weight of water at 60°, soluble in alcohol.

In commerce it usually occurs as a rose-red, very deliquescent mass, obtained by evaporating the solution to dryness. It is used for dyeing cotton manganese-brown or -bronze. The fabric is soaked in a solution of the salt and then passed through a caustic alkali, whereby manganous hydroxide is precipitated in the fibre and by subsequent atmospheric oxidation becomes brown. The material thus treated may also be used for the subsequent dyeing by aniline black. The presence of over 1 p.c. calcium chloride in the salt renders it practically useless for calico-printing and dyeing.

Manganous sulphate $MnSO_4$ may be prepared by dissolving the carbonate or oxide in sulphuric acid. On the large scale it is usually obtained from the black oxide. This is heated with about one-tenth part of powdered coal, and is thus reduced to the monoxide. The mass is dissolved in sulphuric acid, evaporated, gently heated to decompose the ferrous sulphate, and the manganous sulphate dissolved out by water. By another process the peroxide is first digested with dilute sulphuric acid to remove carbonates, and made into a paste with strong sulphuric acid, heated until the evolution of oxygen has ceased, and then to strong redness, cooled, digested in water, and the solution evaporated and crystallised. If iron be still present, it may be removed as in the case of the chloride by boiling with manganous carbonate. Manganous sulphate forms pink crystals with 7 mols. of water very soluble in water, insoluble in absolute alcohol. It is used in calico-printing. It is also used as a drier for pale oils or for conversion into the oxalate or borate which are also used for the same purpose. For other hydrates *see* Forcrand, Compt. rend. 1914, 158, 1760; *ibid.* 159, 12. All manganous salts are strong reducing agents.

Manganese borate, used as a drier, is a salt of a faint pink colour, prepared by adding a solution of borax to one of a manganous salt, washing and drying the powder so obtained.

Manganese oxalate, also used as a drier, is prepared by precipitation of a manganese salt by a soluble oxalate, or by the action of oxalic acid on manganese hydroxide or carbonate. *Manganese linoleate* is also used for the same purpose, and prepared by addition of linseed oil-soap to manganous chloride.

Manganese sulphide MnS occurs in nature as *alabandite*, an almost black mineral (streak green) crystallising in the cubic system, sp.gr.4·00 (artificial variety, 4·03), m.p. 1620 (Röhl). It is precipitated from its solutions by alkaline sulphides in either the rose-coloured or green form (*see under* Detection). Manganese sulphide is of great importance in the manufacture of steel. The addition of manganese to steel containing sulphur prevents red shortness, the latter effect being due to the solubility of iron sulphide in liquid steel, whereas the addition of manganese precipitates the sulphur as insoluble manganese sulphide.

Potassium manganate K_2MnO_4. This compound is produced when equal weights of finely powdered manganese dioxide and caustic potash are fused together, a sesquioxide of manganese being produced at the same time. By the addition of potassium nitrate or by performing the ignition in a flat vessel, a portion of this oxide is re-oxidised, and increases the yield of manganate.

It dissolves in water, forming a fine green solution, which, on evaporation *in vacuô*, produces green crystals isomorphous with potassium sulphate and chromate. The solution, especially if dilute, when exposed to the air becomes converted into the permanganate with precipitation of hydrated manganese dioxide; the liquid passes through various shades from green to pink, whence its name of 'mineral chameleon.' In presence of excess of alkali this change does not take place. On the addition of free acid, especially sulphuric acid, the change is immediate, the alkali and manganese, instead of being liberated as hydrates, being at once converted into sulphates, and thus losing their tendency to reproduce the manganate. Potassium manganate is a powerful oxidising agent. Its general action in this respect resembles that of the permanganate.

Sodium manganate Na_2MnO_4 is largely manufactured for disinfecting purposes on account of its greater cheapness.

Barium manganate $BaMnO_4$ is formed by heating manganese dioxide with barium hydroxide or carbonate with addition of barium nitrate. Is an emerald-green microcrystalline powder, insoluble in water. Sp.gr. 4·85. Has

been used as a pigment in place of the more poisonous Scheele's Green.

Potassium permanganate $KMnO_4$. This salt may be prepared by the addition of 10 parts of potash dissolved in the minimum of water to a mixture of 8 parts manganese dioxide and 7 parts potassium chlorate. The solution is evaporated to dryness, finely powdered, and ignited at a dull red heat for about 1 hour, until the chlorate has become decomposed. The mass is boiled with water, decanted, evaporated rapidly to a small bulk until crystals form on its surface, decanted from the precipitate which has fallen, and allowed to crystallise; 1 part of permanganate is produced from 3 parts of the oxide (Gregory, J. Pharm. Chim. 21, 312).

It is, however, usually prepared by the action of an acid on the manganate.

According to Städeler (J. pr. Chem. [i] 103, 107), 90 p.c. of the oxide may be converted into permanganate by first preparing the manganate and converting it into permanganate by the addition of chlorine instead of acid

$$2K_2MnO_4 + Cl_2 = 2KCl + 2KMnO_4$$

The solution is evaporated and the permanganate crystallised, leaving the potassium chloride in solution.

Tessié du Mothay and Maréchal prepare it by addition of magnesium sulphate to the manganate, according to the equation

$$3K_2MnO_4 + 2MgSO_4 + 2H_2O = 2KMnO_4 + 2K_2SO_4 + 2Mg(HO)_2 + MnO_2$$

It may also be prepared electrolytically by passing a current through a solution of the hydroxide using a ferromanganese anode (White, J. Phys. Chem. 10, 592; Wilson, Horsch and Youtz, J. Ind. Eng Chem. 1921, 13, 763).

On the large scale powdered pyrolusite (96 kilos. of 50 p.c. ore) is placed in an iron basin, 95 litres of potash lye (sp.gr. 1·5) are slowly added with stirring, and the mixture is heated till the mass is completely dry. The stirring is stopped from time to time, and any large lumps are broken down with a wooden hammer (the formation of these lumps is an indication of the favourable working of the process). The operation needs 100 kilos. of coal, lasts 12–14 hours, and results usually in the decomposition of 60–65 p.c. of a natural ore, or 40–45 p.c. of 'regenerated ore' (*see* below). The product is ground in a ball mill, and is then transferred to pressure-heaters, *i.e.* double-walled, cast-iron basins with the interspace filled with lead. These are heated from below to 260°–270°; they are provided with stirrers and with a circular pipe welded on to the lid, through holes in which, corresponding with holes in the lid, compressed air is admitted, preferably heated also to 260°–270°. This operation, which increases the yield of manganate, lasts 10–12 hours for 300 kilos. of substance. The mass is now dissolved in the filtered liquors and wash-waters from the electrolysis and crystallisation of a previous batch, at a temperature of about 40°, in a vessel provided with stirrers; potassium manganate and hydroxide go into solution, and a certain amount of manganese peroxide (known as 'regenerated ore') is formed. This is separated by sedimentation, the liquid drawn off through filters, and the deposit washed. The clear solution (sp.gr. about 1·4) is electrolysed in cylindrical iron vessels with conical bottoms fitted with iron stopcocks, nickel anodes, and iron cathodes, which are fastened by glass and cement to the bottom of the vessel, being used. Each cell holds 960 litres, and is filled to within 20 cm. of the rim. The liquor is preferably warmed to about 30°C., and a current of 30–40 ampères per sq. dcm. used, the voltage being 2·5–2·7. The operation continues from 10–11 hours, and the end is judged by the red colour of a sample on a glass rod. The whole contents, including any crystals, are now poured into cooling cylinders, and cooled—in winter by cold water, in summer by water and ice; the salt is separated from the mother liquor centrifugally, and washed in the centrifuge. The salt is then dried *in vacuô*, and carefully passed through a small ball-mill to break up portions that have caked in drying. In this way a salt of 99 p.c. purity is obtained. When the mother liquor (which goes into the process again) has accumulated as much as 10 p.c. of carbonate, it must be causticised; it is concentrated to sp.gr. 1·32, any separated permanganate or manganese peroxide removed, the liquor diluted to sp.gr. 1·1, causticised with lime, and again concentrated to sp.gr. 1·5 (Schütz, Zeitsch. angew. Chem. 1911, 24, 1628; J. Soc. Chem. Ind. 1911, 30, 1157).

According to Desclabissac (Dingl. poly. J. 201, 58), the following methods are used for the preparation of sodium manganate and permanganate on the large scale. (1) 500 parts of soda lye (45°B.) are evaporated with 100 parts potassium chlorate mixed with 180 parts of the finely powdered oxide, and ignited in iron pots until quietly fused, cooled, with constant stirring, again heated to redness, cooled, and extracted with water. (2) 12 parts of caustic soda, dissolved in 58 parts of water are heated with 12 parts potassium chlorate and 18 parts manganese dioxide, until it begins to crumble; the heat is then increased to redness, and the mass, after cooling, is extracted with 200–220 parts of water. (3) To a fused mixture of 10 parts caustic soda and 1 part nitre are added 6 parts strongly heated manganese dioxide; the cooled mass is ladled out and extracted as before.

Condy's fluid consists chiefly of a mixture of sodium manganate and permanganate (*v. infra*). For its preparation 30 cwt. of soda ash are converted into caustic soda by lime; they are then mixed with 7 cwt. manganese dioxide, and ignited in a shallow vessel at a dull red heat for about 48 hours. The mass is treated with water, decanted, and the solution evaporated to the required concentration. When the product is required to consist only of permanganate the solution is treated with sulphuric acid, and evaporated until crystals of sodium sulphate separate. Sodium permanganate is, however, much more difficult to purify by crystallisation than the potassium salt (*v.* Hofmann, Reports on Chem. Processes at the Exhibition of 1862, 109).

Potassium permanganate forms fine dark purple prismatic crystals of greenish metallic lustre, soluble in 19 parts of water at 15°. Sp.gr. 2·7. When heated they decompose, at 200–240°

$$10KMnO_4 = 3K_2MnO_4 + 2K_2MnO_3 + 5MnO_2 + 6O_2$$

Heated in hydrogen they ignite and leave a green mass containing manganese monoxide and potash.

It is a powerful oxidising agent; each molecule contains five atoms of 'available' oxygen, *i.e.* more than any other salt. It is largely used as a disinfectant.

When triturated with sulphur or phosphorus it detonates; when mixed with carbonaceous matters and many other reducing agents, and heated, it burns. Mixtures containing permanganates and organic substances are very liable to spontaneous decomposition.

The crystals oxidise strong hydrochloric acid in the cold, with evolution of chlorine; in solution the same effect is produced on heating.

A solution of the salt is rapidly reduced by sulphurous acid, ferrous salts, and most other reducing agents; less rapidly by organic matter. The solution is therefore used as a test for such substances, and to estimate their amount.

Solutions of the salt can only be filtered through asbestos or glass wool, as they quickly destroy filter-paper.

Zinc, iron, lead, mercury, and many other metals are oxidised more or less rapidly by the solution. Pure potash has no action on permanganate, even when heated, but in presence of organic matter the permanganate is rapidly reduced to the green manganate.

On mixing concentrated solutions of this salt and of silver nitrate, a red crystalline precipitate of **Silver Permanganate** $Ag_2Mn_2O_8$ is produced. It may be used for the preparation of other permanganates. On mixing with a solution of barium chloride, silver chloride is precipitated, and **Barium Permanganate** remains in solution, from which *permanganic acid* may be produced by the addition of dilute sulphuric as long as a precipitate falls. On evaporating the solution the acid is obtained as a brown, crystalline, very soluble mass, easily decomposed by heat.

Sodium permanganate $Na_2Mn_2O_8$ resembles in its properties the potassium salt (*v. Sodium Manganate*).

Aluminium permanganate. Condy (Eng. Pat. 1884, 10015) patented a method of preparing this salt for disinfecting purposes. It is said to give up five-sevenths of its total oxygen to reducing agents. The alumina present would also assist in the precipitation of impurities in water, &c. To 1000 parts of a solution of aluminium sulphate, containing one-third its weight of the sulphate, is added 53 parts of potassium permanganate, which is dissolved by the aid of heat. On cooling, potassium alum crystallises out, and the decanted solution, which contains the whole of the permanganate and a considerable amount of aluminium sulphate, is ready for use.

MANGANESE BRONZE *v.* MANGANESE; TIN.

MANGANESE-SPAR *v.* RHODONITE; RHODOCHROSITE; and MANGANESE.

MANGANIN *v.* NICKEL.

MANGANITE. A manganese-ore consisting of hydrated sesquioxide $Mn_2O_3 \cdot H_2O$ or MnO(OH). It occurs as well-developed orthorhombic crystals of prismatic habit and as columnar masses. These possess three perfect cleavages in the direction of the length of the prism, namely, one parallel to the brachypinacoid and two parallel to the unit rhombic prism. The colour is dark steel-grey, with a sub-metallic lustre, and the streak is brownish-black; sp.gr. 4·3, hardness 4. Good crystals are found, often in association with barytes, at Ilmenau in Thuringia, Ilfeld in the Harz, Granam in Aberdeenshire, Bridgeville in Pictou Co., Nova Scotia, &c. The mineral readily alters to pyrolusite (MnO_2), owing to loss of water and oxidation, the material becoming softer and heavier and with a blacker streak. Pseudomorphs of pyrolusite after manganite are of common occurrence. Manganite occurs together with the other black oxides of manganese (pyrolusite, psilomelane, &c.), but as an ore of manganese it is less abundant than these. L. J. S.

MANGANOSITE. Manganous oxide, MnO, crystallised in the cubic system, and isomorphous with periclase (MgO). Small amounts of magnesia, lime, and ferrous oxide are also present as isomorphous replacements. The small grains and octahedral or rhombic-dodecahedral crystals have a cubic cleavage, and are transparent with an emerald-green colour, but become black on exposure. The material has a strong selective absorption, the spectrum of transmitted light consisting of a narrow red band and a rather wider green band. The refractive index for these two colours is 2·16 and 2·19 respectively. Sp.gr. 5·18 5·36, H. 6–7. The mineral dissolves with difficulty in strong nitric acid to a colourless solution. It has been found with manganese ores at Längban in Sweden, with magnetite at Nordmark in Sweden, and with franklinite and zincite at Franklin in New Jersey. Possibly it is of more frequent occurrence in manganese ores than has hitherto been recognised. L. J. S.

MANGEL-WURZEL or **MANGOLDS.** *Beta vulgaris* (Linn.). A plant largely grown as a farm crop, the root being used as a winter food for cattle and sheep. It is a variety of the garden beet-root or of the sugar-beet. Many varieties are known, differing in size, shape, and colour. Average composition—

	Water	Protein	Fat	N-free extract	Crude fibre	Ash
Large roots	89·5	1·3	0·1	6·7	1·0	1·4
Medium ,,	88·0	1·2	0·1	8·7	0·9	1·1
Small ,,	86·5	1·1	0·1	10·6	0·8	0·9

Large roots of any variety are more watery, richer in nitrogenous substances and crude fibre than small ones; they are not so valuable for feeding purposes nor do they keep so well. When first harvested, mangolds are not suitable for food, especially for sheep, but after keeping a few weeks they form a valuable addition to the dry, winter food of all farm animals. The beneficial effect of storage appears to be the conversion of nitric nitrogen into amides (Wood, J. R. Agric. Soc. 1898).

The nitrogenous constituents of mangolds include much non-proteid material, in which betaine, asparagine, glutamine, nitric acid, and ammonia are the most important. Of the total nitrogen in the root, about 48 p.c. exists as true proteid, from 1 to 6 p.c. as betaine, about 4 p.c. as ammonia, and from 10 to 15 p.c. as nitric acid; the proportions, however, are subject to great variations.

The nitrogen-free extract consists largely of sugar, but there are also present oxalic acid, citric acid, pectins, and pentosans.

As an example of a more detailed analysis of mangolds the results obtained by Pitsch (Landw. Versuchs-Stat. 1892, 21, 471) in an analysis of the dry matter of 'Golden Tankard' mangolds (the roots contained 86·82 p.c. water) may be quoted—

Pro-tein	Pure proteid	Nitric acid	Fat	Sugar	Other N-free substances	Crude fibre	Ash
8·75	4·06	0·31	0·58	60·17	16·98	6·33	7·36

The ash of mangolds, according to König, contains—

Per cent. of ash in dry matter	K_2O	Na_2O	CaO	MgO	Fe_2O_3	P_2O_5	SO_3	SiO_2	Cl
6·44	53·0	15·4	4·1	4·5	0·8	8·4	3·1	2·3	8·4

The leaves are sometimes used as food for cattle, but are very watery and contain oxalic acid (3 or 4 p.c. of the dry matter). They sometimes produce poisonous symptoms if used in large quantities. The addition of about 1 part of finely divided calcium carbonate to 1000 parts of leaves is found to prevent the poisonous action of the oxalic acid. Kellner gives as the average composition of the leaves—

Water	Protein	Fat	N-free extract	Crude fibre	Ash
89·0	2·4	0·4	4·6	1·6	2·0

Mangold seeds have been examined by Devarda (Landw. Versuchs-Stat. 1897, 49, 239). They consisted of 11·55 p.c. of water and 88·45 p.c. of dry matter. The dry matter contained—

Protein	Fat	N-free extract	Crude fibre	Ash
12·84	6·08	38·41	34·01	8·38

The ash consisted of—

K_2O	Na_2O	CaO	MgO	Fe_2O_3	P_2O_5	SO_3	SiO_2	Cl
22·0	8·0	16·1	11·0	1·0	10·0	5·0	24·6	2·3

Mangolds require a deep, somewhat loamy soil, and, with abundant nitrogenous manuring, yield very heavy crops. They have a longer period of growth than turnips, and are less dependent upon phosphatic manuring. They are one of the few crops which are benefited by applications of common salt to the soil and, perhaps for this reason, grow well on land near the coasts. H. I.

MANGO. The fruit of *Mangifera indica* (Linn.), a tree of the East Indies, now grown in other tropical countries. It is eaten raw or used for the preparation of pickles and chutneys.

Prinsen-Geerligs (Chem. Zeit. 1897, 21, 719) gives the following data :—

	Mean weight in grammes	Flesh p.c.	Rind p.c.	Stone p.c.	The flesh contains Glu-cose	Lævu-lose	Suc-rose
Sweet variety	200	67	3	30	0·6	2·0	9·5
Sour variety	300	75	3	22	0·0	1·9	3·6

The gum of this tree was examined by Lemeland (J. Pharm. Chim. 1904, 19, 584), who found it to consist largely of galactose and pentoses. H. I.

MANGOSTIN $C_{23}H_{24}O_6$, a crystalline substance first isolated from the skin of the mangosteen fruit by Schmid (Annalen, 1865, 93, 83). It crystallises in small, flat, pale-yellow needles, and dissolves in solutions of alkali hydroxides to form unstable salts which are decomposed by carbon dioxide. Ferric chloride gives with an alcoholic solution, a greenish-brown coloration discharged by hydrochloric acid. Oxidised by warm nitric acid or potassium permanganate with formation of oxalic acid and other products. On fusion with potassium hydroxide yields amyl alcohol, acetic, valeric, and benzoic acids. It contains two phenolic hydroxyl groups, one methoxyl group, and one or more amyl groups. *Dimethyl mangostin* $C_{25}H_{28}O_6$, m.p. 123°, obtained by shaking a solution of mangostin in dilute potassium hydroxide with methyl sulphate, forms faintly yellow slender needles (Hill, Chem. Soc. Trans. 1915, 107, 595).

MANGROVE BARK. The bark of the mangrove is exported from Mozambique, Parapat, Ibo, Pemba Bay, and other parts of East Africa, mainly to Germany, Russia, and the United States, and for use as a tanning material. It contains from 35 to 40 p.c. of tannin.

MANILA ELEMI *v.* OLEO-RESINS.

MANIOT or **MANIHOT** is the farina of *Manihot utilissima* (Pohl.), formerly known as *Jatropha Manihot* (Linn.), the plant which furnishes tapioca. Indigenous to America, but also cultivated in Africa and tropical climates generally. Maniot is occasionally imported under the name of 'Brazilian arrowroot.'

MANJAK. A form of asphaltum found in Barbados and Trinidad. It melts above 204°. The principal deposits occur in Trinidad, about 3 miles from San Fernando, as long seams between layers of clay. Boiled with oil and applied in a liquid state it affords a tough, unbreakable, rubber-like protective coating, impervious to air and water. It is used in connection with rotatory drilling for oil, being employed to fill the joints of the pipes between casing-threads and drill stern heads. As a paint it efficiently protects iron and steel goods from sea-water, and is useful as a roofing material in tropical countries.

MANNA. The concrete juice of the manna-ash, *Fraxinus Ornus* (Linn.), *rotundefolia*, *F. o. augustifolia*, *F. fraxinaster oxyphylla*, *F. f. australis*, and *F. f. excelsior*. The *Ornus* trees yield the best manna, but the *Fraxinaster* the greatest quantities. Ordinary manna is procured by making incisions in the bark of the trees during the summer and allowing the sap to evaporate. Most of the manna of commerce comes from Sicily or Southern Italy. When freshly prepared, it is pleasant to the taste and is used, to some extent, as a food; but on keeping, it acquires mild laxative properties and is used medicinally.

Manna consists largely of mannitol (*q.v.*), of which it is usually stated to contain from 50 to 70 p.c., together with some invert sugar, gum, and ash. According to Tanret (Bull. Soc. chim. 1902, 27, 947), however, it contains notable quantities of two complex sugars, which he names *manneotetrose* and *manninotriose*. His analyses show ordinary manna to contain mannitol 40–55, lævulose 2·5–3·4, dextrose 2·2–3·0, manneotetrose 12–16, manninotriose, 6–16 p.c., together with small quantities of resin and ash.

Marogna (Bull. Agric. Intell. 1915, 6, 835) gives analyses of genuine commercial samples

of Sicilian manna as follows: Moisture 5–11; mannitol 33–61; reducing sugars, before hydrolysis, 10–16; after hydrolysis at 100°, 26–55. Dry distillation of manna *in vacuô* yields a dense liquid which apparently contains mannitol anhydrides, *mannide* and *mannitan*, these yielding mannitol on hydrolysis.

Manneotetrose $C_{24}H_{42}O_{21},4H_2O$ forms monoclinic crystals, melts at 100°, and has $[\alpha]_D+150°$; it is very soluble in water, does not reduce Barreswil's solution, and is hydrolysed by acetic acid or enzymes, yielding lævulose and manninotriose; or by dilute mineral acids into 1 mol. dextrose, 1 mol. lævulose, and 2 mols. galactose.

Manninotriose $C_{18}H_{32}O_{16}$ separates from hot alcohol in spherical masses, melts at 150°, and has $[\alpha]_D+167°$. It reduces Barreswil's (Fehling's) solution, slowly ferments with yeast, and is hydrolysed by mineral acids, but not by enzymes.

Among many other vegetable exudations which go by the name of 'manna' the following may be mentioned:—

Australian manna: (*a*) from *Myoporum platycarpum* (R. Br.) contains mannitol 89·6, sugar 3·4, water 3·5, ash 1·1 p.c. (Malden, Chem. Zentr. 1894, ii. 341).

(*b*) From the leaves of *Eucalyptus dumosa* (A. Cunn.) containing sugar, inulin, starch, and gum (Anderson, quoted by König).

(*c*) From *Eucalyptus Gunnii*, var. *rubida*, contains water 9·7, ash 6·8, melitose 68·5, dextrose 20·9, sucrose 2·1, gum 3·2, insoluble 4·3 p.c. (Ebert, Chem. Zentr. 1908, ii. 1874).

Persian manna, from the leaves and thorns of the camel's thorn, *Alhagi maurorum* (Medic.) containing moisture 5·2, ash 9·4, chlorophyll and some gum 0·5, sucrose 42·0, gum 20·3, residue 32·0 p.c. (E.).

Sinai or *Tarfa manna*, exuding from punctures caused by an insect, *Coccus manniparus* (Ehrbg.), in the stems of *Tamarix gallica*, var. *mannifera*, containing chiefly sugar and dextrin. *Cedar* or *Lebanon manna*, from the branches of *Cedrus Libani* (Barrel. Ic.).

Trehala manna from the larval cocoons of a beetle, *Larinus maculatus*, living on the stems of *Echinops persicus* (Stev.), containing water 11·1, ash 2·6, trehalose 17·5, gum 27·1, tannin, starch, and residue 44·5 p.c. (Ebert, *loc. cit.*).

Manna of olives, a morbid secretion of bacterial origin caused by the attacks of insects upon olive trees, contains 52 p.c. mannitol, 7·8 p.c. reducing sugars, and 21·5 p.c. of other organic matter (Trabut, Compt. rend. 132, 225).

The term 'manna' is also loosely used for the seeds of certain cereals, *e.g.* 'Boer manna,' and 'Kaffir manna' are often employed as names for certain millets. H. J.

MANNHEIM GOLD *v.* GOLD, MANNHEIM.

MANNITOL, MANNOSE, MANNOTRIOSE *v.* CARBOHYDRATES. Mannose may be prepared from ivory nut shavings in the form of powder by treatment with a hot 1 p.c. solution of sodium hydroxide, followed by digestion of the perfectly dried residue with 75 p.c. sulphuric acid for 6 hours, the solution diluted with water boiled for 6–8 hours, and, when cold, mixed with calcium hydroxide, filtered, treated at 90° with decolorising carbon, cooled, and, after adding excess of calcium or barium carbonate, again filtered, concentrated *in vacuô* to a syrup, poured into an equal volume of alcohol of 95 p.c. alcohol, again treated with decolorising carbon and again filtered. After further concentration *in vacuô*, the almost solid mass is dissolved in warm glacial acetic acid and crystallisation assisted by seeding (Horton, J. Ind. Eng. Chem. 1921, 13, 1040; Clark, J. Biol. Chem. 1922, 51, 1).

MANQUETA or **MAQUATA.** African names of a fossil gum-resin, resembling copal gum, found in Angola, below the surface of a ferruginous hard clay or soil, at a depth of a few inches to a couple of feet, often in pieces weighing several pounds.

MANTLES, GAS *v.* GAS MANTLES.

MANURE, ARTIFICIAL *v.* FERTILISERS.

MAPÉ. A coarse starch obtained from Tahiti, derived from the fruit of *Inocarpus edulis* (Forst.).

MAPLE. The name of trees of the genus *Acer*. Some species are valued as shade and timber trees, whilst one, *A. saccharinum* (Wangenh.), affords an important source of sugar in America and Canada. This tree, which attains a height of 100 feet with a trunk of 3 or 4 feet in diameter, affords a considerable quantity of saccharine sap if tapped in the early spring. The sap varies in composition, but, on the average, contains from 2 to 3 p.c. of sucrose, small quantities of proteids, ash constituents, and vegetable acids, mainly malic acid. The flow of sap is most rapid when frosty nights are followed by warm days. The sap is received in buckets and rapidly boiled down in an open pan, the proteid matter which coagulates being removed by skimming. A deposit, often containing calcium malate and silica, forms on the pan bottom. When the syrup has attained a sufficient density it is run off and either preserved as syrup, after filtration or sedimentation, or is boiled down still further, until it solidifies to a white or brown mass of sugar on cooling.

Maple sugar and syrup are highly prized for table use in America and Canada, and are chiefly used in the locality where they are produced. They vary considerably in composition according to the method adopted in their preparation, but generally retain a characteristic 'maple' flavour.

Genuine maple sugar is distinguishable from imitations made of cane sugar by the large precipitate it yields with basic lead acetate, mainly due to the malic acid present (*see* Winton and Kreider, J. Amer. Chem. Soc. 1906, 28, 1204). For the results of an investigation into the conditions affecting the flow of sap of the sugar maple, *see* Jones, Edson and Morse (Bull. 103, Vermont, Expt. Stat. 1903). H. J.

MAQUI. The maqui is a small evergreen liliaceous shrub (*Aristotelia Macqui*, L'Hérit.), common in Chile along the course of torrents, and in shady mountainous woods. It is not cultivated, but grows wild, and the berries, which in Chile are eaten either fresh or preserved, contain a red pigment, and are exported largely to Europe for the purpose of colouring wines.

MARBLE (Fr. *Marbre*; Ger. *Marmor*). Although this term should strictly be limited to those varieties of limestone (*q.v.*) which are sufficiently compact to receive a polish, it is

loosely applied in trade to a great range of ornamental stones, including many which, like serpentine and alabaster, are not even limestones. Typical marble, such as that used for statuary, has a crystallo-granular texture, resembling that of loaf-sugar, whence it is termed 'saccharoidal.' Under the microscope it commonly shows an aggregation of grains of calcite, exhibiting twin-lamellæ. The development of such a structure appears to be due to that kind of metamorphic action which Sir A. Geikie has termed *marmorosis*. That an ordinary limestone may be converted by the operation of heat and pressure into a crystalline marble is known to every field geologist, while the fact has been confirmed experimentally by Sir J. Hall (in 1805) and others. Impure limestones, when altered by metamorphic processes, are often rich in various crystallised silicates, such as garnet, idocrase, tremolite, and mica. An analysis of Carrara marble gave: $CaCO_3$ 98·77, $MgCO_3$ 0·90, SiO_2 0·16, $Al_2O_3+Fe_2O_3$ 0·08=99·91.

Of ancient marbles, the most renowned for the purposes of sculpture was the *Parian*, obtained from the isle of Paros, one of the Cyclades, in the Ægean sea. The finest kind, known as *Lychnitis*, had a peculiar sparkling grain and a warm surface, which enabled the sculptor to render the texture of skin with great effect. The old quarries have been described by R. Swan (Brit. Ass. Rep. Newcastle, 1889). The famous *Pentelic* marble, largely used in Athenian architecture in the age of Pericles, was a coarser material, adapted for bold sculpture rather than for delicate statuary. *Carrara* marble, extensively employed in Rome under the name of *Luna* marble, and used by Michael Angelo and Raphael, is a very fine-grained saccharoidal limestone, still worked with other varieties at Carrara, Massa, and Serravezza, in Tuscany.

The ancient marbles used in Italy have been studied by F. Corsi (Delle Pietre Antiche, Roma. 1833, 3rd edit., 1845) and other antiquaries. *Giallo antico* was a fine yellow marble from Numidia, while *Rosso antico* was a homogeneous red marble, probably from Greece, sometimes confounded with *Porfido rosso antico*, a hard red porphyry with white felspar crystals, from Jebel Dokhan in Egypt. *Verde antico* is a mixture of serpentine and limestone from near Atrax, on the Peneus, in Sicily, quite distinct from the *Porfido verde antico*, or Lacedæmonian stone, a felspathic porphyry from Mount Taygetus. Many marbles are known by fanciful names derived from colour, locality, or a superficial resemblance to natural objects: thus, *Bardiglio* is a grey or bluish marble with white veins, whilst *Cipollino* is a white marble with green veins of mica or talc. (On Italian marbles *v.* W. P. Jervis, I Tesori Sotterranei dell' Italia, vol. 4, Torino, 1889. For ancient marbles *v.* M. W. Porter. What Rome was Built with, Oxford, 1907; H. W. Pullen, Handbook of Ancient Roman Marbles, London, 1894.)

The marbles of the British Isles are derived mainly from the Devonian and Carboniferous formations. *Plymouth* marble occurs in the Upper Devonian, while the Great Devon limestone, of Middle Devonian age, has been worked as a marble at Babbacombe and St. Mary Church. The *Madrepore marbles* of Torquay are largely used for trivial ornaments. The Carboniferous limestone of Derbyshire has long been famous for the beauty and variety of its marbles, the best known being the *Encrinital* marbles, which owe their characteristics to the embedded remains of crinoids or 'stone lilies.' Similar encrinitic marble occurs at Dent in Yorkshire and in King's Co., Ireland. *Rosewood* marble is a beautiful brown variety from Ashford in Derbyshire. *Black* marble, such as is worked in Derbyshire, Galway, and Kilkenny, usually emits a fetid odour when struck, and loses its colour on calcination. W. N. Hartley found 1·48 p.c. of carbon and 0·01 of sulphur in the black marble of Kilkenny (Proc. R. Dub. Soc. 1887, 5, 486). The black Carboniferous limestone of Belgium and France, with small white sections of encrinites, is termed locally *Petit granit*.

Lumachella is an Italian name for any shelly marble, but is specially applied by mineralogists to a Liassic limestone from Bleiberg, in Carinthia, containing the remains of ammonites, which by their brilliant play of colour resemble precious opal. An argillaceous limestone, remarkably rich in dendritic markings, occurs in irregular masses in the Rhætic series, near Bristol, and has been polished under the name of *Landscape marble*. The *Ruin marble* of Tuscany is a soft argillaceous material, found near Pisa, and sometimes described as a kind of lithomarge. The *Ammonite* marble, found near Yeovil, is a brown Liassic limestone, rich in the remains of ammonites. The oolitic formation known as *Forest marble* takes its name from Wychwood Forest in Oxfordshire, which yields a coarse shelly limestone, occasionally polished as an ornamental stone. The famous *Purbeck* marble, extensively used in Gothic architecture, especially for slender clustered shafts, is a grey fresh-water limestone of Upper Oolitic age, crowded with *paludinæ*; whilst the *Sussex* marble is a similar shelly limestone, of fresh-water origin, occurring in bands in the Weald clay.

Stalagmitic marbles or *Onyx-marbles* (*q.v.*) consist of banded layers of calcite deposited from solution in caves. These were formerly called alabaster, and are now often known as 'Oriental alabaster,' the adjective being used to distinguish it from true alabaster, which is a native form of calcium sulphate (gypsum). Well-known varieties, often used for decorative purposes and small ornamental objects, are *Algerian onyx* and *Mexican onyx*.

Ophicalcite is a name applied to serpentinous limestones, which generally display clouded patterns, due to the interblending of a white limestone or dolomite with a green serpentinous mineral. The 'Irish green' of architects is a rock of this character from Connemara in western Galway. Of a similar nature are the serpentinous marbles of Anglesey, the eozoonal marble of Canada, and the verde antico previously mentioned. As the two constituents of an ophicalcite are unequally attacked by atmospheric agents, such a rock is unsuited for use in exposed situations, since it soon weathers to a rough surface.

In fact, marble generally is hardly suitable for outdoor work in large towns. The atmosphere of a city becomes charged with the products of the combustion of coal, including

acid compounds of sulphur, and must sooner or later attack all marble monuments. It has been shown by Sir A. Geikie that marble slabs exposed in the churchyards of Edinburgh suffer total destruction in less than a century (Proc. Roy. Soc. Edinb. 1880, 10, 518).

A minor use of marble is for the production of carbon dioxide in soda-water manufacture. In the United States about 25,000 tons of scrap marble are annually ground into dust for this purpose.

MARCASITE. An orthorhombic form of iron disulphide FeS_2, dimorphous with the cubic iron pyrites (*v.* PYRITES) and isomorphous with mispickel (FeAsS). Crystals are not infrequent, but their form is usually much obscured by twinning, producing more or less characteristic forms, which have given rise to the names 'spear-pyrites' and 'cockscomb-pyrites.' Stalactitic and nodular forms with an internal radiated structure are also common. The sp.gr., 4·8, is rather lower than that of iron pyrites, but the hardness (H.=6) is about the same. The colour is pale brass-yellow, rather lighter than that of iron pyrites (hence an old name 'white pyrites'), but the material frequently shows a surface tarnish. Marcasite is less stable than iron pyrites, and in a moist atmosphere it decomposes more readily, with the production of iron vitriol. When the material shows no crystal forms it is not always distinguishable from iron pyrites.

Marcasite occurs in mineral veins, as crystals and nodules in the chalk marl of Kent, in lignite and clay at Littmitz in Bohemia, &c. It is much less abundant than iron pyrites. When found in large amount it is used, like iron pyrites, for the manufacture of sulphuric acid and iron vitriol. L. J. S.

MARCASOL *v.* SYNTHETIC DRUGS.

MARC BRANDY OIL *v.* FUSEL OIL.

MARCTINE. Trade name for an antithermic $CH_3{\cdot}C_6H_4{\cdot}NH{\cdot}NH{\cdot}CO{\cdot}NH_2(1:3)$, *i.e.* methylacetanilide, in which the acetyl radical is replaced by the group $NH{\cdot}CO{\cdot}NH_2$. For reactions and tests, *v.* Lemaire, Rep. Pharm. 1907, 19, 49; J. Soc. Chem. Ind. 1907, 342.

MARETIN *m*-tolylsemicarbazide

Used as an antipyretic, *v.* SYNTHETIC DRUGS

MARGARIC ACID $C_{16}H_{33}COOH$ is stated to occur in the wax of lichens, and is obtained by boiling margaronitrile with alcoholic potassium hydroxide (Becker, Annalen, 102, 209; Heintz, J. 1857, 355).

MARGARINE (American, *Oleomargarine*) is the generic term for butter substitutes, consisting either of a mixture of animal fats alone, or of animal and vegetable oils and fats churned with milk to a butter-like emulsion, and coloured yellow (unless forbidden by law) with annatto, methyl orange, &c. During latter years, with the expansion of the margarine industry, two further kinds of 'margarine' have been brought into commerce, namely (1) margarine made exclusively of vegetable fats and oils churned to an emulsion with cow's milk, and (2) margarine made from vegetable oils and fats, wherein for cow's milk is substituted an emulsion made from kernels of almonds. Thus the last-named article consists exclusively of *vegetable* products and is sold under the name of 'nut butter' for the use of vegetarians. A variety of the last class of butter substitutes, no doubt suggested by the fact that their consistence was too soft, is made from a mixture of oleomargarine and milk of almonds (with an addition of sesamé oil, where prescribed by law).

The industry of butter substitutes owes its origin to experiments (induced by a prize offered by the French Government in 1869) made by Mège-Mouriès, which were worked out to a manufacturing process in Paris in the year 1870.

In the manufacture of the original margarine, as made by Mège-Mouriès's process, the animal fats used were oleomargarine—'oleo oil,'—and (or) neutral lard. Both ingredients must be prepared from the freshest beef fat and (or) hog-fat respectively.

For the production of oleomargarine, the rough fat is removed from the slaughtered animal as quickly as possible and brought into the works, where it is sorted. The kidney and bowel fats are selected, then carefully washed with warm water and thoroughly cleansed. The cleansed fat is brought immediately into large, well-aired, artificially cooled rooms to dry and harden (being allowed to hang there suspended from tin hooks for several hours), or is immersed in iced water in order to secure more rapid hardening. The hardened fat is then cut up and shredded in a shredding machine, and finally ground between rollers. The disintegrated mass is introduced into tin-lined jacketed vessels ('melting kettles') and brought to a temperature not exceeding 42°, this temperature being maintained by steam or hot water passing through the jacket.

At this temperature a portion only of the tallow contained in the tissue separates on the top of the comminuted rough fat. The settling and clearing is assisted by sprinkling salt over the surface of the melted fat. This melted portion, termed 'premier jus,' is run off into shallow tin-lined trays arranged in tiers in a cooled room, when the bulk of the 'stearine' separates in a crystalline condition. The crystallised mass in the tins is cut up into square pieces of about 3 lbs. weight each, wrapped in canvas cloths, and placed in hydraulic or mechanical presses.

For the best qualities of margarine, the 'premier jus' is remelted at a temperature not exceeding 45° and allowed once more to settle out, after salt has been added, whereby the last remnants of membrane and tissue are precipitated. In large works the clear fat is allowed to run into wooden vats, in which it stands for from 3 to 5 days at a temperature suitable for

the crystallisation of the 'stearine.' The whole is then stirred up into a homogeneous pulpy mass; this is wheeled in wooden waggons to the presses and treated as described already.

The oleomargarine, 'oleo oil,' which runs out from the presses formerly constituted the exclusive raw material for the manufacture of margarine.

In some works the rough fat from which the 'premier jus' has been taken off (in the manner described above) is heated once more to about 50°, when a second portion of fat is recovered. This is sold as 'secunda jus,' and is used in the manufacture of inferior kinds of margarine.

Amongst the vegetable oils, cotton-seed oil and cotton-seed stearine, sesamé oil, arachis oil, and recently even soya-bean oil, are preferred. According to the intended quality of the margarine, the quality of the cotton oil varies. In any case the cotton-seed oil must be practically devoid of free fatty acids, and rendered as free as possible from the peculiar flavour characteristic of this oil. The best brand of cotton-seed oil used for margarine making is known under the name 'butter oil.' Arachis oil (also olive oil) and sesamé oil are used to a greater extent in Europe than in the United States. Refined coco-nut oil and palm-kernel oil are now incorporated to a very considerable extent with the fat stock of margarine.

A new source of solid fats has been made available for the manufacture of margarine by the development of the process of hydrogenating oil (*see* HARDENED OILS). The use of hydrogenated oils for this purpose was patented by Deveaux (Fr. Pat. 458611, 1913). In America cotton-seed oil hardened to the required extent is now frequently used in place of oleomargarine. Attempts have been made on the Continent to use hydrogenated fish oils in the manufacture of margarine, but the recurrence of the original odour renders these products unsuitable. In this country margarines containing hydrogenated oils are, as yet, only prepared for special purposes, such as for the use of bakers.

The oleomargarine, 'oleo oil' (and neutral lard) is mixed in *churning machines* at as low a temperature as is consistent with a semi-fluid condition with the vegetable oils and fats, and with milk.

The quality of the resulting product depends, to a great extent, on the quality of the milk and on its treatment previous to its admixture with the fats. The milk may be either sweet milk or sour. Sweet milk is more difficult to amalgamate with the oils and fats, and is retained with greater difficulty than soured milk, but the advantage the employment of sweet milk offers is that the resulting product has a finer taste and keeps better. The soured milk is, however, more easily incorporated with the fats and gives a higher yield. The proper treatment of the milk in the margarine works constitutes one of the most important features, just as the corresponding part of the butter-making process does in large dairies. The milk should be worked up as soon as possible after arrival. In any case it should be pasteurised immediately after it is received, and no preservatives—not even salt—should be used to prevent the fermentation of the milk. If the cream has not been taken off before the milk reaches the margarine works, it is removed (for butter-making) by means of a centrifugal machine, &c. The regular determination of the fat in the milk is necessary, not only for the proper control of the works, but also for the further reason that it has not infrequently occurred (on the Continent) that too much cream is taken off by the seller and replaced by sesamé oil, cotton-seed oil, or even by margarine.

The churning machines consist of oval, jacketed vessels provided with one or two sets of stirring and mixing gear. During the process of churning a constant temperature must be maintained by means of steam sent through the jacket of the churn. The object of churning, besides thoroughly mixing the ingredients, is to destroy the tendency of the oleomargarine to crystallise, and to pulverise ('atomise') the mixture, as it were, into single globules, such as butter-fat forms in milk. The art of the margarine maker at this stage of the process consists, therefore, in carefully regulating the inflow of milk and fat stock, so that a thorough emulsion is finally obtained.

First, the milk is put lukewarm into the churn and is mixed up with a little cream, followed by the addition of butter (if any be added). When the mass is thoroughly emulsified, part of the oleomargarine is added carefully, and when this has been properly incorporated with the emulsion, the oils required for the margarine stock are entered gradually and only then the remaining oleomargarine is mixed in. At this stage some manufacturers add colouring matters. The steam is then turned off, and the warm material cooled to a definite temperature by cold water being sent through the jacket.

In a process no longer used in up-to-date works, the cooled margarine leaving the churn was delivered into a tank and disintegrated by meeting a current of ice-cold water under pressure. This so-called 'wet' method has been practically superseded by the dry method.

The cooling of the still liquid margarine by running it off to a cooled table, has the serious drawback that the cooled mass is of uneven thickness, and hence an unevenly cooled product is obtained. This drawback is avoided by E. and H. H. Schou, who cool the margarine in a thin layer, of a thickness of about 1–1·5 mm., between two hollow cylinders which revolve in opposite directions and are cooled by a cold brine solution.

A large number of patents have been taken out for 'homogenising' or 'atomising' in special machines the mixture of milk and oils and fats. The merit claimed for these machines is that the product is more solid and has no 'oily' but rather 'a nut-like' taste. A drawback of all these apparatus is, however, that the margarine retains more water, and hence the proportion of fat falls below 80 p.c. Therefore in those countries where the maximum percentage of 16 p.c. of water is prescribed by law, the sale of such margarine would meet with difficulties.

In order to obviate this drawback, and at the same time to dispense with the kneading machines, in which the excess of the milk is removed, Schroeder (D. R. PP. 204061; 204062) carries out the blending and emulsifying process in three churning machines arranged one above

the other and working in conjunction with an 'atomiser.' The temperature in the three churns through which the mixture of fats and milk passes is regulated carefully so that the completely emulsified contents of the lowest churn can be discharged on to a cooled table, where the mass solidifies to a thin layer, which is scraped off by a tangentially acting 'doctor,' so that the thin solidified film is curled up and discharged into a waggon. The ingredients forming the margarine are mixed (*v. infra*) in the proportion of 80 parts of fats and oils, 16 parts of milk, and 4 parts of cream, consisting approximately of one-third of butter-fat.

Among other more recent types of emulsifiers mention may be made of that of Silkeborg (Eng. Pat. 4657 of 1914) and that of Blichfeldt (Eng. Pat. 18048 of 1914). The former consists of a horizontal cylinder surrounded by a heating jacket, and containing a rotating agitator, which drives the mixture of milk and fat against fixed baffle plates containing perforations, which effect fine subdivision of the mass.

In Blichfeldt's apparatus the emulsification is effected by means of a rotating disc pierced with slots, which is mounted on a hollow shaft in a vessel the walls of which are close to the disc. The milk is introduced through the hollow shaft, whilst the melted fat is delivered through an opening in a tube passing across the vessel. The use of these newer types of emulsifiers permits of the process being carried out continuously, and thus effecting an economy in space, power, and time.

In the now practically obsolete 'wet' method of cooling the emulsion water chilled to a low temperature by refrigerators is used as the cooling medium. Various modifications of cooling devices are also in use. For example, in Rasmussen's apparatus (Eng. Pat. 29831 of 1913) the fatty mixture is distributed on to a hollow cylinder which rotates in cold water, at a depth of about two-thirds its diameter. The congealed fat is then removed from the surface by means of scrapers which deposit it on a travelling band.

In the 'dry' method of chilling the emulsion the mixture may be distributed on to a travelling band which traverses a current of cold filtered air (Eng. Pat. 20292 of 1911), this method, however, being too expensive for use; or, as in Christensen and Lauridsen's process (Eng. Pat. 20568 of 1912), it is distributed as a thin film on the surface of a rotating cylinder, through the interior of which chilled brine circulates. In Schöu's cooling drum (Eng. Pats. 12561, 1907, and 1160, 1909) brine chilled to $-7°$ is circulated through cylinders revolving in opposite directions, and capable of being adjusted so that a desired thickness of film can be obtained. A similar type of apparatus has been patented by Jurgens (Eng. Pat. 10868 of 1914). After being chilled in this way margarine frequently has a crystalline structure, and requires a final mechanical kneading to give it the consistence of butter.

Effective emulsification depends upon the correct application of the principles of colloidal chemistry. For an outline and discussion of these principles reference may be made to W. Clayton's 'Margarine' (Longmans, 1920).

The solidified margarine is now kneaded to a butter-like mass by means of rollers contained in cylindrical rotating drums. The margarine is thus thoroughly worked through, and the excess of water squeezed out, so that a homogeneous mass results. This is then salted to taste, mixed with a little colouring matter (if permitted by law), and again submitted to thorough kneading in a second set of kneading machines of the same or of different type, in order to produce the required texture throughout the whole mass. The mixture with salt, preservatives, &c., is usually effected by means of a blending machine. The margarine is finally moulded into lumps, pats, rolls, or any other desired shape.

As an example of a good working recipe for margarine the formula officially proposed in 1918 may be quoted, viz.: Premier Jus, 15; coconut oil, 15; palm-kernel oil, 50; arachis oil, 10; and cottonseed oil, 10 p.c. This melted at about 25°. For winter use the formula was modified so as to contain 30 p.c. of liquid oils, 20 p.c. of animal fats, and 50 p.c. of vegetable fats.

The object of the margarine maker being to render his product as closely similar to butter as possible, and to take away the 'tallowy' or too strongly 'oily' taste of the material, some manufacturers (provided the law permits) add cow's butter. Others add small quantities of volatile acids, volatile aldehydes, mixed glycerides containing butyric acid, such as dibutyromonostearin and dicaprylomonostearin, or 'butter perfumes,' which consist chiefly of volatile acids, such as propionic, butyric, caproic, and their ethyl esters. Also coumarin (sold as an emulsion with sesamé oil) would fall under the head of 'perfumes.'

It should, however, be stated that margarines prepared from the best material and in an unobjectionable manner do not require any of these additions. The latter are chiefly used in order to mask low-grade materials, or to afford analytical data which may create a fictitious impression as to the real nature of the product.

An important point in the manufacture is to produce margarine which will froth and 'brown' on heating, so that even in cooking the margarine may resemble butter. Since the property of butter to brown and froth is due to casein and milk sugar, it is evident that the more milk is used in the manufacture of margarine, the nearer will the product approximate to butter.

Milk is liberally used in this country and in America; but in some continental countries where the law forbids the addition of more than a strictly limited quantity of milk, a number of patents have been taken out for substances which are credited with imparting to margarine the desired properties. Prominent amongst these patented products are casein and other proteins. Some patentees claim cholesterol and cholesteryl esters, or lecithin. Lecithin is now incorporated with margarine in the form of egg yolk, which is, of course, cheaper than lecithin.

Vegetable waxes have also been proposed as admixtures, and the use of beeswax for this purpose has even been patented, although the addition of such substances must seriously interfere with the digestibility of the margarine.

Besides the taste, the consistence also plays

an important part in the valuation of margarine. If the finished margarine has not been worked sufficiently on the tables, its consistence may be either too ' greasy ' or too ' sandy,' *i.e.* the semi-crystalline mass has not been properly ' broken,' and its grain differs from that of a properly prepared dairy butter. Some margarines are also finally mixed with a little glycerin, or glucose, or sugar, in order to improve the texture or to give them a glossy appearance and also a sweeter taste. The addition of glucose or cane-sugar must, however, be considered a mistake, as this only leads to premature development of fungus on the margarine.

The manufacture of butter substitutes is differently affected by legislation in different countries. In this country the adding of butter to margarine in any proportion was at first allowed; for, according to the Margarine Act of 1887, any ' butter ' containing even the smallest quantity of foreign fat was looked upon as margarine. By the Margarine Clause of the Food and Drugs Act, 1899, however, the maximum proportion of butter-fat in margarine has been restricted to 10 p.c.

This restriction has been confirmed by the Butter and Margarine Act of 1907, and it has been further enacted that margarine must not contain more than 16 p.c. of water. Margarine factories must be registered, and be open to Government inspection. Prohibited preservatives must not be used, nor is an excess of boric acid allowed. According to the same Act ' margarine ' means ' any article of food, whether mixed with butter or not, which resembles butter, and is not milk-blended butter.' For the latest enactments in other countries the reader is referred to Lewkowitsch, Chemical Technology.

In the *examination* of margarine the determination of the Reichert-Meissl value constituted the most important characteristic, as it indicated in the briefest and surest manner the amount of butter-fat contained in the margarine, either added as butter or originating from the milk which had been incorporated with the oils and fats in the process of manufacture. Since, however, considerable quantities of coconut oil and palm-kernel oil form ingredients of margarines, and since even margarines are made at present which consist exclusively of the last-named two fats, without even an addition of cow's milk, the indications of the Reichert-Meissl value no longer have that importance which they formerly possessed.

The Polenske value, which is based on the determination of the volatile insoluble fatty acids which distil in the determination of the Reichert-Meissl value, affords a more trustworthy indication (Analyst, 1904, 29, 154; 1911, 36, 333, 336). The method of Shrewsbury and Knapp (Analyst, 1910, 35, 385) is based upon the fact that the predominating fatty acid (lauric acid) of coconut oil is readily soluble in dilute alcohol, and may be estimated by titrating the solution with standard alkali solution. Kirschner's extension of the Reichert-Meissl-Polenske method (Zeitsch. Nahr. Genussm. 1905, 9, 65) is essentially an estimation of the amount of butyric acid present. It has been shown by Revis and Bolton (Analyst, 1911, 36, 336) that by determining this value it is possible to ascertain rapidly whether butter-fat is a constituent of a margarine. The relationship between the Kirschner, Reichert-Meissl and Polenske values has been worked out by Bolton, Richmond and Revis (Analyst, 1912, 37, 183), and more fully by Cranfield (Analyst, 1915, 40, 339). According to Richmond (Analyst, 1919, 44, 166), results agreeing with the mean figures are obtained by the use of the equation $P = 0{\cdot}26(K - 14)$, where P and K represent the Polenske and Kirschner values respectively. At one time margarine was adulterated with paraffin wax. The separation and identification of unsaponifiable matter in the fat would detect this fraud.

A test to distinguish between butter and margarine is to examine a thin layer of the fat under the microscope, using polarised light, when margarine showed a crystalline appearance (C. Williams). This test, however, fails in the case of ' renovated ' or ' process ' butters (W. Clayton, J. Soc. Chem. Ind. 1917, 36, 1205).

On heating the clear filtered fat from butter or margarine to a temperature of about 185° the natural butter colour and vegetable colours are destroyed, whereas coal-tar colours are not.

For an account of the occurrence of vitamins in butter and margarine and their significance from a nutritional point of view, *see* Clayton's ' Margarine.' J. L.

MARICOL. Trade name for magnesium ricinoleate.

MARINE ACID. *Syn.* for hydrochloric acid (*q.v.*).

MARINE ANIMAL OILS *v.* OILS.

MARIPA FAT. The fat of the fruit of *Maximiliana* [*Attalea*] *Maripa* (Drude), used in the West Indies as butter. It is employed in French Guiana as a medicinal liniment, and is practically identical with coco-nut fat in characters.

MARJORAM, *Origanum Majorana* (Linn.), a herb employed in flavouring. It is generally used in the air-dried state, when it has the following composition :—

Water	Pro-tein	Fat	Ethereal oil	N-free extract	Crude fibre	Ash	Sand
7·6	14·3	5·6	1·7	35·6	22·1	9·7	3·4

Commercial dried marjoram often contains much sand; a good sample should not contain more than 14 p.c. of ash, of which not more than 3·5 or 4·0 p.c. should be insoluble in hydrochloric acid. The following analyses of the ash of marjoram were made by Rupp (Zeitsch. angew. Chem. 1892, 681) :—

	K_2O	Na_2O	MgO	CaO	Fe_2O_3	Mn_3O_4	P_2O_5	SO_3	Cl	CO_2	Sand
German	20·2	0·7	4·8	17·6	7·3	1·0	8·9	4·9	2·1	6·1	26·5
French .	18·3	0·7	6·7	24·8	6·1	trace	9·1	4·8	1·5	8·6	19·4

(*v.* OILS, ESSENTIAL). H. I.

MARKASOL. *Bismuth borophenate* (*v.* BISMUTH, ORGANIC COMPOUNDS OF).

MARKING-INK is used for stamping or marking fabrics, and should be permanent, and indestructible to the material. The basis of many marking-inks is a silver salt dissolved in aqueous ammonia containing a little gum. This is only coloured on decomposition, so a little dye is needful; dark-brown inks contain

archil and chlorophyll, crimson contain carmine, whilst copper sulphate is an ingredient of blue ink.

Redmond's ink is made thus: dissolve 3 oz. 2 drms. silver nitrate and 3 oz. sodium carbonate each in 2 pints boiling water, mix, and collect the precipitate so formed on a filter, wash with water, transfer to a mortar, add 10½ drms. tartaric acid, triturate the whole, and when effervescence has ceased, add 3½ oz. of ammonia (0·880), stir until dissolved, and add 1½ oz. powdered white sugar. Mix 1 oz. chlorophyll and 1 oz. archil with 4 oz. water, add 2½ oz. of acacia gum to this when dissolved, strain, add to the ammoniacal solution and make up to 20 oz. with water. This ink, if carefully prepared, contains only the tartrate of silver; on heating metallic silver is left on the fabric.

An indelible ink is made by dissolving 1 oz. silver nitrate and 1½ oz. of sodium carbonate separately in 3 oz. distilled water; mix the solution, collect and wash the precipitate with distilled water. Add 160 grs. tartaric acid, dissolved in 1 oz. water, to the precipitate in a mortar, stir until effervescence ceases, and then add 2 oz. liquid ammonia to dissolve the precipitate. Mix in 80 grs. aniline black, dissolved in 1 oz. boiling water, and add 5 drms. glycerol and water to make up to 8 fl. oz. (Spon's Workshop Receipts, 1909, 510).

Aniline marking-ink is prepared thus: in two bottles (1) add 1 fl. drm. aniline and 10 grs. toluidine to 2 fl. drms. mucilage of acacia and dilute hydrochloric acid, and mix; (2) powder 40 grs. cupric sulphate, 20 grs. ammonium chloride, 20 grs. potassium chlorate, and dissolve in 6 fl. drms. water; lastly, add 2 fl. drms. of thick mucilage and mix. Leave for 2 or 3 days before using. Equal parts of each solution are mixed immediately before using and applied with a quill pen (Scient. Amer. Ency. 1903, 276). Single solution aniline inks are also made.

An ink suitable for rubber stamps, as it dries rapidly, is made by adding 15 oz. glycerol to a solution of ½ oz. aniline black and 15 oz. pure alcohol.

To use silver marking-ink for stamping, add to 1 oz. ink, 1 drm. glycerol and 1 drm. treacle.

To make an indelible red ink, dissolve 2 oz. shavings of dry white curd soap in 1 part balsam of copaiba by heating, add sufficient vermilion and stir occasionally until cold.

Indian-inks are used for marking.

An ink suitable for labels which cannot be bleached is made by mixing equal parts of pyrogallol and iron sulphate. The label is varnished when dry (Hiscox, Receipts, 1907, 407).

The juice of the banana and of the marking-nut have to some extent the properties of marking-ink, but no practical method of preparing them for sale has been developed.

MARL (Ger. *Mergel*), a name properly restricted to calcareous clays, but frequently extended so as to include any clay which, when dry, is readily friable. Thus the Keuper or New Red Marls, of Triassic age, often contain little or no calcium carbonate. An analysis of a red Keuper marl, from Worcester, by Voelcker, yielded 4·85 p.c. of lime. The typical marls are soft, earthy, and of a white, grey, or brownish colour. Many of them disintegrate in water; and they are readily attacked by dilute hydrochloric acid with evolution of carbon dioxide. Marls have been used for ages by agriculturists for the purpose of improving certain lands, the material for 'marling' being systematically dug from 'marl pits.' Since a marl is a calcareous clay, it may obviously pass into an argillaceous limestone; the *chalk-marl* is a rock of this kind. When a marl becomes indurated it is often known as *marlstone* or *marl-rock*, and the hard beds of the Middle Lias, which in Yorkshire yield the Cleveland iron ore, are recognised by geologists as the 'marlstone.' A laminated variety of hardened marl is termed *marl-slate*, which readily passes into a calcareous shale. The marl-slate occurring in the Permian series in the north of England is equivalent to the German *Kupferschiefer*, a bituminous marly shale, containing copper ore. The *shell-marl* found at the bottom of certain lakes, especially in Scotland, is a calcareous ooze, consisting largely of organic remains. L. J. S.

MARMATITE *v.* ZINC-BLENDE.

MARRUBIIN *v.* MARRUBIUM.

MARRUBIUM, *Horehound*, *Hoarhound*. (*Marrube blanc*, Fr.; *Andornkraut*, Ger.) Horehound has been employed for its mild tonic, stimulant, and laxative properties, especially in domestic medicine, for a long period. It consists of the leaves and tops of the *Marrubium vulgare* (Linn.), a perennial herb growing throughout most parts of Europe, Asia, and America (Bentl. a. Trim. 210). The only constituent which has been examined, except a trace of *volatile oil*, is the bitter neutral *marrubiin*.

Marrubiin was examined by Gordin (J. Amer. Chem. Soc. 1908, 30, 265, where *see* earlier literature), who assigned the formula $C_{21}H_{28}O_4$, m.p. 155°; b.p. 297°–299°/15 mm.; $[\alpha]_D$ +45·68°, forms large crystals from alcohol. It is the lactone of *marrubic acid* $OH{\cdot}C_{20}H_{28}O_2{\cdot}CO_2H$, m.p. 173°–174°, which can be reconverted into marrubiin in several ways. G. B.

MARSH GAS. *Methane* or *methyl hydride* (*v.* METHYL).

MARSH-MALLOW GUM *v.* GUMS.

MARSH-MALLOW ROOT contains 1·7 p.c. of an oil composed of palmitin and olein, butyric acid, a phytosterol, apparently identical with sitosterol, a hydroxy acid of high molecular weight, an odourous substance of unknown composition, a lecithin containing palmitic and oleic acids and choline, 10·2 p.c. of sucrose and 0·78 p.c. of invert sugar, a mucilage ($C_6H_{10}O_5$), consisting of glucosan (64 p.c.) and xylan, and another saccharocolloid giving *d*-galactose on hydrolysis (von Friedrichs, Arch. Pharm. 1919, 257, 288).

MARSH ROSEMARY. *Andromeda Polifolia* (Linn.); also an American name for *Statice caroliniana* (Walt.) [*S. Limonium* (Linn.)]. *Andromeda Polifolia*, belonging to the *Ericaceæ*, is the only British species of the genus; it is found also in peat-bogs throughout the north of Europe, Asia, and America. It is an acrid narcotic and is fatal to sheep pasturing off it.

Statice caroliniana is found in marshy situations from Maine to Florida. According to Parrish, it contains 12 p.c. of tannin and has been used in the manufacture of leather.

MARTENSITE. The principal constituent of all hardened steels containing over 0·16 p.c. of carbon. It is a solid solution of carbon in iron; when saturated, as in high-carbon steels, it is known as '*hardenite*' (Howe).

On a polished surface, etched with picric acid, it shows under the microscope three systems of cleavage planes inclined to each other at 60°. It is very hard and cannot be scratched by a needle.

Martensite is magnetic and forms one of the principal constituents of permanent magnets.

MARTIUS'S YELLOW. A synonym for Naphthalene yellow; known also as *Jaune d'or, naphthol yellow, Manchester yellow*. The sodium or lime salt of dinitro-α-naphthol (*v.* NAPHTHALENE).

MASOPIN RESIN *v.* RESINS.

MASS ACTION *v.* CHEMICAL AFFINITY.

MASSECUITE *v.* SUGAR.

MASSICOT *v.* LEAD.

MASSICOTITE *v.* LITHARGITE.

MASTIC CEMENT *v.* CEMENTS.

MASTIC RESIN *v.* RESINS.

MASTIC VARNISH *v.* VARNISH.

MATAZIETTE. A name given to an explosive made in Switzerland, formed of nitroglycerin, sand, and chalk, coloured with ochre.

MATCHES. (Ger. *Zündhölzer, Zündhölzchen*; Fr. *Allumette*; Sw. *Tändsticka*, pl. *Tändstickor*; Du. *Zwavelstokje, Fosforus-stokje*; It. *Zolfanello, Fiammifero*; Da. *Svovlstik*; Hung. *Gyufa*.)

Derivation and variants of the word 'match.'—Older Eng. forms, *mec(c)he, metch, matche, mache, macche*; O. Fr. *mesche, meiche*; Mod. Fr. *mèche*; Pr. *mecca, mecha*; Catal. *metxa*; Sp. and Port. *mecha*; It. *miccia*; perhaps from Gr. μύξα, L. *myxa, mixa, myxus*, lamp-nozzle, lamp-wick, mucus of the nose; connected with L. *muccus*, nasal mucus, whence It. *moccolo*, L. *mucculus*, snuff of a candle.

Definitions. 1. (*Ordinary language*).—An instantaneous fire-producer, consisting of a short stem, rod, or tube, tipped at one or both ends with a composition or paste, inflammable by friction; or (as in the earlier forms) when brought into contact with a chemical reagent.

2. (*Military and mining*).—A cord or thread impregnated with combustible material, capable of burning along its entire length, so that fire can be conveyed from one point to another. This kind of match, which is better termed a fuse, is not ignitable by friction, and may be 'slow' or 'quick,' according to requirements.

I. FRICTION MATCHES.

History and development. Friction matches are among the most useful products of the period immediately preceding the Victorian age, and afford a signal instance of the ministration of science to human needs. Developed in less than three-quarters of a century from fire-producing appliances of the most primitive types, they have been so perfected that it is difficult to foresee in what direction further progress is possible.

Since the discovery of phosphorus in 1673 by Brand, of Hamburg, many attempts had been made to obtain light and heat expeditiously by its aid; one of the earliest consisting in rubbing a particle of phosphorus between folds of coarse brown paper, the flame produced igniting a sulphur-tipped splinter of wood. This plan was found to be inconvenient and dangerous, and phosphorus gradually fell into disuse. After the element had been, in a technological sense, left severely alone for more than a century, renewed attempts were made to utilise it. One contrivance was the somewhat impracticable '*phosphoric taper*' (1781). This was of wax, enclosed in a sealed glass tube, at one end of which was a fragment of phosphorus. After the tube had been dipped in warm water, the end remote from the phosphorus was cut off with a file, the taper was withdrawn, with some phosphorus adhering to it, which spontaneously inflamed. Another appliance was the '*phosphorus bottle*' of Cagniard de Latour (1810), containing partially oxidised phosphorus, some of which was withdrawn by a brimstone match, dipped into the phial, and then ignited by friction. A '*briquet phosphorique*,' brought out in Paris in 1786, consisted of a small tin box containing sulphur-tipped matches, together with a bottle coated internally with phosphorus. '*Pocket luminaries*,' soon afterwards sold in London, and '*portable fire boxes*' were similar. Various early devices for quickly producing fire were Homberg's '*pyrophorus*' (an oxidisable powder, free from phosphorus, prepared by roasting alum with flour, honey, or sugar, and inflamed by exposure to air), and Döbereiner's pyrophorus, of similar character; '*pneumatic tinder-boxes*,' containing amadou or ordinary tinder, ignited by the heat generated when air was compressed by a piston, such as Mollet's Pump, and Lorentz's '*light syringe*' (1807); '*electropneumatic fire-producers*' (invented by Brander, 1778, and by Fürstenberger, 1780), in which hydrogen was kindled by an electric spark—to which category belonged Mayer's apparatus (1811); Volta's '*inflammable air lamp*'; Fyfe's '*hydropneumatic lamp*'; and, lastly, Döbereiner's '*platinum lamp*' (in which contact with spongy platinum, or iridium, ignited hydrogen gas)—with Eisenlohr's, v. Babo's, v. Römer's, Palkl's, Hare's, Schiele's, and Böttger's modifications of the same.

The principal stages in the evolution of matches will now be referred to in chronological sequence. During the year 1804, phials charged with a mixture of phosphorus, wax, and oil were sold in cases containing also some brimstone-tipped matches and a piece of cork. The matches were dipped into the mixture, withdrawn, and ignited by friction on the cork. In 1805, Chancel, of Paris, applying the principle discovered by Berthollet, of oxidation by chlorates in the presence of strong acid, invented '*oxymuriate matches*,' strips of wood tipped with a mixture of potassium chlorate, sugar, and gum, ignited by contact with sulphuric acid. In the same year, according to Niklés, *friction matches* containing the element phosphorus were made and used in Paris. In 1806 various improvements in the tinder-box were suggested by Phillips, who was followed by Lorentz (1807), with an apparatus for igniting hydrogen gas by the aid of an electrophorus, and with the 'light syringe' already mentioned (same patent). In

1809, to Derepas, of Paris, was granted a French patent 'for a peculiar composition of phosphorus match lights.' This was an attempt to render phosphorus more manageable and less inflammable, by intimately mixing 8 parts, 'half melted,' with 4 parts of magnesia. When cold, the substance was described as forming 'an opaque body fit for inflaming a common match' (Description des Brevets). During the year 1812, '*chemical matches*,' manufactured according to Chancel's invention, began to be sold extensively, a hundred for a florin, in Vienna. The sticks were tipped with potassium chlorate, sugar, and gum, or with the same ingredients and lycopodium; colophony, gum benzoin, &c., were also used. These matches, packed in suitable cases, together with bottles containing asbestos soaked in sulphuric acid (in accordance with a proposal made in 1812 by v. Römer, of Vienna), were sold more widely on the Continent than any others, up to the year 1844. Among the makers were v. Römer, Peters, Wagner, Siegel, Ehrlich, and Merckel. The cases were known as '*tunkfeuerzeugen*,' '*briquets phosphoriques*,' '*inflammable match-boxes*,' '*instantaneous light boxes*,' '*phosphorus boxes*,' &c.; and one form was prominently sold in this country as Heurtner's '*Eupyrion*.' Violence of combustion, and liability of the acid to be spirted about, were characteristics of these matches. In 1816, friction matches tipped with a composition containing phosphorus are stated to have been manufactured in Paris by François Dérosne, who by Gintl and others is regarded as the first maker of the phosphorus friction-match. The year 1823 is marked by the invention of the Döbereiner lamp, already referred to. About this time, too, were used, at Erfurt, in Prussia, small glass tubes containing equal quantities of phosphorus and sulphur carefully fused together, into which thin sticks or splints of wood were introduced, easily inflamed afterwards by friction. The early attempts to make friction matches in Paris and elsewhere appear to have failed completely; and the honour of having invented, in 1827 or earlier, the first practical and useful matches ignitable by friction, indisputably rests with an Englishman, John Walker, of Stockton-on-Tees, Durham (*d.* 1859). Walker was an apothecary, who had been apprenticed to a local surgeon before starting in business as a druggist. He was much interested in experimental chemistry, and for some years prior to 1827 had been preparing and selling, under the name of 'percussion powder,' dried mixtures of potassium chlorate and antimony sulphide, made up with gum-water. Eventually it occurred to him to dip splinters of wood into such a composition, and to supply these matches in tin boxes, together with a piece of folded glass-paper, under the name of 'friction-lights.' Samuel Jones, of 201, Strand, London, who from 1829–1830 onwards sold imitations of Walker's matches under the designation of '*lucifers*' (a name always repudiated by Walker), publicly announced in 1831 that about a year previously they had been 'lectured on at the London and Royal Institutions.' Matches resembling Walker's, but mostly sulphur-dipped, were made also by Jones's competitor, G. F. Watts, in 1831 ('*Watts's chlorate* or *lucifer matches*'), and by Richard Bell & Company in 1832 ('*improved lucifers*'). Watts and Bell both 'borrowed' the name 'lucifer' from Jones. '*Allumettes infernales*' were brimstone-dipped matches of the same type; and German matches of a similar kind, but not sulphured, were also manufactured. H. Link's '*allumettes chémiques*,' produced in Germany for the French market, and L. Achleitner's (Salzburg) '*snellzünder*,' were of like character. Among French makers of matches of an allied type were J. Joseph et Cie (1833), and A. Perpigna (1834).

Though non-phosphoric, Walker's matches inflamed when pressed between the folds of the glass paper and sharply withdrawn. Thus ignitable by friction, they were the lineal ancestors of twentieth-century matches.

Walker at first used strips of cardboard for the stems of his matches, but later he substituted splinters of wood, which he employed the poor people of the district to cut.

In the year 1828, Samuel Jones patented the '*prometheans*,' a return to the principle of the oxymuriate match. These consisted of slightly tapering, spirally-rolled paper tubes, containing in the broader or ignition end a minute fusiform glass tube (not a bulb, as usually stated), 10·5 mm. long by 1·0 mm. wide which enclosed a dark-blue liquid, shown by the writer's analysis to be composed of sulphuric acid coloured by indigo. The glass vessel was imbedded in a composition, variously stated to contain potassium chlorate and sugar, 'fulminate,' &c., but found by the writer to be composed of potassium chlorate, lycopodium, and sulphur. Neither sugar nor fulminate was present in the prometheans examined.

'*Lucifer matches*' or '*lucifers*,' *i.e.* non-phosphoric matches, of Walker's type, which inflamed when rapidly drawn through folded sand- or glass-paper, were followed in the early thirties by non-phosphoric friction matches, which could be ignited, though with difficulty, by being *struck upon rubbers affixed to the boxes*. Such were the friction matches made by Savaresse and Merckel (Paris), the igniting composition of which was a mixture of potassium chlorate, antimony sulphide, sulphur, and gum. The rubbing surface was composed of potassium chlorate, minium, pumice, and gum. Similar non-phosphoric friction matches were patented in 1832 by Siegel, an Austrian manufacturer; and Link's 'Chemische Streichfeuerzeuge' were of a like description. Matches, capable of being struck upon the box, soon became known as '*Congreves*,' both in this country and abroad; and the name was applied to the phosphoric friction matches which next came on to the market. 'Congreves' succeeded to 'lucifers'; 'lucifers' followed 'friction-lights'; 'friction lights' superseded 'chemical matches.'

It may be mentioned here that Samuel Jones seems to have been the first user of the word *fuzee*, or fusee, as applied to a match for lighting pipes or cigars. But Newton, a few months earlier, applied the term to a match for use by 'smelters.'

Hare's pyrophorus, described in 1831, was made by heating Prussian blue to redness in a glass tube, which immediately afterwards was

hermetically sealed. On breaking the tube and throwing out the contents they took fire.

Efforts meanwhile were being made to produce a practicable and satisfactory friction match, in which *phosphorus* should take the place of antimony sulphide; and this important result appears to have been achieved simultaneously in several different places during the period 1831–1833. At all events, in 1833–1834, v. Römer, Preschel, and Siegel, in Vienna, and Moldenhauer, at Darmstadt, were manufacturing wooden friction matches, the igniting compositions of which contained phosphorus. The date of v. Römer's patent was January 4, 1834. Other pioneer makers, associates or otherwise of the above, were Pollak and Kreutz (Vienna); Anthon (Darmstadt); and Amüller (Waiblingen). Many of these early continental makers called their matches 'congreves.' In France, the invention of the phosphorus friction match is now generally attributed to Dr. Charles Sauria, of St. Lothair (*d.* 1895), who, in January, 1831, while a student at the College d'Arc, Dole (Jura), made very good friction matches containing phosphorus, but neglected to protect his invention. Sauria's claims have been well attested; and it is possible that a rumour of his experiments somehow was conveyed to other countries during the few months following the discovery. The French Government in 1884 recognised 'L'Invention des Allumettes Chimiques' by a grant to Sauria of a '*bureau de tabac*,' the Academie Nationale Agricole bestowed upon him a medal, and during the year 1896 there was a movement to set up a monument to him in Paris. The design was not carried into execution, however. J. F. Kammerer (*d.* 1857), of Ludwigsburg, Würtemburg, is in Germany usually credited with having invented phosphorus friction matches in 1833; and he is said to have worked out the idea during the previous year; but the invention was not protected, and was pirated in every direction. Claims have been advanced also for a young Hungarian student at the Vienna Polytechnic School, named János Irinyi (who in 1895 was still living in south Hungary). He is alleged to have made the discovery in 1835, and to have sold his process to v. Römer. Possibly Irinyi's invention marked an advance upon the type of phosphoric friction match which had already begun to be manufactured. Lastly, a professor at the Technical High School in Stockholm, Dr. J. S. Bagge, between 1830–1840, worked out a method for procuring light by means of phosphorus friction matches, and drafted directions for their manufacture.

The oxidising agent used in the earliest matches was potassium chlorate only, but in 1835 Trévany partly replaced it, as being too violent in its action, by a mixture of minium and manganese dioxide.

In the United States of America the first patent for the invention of phosphorus friction matches was granted in 1836 to A. D. Phillips, whose igniting composition was a mixture of phosphorus, sulphur, chalk, and glue. In 1837, v. Römer substituted lead peroxide for potassium chlorate; in 1838, Preschel and Kreutz patented a composition consisting of phosphorus, manganese dioxide, nitre, and gum arabic; Beyer (Vienna, 1838) and Riess (Vienna, 1843) used as the oxidising agent a mixture of minium and nitric acid; and in 1842–3, Böttger, of Frankfort, recommended the substitution, for potassium chlorate, of mixtures of minium and saltpetre, or of lead peroxide and lead nitrate. Moldenhauer, about the year 1838, introduced the use of calcined magnesia in order to counteract the effects of the formation of hygroscopic oxidation-products of the phosphorus; and chalk also (introduced in 1836 by Ehrlich, of Prague) was used for the purpose. Preschel and Klug (1837) endeavoured to accomplish the same end by coating the match-heads with resinous spirit-varnishes. Between 1820 and 1840 various machines for cutting the wooden stems or 'splints' rapidly and in large quantities, were introduced; and the match industry has since developed in country after country until it is now of very great magnitude and world-wide importance. Although in the conditions and processes of manufacture, as well as in the character of the materials used (especially during the past 25 years), there have been improvements and modifications, so far-reaching and gigantic that the industry may be said to have been revolutionised, nevertheless the ordinary friction match of to-day is not *essentially* different from the 'lucifers' and 'congreves' made during the first third of the 19th century. But the use of machinery has been greatly extended. Continuous and automatic machines are at the present time widely and increasingly employed; and, following upon a gradual diminution in the proportion added, in only a very few countries now is white or yellow phosphorus used at all in the manufacture (*see post*, pp. 230 and 235). In 1855 J. R. Wagner recommended that less phosphorus should be used, and experimented with barium nitrate and potassium dichromate, as oxidising agents. The latter salt he considered too costly, and he remarked that lead dioxide, though more expensive and no better, had then largely replaced the mixture of minium and manganese dioxide. In view of the subsequent introduction and present widespread use of tetraphosphorus trisulphide, or phosphorus 'sesquisulphide,' P_4S_3, it is interesting to record that in 1860, Puscher, of Nuremberg, introduced the use of phosphorus sulphide instead of phosphorus, but found few followers. Bals (D. R. P. 89700, 1896) also tried a fused mixture of sulphur and red phosphorus. For making matches *waterproof*, Zimmermann (1864) used collodion, as an improvement on the resinous varnishes of Preschel, Klug, Winterfeld (1842), and Krutzler. Barker (1845), and, after him, Gaillard, applied a coating of sulphur over the friction composition, such matches being found by Abel (1863) to be waterproof, but somewhat difficult to ignite. Hannan and Mills (1882), for the same purpose, mixed paraffin, fatty bodies, or resins, with the compositions. The inventions of Thomas (1895), Fowler and Bower (1895), and Ramsden and Hirst (1900), had a similar end in view. *Scenting ingredients*, such as gum benzoin, frankincense, &c., were often added to the varnishes; and in 1854 Krakowitzer, of Pottenstein, Austria, introduced a process by which a metallic lustre was imparted to the heads of matches '*de luxe*,' or 'parlour' matches (containing lead compounds), by exposing them

to sulphuretted hydrogen gas. This process was modified by J. Ginzky in 1860, and again by Schindler, in 1867. A later improvement (A. Kielmeyer, 1879) was to varnish over the silvered heads with an alcoholic solution of colophony, shellac, &c., to which an aniline or other dye was added. Thus, to obtain a greenish bronze, Kielmeyer used fuchsine or methyl violet; other colours employed were methyl green, aniline orange and the like.

Great as was the improvement effected by the substitution of phosphorus for the less easily oxidisable antimony sulphide, there were serious disadvantages attending its use. The poisonous nature of phosphorus, the somewhat too ready inflammability of the igniting compositions made with it, and especially the 'phosphorus disease' (a carious affection of the lower jaw-bone, leading to necrosis, from which a small proportion of the workers—especially the dippers—were liable to suffer), were much the most important of these. The phosphorus disease, first described in 1845 by Lorinser, of Vienna, has intermittently called for the anxious attention of manufacturers and statesmen in most countries where white phosphorus has continued to be used in match-making, from 1870 to the present time. Shortly after it had been found that satisfactory friction matches could be produced without the use of yellow phosphorus, legislation was introduced in all the principal countries of Europe and America whereby the use of yellow phosphorus in this industry was prohibited, with the result that phosphorus necrosis may be said to be a thing of the past so far as the manufacture of matches is concerned. Good ventilation, impregnation of the air of the factories with the vapour of oil of turpentine, and scrupulous personal cleanliness on the part of the operatives, combined with particular attention to the condition of their teeth, were found greatly to diminish the number of cases of necrosis. It was shown by Thorpe and Tutton that the disease was caused by the direct action of the vapour of phosphorus oxide P_4O_6 on the bone, and that the characteristic smell, noticeable in the dipping-room of a match-factory where white phosphorus was used was due, not to the vapour of the element phosphorus, but to the fumes of phosphorus oxide. Only those workers with carious teeth are liable to suffer from necrosis of the jaw. Recognising the bad state of the teeth of many of their workers, Messrs. Bryant and May, in London, and the Diamond Match Company, Liverpool, years before white phosphorus had ceased to be used, were the first match manufacturers to take the important preventive step of establishing dental departments, where all the workers could be treated free of charge. This great benefit to the workers is still available at the factories, although the use of white phosphorus in Great Britain has for a long period been discontinued. In the annual report of the German inspectors of factories for 1879 it was stated that, in that year, among 5724 workmen coming in contact with phosphorus vapours, only nine cases of necrosis were observed, six of illness, and three of death (Jettel, Chem. Zeit. 1883, 7, 89). In 1884, however, stringent regulations were put into force in Germany with regard to the arrangements in match-factories, especial stress being laid upon the efficient ventilation of the separate rooms in which the operations of mixing the igniting compositions, dipping, drying, and removal of the splints from the dipping frames, were to be conducted. Finally, in 1906, Germany adopted absolute prohibition of the use of white phosphorus (*see post*, p. 235).

In Denmark and Switzerland, the use of matches containing ordinary phosphorus was forbidden in 1875 and 1879 respectively; and only the so-called Swedish safety matches have been permitted to be used in Denmark since 1875.

Between 1879 and 1882 the use of matches free from phosphorus and inflammable on any surface was allowed in Switzerland; but a committee appointed by the Department of Commerce found that these matches were unreliable and often dangerous: in 1882 the Swiss Government passed an Act, prohibiting the use of any but safety matches: and in 1906 Switzerland was one of the high contracting parties to the international treaty for enforcement of the total prohibition of poisonous phosphorus.

For methods of detecting white phosphorus in match compositions, *see* Thorpe, Chem. Soc. Trans. 1909, 95, 440; Schröder, Arbeit. Kaiser. Gesand. 1913, 44, 1; Analyst, 1913, 289.

Efforts were early made to use red phosphorus, discovered by v. Schrötter in 1845; and G. E. Pasch, in 1844, took out a patent for a red phosphorus-product, which he believed to be an oxide of the element; and he is by some authorities regarded as the pioneer in the utilisation of red phosphorus. It is claimed for him that he discovered that a striking surface containing this substance could be used for matches free from phosphorus. Matches tipped with compositions prepared with red phosphorus were manufactured in Germany in 1850, in England (by Dixon & Co., and Bell & Black), Austria (Fürth, of Schüttenhofen, and Foster & Wawra, Vienna), and France (Coignet & Co., Paris), in 1851: but they were not successful; and, although improved matches of this description were patented by Albright, of Birmingham, in 1856, and were again to be seen at Paris in 1867, and Vienna in 1873, they did not come into general use. The higher cost of red phosphorus had much to do with this; but, in addition, the mixtures used were unstable and dangerous. Some of the earlier igniting compositions made with red phosphorus undoubtedly contained excessive proportions of the element. Of late years, matches of very fair quality have been produced, with far lower percentages; and there are upon the market at the present time various red phosphorus matches, some of which have been analysed by the writer. Many inventors of late years have proposed methods of diminishing the violence of the reaction between this variety of phosphorus and potassium chlorate, of lowering the ignition temperature of mixtures containing red phosphorus, or of rendering matches made with it less absorbent of moisture; such as previously mixing it with zinc (Simonet, 1893) or with sulphur (Bals and Gurowitz, 1896); substituting calcium plumbate for the potassium chlorate in red phosphorus compositions (Schwiening, 1896); adding chalk, &c. (Cordes, 1898); coating the red phosphorus

with paraffin wax or some other suitable hydrocarbon (Akester, 1899, and Thompson, 1899); associating it with a borate or a phosphate (Säfström, 1901); boiling in aqueous solutions of various metallic salts (Purgotti, 1902); admixture with cork and flour (Bokmayer and Swoboda, 1905); or with zinc oxide and chalk (Chem. Fab. Griesheim Elektron, 1909). Schwiening's composition was adopted by the German Government, in consequence of the weighty objections to the use of ordinary phosphorus. The calcium plumbate apparently retards the explosion of the red phosphorus and chlorate mixture, thus moderating the violence of the combustion; but the matches have been subjected to somewhat severe and general criticism, on various grounds.

The Société Caussemille Jeune & Cie and Roche & Cie in 1909 proposed the treatment of red phosphorus by distillation and filtration, for the purpose of purifying it from acidity and alkalinity. The product they termed 'neutral amorphous phosphorus.'

In 1855 Lundström, of Jönköping, Sweden, acting on Böttger's suggestion, that friction matches might be so made as to be capable of igniting only on an especially prepared surface, manufactured the first true '*safety matches*,' by putting the oxidising mixture on the match-sticks and red phosphorus on the *box*. Such matches ignited only when rubbed on the specially prepared surface, or 'rubber,' on the side of the box. Lundström's process was patented in England in 1855 by F. May, of Bryant and May, and since that date 'patent safety matches' have been largely and increasingly manufactured in Great Britain. Matches on the same principle were made, soon after Lundström's invention, by Coignet & Co., by Fürth, of Schüttenhofen, and other continental manufacturers. In the 'allumettes androgynes' of Bombes Devilliers and Dalemagne (1859), the red phosphorus composition was at one end of the splint and the potassium chlorate at the other. The splints were broken, and the ends rubbed together. Field (1882) adopted a similar plan. The Swedish safety matches, so largely imported into this country, are on Lundström's principle. There have been comparatively few attempts to improve upon the safety match. Herz (1894) and Thimann (1894) worked in this direction. Viebig (1895) proposed to coat the heads of safety matches with a layer of the rubbing composition, or with a 'strike-anywhere' paste; and Craveri (1897), also Engl (1903), described safety compositions and rubbing surfaces therefor. It is common knowledge that some safety matches can be ignited, without the aid of an especial rubber, by friction—with a swift, sweeping movement—against a smooth, even surface, such as glass, polished oak or ebony, slate, &c.

A further step was taken in 1857 by Canouil, and by Hochstätter, of Darmstadt, in the production of '*non-poisonous safety matches*,' neither the igniting nor the friction compositions of which contained any variety of phosphorus. In Hochstätter's matches the oxygen compounds used were potassium chlorate, potassium dichromate, lead dioxide, &c., and the phosphorus was replaced by a mixture of antimony oxysulphide and flowers of sulphur. The oxidisable ingredients of Canouil's compositions, where stated, consisted of sulphur, iron pyrites, and various cyanogen compounds of lead. It is probable that some of the earlier so-called non-phosphoric matches were not altogether free from phosphorus. Vaudaux and Paignon improved upon Canouil's formulæ; and other compositions for non-phosphoric matches were those of Lutz (1858) and Kummer and Günther (Königswalde, Saxony, 1861). Schnell (London, 1861), Palmer (London, 1868), and others used lead thiosulphate, recommended by Wiederhold in 1861. Mayer (1865), C. Liebig, and Palmer (1869), also produced friction matches, containing, respectively, antimony sulphide and lead cyanide (Mayer), antimony sulphide and nitromannite (Liebig), and iron thiosulphate (Palmer), in place of lead thiosulphate. Jettel, in 1869, suggested the use of basic lead picrate. (Wiederhold had already tried potassium picrate.) Later, in 1879, L. Wagner, of Mühlheim, patented a match containing lead thiosulphate, antimony sulphide, sulphur, and finely powdered charcoal. Again, in 1881 and 1884, Schwarz, of Gratz, patented compositions containing lead thiocyanate, and lead sulphide in place—partly or entirely—of antimony sulphide. Among other substances proposed as ingredients of non-phosphoric safety match compositions are the thiosulphates of copper and sodium (R. Peltzer); copper thiocyanate, lead chlorate, finely divided metallic sodium (Fleck, 1868); and barium chromate (Garber, 1888).

Most of the compositions for non-phosphoric matches have been described by their inventors as 'ignitable by friction on *ordinary* surfaces'; in some instances, however, a special rubber was necessary. Many of the earlier non-phosphoric friction matches inflamed on ordinary surfaces with great difficulty; others ignited with almost explosive violence, and most were very hygroscopic. The vapours of lead, cyanogen, and thiocyanogen compounds, evolved during the manufacture and ignition of such matches, were probably in some cases injurious.

The more notable compositions for non-phosphoric 'strike-anywhere' matches, as now made, will next be described.

Among the various substitutes for white phosphorus, used of late years in strike-anywhere matches, phosphorus sesquisulphide undoubtedly holds the first place. Discovered by G. Lemoine in 1864, this compound was introduced in 1898 for match manufacturing purposes by H. Sévène and E. D. Cahen, of Paris. Having regard to present conditions, it is, in the opinion of practical match-makers whom the writer has questioned on the subject, unquestionably the best substitute for ordinary phosphorus so far discovered. It is non-poisonous, yields no injurious vapours during the operations in the factory, is reasonable in price, and the matches made with it are as sensitive as can be desired. Phosphorus sesquisulphide is a yellow powder, soluble in carbon disulphide, and inflames in air at 98°-99°. This compound was at first adopted in 1898 by the French Government; it is used for all strike-anywhere matches manufactured in this country, and is now entirely used in the United States of America.

On the continent also phosphorus sesquisulphide is preferred and used to the exclusion of all other substitutes. Scarlet phosphorus or bright red phosphorus patented in the year 1902 by W. Muir, and C. R. E. Bell—was a competitor to a small extent to sesquisulphide of phosphorus, but has now entirely disappeared and given way to the more efficacious body, viz. sesquisulphide of phosphorus.

Scarlet phosphorus was first prepared by Schenk by boiling a solution of ordinary phosphorus in phosphorus tribromide, and is chemically more active than dark red amorphous phosphorus, and inflames at *circa* 170°, and like phosphorus sesquisulphide is non-poisonous.

Several varieties of light red amorphous phosphorus are in use abroad; and different compounds or derivatives of phosphorus have been patented or suggested—such as metallic hypophosphites (Bohy, Gallay & Co., 1898); hypophosphites in conjunction with chromium trioxide Clayton, 1899); hydrides of phosphorus (Wheelwright, 1906 and 1909; Castiglioni, 1907); combinations of phosphorus with proportions of sulphur differing from that present in sesquisulphide (Wheelwright, 1902; Chem. Fab. Griesheim-Elektron, 1902; Huch, 1903; Gartenmeister, 1908); and the supposed suboxide P_4O (Chem. Fab. Greisheim-Elektron, 1903). The last-named company has introduced (D. R. P. 153188, 1902), under the designation 'sulfophosphit,' a product consisting of phosphorus, sulphur, and zinc, very intimately associated together, the basis of the invention being the production of metallic hypothiophosphites and thiophosphites by the union of red phosphorus, sulphur, and metallic sulphides, in theoretical proportions.

Besides the foregoing, inventors have proposed the use of lead thiosulphate, associated with calcium sulphide (Braly, 1897), and with potassium dichromate (Gurowitz and Bals, 1898; Trachsel, 1899); copper thiosulphate (Gans, 1898); tin thiosulphate (Jones and Bates, 1898); antimony thiosulphate (Truillet, 1899); copper thiosulphate and 'thiocyanite' (Rosenthal, 1899); cuprous thiocyanate (Purgotti, 1899); and the like. Craveri (1897) suggested the employment of persulphocyanic acid; and a later dipping-composition prepared by Gans (1903) contained 'sulfocuprobariumpolythionate.'

Various materials for the stems have been suggested at different times, such as earthenware, pipeclay, bass, cotton or linen stiffened with chalk and gum (Bell, 1859); bone (Letchford, 1867); cardboard and stiffened calico (Cribb and Rackham, 1874); asbestos (Hynam, 1874); jute and glue in a double wire spiral (Byrt, 1882); wood pulp and paraffin (Molyneux. 1889); compressed peat, turf, or moss (Rosenkütter, 1891; Stiemer and Ziegler, 1892); paper (Farrel, 1890; Bowman, 1893); straw (Castner and Swoboda, 1897); straw, rushes, grasses of various kinds, and the like, dipped in solutions of inflammable substances (Carré, 1908); stems of dried leaves of alfa or esparto (Schaefer, 1906), &c., &c. Fredrikson in 1897 and Lärn (1907) used wooden cores for the stems of wax matches. Craveri (1899) proposed as a composition for the tapers a mixture of ceresin, resin, calcium sulphate, zinc oxide, and potassium nitrate. Steedman (1906) patented waxed stems made from single strips of veneer, with one or more threads applied longitudinally, the whole coated by wax; and the present writer has come across Finnish 'superior patent vestas' (of very poor quality), with stems made in a similar way; obviously the same patented method.

The treatment of the wooden stems has also varied greatly. In the early days of matchmaking the splints were usually dipped in melted sulphur (v. Römer and others), to ensure ready inflammability of the stems; and hot tallow, resin, and wax were sometimes used for the same purpose. Sulphur-dipping is in this country only of historic interest, but sulphur-coated splints are still to be seen occasionally in matches of the cheapest and worst qualities, mostly of continental manufacture. Of the above-named substitutes for sulphur, Böttger (1843) preferred wax, which was also used by Mennons (1857) and others. Later (1861), Letchford introduced the use of melted paraffin or petroleum, also a mixture of paraffin with stearin and Japan wax. Bruce (1863) saturated the stems with potassium nitrate by immersing them in a boiling solution of that salt. In 1891, Bell proposed the use of coloured paraffin. Match-stems have occasionally been impregnated with camphor. In 1867 resin was again applied by Letchford, and Grawitz (1873) used naphthalene instead of sulphur. Mapple (1881) preferred oil or tallow. Paraffin is now almost everywhere used.

Another method of treating the stems is widely adopted at the present time in Great Britain and abroad, especially for safety matches. It consists in impregnating the stems with solutions which have the effect of preventing the wood from burning or remaining red-hot. Stems so prepared become cool almost instantaneously, and do not readily break; there is thus less chance of the heads and fragments of the splints falling and giving rise to fires—a risk commonly present with the thin badly-cut splints (not so treated) of the cheaper sorts of foreign matches. To render the stems uninflammable, solutions of sodium phosphate, sodium tungstate, zinc sulphate, alum, ammonium sulphate, and magnesium sulphate have been used. Field (1879) employed solutions of phosphoric acid, ammonium phosphate, borax and ammonium phosphate together, or boracic acid and ammonium phosphate; Percival (1887) proposed the use of 'cyanite' for the end held in the hand, the body of the match being impregnated with a 'weak gummy varnish' to prevent the embers from falling about; and Louisa A. Thomas (1896) suggested the employment of sodium silicate.

F. Gerken and G. Goliasch (1883) affixed small friction-tablets to the stems, so that when a match was withdrawn from the case its head came in contact with the roughened surface on the stem of an adjacent match, and in this manner was inflamed. The proposals of Galy (1908) and Walsh (1908) were not altogether dissimilar. The last-named inserted the striking composition in a notch in the stem of the match.

Tubes, to hold a single match, have been so constructed that the match on withdrawal is

inflamed by friction of the head against striking composition lining one end of the tube. The other end is closed. An allied device is a tube open at both ends, and on finger-pressure being applied to the match-stem projecting at one end, the head of the match is pushed past the striking composition lining the other end; on coming into the air directly afterwards it is inflamed.

To render match-stems waterproof, collodion, resinous varnishes, and caoutchouc solutions have been employed.

Headless matches have been suggested by Simonet (1893), Neuberg (1897), Fog and Kirschner (1898–9), Budde (1900), and Haffner (1907). Matches tipped at both ends were proposed by Scarlett (1891), Aldridge (1899), Potts (1901), and Nicolay (1904). 'Double-tip' matches, an important modern invention, are described further on.

The development of the machinery used in match-making has more than kept pace with the improvements in the compositions and in the treatment of the stems. Continuous and automatic machines will be described in the portion of this article devoted to details of the manufacturing operations.

Vestas.—The earliest account of the *wax-taper* as a match stem is in the specification of an English patent taken out by W. Newton in 1832; and, according to Payen, matches of this description were first made in France in 1836 by Savaresse and Merckel, of Paris. Wax, however, in conjunction with colophony, was used in 1832 by Siegel, of Vienna, as an easily inflammable coating (in place of sulphur) for the previously carbonised splints of his oxy-muriate matches. In 1862 J. Childs recommended a mixture, of high melting-point, of one part of Carnaüba wax with 9 parts of paraffin; in 1866 Letchford substituted jute for cotton in the tapers; and J. G. Gomez and P. Franco (1889) used strips of Bristol board, immersed in a mixture of resin, stearin, zinc-white, &c. Baron (1896) recommended wood-fibre. Hathaway (1897), Scott (1899), Glenister (1907), and others have employed paper in strips or coils. The use in the waxed stems of a wooden core has already been mentioned; and pine-wood sticks are very largely taking the place of wax tapers for this class of match. Wax vestas have been sold in metal cases containing sand-paper so folded that, on the withdrawal of a vesta, its head is inflamed by friction against the sand-paper, the act of withdrawal thus igniting the match.

Fusees, &c.—Cigar lighters—of brown paper, cardboard, German tinder and the like—impregnated with a solution of nitre, often scented, and tipped with various igniting compositions, mostly phosphoric, were made by Siegel (1832, 1835), v. Römer, and others. Of the newer kinds of cigar-lighters, variously known as 'flaming vesuvians,' 'etnas,' 'fixed stars,' 'braided lights,' &c., consisting generally of three parts —a stem of wood or glass, a head or ball of 'pastille' composition, and a tip of igniting composition—one of the first was described in 1849 by J. Palmer. Grimes (1859) introduced wires into the composition-ends of his splints, to prevent the heads from falling off when pressed against the cigar or pipe. Bell & Black (1859) made the stems of wire, coated with a non-conducting composition, such as gum and whiting, or glue and whiting or flour. Simlic (1862) put the composition on a tube fitted on to the end of the splint, and preferred glass. He also (1863) tried stems of slag and powdered oyster-shell, mixed into a paste and calcined; and wire covered with thread or cotton, dipped in coloured liquid gum. Battcock (1863) made stems of stone and slate; and Barker, in the same year, used pipeclay stems, tipped at each end. Ford (1878) softened the splints by treatment with caustic potash or soda, and then subjected them to the action of a solution containing 10 parts of nitre, 1 part of potassium chlorate, and 1 part of sugar in 12 parts of water: this process of course rendered the wood highly combustible. Methods of treating the wooden stems with alkaline and other solutions were patented by the Aktieselskabet 'Progress' (1902), and in the previous year by A. G. Haehre. Evans (1882) rendered the stems of his vesuvians incombustible, by the use either of asbestos paint or of sodium tungstate solution. The invention of A. Hill (1904) was similar. G. A. Sweetser (1884) formed his stems of plastic material moulded into the required shape and size round a core. In the 'braided' lights, still manufactured to a small extent by Bryant & May, and J. Palmer & Son, the composition is retained in position by pieces of thin wire, over which strands of cotton are twisted by the braiding machine. T. J. Clanchy, in 1868, obtained provisional protection for a combined match and fusee, consisting of a shaft or stem with a fusee-head at one end and a match-head at the other. In 1885 R. Bell, proceeding on closely similar lines, introduced the 'fusee vestas,' or wax-stemmed vesuvians, in which the essential parts of a vesuvian are present, but the stem was of jute, hemp, flax, cotton, or a mixture of some of these fibres, coated with paraffin, wax, or stearin. According to another patent of the same year, this inventor introduced a wire core into the stems; and in 1886, C. R. E. Bell devised a hollow cylinder or bead of combustible material, to be sold separately, for application to a match or vesta, for use in a light wind. J. J. Williams (1895) had a somewhat similar idea. Salts of strontium and barium have sometimes been introduced into the compositions of vesuvians, to cause them to burn with coloured flames.

Vesuvians have been almost entirely superseded in this country by vestas with pine-wood stems (such as the 'Swan' vestas, introduced by Bryant & May), and in America by the 'double-tip' match, invented in 1905 by the Saginaw Match Company. There is also a considerable production of matches with cardboard stems, somewhat upon the lines of the earlier 'fusees.' The 'book-matches,' made by Bryant & May, are of this type; two layers, stitched together, of flat, cardboard-stemmed matches, united by the base, are contained in a thin pasteboard case, with a red phosphorus striking surface on the exterior. These matches are of the safety class.

Repeating or continuous matches have been invented, but have never had much sale. The earliest English patent of this kind was that of Dove (1862), in which the igniting composition

was attached at intervals to a continuous band or strip of material, inclosed in a box. Later devices of similar nature were those of Tylor (1865); Rogers (1869); Perkins (1869), who mixed the igniting composition with collodion, a strip so composed fitting into a case like a pencil case, from which it could be withdrawn at will; Samuel (1871); Jonas (agent, Pollet, 1878); and Klein, same year.

Cigar-lighting appliances of a special kind. Many instantaneous igniters, not matches, have been invented for the convenience of smokers. These contrivances, though numerous, have not interfered with the steady development and increase of the match industry; and a few types only of such inventions will be mentioned. Among the earliest were the 'D'Bleaml'n Cigarrenzünder,' cigar-lighters, made by Pollak, of Vienna. This appliance consisted of a small, nitre-steeped, variously coloured, artificial flower, the stalk of which was inserted in a cigar. A little boss of igniting composition in the centre of the flower was inflamed by friction. An alloy of the metals sodium and potassium has been used. A small quantity of the alloy is withdrawn from a case or tube by a wire, which is then rubbed across and ignites a charred wick (1887 and 1888). Another appliance is simply a pocket edition of the old flint, steel, and tinder-box. A fourth device (W. D. Borland, 1889) is an attachment to cigars or cigarettes, by which they are easily lighted, even in a high wind. A minute portion of nitrocellulose fabric, forming a ring round the cigarette, is inserted under the paper, and on applying a spark the material takes fire and slowly smoulders until the whole end is glowing.

Automatic igniters in which is used an alloy of cerium are now extensively sold in France, and to a smaller extent in this country.

Statistics and Legislation. According to the Census of Production, 1912, the total value of the output of matches of all kinds including wax tapers, vesuvians, braided lights, &c., of British manufacture was in that year £783,183. The value of the exports of matches of the United Kingdom manufacture amounted in the same year to £110,000, or about one-seventh of the output. The annual output of one British company alone is at present not less than 8,000,000 gross of boxes, each box containing on an average 60 matches, or a total annual output of 480,000,000 matches.

The total value of the materials used in the production of matches of British manufacture was in 1912 £427,281. The consumption in Great Britain and Ireland of all matches in 1912 amounted to about 20,000,000 gross of boxes. Safety matches continue to increase in popularity, whereas in 1899 about 18 p.c. of the matches consumed were safety, and 82 p.c. strike-anywhere, in 1912 the proportions were about 40 p.c. safety and 60 p.c. strike-anywhere. Vesuvians are almost obsolete, but *small* quantities of braided lights and flaming vesuvians are still made Swan vestas, with pine-wood stems, introduced by Bryant & May, have virtually supplanted vesuvians, and have considerably reduced the consumption of wax vestas.

The value of all matches (British and foreign together) consumed in Great Britain and Ireland in 1912 was computed at £1,500,000.

Assuming that 20 million gross of boxes, each box containing 60 matches, were so consumed and taking the population of the United Kingdom at 45·2 millions (Census, 1911), this consumption would be equal to 10 matches per head per day of the population.

In the United States of America, there are said to be manufactured 310,250 million matches per annum. Assuming a census of 85 millions this is equivalent to nearly 10 matches a day *per caput*.

At the present date (June, 1918) there are in Great Britain and Ireland seventeen match factories. By far the largest and the most modern are those of Bryant & May, Limited, at Liverpool and Bow, London, E.

At the present time (May, 1918), owing to conditions brought about by the war, the consumption of matches in the United Kingdom is considerably restricted. The import of foreign matches having been prohibited owing to shipping difficulties, present supplies are restricted to about one-half of the normal.

Owing to the increase in the value of raw materials as well as owing to the introduction for revenue purposes of a match tax, there has been an enormous rise in the value of matches. The tax introduced in the year 1916 amounted to 3*s.* 4*d.* per 10,000 matches, or on a gross of boxes, each box containing 60 matches, 2*s.* 10½*d.* per gross, the tax being more than the total value of the matches under pre-war conditions.

This tax has again been increased, and this year (1918) amounts to 5*s.* per 10,000 matches. It is estimated that the tax at the latter figure will yield a sum equal to £2,000,000 to the exchequer annually.

It will be interesting to recall that this is not the first occasion when an attempt to tax matches was made, but the strenuous opposition of the manufacturers and workpeople combined compelled the then Chancellor of the Exchequer, Mr. Robert Lowe, to relinquish the idea; and since that time there had been no further attempts to tax matches until the present tax was introduced when manufacturers and workpeople patriotically assisted to make it a success.

In Russia there are or were 49 factories, in Sweden 10, in Norway 2, in Belgium 14, in Germany 75, in Austria-Hungary (originally the chief centre of the European match industry) 10, and in France 7. The most important Swedish factories are those of the Jönköpings och Vulcans Tändsticksfabriks Aktiebolag, at Jönköping and Tidaholm, Uddevalla, Wenersborg and Anneberg, and these may be regarded as among the best-equipped of European match works. Among the principal German factories are those of Stahl & Nölke, at Cassel and Kostheim a./M., the Deutsche Zundholzfabriks Aktien-Gesellschaft, at Lauenburg-Rheinau Baden and Vordamm, of the 'Union' Aktiengesellschaft, at Augsburg and Habelschwerdt, Ulm, Göppingen, and elsewhere. The French factories, which are under the direct control and supervision of the Government, the manufacture of matches having been a State monopoly since 1890,

are at Pantin and Aubervilliers (both near Paris), Marseilles, Bégles (Bordeaux), Aix-en-Provence, Saintines (Oise), and Trélazé (Angers). In the United States there are 19 companies and firms and 16 factories, including the Diamond Match Company's five works in New York, Michigan, Ohio, California, and Wisconsin. The Diamond Match Company is by far the largest and most influential American company, and its output is probably about 75 p.c. of the entire production.

By the international treaty of Berne, 1906, most of the countries of Europe have bound themselves to enforce within their territories the prohibition of the use of white or yellow phosphorus. The importation and sale of matches containing ordinary phosphorus are entirely prohibited in Great Britain and her Crown colonies (since 1908); in Germany, France and her colonies, Austria, the Netherlands and the Dutch Indies, Luxemburg, Finland, Italy, Spain, and Switzerland (since 1906); and in Denmark (since 1875). In Australia the importation is forbidden. Since January 1, 1912, similar prohibition has been enforced in Canada. In Norway and Sweden, the use of white or yellow phosphorus is forbidden in the manufacture of matches for home consumption, but not in making matches for export trade. As the outcome of the Conferences at Berne, in 1905 and 1906, of representatives of most European Governments, the British Legislature on Dec. 21, 1908, passed the 'White Phosphorus Matches Prohibition Act' (8 Edward VII., 1908, ch. 42), which has been in operation since January 1, 1910. With practically no exception all civilised countries have prohibited the use of yellow phosphorus in the manufacture of matches, and where this has not been accomplished very stringent regulations have been put in force, making the use of yellow phosphorus very inconvenient and difficult to manufacturers. The United States passed a prohibition Act (January 1, 1911), and yellow phosphorus for match making is now a thing of the past in that country. The stringent regulations in European countries previous to the entire prohibition of yellow phosphorus kept down the quantity used to 6 or 7 p.c. (Denmark 10 p.c.). American manufacturers prior to prohibition were said to be using 14 to 20 p.c. The humidity and warmth of the American climate increased the danger to the workers. The extremely sensitive double-tip match recently introduced in America contained quite 20 p.c. yellow phosphorus. This double-tip match is now made with sesquisulphide of phosphorus.

The President of the United States recommended the imposition of a heavy Federal tax in order to discourage the use of white phosphorus, and the Diamond Match Company have voluntarily surrendered their patent rights for the use of tetraphosphorus trisulphide, so that any match manufacturer in the United States is free to use this compound.

Great Britain's exports of matches to foreign countries are smaller than formerly, and her Colonial trade has diminished owing to the establishment of factories in the colonies themselves, notably by Bryant & May, Bell & Co., in Australia and New Zealand, and the Lion Match Company in South Africa. Notwithstanding excessive competition, the home trade is, nevertheless, very large.

As regards the quantities of phosphorus used in the match industry, there are not at the present time any figures available. Probably about 40-50 tons per annum were used in the British Isles over the 15 years prior to 1890.

Manufacture.

Probably the best way of conveying an idea of twentieth-century methods of manufacturing matches will be to begin by describing the operations as they are conducted in the most extensive and modern match works in this country—the factories in London and Liverpool of Bryant & May, Limited, who are, as already stated, the largest British makers, and among the largest in the world. The operations so described may be regarded as typical of the work as now carried on under the latest and most advantageous conditions. Some account will then be given of the manufacture as conducted upon a smaller scale, and of the more noteworthy differences and modifications in the machinery used, or processes followed, in other British, and—so far as space permits—in the more important foreign, match works.

The manufacture may be considered under the following heads: (1) *Ordinary matches*:—the nature of the wood used; making the match-sticks or splints, and boxes; making and packing the matches; (2) *Wax matches*:—making the tapers; making and packing the matches; (3) *Safety matches*; (4) *Vesuvians*; (5) '*book-matches*,' and (6) '*double-tip*' matches.

1. **Ordinary matches.** *Nature of the wood used.*—There is considerable variety in this. Pine, aspen, spruce, fir, poplar, lime, willow, and beech-wood are used. Alder- and cedar-wood have also been employed. Aspen, and poplar-woods are imported into this country mostly from Russia (Riga, Libau, Windau, and Petrograd); pine, spruce, and fir from Canada and the United States of America. There is an increasing scarcity of timber, especially of pine-wood. For British matches, the splints formerly were chiefly, and still are largely, manufactured from pine-wood: aspen, poplar, and other woods have long been used for this purpose by continental makers. Aspen-wood for match manufacturers' requirements must be free from pith and knots; and stems from 10 to 20 inches in diameter are the most serviceable. Rafted aspen is less satisfactory than unrafted. Spruce-wood is employed for the packing cases, planed and dovetailed boards for which are imported into this country.

Making the boxes and splints.—Although some of the smaller match-makers, here and in parts of the Continent, still use boxes made, or put together, by workpeople in their homes, a highly important and prominent department in the leading manufactories of Great Britain, America, and continental Europe, is that devoted to match-box making by machinery. The operations, both for box-making and splint-cutting, begin with 'cross-cutting,' by a circular

saw, of the 7-feet long aspen-logs into 26-inch lengths. These are barked by hand, taken to the 'log-peeling-' or 'skillet-' (squelette) room, and placed in a species of lathe, the '*peeling-*' or *veneer-cutting* machine (Fig. 1), in which they

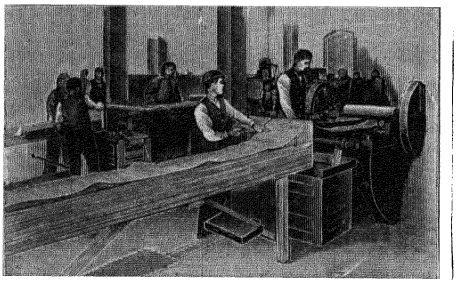

Fig. 1.

Log-peeling or veneer-cutting machine.

revolve against a horizontal planing knife acting upon the entire length of the log. A veneer is thus cut from the log, as wide as the rotating wood is long, and of a thickness which depends upon circumstances.

(*a*) *Splints.*—If the veneers be required for the production of splints, the machine is adjusted so that they are the thickness of the splint required—usually from 2·2 to 2·4 mm. for the ordinary small match: if the thinner veneers, used for wooden match-boxes, are desired, the thickness is about $\frac{18}{1000}$ of an inch. Cutters, placed slightly above the planing knife, divide the veneers into narrow bands (=the length of a match), or wider bands (for box-work), as required. In the former case, the narrow bands, divided into convenient lengths and superimposed into piles of 70 or 80 veneers together, are passed under an alternately rising and falling knife, in a guillotine machine, which cuts them into square or rectangular splints. These fall into a hopper, from which by a cyclone fan they are blown along a pipe into another building, where they are 'impregnated' with an acid ammonium phosphate solution and then dried in revolving cylinders heated by steam radiators. Next, they are cycloned back to the peeling-room, where they are 'cleaned' in a '*splint-cleaning*' machine, 'straightened' in a '*straightening*' machine, and packed in trays ready to be fed to the *match-machine*. During both the cleaning and straightening operations, the splints are subjected to a 'jogging' or oscillating motion. This description of splint-making applies only to the rectangular splints, of aspen and similar woods. The stouter and longer square match-sticks, used for the large ordinary and safety matches, are often cut from Canadian pine-wood. The blocks are sawn from a deal, and fed into the hopper of a machine which cuts by means of lancets set horizontally, instead of vertically. These splints, after impregnation, are dried by drying-chamber process. There are two other kinds of wooden match-splints: round-sticks and grooved-sticks. But as these are cut actually in the match machines, an account of the process will be given when those machines are described.

(*b*) *Boxes.*—The thin veneers, intended for the boxes, are wider than those for splints, but they are produced by the peeling-machines in the manner already detailed, the wood being simultaneously scored in readiness to be folded by the box-making machine. They are then guillotined into sizes suitable for the insides and covers of boxes. The skillets for the 'cases,' 'covers,' 'outers,' or (as they are sometimes uneuphoniously called in America) '*shucks*,' are next folded up, pasted and labelled by '*outer*' box-machines, of which there is a row on each side of an endless band or conveyer, carrying the box-covers onwards to a drying chamber. The 'inners,' or drawers of the boxes, are made by machines (Lundgren's patent), which fold up the skillets, paste, and paper-coat the drawers, and similarly feed them on to a carrier, by which they are transported to a drying chamber. Fig. 2 shows some of the box-making machines.

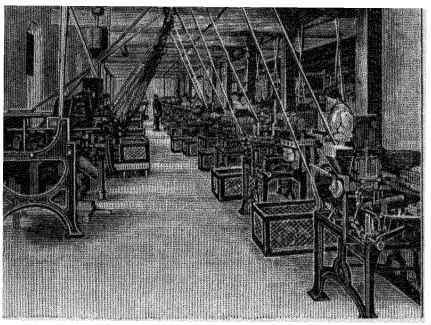

Fig. 2

Wooden box-making machines.

The next step is the application of sand to the 'outers' by the 'sanding-machine' or '*sander*.' The 'inners' are put into the 'outers' by a machine called in the works a '*nester*.' In one room of one of the factories there are about 120 wooden-box machines. Thicker skillets are by

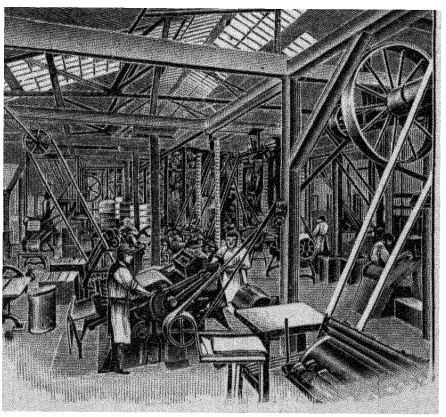

Fig. 3.

Cardboard box-room.

some manufacturers used for vesta boxes, and these are cut from spruce-wood by an ordinary

'flaking' machine (Day's): but spruce is becoming scarce, and will probably be discarded for the purpose.

Cardboard box-making.—The 'outers' of some strawboard boxes are made by a machine which cuts and scores the cardboard for folding, pastes, and folds it into the form of a flattened tube, prints it above and beneath, glues and sands one side, cuts off the proper lengths, and ejects the finished cases at the rate of 1000 per minute. The insides are made by an equally ingenious machine which cuts out the pieces of cardboard, scores, folds up, glues the ends, and conveys the completed 'inners' in links of a travelling chain until they are dry and ready for filling. A cardboard box-room is shown in Fig. 3. In one room at Liverpool there are 150 cardboard box-machines. The 'inners,' of chip-wood, are machine-made, as above described.

Metal box making.—The metal match-boxes used for 'knapsack' matches are made at Liverpool by a machine invented by Carbone.

The Manufacture of Wooden Matches.

A. By continuous and automatic machinery. In one form of match machine, used by Messrs. Bryant & May, the ready-cut square splints are fed into a hopper near the front of the machine, 'jogged,' and pushed by plungers into apertures in the iron match-plates, or carrier-plates, composing an endless chain about 700 feet long. The chain conveys the splints in enormous numbers, tips downwards, over a hot plate, then through a steam-heated bath of melted paraffin wax (m.p. 102°–105°F.), temperature c. 220°F., next over the dipping-roller, which revolves in a trough or vat charged with the match composition, and finally over a great series of drums or carrier-wheels. The period occupied by this is about an hour, and during the passage over the carrier-wheels the matches are dried by the currents of air to which they are freely exposed. There are 100 matches in each row on a match-plate. Having traversed the carrier-wheels, the dry and finished matches arrive near the starting-point, are ejected by plungers from the holes in the match-plates, and are filled into boxes by a '*box-filling* machine,' manufactured by the Diamond Match Company. This machine neatly and regularly deposits the matches in the drawers or insides of the boxes (to which a shaking motion is given, so that the drawers become filled, and there are no spaces left); sheaths the drawers in the covers; and passes the completed boxes along an endless band to *packing* or *wrapping* machine (Lundgren's patent), by which they are put in the familiar 'dozen-packets.' Eight girls attend to a match machine; and the daily output of one machine is 1000 gross of boxes, averaging about 60 matches to a box=8,640,000 matches *per diem*. The machinery is continuous in its production, and automatic, from the feeding in of the match-sticks to the wrapping of the dozen-packets, which girls put up into gross parcels by hand. The gross parcels are packed in cases, which are nailed together at the factories by an automatic nailing machine (W. S. Doig's patent).

The machines so far described yield square matches. But Messrs. Bryant & May use other match machines, also continuous and automatic, called *grooved-stick* machines. These yield matches with pine-wood stems, nearly circular, but scored longitudinally by two grooves, so that the stems are of the section shown in the figure (Fig. 4). A machine of this kind cuts its own match-sticks from pine blocks, $1\frac{7}{8}$ inches deep, fed in horizontally, but at an angle of 17° with the front of the machine. The match sticks are cut from the blocks by dies which act on the downward stroke, leaving the splints sticking up, to be grasped by their upper ends in the apertures of carrier-plates composing a conveyer-chain, just as in the machines last described. The match sticks, bristling from the under surface of the endless chain, pass successively over a hot plate, paraffin-bath, dipping-roller, and series of carrier-wheels, returning to the forepart of the machine, where the finished matches are discharged, and filled into the drawers or 'inners' of cardboard boxes fed to the filling apparatus by hand. Thence the filled drawers are passed along in a continuous stream to a revolving circular table, where sit six or eight girls to receive and sheath them in the cases. Fifteen workers attend to a machine, including wrappers, and each machine produces 800 gross of boxes of matches (averaging 55 matches to a box) in a day of ten hours. The yield of matches per minute may be estimated at 12,000. One girl can feed the machine with 106 boxes a minute, or nearly two boxes a second. From the splint-cutting station of this match machine an exhaust fan draws out wood-dust and imperfect sticks, and conveys them by a pipe to the boiler-house.

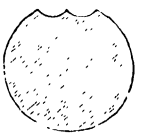

Fig. 4.
Section of a 'grooved stick.'

The *round-stick* machines, which produce the circular-stemmed, pine-wood 'Swan' vestas, punch out round splints, but are constructed similarly to, and upon just the same principles as, the grooved-stick machines. Blocks of pine-wood are fed in; finished matches come out, and are automatically filled into the 'inners,' the final operations of 'boxing' being performed by eight girls stationed at a revolving circular table. Dust and imperfect splints are removed in the manner already described. One of these round-stick machines can turn out about 3,000,000 vestas *per diem*.

Larger-sized matches.—For the production of the larger-sized strike-anywhere matches and safety matches, with square sticks $2\frac{1}{4}$ inches long, the continuous and automatic machinery is of exactly the same kind as that used for the matches of 'minik' size, with sticks $1\frac{7}{8}$ inches long. The splints are fed into the receptacle or hopper of the machine, and the finished matches are deposited in the drawers of the boxes by the filling apparatus previously mentioned. The drawers pass along a channel on to a circular table, where the cases or covers are put on by hand. The productive capacity of one of these machines may be estimated at 6,960,000 matches per day of ten hours. [*v.* Amer. Pat. 389435, 1888 (E. B. Beecher); and Eng. Pats. 20786, 1894 (E. B. Beecher and J. P. Wright); 17022, 1896 (J. P. Wright).]

Fig. 5 gives an idea of the general appearance of a match machine; Fig. 6 shows one of the machines at first installed, in greater detail and

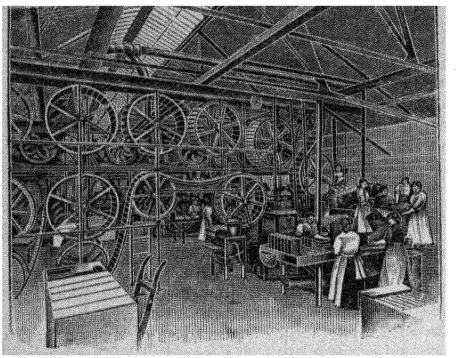

FIG. 5.

A match machine.

on a larger scale; and Fig. 7 shows a machine-room with its range of automatic machines.

The adoption of automatic machinery has wrought so great a change in most of the operations of match making, in the conditions under which they are performed, and in the rate and amount of the output, that to describe the present mode of manufacture is virtually to relate the particulars of a new industry. The advantages of the automatic machinery, with the continuous system of manufacture, are enormous. Production is greater, with less labour, than in former days; and the operations are immeasurably more healthy for those engaged. It is scarcely an exaggeration to state that hand labour has been almost entirely eliminated from the actual manufacturing processes. Three or four workers now produce as much as 15 or 20 under the old conditions.

Examples of other forms of automatic match machines are Lagerman's machine, used at Jönköping (described on pp. 239–240, and Figs. 9 and 10), and Roller's. The last-named is constructed upon the same general principles as the match machines already described, but it is of smaller dimensions and capacity. This type of machine is used at Messrs. J. Palmer & Son's, Maguire Miller & Co.'s, W. J. Morgan & Co.'s, R. Bell & Co.'s, and Paterson & Co.'s, factories. Ready-cut, single-length splints of aspen-wood are fed into the hopper of the machine; pushed into apertures—150 in a row—in an endless chain; paraffined; dipped; dried by passing over a series of drums; discharged or 'racked out,' and filled into the box 'inners.' These are sheathed in the covers by four workers. There are seven girls to a machine.

Besides the match machines described, there are other continuous and automatic machines, of which the 'Ideal,' made and supplied by Messrs. Sebold, of Durlach, Germany, is an example. Several of these machines are used by S. J. Moreland & Sons, of Gloucester.

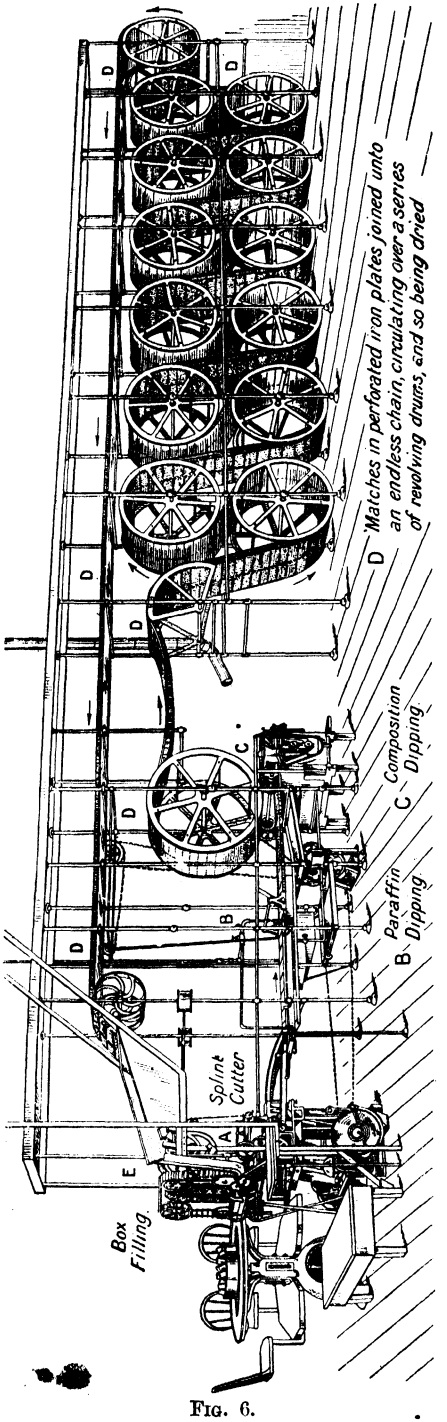

FIG. 6.

A match machine.

Preparation of the Dipping Composition.

Almost every maker has his own especial composition and way of preparing it. But the mixtures in use for ordinary matches invariably contain—(1) an *oxidisable body* in a fine state

of division, and intimately mixed with (2) *oxidising agents*; (3) *cementing* or *binding*

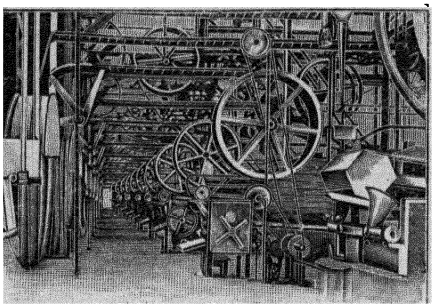

FIG. 7.

A match machine-room.

materials; (4) certain chemically *inert bodies* added to increase friction; and (5) *colouring matters*. In strike-anywhere matches, the oxidisable or combustible body in general use is tetraphosphorus trisulphide. Other combustible ingredients are employed, mostly abroad. The more important have been mentioned (pp. 229-232). The oxidising agents principally employed are potassium chlorate, potassium nitrate, lead nitrate, minium, manganese dioxide, and lead peroxide: potassium dichromate, 'oxidised minium' (made by heating minium with nitric acid), ferric oxide, and litharge must also be mentioned. In English matches, potassium chlorate is the customary oxidising agent, used alone or with manganese dioxide, &c. Potassium nitrate is frequently present in continental matches. Glue, gum, gelatin, and dextrin are the binding media mostly used: in Great Britain glue is almost exclusively employed. Very much depends on the quality of the glue, and its drying properties. Powdered glass, chalk, gypsum, and fine sand are among the indifferent bodies added. Prussian blue, ultramarine, smalt, vermilion, chrome

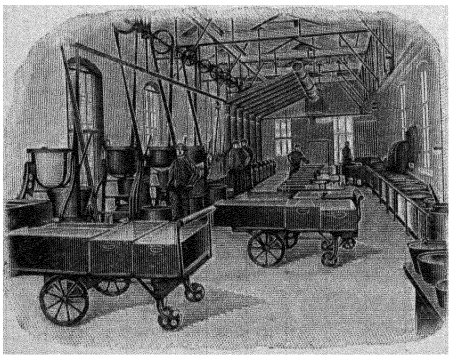

FIG. 8.

Composition mixing-room, Liverpool.

yellow, and coal-tar dyes are used to colour the mixtures.

Excepting that phosphorus sesquisulphide is now in general use, and that coarsely crushed glue is preferred to glue in large pieces or cakes, there is not much that is new to relate about the operations in the composition mixing-room. There are, of course, numerous minor differences in the methods of mixing the ingredients of an igniting paste; but the guiding principles usually are that the oxidisable body is first mixed with a portion of the inert substances, and with part of the glue or other binding medium, previously dissolved in water, and that the oxidising substance or substances must be mixed separately in another vessel, with the remainder of the glue, &c. Each mixture is passed through a mill, after which the two sections are combined and the whole mass is milled. All quantities are weighed and checked, and proper precautions are taken to avoid 'firing.' Fig. 8 shows a composition mixing-room of the latest type. Some additional particulars, especially with regard to older methods of working, will be found on pp. 231 *et seq.* The other operations, paraffining, dipping, drying, discharging, box-filling, and packing, by automatic machinery, have already been described.

THE MANUFACTURE OF MATCHES ABROAD.

Sweden.—The most important Swedish match manufactories are those belonging to the Jönköpings och Vulcans Tändsticksfabriks Aktiebolag. The Jönköping works of this company are particularly well provided with labour-saving machinery, much of it the invention of the former chief engineer, the late Mr. Alexander Lagerman. These mechanical appliances for saving manual work have been in use for a considerable number of years, and include continuous machinery for paraffining, dipping, drying, and discharging the matches, machines for box-filling, 'sanding' or 'coating' machines, and wrapping machines. The writer is indebted to Chamberlain Berndt Hay, the general manager of the company, for the following particulars of the continuous machines at present in use at Jönköping.

The match sticks, cut and dried, are placed in magazines on the front top of the machine, whence the splints are pushed out into perforated wooden frames, moving upwards on endless chains. The frames, holding the sticks at one-third of their length by means of springs, are brought along, one by one dipped in melted paraffin wax, and then in the strike-anywhere or safety-composition, as the case may be. After passing a 10-metre track, to dry the match heads, the frames return to the front bottom part of the machine, where the matches are discharged, apportioned off, and filled into the empty boxes brought to this part of the machine on a transporting chain, consisting of small iron plates. In Fig. 9 is shown some of the Jönköping machinery. A number of these machines are installed at the older of the two Jönköping factories. Fig. 10 shows one of the box-filling machines used at Jönköping. The striking-surfaces, whether of sand, emery, glass, or of a red phosphorus composition, are applied to the sides of the boxes by machinery ('sanding' or 'coating' machines); and the finished boxes are mechanically wrapped in parcels of ten or a dozen ('wrapping' machines). One of these machines will pack in a single day, under the

management of two girls, a quarter of a million boxes of matches into finished, labelled 'dozen-packages,' thus doing the work of 16 or 17 hand-packers.

The Vulcan Factory, at Tidaholm, is a large, well-equipped match-works, where safety matches (chiefly) are now manufactured on a great scale.

Holland. The industry in Holland is of comparatively small dimensions. At Loyens'

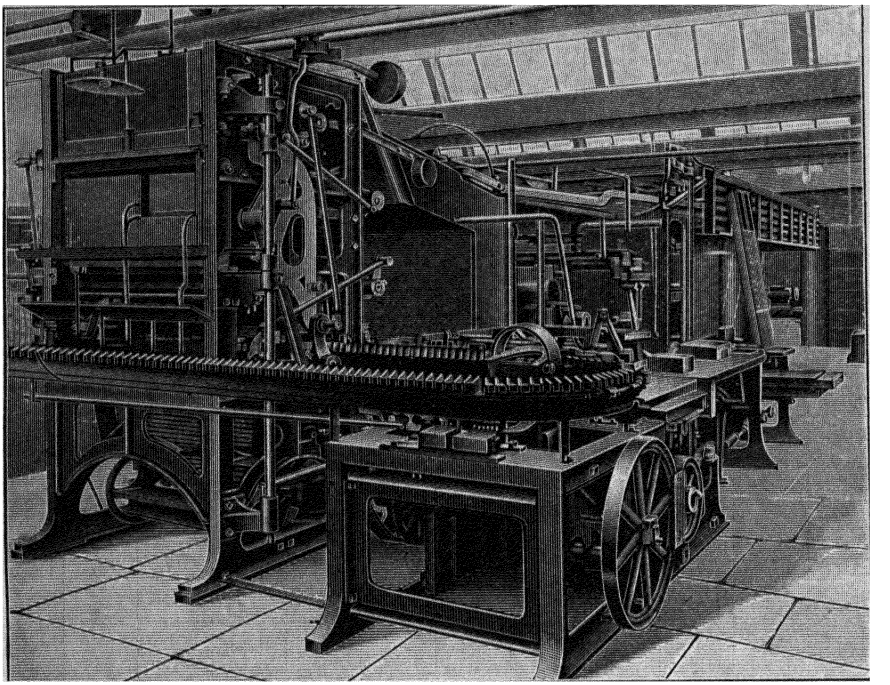

FIG. 9.

Automatic and continuous match machine used at Jönköping. (Inventor, the late A. Lagerman.)

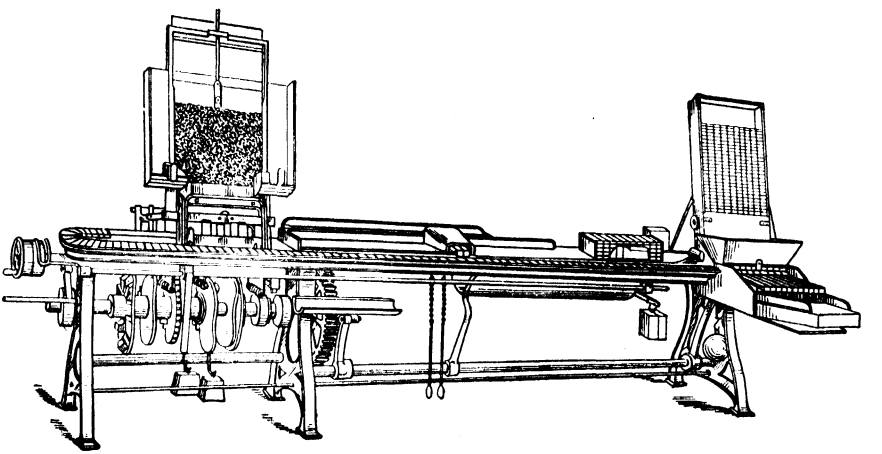

FIG. 10.

Box-filling machine used at Jönköping. (Lagerman's invention.)

factory at Breda, a box-filling machine, invented by Paulson, is in use, and is said to be very satisfactory.

Belgium. The principal Belgian factory is that of La Société Caussemille Jne & Cie. et Roche & Cie. (Ghent). Although there have been great improvements in the conditions of the industry, Belgium was behind other countries in regard to match factory legislation prior to the commencement of the late war (July, 1914).

Germany. The match manufacture is of considerable proportions in Germany. The largest German companies, the Deutsche Zundholzfabriks Aktien-Gesellschaft, previously mentioned (p. 234), the Aktien-Gesellschaft für Zündwarenfabrikation Stahl & Nölke, and the Union Company at Augsburg, use aspen-wood for the production of both splints and boxes, the veneers for which are cut in a 'peeling' machine of the usual type. 'Inner' and 'outer' machines, like those already described, are employed to make the boxes, into which the dipped matches are filled by a machine, similar in principle to those in use at Jönköping. The productive capacity of the box-filling or 'boxing' machine is such that, under the superintendence of one girl, it will yield 25,000 filled boxes in 10 hours. After filling, the boxes are coated on the two narrow sides with a striking composition, by conveyance on an endless band between two revolving brushes, supplied with the composition by rotating discs. The boxes are next carried through a drying channel 6 metres long; and, finally, a 'packing' or 'wrapping' machine automatically assembles the boxes in series of ten or twelve, wraps these in paper (cut by the machine from a roll, and properly folded), pastes the folded flaps, and labels the package. The writer is indebted to the Stahl and Nölke Company for some of the foregoing particulars, and for further information relating to the industry in Germany. Other German manufactories have been referred to on p. 234. One of the principal manufacturers of modern types of match-making machinery is A. Roller, of Berlin. A large part of the aspen-wood used in Germany is imported from Russia; some, however, comes from native forests. But there is a growing scarcity.

Austria-Hungary. In Austria-Hungary, probably the most important factory, and certainly one of the oldest, is that of Bernard Fürth, at Schüttenhofen, in Bohemia, established in 1838. The founder is stated to have been the first to use red phosphorus as a substitute for white or yellow phosphorus, and in 1854–55 he sent into the market matches with red phosphorus in the rubbing surface on the box thus adopting a suggestion made by Böttger. These first matches of the safety type were not commercially successful, however, and it was not until in 1855 Lundström improved the invention, that the 'safety match' of the present day became a practical match.

France. The processes and machinery in use at the two chief State factories in France are here briefly described. In the match factory at Aubervilliers, twenty automatic machines, invented by H. Sévène and E. D. Cahen, are employed. One of these machines, worked by only three operatives, can produce in 10 hours 50,000 boxes of 50 finished matches, or about 15 million boxes per annum. For the same output in the old days twenty workers would have been required. The French machinery is constructed upon the same general principles as that already described. Splints, fed into a receptacle by hand, fall from a vibrating hopper into 110 grooves of a horizontal iron plate, to be expelled by a plunger at every stroke of the machine into corresponding grooves of a charger, bridge, or transporting table, having a backward-and-forward motion between the horizontal plate and a vertical part of a long, endless band of carrier plates—the carrier or 'presse.' Each carrier plate is 2½ inches long (in the direction of its journey), 48 inches wide, and is perforated by five rows of equidistant circular holes, 110 in each row. The diameter of an aperture is equal to the side of the square section of a match-stick. When the charger approaches the 'presse,' a plate or 'follower' rises behind the grooves and prevents the sticks from receding. The splints, being longer than the width of the charger, project beyond its edge, and are pushed into the 110 holes of a row in the carrier plate. To prevent bending and breakages of the splints, a horizontal plate presses upon the grooves of the charger, which retreats empty to receive its fresh load. The endless band moves along, bristling with splints, which are carried, over a hot plate, and through a paraffining-bath, secondly, through a sulphur-bath, and thirdly over a rotating grooved cylinder partially immersed in the igniting composition or 'paste.' Thence the conveyer chain travels many yards, for the drying of the matches to be effected; and, finally, at the end of the cycle of operations, plungers expel from the holes the finished matches. These fall, in regulated series, into receptacles, whence pistons fill them into boxes, fed into the machine by an operative, but mechanically opened and shut.

In France, the splints are made of Russian aspen and French willow, the former being preferred. Birch and poplar are used as well. The timber is sawn and cut into splints at Saintines. 'Parlour' and safety matches are largely manufactured at Pantin; wax stems or tapers only at Marseilles.

Norway. The chief match works in Norway is the factory of the Nitedals Tandsticksfabriks, near Christiania. Fig. 11 shows Arehn's box-filling machine (Lundgren's patent) in use at most of the European factories and in many parts of the world.

America. An account has already been given of the present conditions of the industry in the United States of America, and of the Diamond Match Company's machinery, used in the States by that company, as well as in Great Britain by Bryant & May.

Japan. In Japan, a country enjoying at one period a virtual monopoly of the markets in the Far East, there are about 150 factories. Three-fourths of the workers, 25,000 in number, are women. Osaka and Kobé are the centres of the industry. As long ago as 1892 matches ranked fourth among the articles exported from Kobé, and in the following year many new factories were established in Japan, with the result that the output and export of matches enormously increased, and continued to expand until about six years ago. Depression of trade set in, and in 1910 seventeen factories in Kobé and thirteen at Osaka for a while suspended operations, with the result that the output fell off considerably. The most formidable competitors of the Japanese are the Swedish and Austrian manufacturers, who have encroached upon the markets in the Far East. Phosphorus and sulphur matches are manufactured at Osaka; safeties at Kobé. The production of wax matches is almost entirely a household industry.

In the year 1909, the total export of matches from Japan amounted to 41,407,083 gross, valued at £1,186,738. During the first half of 1910 there was a decrease of 40 p.c. in the export as compared with the corresponding period in 1909. There has been an enormous increase in the production in recent years.

China. In 1907 there were three factories in the Canton district: now there are works in Pekin, Hankow, Tientsin, Shanghai, and other towns. The largest works are at Hankow with 3600 operatives.

India. Hitherto the match industry has not prospered in the Indian Empire, but it has been pointed out that the natural advantages of the country, such as plentiful timber, cheap labour, and inexpensive water transport, justify a belief that the prospects of success are good, provided that the industry is developed on proper lines. India might ultimately secure

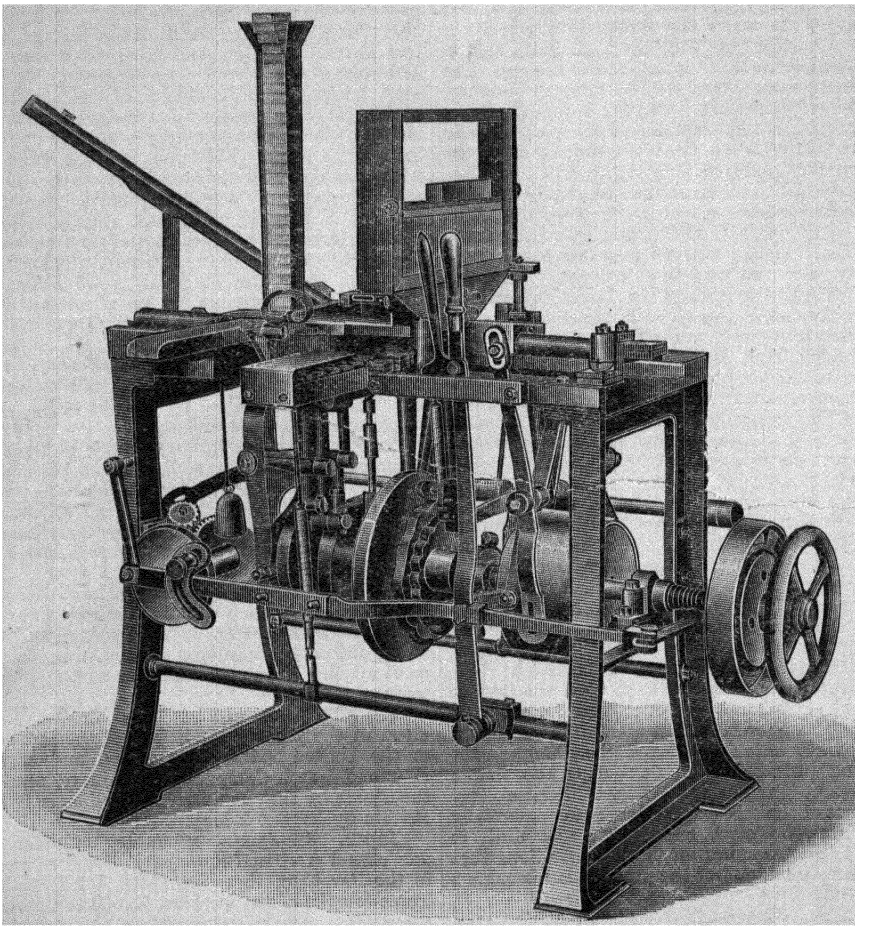

FIG. 11.

Arehn's (Lundgren's patent), box-filling machine.

some of the considerable trade of the Persian Gulf, at present enjoyed by Sweden.

2. **Wax matches.** The tapers for these are made as follows: from 60 to 100 strands of cotton, of about 20 threads each, are led from a bale, through a measuring machine and guides arranged at a convenient height, into a steam-jacketed tank, containing a mixture of stearin and gum copal or gum dammar, thence through perforations in a draw-plate, and afterwards over a '*drawing drum*' (Fig. 12), 6–10 feet in diameter, revolving on an axis, by hand or steam power (Fig. 13).

From this drum the tapers are led back again through the bath to a similar drum on the opposite side of the tank, and by winding alternately from one drum to the other, they are made to pass 6–7 times through the bath, until the cotton has a coating of fat just sufficient to allow it to pass through holes in a suitable gauge plate. The tapers lastly pass through a perforated hot plate, which imparts a polish to the surface, and are again wound on to a drum, from which they are fed to a 'wax-match machine' of the above-described continuous type. In this machine, patented by the Diamond Match Company, the tapers are cut into stems of the usual length, and inserted in spaces

(in which they are held in position by brass springs or clips) in the sections of an endless carrier chain. By this they are conveyed over the dipping roller. Of course, neither the steam-heated plate nor the paraffin-bath is in this case employed. The heads of the wax matches are dried by the journey over the carrier wheels, and the finished matches are

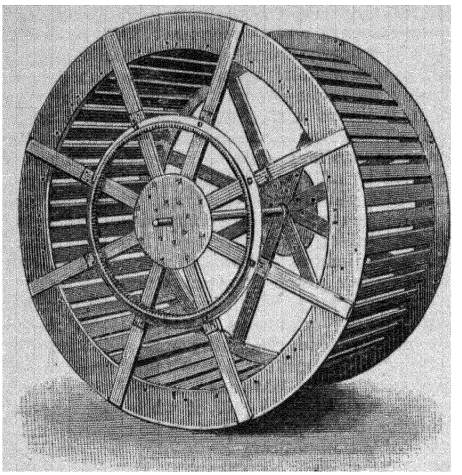

FIG. 12.

A drawing drum.

automatically filled into the drawers of the boxes. These pass on to a circular table, where girls put them into the covers or outers—just as in the wood-match machines. Some wax matches, however, are filled into the boxes by hand. Each wax-match machine yields about 3 million matches *per diem*. Some manufacturers, Messrs. Palmer & Son, for instance, still use the frame-dipping method for wax matches.

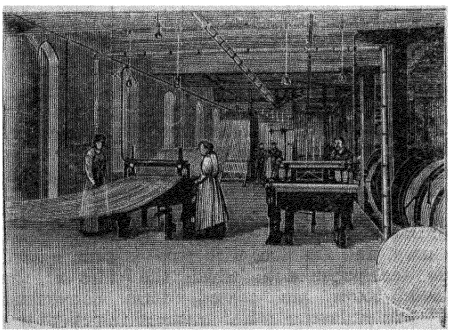

FIG. 13.

Taper-making room.

The taper is then either cut into lengths, which are bundled together and cut into vesta stems by a pivoted knife, the stems being afterwards filled into dipping frames by a small filling machine (Day's) worked by hand or steam, or 60–100 strands of it are wound upon a small drum, and passed from it through guides to a 'cutting and filling' machine of the kind indicated in Fig. 14.

In this class of machine the tapers are caused to advance between two feed rollers covered with caoutchouc or other elastic material, and having an intermittent motion, their rotation at each revolution of the driving shaft, or movement of the treadles, being through such an angle as to advance the tapers the required distance under a cutter or cutters working in a vertical plane in front of the feed rollers. The dipping frame (which will hold 6400 stems (80×80)) is held immediately in front of a perforated plate through which (when the machine is worked) the cut stems are pushed, so as to rest on a lath of the frame; the frame is now lowered, and the next lath is dropped into position, to receive a row of cut stems, immediately the treadles have been pressed down. When the frame is

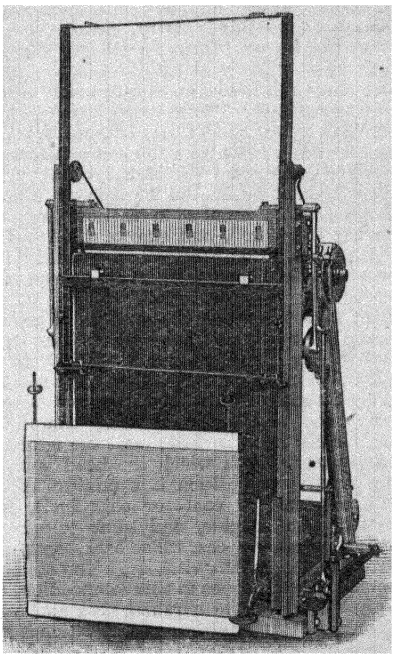

FIG. 14.

Wax-taper cutting and filling machine.

filled, the stems are dipped, on one side only, in the striking composition. At Messrs. Palmer's factory, the dipped frames of wax matches are dried on shelves in a square chamber, heated by steam pipes, and with a paddle fan in the centre. The 'racking out' is effected by hand.

(For wax match machinery, *v.* patents of Beecher and Wright (1895), Hargreaves & Clegg (1896), Pickles (1899), Wiessner (1900), and Harvey (1901).)

3. **Safety matches.** All that has been stated, with regard to the processes of manufacture of ordinary matches, applies to safety matches, excepting the section on dipping compositions. Many more ingredients have been and are used for safety match compositions than are added to ordinary match pastes. So far, safety matches for the most part have been made with red phosphorus in the rubbers only; but

attempts, mostly unsuccessful, have been made to manufacture matches, more or less of the safety type, but without phosphorus, either in the heads or rubbers. The best-known English, Swedish, and other safety matches belong to the first class. The igniting compositions of ordinary safety matches usually contain, as an oxidisable ingredient—apart, of course, from the red phosphorus in the rubbers—grey antimony sulphide, with or without sulphur; charcoal, too, is occasionally added. Potassium chlorate, potassium dichromate, and minium are the ordinary sources of oxygen, but manganese dioxide and nitre are also used: glue is the usual binding medium. Colouring matters are seldom added to safety match pastes, which are usually black.

Certain safety matches, made abroad and imported into this country, bearing on their boxes the legend 'Utan swafel och phosphor,' some years since were analysed in the writer's laboratory and found to contain much sulphur.

4. **Vesuvians.** The manufacturing processes for cigar lights, fixed stars, braided lights, and the like, differ little from the methods in use for ordinary matches. The stems, however, are generally of alder or other hard wood (when not of glass, &c.), circular in section, sometimes braided and wired, and shorter than ordinary match sticks. Comparatively few braided lights are now made. Single workers are now employed occasionally in this branch of the industry, which used to engage the services of scores of hands. The dipping frames are smaller, usually filled by hand, and contain from 1600 (40×40) to 2000 short splints, which are dipped at one or both ends. Two distinct compositions are used: the pastille or burning composition, used for the head or ball; and the igniting or striking paste, with which the head is tipped. The pastille composition is a mixture of nitre with charcoal (or coal- or coke-dust), glass-powder, gum or glue, and some scenting ingredient, such as cascarilla bark, satinwood, gum benzoin, lignum vitæ, &c. The stems are dipped more than once in this composition, until the heads are of the required size, and a final dip in any ordinary striking composition is given to the heads after they have been dried. The early 'fusees' (of brown paper or cardboard, impregnated with nitre, tipped with sulphur, &c.) gave place to vesuvians, which in their turn have been largely superseded by wax matches, and these are being supplanted by pine-stemmed vestas. It will be seen in the next section that cardboard stems are at the present time once more used for certain sorts of matches (*cf.* 'book-matches').

5. **'Book' matches.** These, in one respect, are an interesting reversion to some of the very earliest types of matches, and to the original 'fusee'; the stems are of cardboard. Two layers of such matches connected together at the base are fastened in a little flat book, the pasteboard covers of which carry a special striking surface. These matches are of the safety type, striking only upon the prepared surface; they are manufactured by machines which automatically print the cardboard, cut it into combs, dip the teeth in the igniting composition, fold up, stitch into books, and affix to the outsides the special striking composition. [*v.* English Patent of Diamond Match Co. (C. H. Palmer, and J. W. Denmead), 21788, 1899.]

6. **'Double-tip' matches.** Double-tip matches have been manufactured in some form for many years and the so-called 'Vesuvian,' 'Braided Light,' and 'Flamer,' were all double-tip. More recently, however, this idea has been applied to the ordinary match, and the genesis of the application is perhaps to be found in a proposal of R. and D. Maguire (1898), according to which a large flame-producing head consisting of a composition containing no phosphorus, highly inflammable, but not ignitable by friction, is tipped with a cap composed of a white phosphorus bearing composition readily ignited on any striking surface. The cap which is applied by a second dipping may contain 6 p.c. of white phosphorus (but this, of course, has now been superseded by a composition containing sesquisulphide of phosphorus). Somewhat similar suggestions were those of Lindner (1899), and the Saginaw Match Company (1905). The last-named company, which in America is credited with having originated the double-dip match formerly used for the bulky part of the head, a detonable composition, consisting of an ordinary strike-anywhere 'parlour' match compound, containing about 6½ p.c. of white phosphorus, and for the cap or tip a noiseless and non-detonable composition containing no less than 22 parts of white phosphorus. Matches of this character strike with delightful ease on any surface and virtually without noise. But the large quantity of white phosphorus which was present was an obvious objection. The use of white phosphorus for double-tip matches has now, of course, been superseded by the inocuous sesquisulphide of phosphorus, and the caps or tips of the double-tip matches are now entirely made with the latter body; whilst the bulky part of the head is made with a similar composition to that employed on the safety match and is not ignitable by ordinary friction. Double-tip matches have become very popular in America and have to an enormous extent taken the place of the ordinary strike-anywhere 'parlour' matches. In 1909, J. E. State patented a process for producing matches of an allied type, by dipping them successively in a material ignitable by friction, and in a material not so ignitable. The latter is then pushed back by mechanical means, such as a series of rollers, so as to leave exposed a portion of the striking composition at the extreme tip.

The striking surfaces or rubbers. For ordinary matches, mixtures of sand, glass, emery, and the like, with glue or gum, spread on the paper with which the sides of the match-boxes are coated, form convenient friction surfaces; metal gratings, tablets of unglazed porcelain, and porcelain or metal plates with parallel ridges very close together, are frequently employed; and practically any rough or uneven surface—even cloth—can be made to answer. The compositions used in the special rubbing surfaces for safety matches are very various; but the ingredients chiefly present are red phosphorus, antimony sulphide, and powdered glass, made into a paste with glue. The antimony sulphide is sometimes omitted, and manganese dioxide is not infrequently added to safety rubbers.

Among the patents for match striking or rubbing surfaces may be mentioned those of Neuberg (19418, 1897); Craveri (27520, 1897); and Prestwich (23048, 1904).

Older Methods of Manufacture.

The complete process of manufacturing wooden matches formerly comprised the following separate and distinct operations, carried on for the most part, or at all events very largely, by hand labour: 1. 'Scurfing'; 2. Cross-cutting; 3. Steaming; 4. Splint Cutting; 5. Drying the Splints; 6. Filling the Dipping Frames or Coils; 7. Paraffining (originally Sulphuring); 8. Dipping; 9. Drying the dipped splints; 10. 'Laying out,' 'Racking out,' or 'Racking off'; 11. Halving (sometimes also called 'cross-cutting'); 12. 'Boxing'; 13. Packing. It has been shown that nearly all the work can be, and in the more extensive factories is, carried on automatically by continuous machinery; but in some smaller establishments the operations, or most of them, are still performed by the old ways. The three main operations are splint-cutting, dipping, and drying, but a summary of the entire older process will be given.

Splint-cutting. The planks of wood, usually 12–13 feet long, and 3 inches thick by 11 inches wide, were first of all freed from irregularities and roughnesses by the operation called *scurfing*, knives or cutters, rotatory or otherwise, cleaning and smoothing the surface. The planks were then *cross-cut* into blocks or lengths $4\frac{3}{4}$ inches long × 3 inches thick × 11 inches wide. An ordinary English match-splint, to yield two match-stems, $2\frac{3}{8}$ inches long, was $4\frac{1}{4}$ inches long, so that the pieces cut off from the plank, measured in the direction of the grain of the wood, had just the length of a splint. Unless the wood were newly felled, and therefore sappy, these blocks must next be *steamed* (third operation) for about 20 minutes. They were then taken to the *splint-cutting* machine (fourth operation). Very many forms of such machines were invented, but only three kinds were at all generally used in the United Kingdom. The two earlier types of splint-cutting machines were the *toothing* machine and the *flaking* machine. The toothing machine answered well for 'clean' wood, such as pine-wood, but was not adapted for poplar, aspen, &c. The 'vertical flaking' machine is suitable for coarse-grained and even knotty wood, requires little skill in working, and is capable of cutting 650 bundles of splints in a day. The earliest machine belonging to the third class, or combined '*toothing and flaking*' machines, was invented by Tillett (1859). A machine, which for London work to a great extent superseded the foregoing kinds, was Pace and Howard's, and was an improvement upon Tillett's. Some years since, all English and nearly all foreign match-splints were square or rhombic in section. Round splints, such as were yielded by the early machines, were comparatively rarely seen, excepting in Vienna. But at the present time, as has been shown, round-stick matches, such as the pine vestas, and grooved-stick matches, are extensively used. Vesuvians, also, usually are round-stemmed

Splints made from previously separated veneers are now very largely employed, and many of the later machines for splint-cutting have been upon this principle. Some account has been given (*cf.* p. 236) of log-peeling and splint-cutting machines; and this must serve; merely a reference can be made to the numerous patents for splint-cutting appliances taken out during the past 14 years. Some of these inventions relate not only to splint-cutting from veneers or otherwise, but to means of assembling the splints in coils, plates or other holders; also, in certain cases, the splint-cutting is described as the initial stage of a process of continuous manufacture.

The next operation is the *drying of the cut splints*. The splints were formerly always made into *bundles* and then dried. Now they are sometimes thrown loosely into large trays and dried by exposure to warm dry air. (Swedish splints are dried in wire-gauze cylinders revolving within a brick stove.) The dried splints are ready for the operation of *filling the dipping clamps or frames* (sixth operation). Prior to the use of dipping frames, there were the so-called 'bundle-dipped' and 'block-dipped' matches. In the earlier days of match-making, 'dipping-boards' were sometimes employed. 'Frame-' or 'clamp-dipping' was introduced in 1849, and its adoption, which by degrees became general, effected a great saving of time and labour. The dipping clamps are square frames with sides consisting of iron rods, on to which slip laths, each having grooves on its upper surface, and being lined with felt below. The match-splints are firmly held in the grooves by the pressure of the felt. Each frame holds 3900 splints, which, dipped at each end and halved, will yield 7800 matches. The dipping frames were at first filled by hand, but Hynam (1850) and Bell and Grimes (1854) invented machines for the purpose. Improvements followed, and in 1865 Simlick introduced self-acting machinery, driven by steam power, to produce the various movements of these frame-filling machines with greater rapidity and economy of labour.

In 1876, E. B. Beecher, of New Haven, Connecticut, invented machinery to replace frame-dipping, by 'coil'-dipping. This system of working having been introduced into the largest English match-works, effected great and, in many respects, beneficial changes in the method of manufacture; and coil-dipping, where it was adopted, for wooden matches entirely superseded frame-dipping. It is not adapted for the manufacture of vesuvians.

In Beecher's original machine (Eng. Pat. 4293, 1876) the splints were so delivered from a hopper as to be set at regular intervals between the coils of a long flexible tape band, or belt of cotton webbing, about the thickness of a splint, but considerably narrower than its length; this belt was continuously wound upon a short cylinder or drum adapted to a rotating mandril or axis, until a coil, or bundle, or frame, of the desired size was completed. The end of the binding tape was then secured to the preceding coil by a pin or otherwise, the drum and coil of match-splints thus bound upon it being now ready for removal from the mandril for dipping. Being separated from each other

by the thickness of the webbing, and by an interval the width of a splint between every two splints, the splints individually received the proper proportion of composition when dipped, and could be conveniently dried in the coil. In an improved form of the machine (1887), Beecher employed an auxiliary or secondary band in connection with the first, for the purpose of holding the match-splints more securely.

The match-splints, having been arranged for dipping in one or other of the ways described, according to the older method now being described, are ready for *paraffining*, or 'the first dipping,' as it is sometimes called (seventh operation). The frames are put on a table, and the splint-ends are levelled, if necessary, by taps with a piece of wood; they are afterwards heated (to facilitate absorption of the paraffin) by application to a hot iron plate, and then immersed in melted paraffin contained in a shallow steam-heated iron tank. Both ends of the splints are thus treated. Sometimes the operation is effected in a brick stove, on the top of which are three shallow, flat-bottomed, square pans, one serving for the preliminary heating of the splint-ends, the second for the paraffining, and the third for the subsequent dipping in the igniting composition.

In all but the most inferior matches, paraffining has entirely superseded treatment with sulphur.

8. **Dipping.** The usual constituents of a match-igniting composition have already been enumerated (pp. 238, 239), and are mixed in the following manner. The glue and potassium chlorate or nitrate are dissolved in warm water, and the phosphorus (assuming that the worker is in a country where it is still legal to use it) is then added to and stirred in the liquid (which should be of a syrupy consistence and at a temperature of about 38°), until a perfect emulsion is obtained. The rest of the constituents, powdered glass or sand, colouring matters, and metallic oxides, if present, having been previously 'milled,' are now added, and thoroughly mixed with the emulsion. When, as is now generally the case, a substitute for white phosphorus is used, it is at first intimately mixed with part of the glue solution and inert materials only; the potassium chlorate, with the rest of the ingredients, being added later. The whole is finally put through a mill.

For the operation of dipping, which—in manufacturing upon the older lines—is performed by workmen in a separate apartment called the dipping-room, the emulsion is ladled from a steam-jacketed iron pan on to the dipping plate or table—generally a shallow, flat-topped, iron box, kept hot by steam admitted to its interior. The composition is spread over the plate, and levelled to the required depth by a gauge or 'strickle.' The ends of the splints in the filled frames are then dipped in the thin layer of igniting composition. After the splint-ends have been dipped, the frames are placed in racks to dry.

Dipping by hand, as already described, is most usual in working upon a comparatively small scale; but the igniting composition is sometimes applied by the aid of cylinders or rollers, partly rotating in hot-water jacketed cases, receptacles, or boxes containing the mixture, endless chains conveying the frames or coils over the rollers. And it will have been seen (*ante*, pp. 237, 238) that this system is generally employed in the newer, automatic, and continuous methods of manufacture. Bevelled wheels and other devices (L. Urion, 1856) have also been used for the purpose.

9. **Drying.** The frames of tipped splints are placed on supports or racks, either in the open air or in the drying-room—an apartment maintained during the summer at a suitable temperature by fans or otherwise, and in damp weather and winter kept warm and dry by pipes conveying steam or hot air.

10. **Laying out**; 11. **Halving**; and 12. **Boxing.** The 'headed' and dried splints are next taken out of the frames or coils, as the case may be. The operation is usually termed 'laying out,' 'racking out,' or 'racking off,' and in England is sometimes effected by hand, if the establishment be not very extensive. The nuts and crosspiece at the top of a clamp are removed, and then lath after lath is lifted and the row of double-tipped splints beneath deftly withdrawn. Laying out is also performed mechanically, the machines of Sebold, Schnetzer, and others being used, especially abroad. In the case of coil-dipped splints the process was called 'unwinding,' and differed, of course, materially from the methods applicable to frames. Beecher (1877) invented a machine which simultaneously performs this operation and the next, 'halving,' 'cutting-down,' or 'cross-cutting.'

According to the older method, for frame-dipped matches, handfuls of the laid-out, double-headed splints were divided, 'halved,' or 'cross-cut,' generally by a pivoted or 'lever' cutting knife, and the resulting matches were at once *boxed* (*i.e.* put into boxes) by women, who became exceedingly dexterous in taking up handfuls of splints of just the required number to fill two boxes. The operations of halving and boxing, where white phosphorus was used, caused more loss by 'firing' than any other part of the proceedings in a match factory. It has been mentioned that the loss during boxing or filling is quite trivial under modern working conditions. And, with the continuous manufacture, there is now no halving.

The writer is under obligations to Messrs. Bryant & May, and to Messrs. Bridwell, Hammond, Parrott, Marchant, and Crowther-Beynon for help in the preparation of this article.

E. G. C.

MATÉ *v.* PARAGUAY TEA.

MATECERIC ACID. An acid obtained from the wax of the yerba maté (*Elaeodendron quadrangulatum*) (Reiss.). When the solution obtained by exhausting the leaves of this plant with ether, or better with ether-alcohol, is treated with lime, then filtered and evaporated, a waxy residue is left, which may be freed from chlorophyll by treating its ethereal solution with animal charcoal. This solution, agitated with water to remove caffeïne and other substances, and evaporated, leaves the pure waxy matter, which, when boiled with aqueous potash, partly dissolves, leaving a residue soluble in ether, much more butyraceous than the original substance and separable by treatment with alcohol into an insoluble yellow

transparent substance, and a soluble portion which is white and melts at 55°. On neutralising with hydrochloric acid, the alkaline solution obtained by saponification of the wax, matecéric acid, is obtained as a white precipitate which has acid properties, and is soluble in ether and in boiling alcohol. It melts at 105°–110°, and has a density of 0·8151 at 26°. From the results of its analysis, it does not appear to belong to the acetic series, but its molecular weight is very high (Arata, Gazz. chim. ital. 1877, 366).

MATEZITE. A saccharine substance obtained by Girard from Madagascar caoutchouc; when treated with hydriodic acid, yields methyl iodide and *matezo-dambose*, an isomeride of glucose. Crystallises in radiating nodules. Rotatory power $[\alpha]_D$+65; m.p. 187° (Girard, Compt. rend. 77, 995, and 100, 84; Combes, *ibid.* 110, 46).

MATICO CAMPHOR *v.* CAMPHOR.

MATLOCKITE. A lead oxychloride

$$PbCl_2 \cdot PbO$$

of a yellowish colour, found at Cromford, near Matlock, Derbyshire; sp.gr. 7·21.

MATRASS. An egg-shaped glass vessel with a narrow neck, used by the older chemists, mainly for sublimations.

MATRINE $C_{15}H_{24}ON_2$. An alkaloid occurring in the roots of *Sophora flavescens* (Ait.). Is a monoacidic tertiary amine. Of the two nitrogen atoms, one forms a lactam ring with a carboxyl group and is changed to an imino-group by hydrolysis with alkali, *matrinic acid* being formed. For its salts and derivatives, *see* Heizaburô Kondô and co-workers, J. Pharm. Soc. Japan, 1921, 659, 1047.

MAURITIUS ELEMI *v.* OLEO-RESINS.

MAUVANILINE $C_{19}H_{17}N_3$. A base isolated by Girard, De Laire, and Chappolot, from the insoluble residues obtained in the manufacture of rosaniline (Zeitsch. Chem. 1867, 236).

MAUVE or **MAUVEÏNE** *v.* AZINES.

MAYNAS RESIN or **CALABA** *v.* RESINS.

MAZOUT. Petroleum residue used as a fuel oil, usually by atomising by a jet of steam after preheating above the flash-point.

MEAD or **HYDROMEL.** An alcoholic drink prepared by the fermentation of honey. Well-made hydromel has a colour between that of champagne and Madeira, is fine in flavour, and contains about 13 p.c. of alcohol.

MEADOW ORE *v.* LIMONITE; also IRON.

MEADOW SAFFRON *v.* COLCHICUM.

MEAT EXTRACTS. *Historical.* It is well known that extract of meat consists of beef tea evaporated to the consistency of a thick syrup. It therefore contains the whole of those constituents of meat which are soluble in hot water.

It was first correctly prepared in 1821 by Proust, by whom, in conjunction with Parmentier, it was very highly recommended as a stimulant quite as valuable for the strong and healthy as for invalids. In 1847 Liebig, in his celebrated treatise on 'Researches on the Chemistry of Food,' most warmly approved of Proust and Parmentier's extract, and subsequently made every effort to popularise the use of the preparation. The attention of many men of science, but more particularly of the medical profession in Germany, was attracted to Liebig's abstract scientific researches into the nature of meat, and it was ascertained that extract of meat was of great usefulness in medical cases.

In consequence, the *Extractum Carnis* was, without Liebig's assistance, introduced into the Bavarian Pharmacopœia of 1856, and from that time all Bavarian apothecaries were legally bound to keep the extract in stock, or to make it when required, just as any other drug. From Bavaria the knowledge and medical use of the extract spread over the whole of Germany, but its manufacture remained confined to pharmaceutical chemists, and its use to the sick-chamber. Liebig, on the other hand, while fully appreciating the clinical importance of the extract, and further endeavouring to improve the alimentation of sick persons by various modifications of this invention, proposed to bring meat extract into commerce as an article of food, and to make its manufacture the object of industrial enterprise on a large scale. His endeavours were, however, without success until, early in 1862, George Christian Giebert, an engineer, well acquainted with the meat-producing districts of South America, went to Munich to receive instruction in the method of preparing the extract by Liebig himself, aided by von Fettenkofer, and then returned to Uruguay and established a manufactory on a considerable scale. In November, 1864, the first samples of Giebert's manufacture arrived at Munich and their quality far exceeded the expectation of Liebig. He consented to Giebert's proposition that the extract should bear the name of the inventor, on condition that it should always be free from fat and gelatin, and that each consignment should be subjected to a gratuitous analysis by him or his delegate.

The industry has flourished and immense areas of land are farmed to produce cattle required for the manufacture of meat extracts. Take, for example, some facts connected with the enterprising company to which Liebig gave permission to bear his name. The Liebig's Extract of Meat Company farmed, in 1868, some 28,494 acres of land, and the total herd of horned cattle reared on this area was 12,000. In 1908, the acreage was 1,302,386 and the number of cattle 224,406, and in 1922 the acreage was 5,250,000, of which 2,500,000 acres are in South Africa—the total head of cattle carried on these areas being approximately 500,000. Striking as the figures may be as illustrating the enormous expansion of the cattle-rearing industry, they become still more impressive when regard is paid to the fact that the cattle are no longer, as in Liebig's day, and according to his own words, 'half-wild animals,' but are bred from the choicest pedigree stock taken from the farms of our best English breeders.

Each animal is allotted about 5 acres of pasturage. The average daily amount of grass consumed by one animal is 88 pounds; a herd of 250,000 would therefore consume *per diem* 22,000,000 pounds of grass, or approximately 10,000 tons. Thus the yearly consumption of grass would mean not far short of 4,000,000 tons. The composition of pasture grass,

according to the average of a large number of analyses, is as follows:—

	Per cent.
Water	80·00
Proteins with a small quantity of nitrogenous extractives [1]	3·50
Fat	0·80
Carbohydrates	9·70
Fibre	4·00
Mineral salts	2·00
	100·00

This means for a herd of 250,000 head of cattle per year a food yield in the form of grass of the following quantities of its individual solid constituents:—

	Tons
Protein or flesh-forming substances	140,000
Fat	32,000
Carbohydrates	388,000
Fibre	160,000
Mineral salts	80,000
	800,000
Balance due to 80 p.c. of water in grass	3,200,000
Total	4,000,000

Similarly, the annual amount of water consumed, based on the fact of one animal requiring 30 litres per day, would amount to 700,000,000 gallons per annum for the herd. These figures refer only to the stock of one company. The Argentine, Uruguay, and Paraguay republics are immense fodder-yielding tracts, and the metamorphosis of grass proceeds steadily and uninterruptedly day by day on a colossal scale. There are occasions when the ordinary grass is supplemented by 'Alfalfa,' a rich clover corresponding to our lucerne and containing a good proportion of nitrogenous food.

Method of manufacture. In principle the lines laid down by Liebig, which he considered essential to success, are still followed by the Liebig Company. In the first place, the meat is hung in the cooling halls for 12 or more hours, then the fat and sinews are carefully removed, and the meat is fed to chopping machines with revolving knives. From the chopping machines the meat emerges in chunks, which drop into mincing machines especially constructed for the purpose. The meat emerges from these machines as mincemeat, and is then transferred to the extracting pans, each capable of holding about 4 tons, in which it is left with its own weight of pure filtered water. After the addition of more water the mixture is heated to a temperature not exceeding 95° by means of steam jackets. During this time fat continuously rises and is skimmed off. The more or less clear liquor is then run off and the work of concentration is commenced. Fat is again skimmed off until at length the extract or soup is practically fat-free. Concentration proceeds again *in vacuô*, and during evaporation is twice filtered before passing into the final concentrator, which is fitted with a revolving worm through which low pressure steam is passing. Constant stirring during the final stages of evaporation is essential to secure uniformity in regard to consistency and composition of the finished extract. The treacly mass is then run off while hot into 100 lb. tins, cooled, hermetically sealed and dispatched to the European blending factories.

[1] N × 6·25.

The extract is finished within 3 days of the death of the animal.

One thousand pounds of lean meat, treated upon a manufacturing scale, furnishes 31 lbs. of extract. A standard extract manufactured as described contains an average of 18·25 p.c. moisture, 61·5 p.c. of organic matter, 20·25 p.c. of mineral substances, and yields an alcoholic extract of 57 p.c.

It should be as free as possible from gelatine, fat, and coagulable or insoluble albumen. By far the greater proportion of the meat constituents, namely, the fibrine, gelatine-yielding tissue, and fat is therefore rejected in the preparation of extract.

Lemco, a typical first grade extract, has the following composition:—

	Per cent.	
Water		20·05
Organic matter		58·52
Mineral matter		21·43
		100·00
The mineral matter contains:		
Combined chlorine		1·88
Phosphates as P_2O_5		6·00
The organic matter contains:		
Total nitrogen		9·45
Distribution of the total nitrogen:		
Nitrogen in fibrine and albumen	0·14	
,, meat bases soluble in alcohol	5·64	
,, meat bases rendered insoluble in alcohol	0·70	
,, gelatine	0·02	
,, albumoses	1·73	
,, peptones	1·17	
Ammoniacal nitrogen	0·05	
	9·45	
Creatine		1·85
Creatinine		4·95
Total		6·80
Fat (ether extract)		0·12

The meat bases constituting the essential part of the extract contain creatine, creatinine, xanthine bases, carnine, carnic acid, and other complex organic bodies.

Reference may be made here to the ratio between the creatine and creatinine in the above analysis which is as 1 : 2·6. The creatine of the meat has been altered to the anhydride creatinine by loss of water during evaporation. Experience has shown this to be reversed on storage, water being taken up and creatine again formed

Whilst all commercial extracts are essentially of the same character, the proportions and derivation of the various constituents differ. The following analyses in Table I. may be taken

as representing the composition of the leading meat extracts on the British market:—

TABLE I.

	Average composition of

Total	3·26	3·09	3·13	3·27

A practice has arisen of mixing meat extracts with extracts of yeast. The extract of yeast has valuable dietetic properties and contains the active principles of fermentation. It also resembles, in many respects, physically and chemically, but not in taste, extract of meat. The addition of more than 2 p.c. of this to a meat extract imparts a distinctive taste.

According to Wiley the presence of yeast extract in meat extract can be determined by treating the mixture with a strong solution of zinc sulphate and filtering. In meat extract the filtrate obtained is always quite clear, but when a yeast extract is present the filtrate is turbid. Hehner applied the Folin reaction for the estimation of creatine and creatinine in meat extracts, and as yeast extract contains neither creatine nor creatinine, the test is of importance in determining the source and value of a meat extract.

The Folin method for the estimation of creatinine is a colorimetric one, based on the fact that creatinine gives with picric acid, in presence of alkalis, an orange to deep red solution, the intensity of the coloration depending upon the amount of creatinine present (Zeitsch. physiol. Chem. 1904, 41, 223). Folin recommends the use of Dubosq's colorimeter for making the colour comparisons.

The test is carried out as follows: With good quality extracts 5 grams are dissolved in water and the solution made up to 500 c.c.

Creatinine. 20 c.c. of this solution are taken for the determination of creatinine, viz. 0·200 gram of extract. To 20 c.c. of the solution in a 500 c.c. flask are added 20 c.c. of picric acid solution (saturated) and 5 c.c. of a 10 p.c. caustic soda solution.

The mixture is shaken and allowed to stand exactly 5 minutes, and is then made up to 500 c.c. with pure water at 18°, and its colour compared with that obtained from a standard solution of potassium dichromate (24·565 grams per litre).

All colorimetric readings are made with a Dubosq colorimeter, having the left-hand cylinder fixed at exactly 8 mm. depth of bichrome solution.

The following readings were obtained:—

8·2 mm.	8·1 mm.	
8·2 ,,	8·0 ,,	Jaffe's formula
8·1 ,,	8·0 ,,	8·11)81·00(9·99 mgms.
8·1 ,,	8·1 ,,	creatinine.
8·2 ,,	8·1 ,,	9·99 mgms. found in
		0·2 grm.
8·16 ,,	8·06 ,,	
Average	8·11 mm.	

$0·2 : 100 :: 0·0099 : x$

$x = 4·99$ p.c. creatinine.

Total creatinine and creatine. 15 c.c. of the extract solution (5 grams in 500 c.c. water) =0·15 gram extract, are placed in a porcelain basin 8 cm. diameter, and 10 c.c. of normal HCl (1 c.c.=0·0365 gram HCl) added, and slowly evaporated to dryness on a water-bath taking at least 2 hours for the evaporation. The residue is dissolved in 15 c.c. of water, then to the contents in the basin 20 c.c. picric acid are added, and 5 c.c. of the caustic soda solution. The mixture is stirred with a glass rod, and exactly after 5 minutes' standing transferred to a 500 c.c. flask, the basin being washed out several times into the flask, and the liquid made up to 500 c.c. at 18°. The following readings were obtained:—

8·4 mm.	8·5 mm.	
8·4 ,,	8·6 ,,	Jaffe's formula
8·5 ,,	8·6 ,,	8·49)81·00(9·54 mgms.
8·4 ,,	8·6 ,,	creatinine.
8·4 ,,	8·5 ,,	9·54 mgms. found in
		0·15 grm. extract.
8·42 ,,	8·56 ,,	
Average	8·49 ,,	

As $0·15 : 100 :: 0·00954 : x$.

$x = 6·36$ p.c.

6·36 p.c. acid treated.
4·99 p.c. creatinine.

1·37 creatinine due to creatine.
1·16 factor for converting creatinine to creatine.

$1·37 \times 1·16 = 1·5892$ creatine.

Corrected results:

Creatinine	4·99 p.c.
Creatine	1·59 ,,
	6·58 ,,

In carrying out this test care must be taken to observe all the details as regards:

(*a*) Strength of solutions employed;

(*b*) Time of contact;

(*c*) Dilution of original liquid;

(*d*) Depth in mm. of the unknown solution should be within the range of 7 mm. and 9 mm.;

(*e*) Temperature to be as near 18°C. as possible.

With extracts that yield low creatine and creatinine figures it is necessary to treat the extract before applying the test. 10–50 grams of the substance are dissolved in the smallest bulk of water possible. Then 250 c.c. methylated spirits are added and allowed to stand for 12–16 hours, filtered, the alcohol distilled off, the residue dissolved in water, and made up to 100 c.c., an aliquot part not exceeding 20 c.c. being taken for the estimation.

It has been pointed out by Jaffé (Zeitsch. physiol. Chem. 1886, 10, 391), and more recently by A. C. Chapman (The Analyst, Nov. 1909), that other substances, such as acetone, dextrose, and lævulose reduce picric acid and produce the same coloration. When the presence of any reducing substance other than creatinine is suspected, preliminary treatment with methylated spirits is desirable. *See* further, CREATINE and CREATININE, Vol. II. pp. 410 and 412.

Methods of analysis. For the examination of commercial high-grade extracts the following method is applied.

In some meat extracts during the cooling in pots, crystals and other solids settle to the bottom before the mass becomes semi-solid, consequently the material must be well mixed without warming before analysis.

Water. 2 grams are evenly spread by means of a glass rod round the inside of a porcelain crucible 37 mm. high and 55 mm. wide on top to within 10 mm. of top edge; dried for 36 hours in a water-oven at a temperature of 97°, cooled for 20 minutes in a desiccator over vitriol and quickly weighed. A Moslinger's cellular water-oven is best for this class of work.

Ash. 2 grams are weighed in a platinum basin and slowly burned without the basin becoming visibly red. The burner employed has a round cover 7 cm. in diameter with 28 holes, each 1 mm. in diameter. After carbonising, the mass is crushed twice and the ash obtained should be a greyish-white without showing fusion—too strong or too quick ignition will cause loss.

For absolutely correct ash estimation the basin is put on an asbestos sheet to protect the contents from sulphurous acid of the gas, or better still, burned in an electric furnace at 6–8 ampères until the ash is clear grey. This is weighed when cold and washed into a small beaker, acidified with nitric acid, and warmed until the light brown coloured matter coagulates. Filter and use the filtrate for the chlorine estimation, wash the carbonaceous matter from the filter into a small crucible, dry at 105° and weigh. Deduct this carbon from the former weight to get the true pure ash.

The chlorine is estimated in the acidified filtrate from the ash gravimetrically, as phosphates interfere with the volumetric estimation.

Alcoholic extract. By this is meant that portion of the extract soluble in ethyl alcohol, 80 p.c. by volume. 2 grams are weighed out into a small Soxhlet flask, 9 c.c. water added, and the extract dissolved without warming, 50 c.c. alcohol (93 p.c. by volume, sp.gr. = 0·8234) slowly added with gentle shaking, allowed to stand over night at 17°–18°, and then carefully poured from the fast-sticking mass into a weighed porcelain basin 76 mm. diameter and 34 mm. deep; the alcohol is evaporated slowly on a water-bath at 70°–75°. In order to prevent creeping the basin is placed on a layer of flannel over the hole in the bath, or in a copper basin soldered into the opening in the bath and having a layer of sand between the copper and porcelain basins. Meanwhile to the insoluble mass in the flask 50 c.c. alcohol of sp.gr. 0·8639 (80 p.c. by volume) are added with gentle shaking and allowed to stand at 17° until the first alcoholic solution is evaporated when the second portion is decanted into the basin, and this again evaporated until the contents have the consistency of honey. The basin is then dried at 98° in the water-oven for exactly 6 hours, cooled 20 minutes in the desiccator, and quickly weighed. The extraction temperature must be within 17°–18°, or variable results will be obtained.

GENERAL ANALYSIS OF MEAT EXTRACTS.

Modified Stutzer method. 30 grams are weighed, dissolved in water and made up to 250 c.c. A fair average sample is thus obtained, and all estimations necessary can be begun the same day.

Moisture. Cleaned ignited Calais sand is put into a flat nickel basin 9 cm. in diameter along with a small glass stirring rod until the whole weighs exactly 100 grams. Dried in steam oven until weight is constant, then 25 c.c. extract solution added (=3 grams extract), stirred amongst the sand, evaporated until granular on a water-bath, transferred to a steam oven for 36 hours, cooled and weighed.

Ash. 25 c.c. (=3 grams) evaporated and carbonised. Owing to the quantity of carbonaceous matter the estimation of ash cannot well be made direct, hence the charred mass has to be extracted three times with boiling water, and filtered through an ashless filter paper into a porcelain basin, the char and filter paper burned off in the platinum basin, and the filtrate put back in the platinum basin, evaporated, dried, ignited gently, and weighed. The ash is dissolved in cold water, acidified with nitric acid, made up to 250 c.c., and used for estimation of chlorides and phosphates.

Chlorides are estimated gravimetrically in 50 c.c.

Phosphates are estimated by the molybdate and magnesia mixture method in 50 c.c.

Fibrine and **already coagulated albumen.** 25 c.c.(=3 grams) are diluted and settled in a 100 c.c. cylinder over night. The top liquid decanted and the residue either transferred to a counterpoised filter, washed, dried at 100°, and weighed, or the residue transferred to a centrifuge tube, washed, and the nitrogen estimated by Kjeldahl's method.

Soluble albumen. The decantations from the above are acidified with acetic acid, boiled for

5 minutes, settled, filtered, and weighed or treated by Kjeldahl's process. If the total fibrine and albumen together be required, then it is only necessary to acidify 25 c.c. of extract solution diluted to 100 c.c., with acetic acid, boil for 5 minutes, settle, filter, and either weigh at 100° or estimate by Kjeldahl's method.

Gelatine. 25 c.c. of extract solution (=3 grams) are poured on to asbestos fibre in a small porcelain basin, evaporated to dryness, extracted with 93 p.c. alcohol three times, then with ice-cold water containing 10 p.c. alcohol, until the decantations are free from colour (the temperature must never rise above 5°). The gelatin is either dissolved and washed from the asbestos and treated by Kjeldahl's process, or the asbestos and gelatine may be put direct into the Kjeldahl flask. With some extracts it is better to take 25 c.c. extract solution, and, without evaporating, add 250 c.c. methylated spirit, stand 8 hours, decant off alcohol from the sticky mass and wash with 10 p.c. ice-cold alcohol until free from colour, then treat by the Kjeldahl method.

Total nitrogen. 10 c.c (=1·2 gram extract) are treated by Kjeldahl's method direct.

Meat bases soluble in alcohol. 25 c.c. (=3 grams extract) taken in beaker, 250 c.c. absolute alcohol added with constant stirring and settled for 12–16 hours. The alcohol passed through filter into a 500 c.c. round-bottomed flask, the residue washed twice with 25 c.c. absolute alcohol, and the alcohol distilled off, standing the flask inside a water-bath. The meat bases are then treated by the Kjeldahl process in the flask without transference so as to avoid loss.

Residue insoluble in alcohol. The insoluble residue from the absolute alcohol is dissolved in water on the water-bath. A few drops of acetic acid added to coagulate the soluble albumenoids, then boiled and filtered into a 250 c.c. flask for the estimation of gelatine, albumoses, and peptones. The residue on the filter, consisting of fibrine and albumen, may be treated by Kjeldahl's method as a check on former estimation.

Total nitrogen in gelatine albumoses and peptone fraction. 50 c.c. of the 250 c.c. taken for the Kjeldahl process.

Albumoses and gelatine. 50 c.c. of the 250 c.c. are taken in a porcelain basin, and powdered zinc sulphate crystals added with frequent stirring until saturated and allowed to stand overnight. The precipitate is filtered, washed with saturated zinc sulphate solution, and subjected to Kjeldahl's process. The filtration of the precipitate is slow, but proceeds steadily, and works better if the liquid is rendered slightly acid with sulphuric acid (1 : 4).

Peptones, albumoses, and gelatine. 50 c.c. of the 250 c.c. are put into a beaker 50 c.c. sulphuric acid (1 : 3) added, and an excess of phosphotungstic acid, prepared by making a strong solution of sodium tungstate in boiling water, and adding phosphoric acid with continued boiling until the mixture gives a constant acid reaction.

An alumina-like precipitate is formed which, if left for a few hours, filters fairly well. The precipitate is washed several times with dilute sulphuric acid, and then treated by Kjeldahl's method. This operation has to be carefully conducted as the precipitate causes bumping.

The nitrogen from this estimation comes almost up to the total nitrogen of the section insoluble in alcohol, but a little of the meat bases are sometimes rendered insoluble by the alcohol, and the traces obtained by difference are to be added to the meat bases. Having obtained the gelatine figure by a separate estimation, then (gelatine and albumoses) − gelatine = albumoses, and (gelatine + albumoses + peptones) − (gelatine + albumoses) = peptones.

Ammoniacal nitrogen. Traces only of this are present, 50 c.c. of the standard extract solution (=6 grams extract) are distilled with barium carbonate into standard acid.

All nitrogen determinations are made by the Kjeldahl-Gunning method, using about 25 c.c. nitrogen-free vitriol to start with. After frothing, and the thick carbonaceous mass has disappeared, 10 grams of potassium sulphate and a small crystal of copper sulphate are added. Heating must be continued until the yellow colour has changed to a clear blue, indicating complete oxidation. In distilling off the ammonia it is preferable to use steam with a small flame under the alkaline liquid to prevent dilution by condensation, instead of a naked flame under the distillation flask. Zinc-dust is added to separate the copper, and to prevent bumping. The period of distillation should be 40 minutes

In calculating the percentage of the various nitrogenous compounds in extracts it is usual to use the factor $N \times 6{\cdot}25$. This is not, however, strictly accurate, but is generally accepted as the best approximation to the truth. Analyses, therefore, should disclose the actual nitrogen figures obtained. The use of nitrogen factors is discussed in Analyst, 1915, 40, 310–326.

An auxiliary method for the estimation of gelatine and hydrolised gelatine is that of Beckmann (Forschungs Berichte, 1896, 3, 324) based upon the fact that gelatine and albumenoids are rendered insoluble by formaldehyde. 3 grams extract dissolved in 20 c.c. cold water are treated with 3 or 4 drops of formaldehyde solution (40 p.c. strength) and evaporated to dryness on a water-bath and for 2 hours in an air oven, then moistened with a 5 p.c. formaldehyde solution, and after standing 5 minutes, warm water, 60°–70°, is added and allowed to digest 15 minutes, the water is then decanted, and the washing repeated until free from colour. The insoluble mass is subjected to the Kjeldahl process. Care must be observed to use a formaldehyde solution which is neutral, since free acid affects the reaction.

A convenient method for the determination of the total soluble proteids in extract is based on the fact that halogens precipitate those bodies. Bromine water is for convenience employed. Allen and Searle take 1 gram of the substance dissolved in 100 c.c. water in a flask and acidify with dilute hydrochloric acid. A considerable excess of bromine water is added and the liquid shaken for some time. The precipitate is allowed to settle for several hours, the supernatant liquid decanted through an asbestos filter, the precipitate washed with cold water and treated by Kjeldahl's method. Van Slyke's method of protein analysis (Vol. IV. 403, and Plimmer's Biochemistry, 1915, 146–149) has been applied by Hartley to the determination of the amino nitrogen contents of meat extract. He

found that of the total nitrogen 12 p.c. was in the amino form, being liberated on treatment with nitrous acid. The method can be carried out in fifteen minutes, and enables the analyst to at once differentiate the various forms of nitrogen in this and similar substances (*see* Analyst, 1915, 40, No. 472, 310–326; *cf.* Smorodinzer, Zeitsch. physiol. Chem. 1914, 92, 214). On the changes in the composition of the nitrogenous constituents of meat extracts, *see* Wright, J. Soc. Chem. Ind. 1911, 30, 1197; *ibid.* 1912, 31, 176. F. S.

MECCA BALSAM. *Opobalsam*; *Balm of Gilead* (*v.* OLEO-RESINS).

MECONIC ACID, MECONIDINE *v.* OPIUM.

MECONINE *v.* LACTONES.

MEDINAL. A sodium compound of veronal. Used as a hypnotic.

MEDLAR. The fruit of *Mespilus germanica* (Linn.). When fresh, the fruit has a yellowish-white flesh, which is hard and of an unpleasant astringent taste; on keeping for some weeks, the flesh becomes brown, soft, and doughy, and possesses an agreeable flavour. In the latter condition, Bersch (Landw. Versuchs. Stat. 1896, 46, 471) examined the various parts of the fruit and obtained the following results :—

Percentage of dry matter	Whole fruit	Rind	Flesh	Pips
	30·9	36·9	24·8	61·6

The dry matter contained—

	Protein	Fat	Invert sugar	Other N-free extract	Crude fibre	Ash
Whole fruit	2·79	1·04	36·08	40·98	16·29	2·82
Rind .	4·12	2·66	—	72·62	17·51	3·09
Flesh .	2·62	0·57	48·56	37·63	7·35	3·27
Pips . .	2·55	0·62	—	46·66	48·52	1·65

Malic acid, acetic acid (0·03 p.c.) and alcohol were present.

The ash of the medlar has been found to contain about 0·3 p.c. boron trioxide. In the N-free extract there is a considerable portion of pectin matter. H. I.

MEDULLADEN *v.* SYNTHETIC DRUGS.

MEDULLIC ACID $C_{20}H_{41}\cdot CO_2H$, m.p. 72·5°, an acid found as a glyceride in beef suet and in beef marrow, associated with oleic and palmitic acids.

MEERSCHAUM or **SEPIOLITE.** A hydrated magnesium silicate $H_4Mg_2Si_3O_{10}$, occurring as nodules and compact masses, of white, grey, or creamy colour. From its appearance and its extreme lightness (sp.gr. about 2) it has acquired the name of *meerschaum* or 'sea-froth' (*écume de mer*), although it is sometimes described by mineralogists under the name of *sepiolite*, a word introduced by Glocker to indicate its resemblance to the light white porous material known as the bone of the cuttle-fish or sepia. Meerschaum is a soft mineral (hardness 2–2·5), easily carved; has a greasy feel, and readily adheres to the tongue. In consequence of its porosity, a meerschaum pipe absorbs the oily matter of the tobacco; and for a like reason the proportion of water present in the mineral depends on the humidity of the atmosphere. In a moist atmosphere the composition corresponds with $2MgO\cdot3SiO_2\cdot4H_2O$, with 21·7 p.c. water. About half of this water is lost over sulphuric acid, and the remainder is expelled only at a high temperature, about 300°. Up to this temperature the mineral retains its optical characters, the formula being then $2MgO\cdot3SiO_2\cdot2H_2O$ (with 12·2 p.c. water). The following analyses illustrate the composition of meerschaum :—

	I	II	III
Silica . .	60·87	61·30	53·8
Magnesia . .	27·80	28·39	23·8
Alumina . .	—	—	1·2
Water . .	11·29	9·74	20·0
	99·96	99·43	98·8

I. From Asia Minor, by Lynchnell. II. From Greece, by Scheerer. III. From near Madrid, by Berthier.

Meerschaum is found as nodular masses in alluvial deposits in the plains of Eski-Shehr, in Asia Minor, where it is associated with compact magnesite ($MgCO_3$) and serpentine. It is here dug from a number (now some 1270) of shallow pits, from the bottom of which short galleries are occasionally run. The nodules are scraped free from earthy matter with a special knife, air dried, polished with wax, and sorted into a number of grades and sizes (J. Soc. Arts, 1909, 57, 411). It also occurs at Kiltschik, near Konieh, in Natolia; in Greece, Negroponte, and Samos; in Moravia; with magnesite and serpentine at Kraubat in Styria; and in New Mexico. In New Mexico it occurs as nodules and seams in limestone, and has been exploited at two localities, namely Gila valley and Bear Creek in Grant County (D. B. Sterrett, Bull. U.S. Geol. Survey, 1908, No. 340, 166). At Vallecas, near Madrid, it is said to be used as a light material for constructive purposes. Meerschaum has been employed as an ingredient in porcelain, while in Turkey it is used, when fresh, in the place of soap, and as a kind of fuller's earth. From the East large quantities are sent to Vienna to be carved as tobacco pipes. The pipes are prepared for use by being soaked in melted tallow and wax, and are polished with shave grass. Imitations are fabricated in plaster of Paris hardened with paraffin, and in a preparation of potatoes treated with dilute sulphuric acid. L. J. S.

MEGASSE. Spent or crushed sugar-cane.

MEILER. The German name for the stack of timber piled up for burning into charcoal (*v.* CARBON).

MEKOCYANIN *v.* ANTHOCYANINS.

MELACONITE or **BLACK COPPER.** Cupric oxide, CuO, crystallised in the monoclinic (or perhaps triclinic) system. As a black, sooty powder, soiling the fingers, it is of frequent occurrence on the weathered surface of copper-pyrites and other ores of copper. In the massive form it is sometimes found in considerable quantity, sufficient for use as an ore of copper, *e.g.* in the Ducktown mines in Tennessee, Copper Harbor, or Lake Superior in Michigan, Bisbee in Arizona, and Copiapo in Chili. Crystals are rare and have the form of minute scales with a steel-grey colour and brilliant metallic lustre; sp.gr. 5·82. They have been found only in Cornwall and on lava at Vesuvius. The name *tenorite* was applied to the Vesuvian crystals; and the name melaconite (from *μέλας*, black, and *κόνις*, dust) is more properly used for the earthy, probably colloidal, form, which contains

admixtures of hydrated silicate and carbonate of copper and grades into melanochalcite (G. A. Koenig, 1902) and pitchy copper-ore. L. J. S.

MELANTERITE or **IRON VITRIOL.** Hydrated ferrous sulphate, $FeSO_4 \cdot 7H_2O$ crystallised in the monoclinic system. As a mineral, this is usually found as a white, silky, fibrous efflorescence, resulting from the decomposition by weathering of iron-pyrites and marcasite. Stalactitic and concretionary masses also occur, but well-formed, green crystals similar to those obtained artificially are rare. It is of wide distribution, but usually only in small amounts. Considerable quantities were, however, formerly obtained from the pyrites mine at Goslar in the Harz. L. J. S.

MELDOLA'S BLUE *v.* OXAZINE COLOURING MATTERS.

MELDOMETER. An instrument designed for the purpose of ascertaining the melting and boiling points of small quantities of substances It consists essentially of two pairs of forceps mounted on a stage and carrying between them a thin platinum ribbon. Through this ribbon an electric current may be passed, the strength of the current being regulated by a carbon-mercury rheostat. The apparatus is mounted on the stage of a compound microscope, provided with a 1-inch objective. The substance to be examined is placed in focus on the platinum ribbon, and then the current is gradually increased until the substance is melted or volatilised. Experiments made in this way show interesting phenomena, sufficiently characteristic in many cases to identify a substance at once. By arranging side by side different fragments it is easy to find their order of melting-points with greater exactness than can be the case when the blow-pipe is employed.

The meldometer is also of value in studying sublimates. A piece of glass is held over the heated strip and upon this the sublimate deposits. A long series of trials have led to the conclusion that the appearances so obtained are excellent as tests to the mineralogist and chemist (J. Joly, Industries, 1889, 29, and J. Soc. Chem. Ind. 8, 306).

MELEZITOSE *v.* CARBOHYDRATES.

MELIBIOSE *v.* CARBOHYDRATES.

MELICITOSE *v.* CARBOHYDRATES.

MELILITE. A rock-forming mineral consisting of silicate of calcium, aluminium, iron, magnesium, and sodium, crystallised in the tetragonal system. The formula is uncertain, and, like the allied minerals gehlenite, åkermanite (known only as an artificial product in slags), and fuggerite, its composition may be explained by isomorphous mixtures of the following molecules: $3CaO \cdot Al_2O_3 \cdot 3SiO_2$ (sarcolite), $3Na_2O \cdot Al_2O_3 \cdot 3SiO_2$ (a hypothetical soda-sarcolite), $2CaO \cdot Al_2O_3 \cdot SiO_2$ (velardeñite), and åkermanite ($4MgO \cdot 8CaO \cdot 9SiO_2$). Melilite forms short square prisms resembling cubes; its colour is white, grey, yellow (hence the name, from μέλι, honey) or brown. Sp.gr. 2·9–3·1, H. 5. It occurs principally in volcanic rocks poor in silica and rich in alkalis, *e.g.* in melilite-basalt and in the leucite lavas near Rome. It is also found in the blocks of metamorphosed limestone enclosed in the vesuvian lava on Monte Somma. It is frequently found as well-developed crystals in the slags of blast furnaces, and has been observed in Portland cement clinkers. L. J. S.

MELINITE *v.* EXPLOSIVES.

MELISSA. The leaves and tops of *Melissa officinalis* (Linn.) contain a small quantity of a volatile oil. They are used occasionally in the form of a warm infusion as a diaphoretic in slight febrile conditions.

MELISSIC ACID $C_{29}H_{59}COOH$ is obtained by heating melissyl alcohol with soda-lime at 220° until hydrogen ceases to be evolved (Stürcke, Annalen, 223, 295); m.p. 91° (Marie, Ann. Chim. Phys. [vii.] 7, 145); 90° (Heiduschka and Garcis, J. pr. Chem. 1919, [ii.] 99, 293. It is probably identical with an acid found in beeswax (Nafzger, Annalen, 224, 225; Marie, *l.c.*); according to Heiduschka and Gareis, the acid from beeswax has the composition $C_{31}H_{62}O_2$ and melts at 88·5°.

MELISSIN, MELISSYL ALCOHOL *v.* WAXES.

MELITOSE, *Raffinose* (*v.* CARBOHYDRATES).

MELLITIC ACID. *Benzenehexacarboxylic acid* (Ger. *Mellithsaüre*) $C_6(CO_2H)_6$. Obtained by oxidising charcoal with fuming nitric acid, fuming nitric acid and potassium perchlorate, or with sulphuric acid (Dickson and Easterfield, Chem. Soc. Proc. 1898, 163; Staudenheimer, Ber. 1899, 2824; Hübner, Chem. Zeit. 1890, 440; Verneuil, Compt. rend. 1907, 132, 1340; Bartoli and Papasogli, Gazz. chim. ital. 15, 546; Schulze, Ber. 1871, 802, 806; Meyer and Steiner, Monatsh. 1914, 35, 475; also *v. infra*). By the electrolysis of alkaline solutions, using graphite electrodes, mellitic acid $C_6(CO_2H)_6$, hydromellitic acid $C_6H_6(CO_2H)_6$, and pyromellitic acid

$$C_6H_2(CO_2H)_4$$

are formed (Bartoli and Papasogli, Gazz. chim. ital. 1882, 113; 1883, 37). Also formed together with pyromellitic acid as a decomposition product of sugar (Lippmann, Ber. 1894, 3408; *ibid.* 1917, 50, 236). Has been synthesised by passing a current of methyl chloride through a warm solution of toluene containing aluminium chloride and oxidising the hexamethylbenzene thus formed with potassium permanganate (Friedel and Crafts, Compt. rend. 91, 257; Ann. Chim. Phys. [vi.] 1, 470). Mellitic acid is best prepared in the following way: Carbon, fine enough to pass through an 80 or 90 sieve is boiled vigorously with nitric acid (sp.gr. 1·5) until the liquid becomes faintly amber in colour; this usually takes 3 days. The excess of nitric acid is distilled off at 130°–140° and the residue, containing 80–90 p.c. mellitic acid extracted with water (Holliday & Sons and Siberrad, J. Soc. Chem. Ind. 1908, 522; Eng. Pat. 24662; D. R. P. 214252). According to Michael (Ber. 1895, 1631), the raw material may be purified by boiling with acetic acid, filtering and concentrating the filtrate.

For its preparation from diethyl mesitylene, *see* Philippi and Rie, Monatsh. Chem. 1921, 42, 5.

Mellitic acid decomposes when heated in an open tube at about 260° and has no definite melting-point under these conditions, but when heated in a closed tube melts at 286°–288° (Michael, Ber. 1895, 1631); crystallises in long needles, soluble in alcohol and ether: heat of formation, 546·8 cal.; heat of combustion

788·2 cal. (Stohmann, Kleber, and Langbein, J. pr. Chem. [ii.] 40, 128); heat of solution +3·672 cal. at 20·4° (Berthelot, Compt. rend. 101, 685): dissociation of acid (Quartaroli, Gazz. chim. ital. 1905, 35, i. 470). It dissolves unchanged in boiling sulphuric acid, and is not acted on by chlorine, bromine, concentrated nitric or hydriodic acids. Dry distillation yields carbon dioxide and pyromellitic acid, and by strong heating with glycerol trimesic acid and carbon dioxide are produced. When mellitic acid is subjected to the action of dehydrating agents it is converted into the anhydride of pyromellitic acid. By boiling mellitic acid with benzoyl chloride *mellitic anhydride* $C_{12}O_9$ separates in colourless crystals, insoluble in cold water, but uniting with warm water to form mellitic acid. It gives characteristic colorations with various solvents, *e.g.* rose-red to bluish-red with naphthalene, retene phenanthrene, and fluorene, and bluish-green with nitrobenzene (Meyer and Steiner, Ber. 1913, 46, 813; Monatsh. 1914, 35, 475). By fusion with caustic soda, benzene and carbon dioxide are formed (Baeyer, Annalen, Suppl. 7, 5); reduction with sodium amalgam yields hydromellitic acid. By the electrolysis of the aqueous solution, the chief gaseous products are oxygen, hydrogen, and carbon dioxide, very little carbon monoxide being produced (Boungué, Bull. Soc. chim. [ii.] 35, 561). Acetonitrile and mellitic acid give rise to the triimide, *paramide* $C_6(C_2O_2NH)_3$ and the diimide, *euchrone* $C_6(C_2O_2NH)_2(CO_2H)_2$, when heated at 225°–235° (Mathews, J. Amer. Chem. Soc. 20, 648). A warm aqueous solution of the acid acts on anhydrous or hydrated bismuth oxide producing bismuth mellitate $Bi_2C_{12}O_{12}$, which when heated under reduced pressure in closed tubes at 350° yields pyrophoric bismuth (Thibault, Bull. Soc. chim. 1904, [iii.] 31, 135). Mellitic acid condenses with resorcinol to form phthaleins (Silberrad, Chem. Soc. Trans. 1906, 1787; Green, Chem. Soc. Proc. 1907, 12) and with amino-phenols to form rhodamines (Silberrad and Roy, *ibid.* 1908, 204; J. Amer. Chem. Soc. 32, 189); these compounds are dyestuffs (Eng. Pat. 28638; J. Soc. Chem. Ind. 1903, 414). According to Van Loon (Ber. 1895, 1271), mellitic acid is not esterified by alcohol and acids; but Meyer (Monatsh. 1904, 25, 1201) states that by heating mellitic acid with methyl alcohol and sulphuric acid in a benzene bath, the *pentamethyl ester*, m.p. 141°–144°, is formed; at 100° a mixture of the pentamethyl and hexamethyl esters is produced and at higher temperatures the hexamethyl ester predominates. The *hexamethyl ester* melts at 187° and may be formed by the action of methyl iodide on the silver salt (Kraut, J. 1862, 281; Kraut and Busse, Annalen, 177, 273) or by the action of diazomethane on the acid (Pechmann, Ber. 1898, 501). The *hexaethyl ester* melts at 73°.

MELON. The fruit of various plants of the *Cucurbitaceæ* of tropical or sub-tropical countries. There are many varieties, among which may be mentioned musk melon, *Cucumis melo* (Linn.), and water melon, *Citrullus vulgaris* (Schrad.). The characteristic of melons is the large quantity of water which they contain, while the solid matter consists mainly of dextrose.

Bersch (Landw. Versuchs. Stat. 1896, 46, 473) found the following:—

	Sugar melon		Persican melon		Water melon	
	Whole fruit	Flesh	Whole fruit	Flesh	Whole fruit	Flesh
Water	92·85	95·15	93·87	95·90	93·44	93·69
Dry matter	7·15	4·85	6·13	4·10	6·56	6·31

The dry matter contained—

		Protein	Fat	Dextrose	Other N-free extract	Crude fibre	Ash
Sugar melon	Whole	22·25	6·73	36·32	12·97	14·90	6·84
	Flesh	13·39	1·69	70·63	0·29	6·90	7·09
Persican melon	Whole	20·71	13·14	30·18	4·49	21·56	9·94
	Flesh	11·80	1·85	65·85	3·44	8·44	8·62
Water melon	Whole	13·74	6·89	37·36	21·74	15·41	4·86
	Flesh	9·73	1·06	66·73	16·95	1·95	3·58

The seeds of melons contain much oil (30–40 p.c.).

For analyses of the pulp of several varieties of melon, *v.* Sace (Compt. rend. 94, 1126); also Jaffa (Rep. Agric. Expt. Stat. California, 1894–95, 155).

The ash of water melon is rich in potash and iron (Payne, J. Amer. Chem. Soc. 1896, 18, 1061). H. I.

MELONITE. Nickel telluride $NiTe_2$ crystallised in the hexagonal system. There is a perfect cleavage parallel to the base, and the mineral is usually found as foliated grains of a reddish-white colour with metallic lustre. It is found only in the Melones and Stanislaus mines in Calaveras Co., California, Boulder Co., in Colorado, and in New South Wales. L. J. S.

MELON PUMPKIN SEEDS. *Cucurbitæ semina* of the B.P. The ripe seeds of *Cucurbita maxima* (Duch.).

MELRUBIN. Trade name for sodium 1-phenyl-2·3-dimethylpyrazolone-4-amino methane suphonate.

MELTING-POINT. A knowledge of the melting-point of a substance, *i.e.* the temperature of its transition from the solid to the liquid state, is of importance for many reasons. Thus the melting-point of an *organic compound* affords a criterion of purity and constitutes a means of identification, and is of service in elucidating relations in chemical constitution.

Melting-points of *alloys* yield evidence of the existence of eutectics and compounds formed from the constituent metals.

Melting-points of *hydrates* may be used to determine their degree of hydration (Roosceboom, Zeitsch. physikal. Chem. 1893, 10, 477; Lidbury, *ibid.* 1902, 39, 453).

Melting-points of *silicates* serve to indicate the formation of double and complex silicates, and the dissociation of complex silicates into simpler molecules.

Melting-points of *pure substances* provide standards in calibrating thermometric apparatus.

Occasionally, on heating under ordinary conditions, sublimation occurs without melting, as in the cases of iodine and fumaric acid, when the usual methods are not applicable. But, generally speaking, every pure substance exhibits a definite melting-point, sharp and well-defined, and identical with its solidifying point The slightest impurities, however, such as traces of moisture, frequently lower the melting-point considerably, although it may be still apparently sharp; whilst if foreign substances are present in larger quantity, it is no longer well-defined, nor coincident with the solidifying point. It has been observed (Rohland, Chem. Zentr. 1906,

. 1401) that in some instances addition of impurities may raise instead of lower the melting-point. Pure aluminium melts at a lower temperature than the impure metal, and alumina raises the melting-point of pure kaolin.

Within the ordinary limits, change of atmospheric pressure has no sensible effect upon the melting-point, but at high pressures the effects may be very considerable, *cf.* Demerliac (Compt. rend 1897, 124, 75); Hulett (Zeitsch. physikal. Chem. 1899, 28, 629); Tammann (Ann. Chim. Phys. 1899, [ii.] 68, 553, 629). The melting-point of benzene, for example, varies from 5·4° to 36·5° with pressures ranging from 1 to 1200 kilos. per sq. cm.

For theoretical relationships, *see* Thomson Phil. Mag. [iii.] 37, 123), Negreanu (Chem. Zentr. 1906, i. 116).

Pawloff (Zeitsch. physikal. Chem. 1908, 65, 1; 1909, 65, 545) finds that even with a pure substance, the melting-point is affected by the state of subdivision, that is, it is dependent on the surface energy, and he deduces an equation expressing the relation between the melting-point of a substance and the radius of its granules. Experiments with salol showed that particles of less than 2μ diameter melt 1·1° lower than those of 40μ.

He considers that the lowest attainable temperature in the region of fusion is determined by the melting-point of the crystalline germ of maximum surface, and that larger solid particles above this temperature are super-heated. Similarly the super-cooling of liquids is a general phenomenon, a liquid super-cooled to a definite extent being in equilibrium with solid particles of a definite size, larger particles causing crystallisation and smaller particles dissolving, and the limit of super-cooling is that temperature below which the crystalline germ can arise of itself in the interior of the liquid.

Apart from the foregoing considerations, the manipulative details concerned in the actual determination of a melting-point, particularly by the capillary tube method, *v. infra*, affect the result. This is due partly to unequal heating of the thermometer stem, which may be corrected by adding the value $n(T-t)\times 0{\cdot}000143$ to the observed point of fusion (n=length of mercury column in degrees outside the bath, T=observed temperature, and t = temperature registered in the middle of the projecting portion of the column), or avoided by using a short-stemmed thermometer (*see* Fig. 1). Irregular and too rapid heating is also found to affect the value. Schuyten (Chem. Zentr. 1901, ii. 1326) adduces instances of the variations which may be obtained under different conditions of experiment.

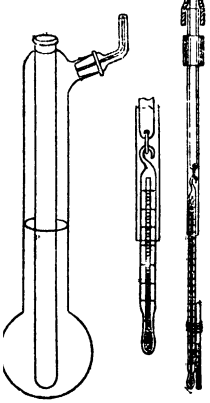

FIG. 1.

The fusion of a solid substance is accompanied by an absorption of heat ('latent heat of fusion'), the temperature remaining constant till all the solid has melted. This provides the most accurate means of determination (Landolt, Zeitsch. physikal. Chem. 1889, 4, 349), the thermometer, or thermo-element with galvanometer attachment, being immersed in the molten substance, and the temperature of the slowly cooling liquid noted at short intervals, the resulting curve indicating the stationary temperature. This method is suitable for all ranges of temperature and for all substances giving a definite melting-point, but requires the use of large quantities of material. In the case of organic compounds, a small quantity of the finely pulverised substance is introduced into a capillary tube closed at one end, and attached to a thermometer, close to the bulb, usually by a thin platinum wire or indiarubber ring, or by adhesion through a drop of sulphuric acid. Weyl (Chem. Zeit. 1910, 34, 488) uses a thermometer slightly expanded just above the bulb, supporting a glass ring carrying glass hooks upon which the tubes are hung in position close to the bulb. Other methods of attachment are described by Lenz (Chem.Zentr.1906, i. 169); Landsiedl (Chem. Zeit. 1905, 29, 765).

The heating bath may be of glycerol, paraffin, or sulphuric acid, the last-named substance being most generally used. It is contained in a small beaker or long-necked flask, the thermometer and tube being either immersed in the liquid or enclosed in a tube dipping into the liquid.

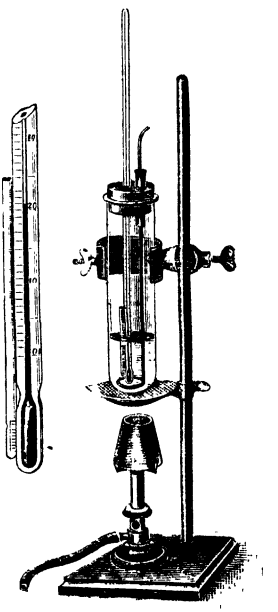

FIG. 2.

A form of laboratory apparatus is shown in Fig. 2, unequal heating being avoided, as far as possible, by stirring with a glass stirrer passing through the cork holding the thermometer, or by heating very slowly with a small flame. For temperatures at which the escape of sulphuric acid fumes becomes unpleasant, the flask is provided with a side tubulure (Roth, Ber. 19, 1970), as shown in Fig. 1. Alternative apparatus for condensing the fumes are described by Houben (Chem. Zeit. 1900, 24, 538) and Matton (Zeitsch. angew. Chem. 1910, 23, 557).

A mixture of three parts potassium sulphate with seven of sulphuric acid, sp.gr. 1·84, boiled together for five minutes, may be used for temperatures up to 325° From 360° to 600°,

fused zinc chloride gives satisfactory results (Scudder, J. Amer. Chem. Soc. 1903, 25, 161).

Thiele (Ber. 1907, 40, 996) has devised a simple and effective apparatus, consisting of a glass tube 2 cm. diameter and 12 cm. long, with a bent tube of 1 cm. diameter sealed in as shown in Fig. 3. Sufficient sulphuric acid is poured in to cover the upper opening of the bend, and the lower bend is heated by a small flame which causes an even circulation of the acid.

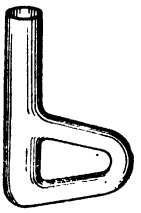

Fig. 3.

If the material is transparent, or becomes so before the melting-point is reached, observation of the exact point at which it liquefies is difficult, and Piccard (Ber. 8, 687) has proposed the apparatus shown in Fig. 4, in which the wide tube (*b*) is sealed after a small quantity of the substance has been melted and allowed to solidify in the capillary bend. On fusion the air pressure in *b* forces the liquid forward. The melting-points of coloured substances are conveniently obtained in this way (Baither, Ber. 1887, 20, 3290). The values are, however, slightly too high.

As modified by Potilitzin (Chem. Zentr. 1893, i. 379) for the melting-points of salts, the apparatus consists of a glass tube, 5 mm. wide and 50 cm. long, drawn out to a capillary at one end, the other being bent first at right angles, and then in the shape of a **U** to form an open manometer. The capillary is sealed with the molten salt and immersed in the bath. When the salt melts, the mercury sinks in the open end of the manometer. The method is employed to advantage where a non-transparent heating bath is used.

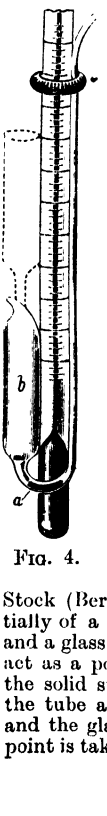

Fig. 4.

For organic compounds which decompose at or near the melting-point, Maquenne (Bull. Soc. chim. 1904, 31, 471) advocates the use of a metal block, rapidly heated, upon which the substance is thrown in small portions (0·1 m.g.) at a time, till the point is reached at which the substance melts instantaneously. *See also* Michael (Ber. 1895, 28, 1629).

Rassfeld (J. pr. Chem. 1916 [ii.] 92, 467) has devised an apparatus for determining melting-points above 270°, consisting essentially of an inverted **T**-tube, the horizontal limb of which passes through opposite sides of a small tin bath. The thermometer and capillary tube are adjusted in the vertical limb, so that the substance can be seen by looking through the horizontal tube against a light. An arrangement which is equally serviceable for high and low temperatures has been devised by Stock (Ber. 1917, 50, 156). It consists essentially of a thin-walled tube about 6 mm. wide and a glass rod about 2 mm. thick, elongated to act as a pointer. By suitable means a ring of the solid substance is deposited on the wall of the tube a short distance from the sealed end and the glass rod is rested on it. The melting-point is taken when the upper end of the pointer is seen to sink (Chem. Soc. Abstr. 1917, 112, ii. 192).

Fatty acids, waxes, and similar bodies are not easily introduced into capillary tubes, and in such cases Kuhara and Chikashigé (Chem. News. 1899, 80, 270) place a thin layer of the substance between microscope cover glasses suspended in a platinum foil support in a test-tube placed in the sulphuric acid bath. A modified method is described by Bunker (Pharm. J. 1909, [iv.] 28).

Air baths, which may be used at high temperatures instead of liquid baths, are described by Anschütz and Schultz (Ber. 1877, 10, 1800) and Kutscher and Otori (Zeitsch. physiol. Chem. 1904, 42, 193).

For a comparison of the different methods of procedure in the case of minute quantities of material, *see* Reinhardt (Zeitsch. anal. Chem. 25, 11).

The air thermometer has been adapted for use at extreme temperatures (Haase, Ber. 1893, 26, 1052; Meyer, Riddle, and Lamb, *ibid.* 1894, 27, 3129), but is less convenient than the thermo-element, for the application of which consult McCrae (Ann. Phys. Chem. 1895, [2] 55, 95); Carrara and Coppadoro (Gazz. chim. ital. 1903, 33, 1, 329); Guttmann (Chem. Soc. Trans. 1905, 87, 1037).

Stolzenberg (Ber. 1909, 42, 4322) has described two ingenious forms of apparatus for temperatures up to 350° and down to −60° respectively, which are similar in principle to that of Thiele, but the circulation is brought about not only by heating or cooling a spiral side tube, but also by bubbling dry carbon dioxide through it. For high temperatures, paraffin is used, and for low temperatures alcohol, the spiral being cooled in a Dewar flask with ether and solid carbon dioxide.

Slightly modified, it provides an accurate means of determining solubilities and (Chem. Zeit. 1910, 34, 66; Zeitsch. physikal. Chem. 1910, 71, 649) of measuring temperatures down to −140°, and is recommended as a low-temperature bath in physico-chemical laboratories. For further particulars and diagrams of apparatus, the original papers should be consulted.

A number of electrical methods have been devised, depending upon the completion of a circuit when the insulating coating of a substance on a platinum wire dipped in mercury melts (Löwe, Zeitsch. anal. Chem. 11, 211; Thierry, Arch. Sci. Phys. Nat. 1905, [iv.] 20, 59), or the breaking of a circuit when a wire connection in the case of metals (Loebe, Zeitsch. Elektrochem. 1907, 13, 592; Shukoff and Kurbatoff, J. Russ. Phys. Chem. Soc. 1907, 39, 1546; Jacquerod and Perrot, Arch. Sci. Phys. Nat. 1905, [iv.] 20, 28), or a bead connection in the case of borax and other glasses (Burgess and Holt, Proc. Roy. Soc. 1904, 74, 285) is broken on fusion, the temperature being ascertained by a thermo-element.

Burgess (Bureau Stand. Washington, 1907, 3, 345) describes an adaptation of the optical pyrometer to the determination of the melting-points of metals.

The melting-points of silicates are determined by Doelter by placing the finely powdered substance upon a small quartz plate heated in an

electric resistance furnace, and observing with a microscope as the temperature is slowly raised (Zeitsch. Elektrochem. 1906, 12, 617).

A general account of melting-point methods at high temperatures is given by White (Amer. J. Sci. 1909, [iv.] 28, 453).

For the official method of determining melting-points in connection with the U.S. Pharmacopœia, *see* Menge (J. Soc. Chem. Ind. 1911, 30, 108).

For a method of determining melting-points by means of electric heating, *see* Malowan (Zeitsch. angew. Chem. 1919, 32, i. 16; Chem. Soc. Abstr. 1919, ii. 135; *cf.* Dana and Foote, Chem. and Mel. Eng. 1920, 22, 63).

The United States Bureau of Standards has published the following table of the melting-points of the chemical elements.

	°C
Helium	<−271
Hydrogen	−259
Neon	−253(?)
Fluorine	−223
Oxygen	−218
Nitrogen	−210
Argon	−188
Krypton	−169
Xenon	−140
Chlorine	−101·5
Mercury	−38·87
Bromine	−7·3
Cæsium	+26

Those elements of which the melting-points are used as standard temperatures are printed in italics.

MELUBRIN. Trade name for mercury salicyl sulphonate.

MENDIPITE. A lead oxychloride $PbCl_2 \cdot 2PbO$ found near Churchill on the Mendip Hills in Somersetshire. Crystallises in yellowish-white rhombic prisms; perfect prismatic cleavage; adamantine lustre, sp.gr. 7·1.

MENHADEN OIL is obtained from the body oil of the 'Menhaden fish' *Alosa menhaden*, Cuv. (*Brevoortia tyrannus*), a fish somewhat larger than a herring. From about May until November this fish appears in enormous quantities off the Atlantic coast of America (especially of New Jersey), so that as much as 400,000 tons of fish are caught in one season.

The fish are delivered from the steamers by means of elevators, on to automatic conveyors, from which they are passed over automatic scales into large boiling pans. These are provided with false bottoms, below which open steam coils are fixed. On boiling the contents of the pan, the fish are disintegrated and the oil separates easily from the flesh. After turning off the steam and allowing the mass to rest, the oil rises to the top and can be easily skimmed off by means of swivel skimmers.

During the last few years, 'boiling' vessels have been introduced which permit of continuous working, the fish being passed on conveyors through the boilers continuously, and exposed to the action of free steam. The time required for the fish to pass lasts from 15 to 20 minutes. The whole mass is then transported by screw conveyors into settling tanks, where the oil separates by gravitation. In either process, the 'fish scrap' falls to the bottom of the vessels, and is then pressed in hydraulic presses, similar to those used in the working up of 'tankage,' when a further quantity of oil, inferior in colour, is obtained. In some works, such pressed cake —termed 'chum'—is boiled out with hot water and pressed once more; but this process being unremunerative, except when the oil is very high

in price, is not carried out in large works. The scrap is finally dried in continuous dryers, of which various types are in use (Anderson dryer, Cummer dryer, vacuum dryers), and is sold as a valuable manure. In fact, the 'scrap' was formerly considered as the main product, and it is owing to the demand for scrap that the fish oil industry has assumed such large dimensions. As the fish contain only from 1 to 16 p.c. of oil —rarely more—processes for its recovery from the scrap by means of solvents are most unlikely to prove remunerative, considering the enormous quantities of fish that must be dealt with.

With the extension of the industry, new uses have been found for the oil, which now not only ranks equal in value to the scrap, but has acquired a much higher price, especially at times when the price of linseed oil is very high.

The colour of menhaden oil varies in the first instance with the state of freshness in which the fish arrives, and in the second instance with the duration of the boiling process. The longer the oil has been allowed to remain in contact with the putrescible mass and the longer the fish has been boiled and hence the longer the oil has been in contact with the gluey water, the darker is its colour. Therefore, the separation of the oil from the gluey water is carried out as rapidly as possible. Fresh fish yield a light-coloured oil; the oil running from the 'scrap' in the presses is the darkest in colour.

In commerce the following three qualities are known: 'Prime crude,' 'Brown strained,' and 'Light strained oil.' Frequently the oils are differentiated into four grades—A, B, C, and D; A being extra pale, B pale, C brown, and D dark brown oil. Since the menhaden oil industry has extended along the Atlantic coast even down to Texas, the trade differentiates also between *northern menhaden oil* and *southern menhaden oil*. The process of refining consists mainly in brightening the oil by filtering, &c.

The light-coloured oils are allowed to rest some time in the cold, whereby 'stearine' separates; thus the 'winter oils' are obtained. They are then bleached by filtering over fuller's earth, &c.; in this manner two grades are obtained, viz. 'bleached winter white' and 'bleached winter' oils.

The sp.gr. of menhaden oil is 0·930 to 0·935. Freshly prepared menhaden oil has an iodine value reaching as high as 200 (Lewkowitsch). Most of the earlier analytical data contained in text-books must be corrected, especially as regards the iodine value, as those samples, the iodine values of which had been recorded, refer to oils which had undergone considerable oxidation on standing. Menhaden oil contains considerable amounts of clupanodonic acid. Thus the author obtained from specimens of pure menhaden oil as high a yield as 40 p.c. of clupanodonic octobromide.

The unsaponifiable matter consists chiefly of cholesterol, to the presence of which the slight optical activity of menhaden oil is due.

The principal use of menhaden oil is in the currying trade, and in the manufacture of sod oil. The oil is also employed in soap-making and for the tempering of steel. When linseed oil is high in price, menhaden oil is used to a considerable extent to adulterate it (to the detriment of the quality of the product) and, further, as a substitute thereof in the manufacture of varnishes, paint oils, and even linoleum. Menhaden oil is also used for adulterating Newfoundland cod-liver oil. J. L.

MENISPERMINE $C_{18}H_{24}O_2N_2$ (?), a crystalline alkaloid from *Anamirta Cocculus* (=*Menispermum Cocculus*), does not appear to have been examined since its discovery by Pelletier and Couerbe (Annalen, 1834, 10, 198).

MENOSAL. Menthyl salicylic methyl ester.

MENTHANTHONES *v.* KETONES.

MENTHENE *v.* CAMPHORS, TERPENES, PEPPERMINT.

MENTHENONE *v.* KETONES.

MENTHOL *v.* CAMPHORS, PEPPERMINT.

MENTHONE *v.* CAMPHORS, PEPPERMINT.

MENTHOSPIRIN. Menthol ester of aspirin.

MENTHYL BORATE (*Estoral*) $BO(C_{10}H_{19})_3$.

MENTHYLETHOXYACETATE (*Coryfin*)

$$C_2H_5\cdot O\cdot CH_2\cdot COOC_{10}H_{19}.$$

MENTHYL ISOVALERATE (*Validol*)

$$C_4H_9\cdot COOC_{10}H_{19}$$

MENTHYL SALICYLATE (*Salimenthol*)

$$C_6H_4(OH)COOC_{10}H_{19}.$$

MERCAPTANS (*Thiols*) are a group of substances derived from sulphuretted hydrogen in the same way as alcohol from water by the replacement of one hydrogen atom by an alkyl group. The mercaptans differ from alcohol in the same way that sulphuretted hydrogen differs from water; thus they have considerably lower boiling-points than the corresponding alcohols. They also possess one hydrogen atom replaceable by metal, but they are more acidic than the alcohols and form mercaptides of the heavy metals. The mercaptans were discovered by Zeise in 1833 (Annalen, 11, 2), and the name is derived from 'mercurio aptum,' owing to the formation of a characteristic mercury salt by the action of ethyl mercaptan on mercury oxide.

Formation.—General methods:

(1) By warming alkyl halides with potassium hydrogen sulphides in concentrated alcoholic solution.

$$R\boxed{X+K}SH=R\cdot SH+KX$$

(where R=alkyl, X=halogen).

(2) By heating alcohols or phenols with phosphorus pentasulphide

$$5ROH+P_2S_5=5R\cdot SH+P_2O_5$$

(3) By distilling a solution of potassium alkyl sulphate with potassium hydrogen sulphide.

$$R\boxed{OSO_3K+K}SH=R\cdot SH+K_2SO_4$$

They are also formed in the reduction of thiocyanic esters, $CNS\cdot R+2H=HCN+HSR$.

(4) By the action of sulphuretted hydrogen on the alcohol vapour at 300°–350° in presence of anhydrous thoria (ThO_2) (Sabatier and Mialhe) *e.g.* $C_2H_5\cdot OH+H_2S=C_2H_5\cdot SH+H_2O$.

Cf. Kramer and Reid, J. Amer. Chem. Soc. 1921, 43, 880.

(5) By reduction of disulphides by dextrose (Claasz. Ber. 1912, 45, 2424).

(6) By treating a mixture of the alcohol, red phosphorus, sodium sulphate and sodium

sulphide with bromine. This method which gives yields of 50–60 p.c. is based on the reactions :

(1) $3R{\cdot}OH+3Br+P=3RBr+H_3PO_3$.
(2) $4H_3PO_3+Na_2SO_4=Na_2S+4H_3PO_4$.
(3) $Na_2S+H_3PO_4=Na_2HPO_4+H_2S$.
(4) $RBr+H_2S=R{\cdot}SH+HBr$.

(Mereshkovski, J. Russ. Phys. Chem. Soc. 1914, 46, 1082.)

Aromatic mercaptans can be obtained by acting on the diazo-aromatic compounds with potassium ethyl xanthate and decomposing the compound thus formed with caustic alkali (Lenhart, J. pr. Chem. [ii.] 41, 179 ; Bourgeois, Rec. trav. chim. 1899, 18, 426) ; by the reduction of the chloride of the sulphonic acid derivative, and by the electrolytic reduction of the thiochlorides or their nitro derivatives in sulphuric acid solution using lead electrodes and keeping the anode liquid at 20° (Fichter and Bernouilli, Ber. 1909, 42, 4308).

Mercaptans of the anthracene series are obtained by heating together the halogenated anthraquinones and the alkali sulphides or hydrosulphides (D. R. P. 204772, 208640 ; Frdl. 1908–10, 20).

Mercaptans of the anthraquinone series are obtained in the following manner : 10 kilos. of anthraquinone-α-thiocyanate are made into a paste with 20 litres of alcohol and boiled under a reflux condenser with 60 litres of a 10 p.c. sodium hydroxide solution until the product forms a clear cherry-red solution in water. Hot water is now added until the whole product is dissolved, and after filtration the mercaptan is precipitated by addition of hydrochloric acid containing a little sulphurous acid (D. R. P. 208640, 1907 ; 212857, 1909 ; J. Soc. Chem. Ind. 1909, 469).

Mercaptans yielding dyes with diazo compounds can be obtained by heating sodium naphthalene-β-sulphonate and a 50 p.c. solution of potassium hydrosulphide for 3 hours at 200°–220° under a pressure of 10–12 atmospheres in an iron vessel. The product is then treated with dilute hydrochloric acid and extracted with ether. The disulphide which remains undissolved can also be converted into the mercaptan by heating with potassium hydrosulphide and alcohol. When benzene sulphonic acid and *m*-disulphonic acid are similarly treated, coloured products having the odour of mercaptans are formed (Schwalbe, Ber. 1906, 39, 3102).

Properties.—The mercaptans are mostly liquids insoluble in water, soluble in alkalis and, particularly the lower, more volatile ones, have a very characteristic disagreeable odour, their smell being indeed a far more delicate test than any of their chemical reactions. Like hydrogen sulphide they are readily oxidised by oxidising agents and even by air, forming disulphides $2R{\cdot}SH+O=RS{\cdot}SR+H_2O$. When oxidised with nitric acid they form sulphonic acids

$$R{\cdot}SH+O_3=RSO_3H$$

Mercaptans condense with nitriles thus :

$$RSH+R'CN=NH : CR'{\cdot}SR$$

Thus by the action of ethylene cyanide on ethylene sulphhydrate, *succiniminodithioethylene ether* $(CH_2C(NH){\cdot}S{\cdot}CH_2)_2$ is formed, the hydrochloride of which is an amorphous dark green powder soluble in water ; the solution dyes wool and silk a bright green, fast to light but turning yellow (owing to the liberation of the free base) when treated with alkalis (Autenrieth and Brüning, Ber. 1903, 36, 3464).

The alkyl mercaptans and their derivatives react in general with acid chlorides to form esters of the corresponding thio acids thus :

$$3RSH+PCl_3=P(SR)_3+3HCl$$

or $(COCl)_2+Pb(SC_6H_5)_2=(CO{\cdot}S{\cdot}C_6H_5)_2+PbCl_2$.

The final products of the reaction, however, depend on the stability of the ester formed, or, if it is unstable, on the manner of its decomposition. When treated with hot potassium hydroxide solution, the stable esters are converted into the mercaptide, whilst with alcoholic potassium hydrosulphide they yield potassium thio salts (Jones and Tasker, Chem. Soc. Trans. 1909, 1904).

With sulphuryl chloride, the mercaptans react thus :

$$8RSH+4SOCl_2=8HCl+2SO_2+3(R{\cdot}S)_2+R_2S_4$$

and $4RSH+SOCl_2=(R{\cdot}S)_2+R_2S_3+H_2O+2HCl$

which reaction preponderates depending on the conditions of the experiment (Jones and Tasker, *l.c.* 1910). The reaction of mercaptans with nitrosyl chloride and with thionylaniline is similar to that with sulphuryl chloride. When nitrosyl chloride is added to a mercaptan, the latter absorbs it, forming a rich cherry-red coloured solution which rapidly evolves nitric oxide and finally loses its colour. In a freezing mixture of solid carbon dioxide in ether, however, hydroxylamine hydrochloride is formed (Jones and Tasker, *l.c.* ; Holmberg, Ber. 1910, 43, 226).

Mercaptans combine with aldehydes in the presence of hydrogen chloride, forming *mercaptals*, $R{\cdot}CH\overline{O+2H}SR'=R{\cdot}CH(SR')_2$ (Baumann, Ber. 1885, 18, 883 ; Blanksma, Rec. trav. chim. 1901, 20, 399). They are insoluble in water, stable in the cold but readily decomposed on warming.

Mercaptans combine with certain sugars in cooled hydrochloric acid solution, forming mercaptals (Fischer, Ber. 1894, 27, 673).

Glucose ethyl mercaptal $C_6H_{12}O_5(SEt)_2$ forms slender colourless needles or thin plates, m.p. 127°–128°, $\alpha_D=-29{\cdot}8°$ at 50°. It has a bitter taste and decomposes on distillation, yielding a product with an odour of roasted onions. A number of other similar mercaptals are described by Fischer.

Similarly, the mercaptans condense with ketones, forming *mercaptoles*

$$R_2C\overline{O+2H}SR'=R_2C{\cdot}(SR')_2+H_2O$$

(Baumann, *l.c.* ; Posner and Fahrenhorst, Ber. 1899, 32, 2749 ; Blanksma, *l.c.*), and the latter, on oxidation, yield disulphones.

The nature and stability of the mercaptoles and disulphones formed by the interaction of ketonic esters and the mercaptans depend both on the nature of the ester and of the mercaptan (Posner, Ber. 1901, 34, 2643).

α-, β-, or γ-Diketones containing both carbonyl groups attached to methyl radicles, readily react with four molecules of a mercaptan yielding dimercaptoles which on oxidation yield tetrasulphones. If, however, one of the carbonyl groups of the diketones is attached to a substituted methyl group, the ketone reacts

with only two molecules of a mercaptan forming a ketomercaptol which on oxidation gives a keto-disulphone. A number of these products are described by Posner (Ber. 1900, 33, 2983).

In the presence of hydrochloric acid, the mercaptans react with unsaturated ketones, forming both addition and condensation products (Posner, Ber. 1902, 35, 799; 1904, 37, 502; *see* also Fasbender, Ber. 20, 460); but if piperidine or sodium ethoxide is employed as catalytic agent instead of hydrogen chloride, only additive products are obtained (Ruhemann, Chem. Soc. Trans. 1905, 17, 461; Proc. Roy. Soc. 1904, 251). The number of mercaptan groups uniting with a diolefinic ketone also depends on the nature of the catalytic agent. The mercaptans also combine with many unsaturated hydrocarbons and acids (Posner, Ber. 1905, 38, 646; *ibid.* 1907, 40, 4788).

According to Stadler (Ber. 1884, 17, 2075), the mercaptans of the aliphatic series react with diazo compounds yielding explosive substances.

Ethyl mercaptan (mercaptan), produced technically by the interaction of ethyl chloride and potassium hydrogen sulphide, is a sparingly soluble liquid with a very disagreeable smell, b.p. 36·2°, sp.gr. 0·83907 at 20°/4° (*v. Ethyl sulphydrate*, art. ETHYL). It may be formed synthetically by passing hydrogen sulphide through a solution of aluminium bromide in ethyl bromide and treating the $AlBr_3{\cdot}EtBr,H_2S$ (snow-white crystals, m.p. 81°) with water (Plotnikov, J. Russ. Phys. Chem. Soc. 1913, 45, 1162). It is also produced by the action of yeast or zymese solution on thioacetaldehyde (Neuberg and Nord). It combines with acetone, forming dimethyl diethyl mercaptole, which when oxidised with potassium permanganate yields diethyl sulphomethyl methane (acetone-diethyl sulphone) $Me_2C(SO_2Et)_2$. The latter crystallises in colourless prisms, m.p. 126°, is sparingly soluble in water and is employed in medicine, under the name 'sulphonal,' as a soporific. Trional $MeEtC(SO_2Et)_2$, m.p. 75°, and tetronal $Et_2C(SO_2Et)_2$, m.p. 85°, are prepared similarly and are also used in medicine (*v.* TETRONAL AND TRIONAL).

Ethyl mercaptan has no action on anthraquinone or phenanthraquinone, but it reacts with quinone forming quinol, quinhydrone, and thioaldehyde and under certain conditions it forms a red crystalline compound in which two hydrogens in the quinone nucleus are substituted by SEt groups (Tarbouriech, Bull. Soc. chim. 1901, [iii.] 25, 313; Sammis, J. Amer. Chem. Soc. 1905, 27, 1120).

Ethyl mercaptophthalimide

$$C_6H_4{<}\begin{matrix}CO\\CO\end{matrix}{>}N(CH_2)_2SH$$

becomes plastic at 76° and melts at 79°–80°. When boiled with 20 p.c. hydrochloric acid it yields phthalic acid and aminomercaptan hydrochloride $NH_2C_2H_4SH,HCl$ (Gabriel, Ber. 1891, 24, 1110, 3098).

Phenyl mercaptan has b.p. 169·5°; *p-tŏlyl mercaptan*, b.p. 195°; *m-tolyl mercaptan*, b.p. 195·5°; and *β-naphthyl mercaptan*, b.p. 288° (Bourgeois, *l.c.*; Autenrieth and Geyer, Ber. 1908, 41, 4256).

p-Tolylaminoanthraquinone mercaptan

$$C_7H_7NHC_{14}H_6O_2SH$$

forms dark blue needles and yields on sulphonation a violet wool dye (D. R. P. 206536, 1909).

Anhydroformaldehyde dimethyl-p-phenylenediamine mercaptan (*5-dimethylamino-2-methyleneaminophenyl mercaptan*) $SHC_6H_3(NMe_2)N:CH_2$ is formed by treating *as*-dimethyl-*p*-phenylenediamine thiosulphonic acid dissolved in aqueous ammonia, with formaldehyde and hydrochloric acid. It rapidly polymerises and is isolated as the ferrocyanide $3C_9H_{12}N_2S,2H_4Fe(CN)_6,5H_2O$. When the freshly prepared mercaptan is treated with sodium nitrite and hydrochloric acid it yields 5-dimethylaminobenzthiazole

$$NMe_2{\cdot}C_6H_5{<}\begin{matrix}N\\S\end{matrix}{>}CH$$

m.p. 73°–74° (Schmidt, Ber. 1906, 39, 2406).

Mercaptothiazoles are prepared by the condensation of α-halogenated ketones with ammonium dithiocarbamate (Miolati, Gazz. chim. ital. 23, i. 575)

Ethyl methyl mercaptothiazolecarboxylate

$$N{<}\begin{matrix}C(SH){\cdot}CO_2Et\\|\\CMe:C\end{matrix}$$

melts at 141°, and is soluble in alcohol and ether but not in water; the free acid has m.p. 211°–212°.

Methylmercaptothiazole melts at 89°–90° and is soluble in organic solvents. *Phenyl mercaptothiazole* melts at 168°.

For a number of mercaptothiazoline derivatives, *see* Hirsch (Ber. 23, 964); Kahan (*ibid.* 1897, 30, 1318); Gabriel and Leupold (*ibid.* 1898, 31, 2837); Jänecke (*ibid.* 1899, 32, 1103); Straus (*ibid.* 1900, 33, 2830).

Mercaptogalactoxazoline

$$N{<}\begin{matrix}CH_2{\cdot}CH(CH{\cdot}OH)_3CH_2{\cdot}OH,\\|\\CSH{\cdot}O\end{matrix}$$

m.p. 185°–186°, is formed by heating galactamine with carbon disulphide. Like the corresponding dextrose derivative it gives a crystalline compound with silver nitrate (Roux, Compt. rend. 1902, 135, 691).

2-*Mecaptoquinazoline* $C_6H_4{<}\begin{matrix}CH:N\\|\\N:C{\cdot}SH\end{matrix}$, is prepared by the action of potassium hydrosulphide on the chloro compound. It crystallises in hexagonal plates, sinters at 225° and melts at 229°–231° (Gabriel, Ber. 1903, 36, 800). Mercapto oxazoline derivatives are described by Maquenne and Roux (Compt. rend. 1902, 134, 1589).

Many other mercaptan derivatives have been prepared (Baumann, Ber. 1885, 18, 891; Jacobson, *ibid.* 1887, 20, 1895; *ibid.* 1888, 21, 2624; Klason, *ibid.* 20, 3409; *ibid.* 28, ref. 942; Freund, *ibid.* 1896, 29, 2483; Brjuchonenko, J. pr. Chem. [ii.] 59, 46, 596; Eibner, Ber. 1901, 34, 657; Freund and Bamberg, *ibid.* 1902, 35, 1753; Posner, *ibid.* 799; de Jong, Rec. trav. chim. 1902, 21, 295; Autenrieth and Geyer, Ber. 1908, 41, 4249, 4256; Pollak, Monatsh. 1914, 35, 1445, 1467; Rennert, Ber. 1915, 48, 459; Pollak and Schadler, Monatsh. 1918, 39, 129; Pollak, von Fielder and Roth, *idem*, 179)

Mercaptides are formed by the action of the metal on the mercaptan (as in the case of the alkali salts) or by the interaction of an alcoholic

solution of the mercaptan with the oxide or acetate of the metal.

Many such crystalline compounds are known. They are mostly decomposed by mineral acids, with liberation of the mercaptan, and react with alkyl halides forming thio ethers, thus:

$$RS|\overline{Na+I}|R' = R{\cdot}S{\cdot}R'$$

(Otto, J. pr. Chem. 1895, [ii.] 51, 285). With ethyl α-chloroacetoacetate they yield alkyl sulphide and ethyl diacetyl succinate:

$$2RSNa + 2ClMeO{\cdot}CHCl{\cdot}CO_2Et = 2NaCl + R_2S_2 + (CHAc{\cdot}CO_2Et)_2$$

(Finger and Hemmeter, J. pr. Chem. 1909, 79, 449). The mercaptides react with mustard oils, forming dithiourethanes:

$$RNCS + R'SNa = R{\cdot}N:CSNa{\cdot}SR' \xrightarrow{HCl} NaCl + RNH{\cdot}CS{\cdot}SR',$$

and this is suggested by Roschdestvensky as a good method of identifying the mercaptans (J. Russ. Phys. Chem. Soc. 1909, 41, 1438).

Mercury mercaptide $(EtS)_2Hg$ crystallises in white leaflets. With mercuric chloride, however, ethyl mercaptan forms a sparingly soluble double salt, $EtS{\cdot}HgCl$. Similar iodide and bromide compounds are also known (*cf.* Rây, Chem. Soc. Trans. 1919, 871.

Mercapturic acids are hydroxycarboxylic acids in which the hydroxyl group is replaced by an SH group (Carius, Annalen 124, 43; Claesson, Ber. 1877, 1346; Friedmann, Beitr. Chem. Physiol. Path. 1903, 4, 486).

Mercaptal acids are obtained by the condensation of aldehydes with thiol acids (Holmberg and Mattisson, Annalen, 1907, 353, 123).

Selenium and tellurium form compounds corresponding with the mercaptans and having a similar offensive smell.

MERCERISING. Mercerising or 'lustreing' consists in impregnating cotton fibres with concentrated caustic soda lye, either with or without the application of tension, and in stretching the material before and during the removal of the soda by means of washing.

John Mercer noticed in 1844 that cotton fabrics, when immersed in concentrated soda lye, became transparent and that a considerable swelling and shrinkage of the fibres occurred. He also found that the soda could be readily removed by washing with water and that the fibres afterwards again became opaque and exhibited increased affinity for a number of dyestuffs. The fact that concentrated caustic soda lye causes the cotton fibre to contract seems, however, to have been known in France at the time when Mercer made his discovery (J. Hübner, J. Soc. Dyers and Col. 1911, 27). The treatment briefly described above was patented by Mercer in 1850. About the same time, he applied his discovery to the 'crimping' of cotton fabrics, by printing stripes upon the fabric with thickened concentrated caustic soda lye, with the result that the portions printed upon became contracted, whilst the parts which had not been acted upon by the soda became drawn together or 'crimped.'

It has been suggested that 'hydrated cellulose' is the result of mercerisation, but although mercerised cellulose contains more water in the air-dry condition than ordinary cellulose, C. G. Schwalbe (Zeitsch. angew. Chem. 20, 2172, 1907) and H. Ost and F. Westhoff (Chem. Zeit. 33, 197, 1907) state that they have not been able to prove that mercerised cellulose contains chemically combined water. It should also be pointed out that the excess of water contained in mercerised cotton can be readily removed by drying (J. F. Copley, J. Soc. Dyers and Col. 24, 72); by the application of heavy pressure after mercerising, whilst the material is still in the wet state (J. Hübner, Eng. Pat. 12455); by extraction with absolute alcohol (J. Hübner and F. Teltscher, J. Soc. Chem. Ind. 1909, 28, 641) and by drying at ordinary temperature over calcium chloride or phosphorus pentoxide.

In 1889, H. A. Lowe observed that if a cotton fabric is prevented from contracting during treatment with concentrated caustic soda lye and subsequent washing it acquires a silk-like lustre (Eng. Pat. 20314). Lowe allowed his patent rights to lapse and in 1895 Thomas and Prevost patented the same process in Germany (Ger. Pat. 85564). This patent was, however, ultimately annulled.

Mercer had already noticed that effects, similar to those obtained by caustic soda, could be produced by the application of sulphuric acid, phosphoric acid, and zinc chloride. Soon after the publication of Thomas and Prevost's patent, a large number of patents of doubtful value were taken out in order to protect the application of various mercerising agents. The fact that a superior lustre could be obtained on the long-stapled Sea Island and Egyptian cottons was also made the subject of a patent (*see* Gardner, Die Mercerisation der Baumwolle).

Knecht (J. Soc. Dyers and Col. 1896, 12, 89) found that cotton could be mercerised by treating it with nitric acid of 83° to 84°Tw., and J. Hübner and W. J. Pope (J. Soc. Chem. Ind. 1903, 22, 70) discovered that saturated solutions of iodides produce a similar effect. A saturated solution of barium-mercuric iodide produces practically the same degree of shrinkage and increased affinity for dyestuffs as concentrated caustic soda lye.

Mercer pointed out that soda lye of as low a strength as 20°Tw., produces a distinct effect on the cotton fibre, and it had been commonly accepted that lyes below this strength exerted practically no action on the fibres. Hübner and Pope (J. Soc. Chem. Ind. 1904, 23, 404), however, found that a lye of only 1°Tw. concentration appreciably increases the affinity of the cotton fibre for the substantive dyestuffs and produces a certain degree of shrinkage. They also showed that the degree of shrinkage is not directly proportionate to the concentration of the lye used, and that maximum shrinkage is produced by a soda lye of about 45°Tw., whilst the shrinkage again decreases if the strength of the lye is increased above 45°Tw.

This supplied an explanation of the fact that cotton yarn and cloth, after treatment under tension with soda lye of 60° to 70°Tw., are frequently torn on the mercerising machine during the first stages of washing.

It had been generally assumed that a mercerising agent, in order to produce lustre on the fibre, must exert a shrinkage and swelling action. Hübner and Pope (*l.c.*) observed that the agent

must also be capable of untwisting the naturally twisted cotton fibre.

This, coupled with the fact that single cotton fibres (Fig. 1) are twisted in parts to the right and in parts to the left, several changes in the direction of the twist being noticeable in a single fibre, affords a rational explanation of the production of lustre in mercerising. As a result of the untwisting of these different twists during mercerisation under tension, during which operation the fibres are firmly held by the twist of the yarn, the original ribbon-like twisted fibre becomes converted into a straight rod, of nearly circular cross-section, which carries on its surface smooth elevations in the shape of rounded

Fig. 1.

ridges, which reflect the light falling on them from any direction (Fig. 2). Maximum lustre can, therefore, only be obtained if the mercerising agent is capable of producing shrinking, swelling, and untwisting of the fibres in a high degree. Waterglass, glycerol, common salt, if added to the caustic soda lye used in mercerising, diminish the extent of the swelling and the shrinking of the fibres, the lustre obtained is, therefore, inferior to that produced by caustic soda alone. Sodium sulphide, nitric acid, and hydrochloric acid, which cause untwisting of the fibre, accompanied, however, with but little shrinking and swelling, give still less lustre, whilst barium-mercuric iodide, which produces maximum swelling and shrinking but no untwisting, produces practically no lustre.

Gladstone (J. Chem. Soc. 1853, 5, 17) suggested that in mercerising a definite chemical compound, 'soda cellulose' $(C_6H_{10}O_5)_2NaOH$, is formed, which decomposes readily on treatment with water. J. Hübner and F. Teltscher (J. Soc. Chem. Ind. 1909, 28, 614) have shown that the existence of such a definite compound is very doubtful and that the amount of soda retained by the cellulose after extraction with absolute alcohol is much smaller than that given by Gladstone.

The dyeing properties of mercerised cellulose have been studied by a number of investigators. R. Haller (Zeitsch. Farb. und Textilchemie, 1907, 8, 125) assumes that the soda lye removes the cutinised layer from the fibres, thus exposing

Fig. 2.

pure cellulose, which is capable of absorbing dyestuffs more readily.

In order to thoroughly mercerise the fibres, the material must be allowed to remain in contact with the soda lye for about ½ to 1 minute. Although it is the practice in some works to allow the material to remain for a considerable time in contact with the soda lye after impregnation, and before stretching and washing, the results obtained are in no way superior to those obtained when working continuously.

Uniform results in mercerising can only be obtained if the soda lye used is kept at uniform strength and temperature. Special refrigerating machines are frequently employed for cooling the soda lye.

Doubled yarns, made of long-stapled Sea Island or Egyptian cotton, give the most

brilliant results in mercerising, but good results can also be obtained on yarns spun from combed American cottons. Single yarns cannot be successfully mercerised on account of the twist being too weak to resist the shrinking of the fibres. The best results in mercerising cotton fabrics are obtained on face cloths, such as sateens, Italian linings, &c. A considerable change in the structure of the fabric takes place during mercerisation (J. Hübner, J. Soc. Dyers and Col. 1911, 27, 128).

The removal of all loose fibres from the surface of the material by careful singeing leads to an increase of the lustre of the mercerised fabric.

Cotton yarn is usually mercerised after it has been boiled in the kier, whilst cotton fabrics are sometimes only scoured before mercerising. More frequently the fabrics are mercerised after the first 'boil' in the kier, or in some cases after they have been bleached ('chemicked'). Cotton in the loose state, as it comes from the bale, cannot be successfully mercerised.

A number of methods have been suggested for mercerising cotton in the state of 'sliver,' but none of these methods has, so far, found any extensive practical application.

No satisfactory lustre can be produced by treating cops or 'cheeses' (cross-wound spools) with caustic soda lye; but cotton yarn in the hank is very largely and successfully mercerised. Automatically working machines are used for this purpose, in which the yarn is stretched, by subjection to tension, over heavy iron rollers, both during impregnation with the lye and during washing.

Cotton warps can be mercerised in a machine resembling the ordinary warp-dyeing machine. The warp is usually impregnated with the soda lye in the first two compartments, while it is washed free from soda in the other compartments. Provision should be made in order to allow each successive set of squeezing rollers to be run at a slightly higher speed. In some cases, warps are mercerised in a machine resembling the 'warp slasher.'

Although a great variety of machines have been invented and used for mercerising cotton piece goods, machines in which the fabric after impregnation is stretched on a 'clip stenter,' are now chiefly employed. A complete mercerising range consists of a padding mangle, the stenter with washing arrangement and the necessary washing, souring, and washing cisterns. In the padding mangle, the cloth is usually twice impregnated with the caustic soda lye and squeezed after each impregnation between cast iron and indiarubber bowls. The trough containing the lye is often provided with an outer cavity to which ice may be supplied or through which refrigerated brine may be circulated in order to keep the lye at a low and uniform temperature. After impregnation, the cloth passes usually directly on to the stenter in which the edges are seized and held by two endless chains of clips, which travel along each side of the stenter. The end of the stenter at which the cloth enters is tapered and thus the fabric is gradually stretched out to its 'grey width,' after which the chains run parallel to the delivery end. While on the stenter the caustic soda is removed by showering hot water on the cloth. The economy of recovery of the caustic being of importance, it is customary, in order to obtain a wash-water containing a high percentage of caustic soda, to conduct the washing on the counter-current principle.

For this purpose three or more sets of spirt pipes are provided, clean hot water being introduced into the first set of pipes, which are placed nearest the delivery end of the machine, whilst the same water is then used successively in the other sets. The cloth is ultimately released from the clips and passed through a number of tanks containing hot water and weak acid and passes finally through a washing machine.

With a view to ensure complete penetration of cotton fabrics when mercerising at a high speed, Mather and Platt have introduced a mercerising plant in which the fabric, after having been impregnated in the mangle, is conducted over a number of iron drums, from which it passes into a second impregnating mangle, before being conducted on to the stentering frame.

Krais has patented an arrangement by means of which the soda lye is forced out of the cloth by blowing steam against it.

In order to enable the soda lye to be used over again, the washwaters are concentrated in multiple-effect evaporators and ultimately treated with caustic lime.

Reactions for the characterisation of mercerised cotton.—Although thoroughly mercerised cotton fibres exhibit very specific microscopic characteristics (see Fig. 2), it is exceedingly difficult in many instances to decide with certainty whether goods have been mercerised or not, because the fibres have frequently only been incompletely penetrated by the soda lye. The following chemical reactions (J. Hübner, J. Soc. Chem. Ind. 1908, 27, 105) may be used in order to ascertain whether cotton has been treated with caustic soda lye.

1. If dark-coloured samples have to be tested, it will be necessary to first discharge the colour and to completely remove any starch which may be present. The sample should then be squeezed between filter-paper and immersed for a few seconds in the following solution: 20 grams iodine dissolved in 100 c.c. of a saturated solution of potassium iodide. If a non-mercerised sample is immersed along with a mercerised one and if, after removal from the iodine solution, both samples are washed repeatedly in water, it will be noticed that the non-mercerised cotton becomes white, whilst the mercerised sample remains of a bluish-black colour, which only fades very slowly on prolonged washing.

2. Two solutions are prepared, (*a*) containing 280 grams of zinc chloride in 300 c.c. of water and (*b*) 1 gram of iodine, 20 grams of potassium iodide, 100 c.c. of water. The reagent is prepared by adding about 10 drops of (*b*) to 100 c.c. of (*a*). A mercerised pattern, immersed in this solution for about 20 minutes, turns a dark reddish-blue, whilst non-mercerised cotton remains practically white.

By immersing samples which have been mercerised with known strengths of caustic soda along with the one under examination, it is possible, by comparing the depth of coloration of the samples, to ascertain, with a certain

degree of accuracy, the strength of caustic soda which has been employed in mercerisation.

J. Hü.

MERCURIC FULMINATE *v.* FULMINIC ACID; also EXPLOSIVES.

MERCURIOCOLOLEO. Double oleate of chlolesterol and mercury.

MERCUROCHRÓME. The disodium salt of dibromoxymercuryfluorescein used as an antiseptic for the genito-urinary tract. Iridescent green scales or granules, odourless and permanent in the air. Freely soluble in water, soluble in dilute alcohol, insoluble in chloroform or ether. Does not precipitate proteins and does not give the usual tests for mercury. Gives with hydrochloric acid an orange-red precipitate. The solution stains the skin red. The free acid is a red powder insoluble in water but readily soluble in sodium hydroxide solution with a deep cherry-red colour showing fluorescence on dilution.

MERCUROL, MERCURIOL, MERCOCHINOL, MERGOL, MERIODIN *v.* SYNTHETIC DRUGS.

MERCUROPHEN. Trade name for oxymercuri-*o*-nitrophenoxide, an odourless, brick-red powder, used as an antiseptic. Has a lower toxicity than mercuric chloride, but is much more active as a germicide.

MERCURY. Quicksilver. (*Mercure*, Fr.; *Quecksilber*, Ger.) Sym. Hg. At.w. 200·63 (Easley and Brann); 200·37 (Taylor and Hulett); 200·57 (Baker and Watson).

Ores. *Native mercury* occurs as a decomposition product of cinnabar in the upper portions of the deposits of that mineral. The mercury is usually disseminated through the ore in the form of minute globules which sometimes collect in cavities in the rock. In California, native mercury disseminated through serpentine or in detritus has been found near the outcrops at the Sonoma mine, Rattlesnake mine, &c., associated with mere traces of cinnabar. At greater depths the ore is always cinnabar alone (Egleston's Metallurgy of Silver, Gold, and Mercury in the United States, ii. 801).

Native amalgam containing about 70 p.c. of silver is found in crystals belonging to the cubic system at Arqueros, near Coquimbo, at Moschellandsberg in the Rhine provinces and elsewhere. Native calomel (*horn mercury*) HgCl occurs at Idria and Almaden, and selenide, sulphoselenide (*onofrite*), and other compounds of mercury have also been found in small quantities in various localities. Oxychlorides of mercury (*terlinguaite*, *eglestonite* and *montroydite*) occur with cinnabar in Texas.

Cinnabar HgS is the only ore which is regularly worked for mercury. It is dimorphous. The red variety, cinnabar proper, occurs in rhombohedral crystals, but is usually found massive or earthy, intermixed with quartz, sandstone, schists, bituminous substances, iron pyrites, &c. It is distinguished by its red colour and scarlet streak. Its hardness is 2·5 and its specific gravity 8·1. When intermixed with bituminous substances which give it a dark colour, it is known as hepatic cinnabar. Cinnabar occurs in eruptive rocks and in sedimentary rocks of all ages. Meta-cinnabarite is a black variety of cinnabar with a black streak It occurs in tetrahedral crystals but is usually massive, associated with cinnabar. Its hardness is 3 and its specific gravity 7·8. (Quicksilver, 1913–1919, Imperial Mineral Resources Bureau.)

The chief deposits are at Almaden in Spain, at Idria in Carniola, at Monte Amiata in Tuscany, and at New Idria, and other localities in California. There are also deposits in Texas, Nevada, Mexico, the Carpathian mountains, Russia, China, Asia Minor, and in other countries.

The famous Almaden mines in Spain were known to Theophrastus, 315 B.C., as furnishing cinnabar to the Greeks, and they were afterwards worked by the Romans. The cinnabar permeates or occurs as pockets in thick veins of quartz inclined at a high angle and contained in Silurian slates (Phillips' Ore Deposits, 374). The ore contains bituminous matter and iron pyrites. Native mercury accumulates in the numerous clefts and cavities in the deposit. The richest ore contains about 25 p.c. of mercury, and the mean yield of the ores, worked in 1918, was 6·5 p.c. (Quicksilver, 1913–1919. Imperial Mineral Resources Bureau).

At Idria the sulphide occurs as a dark red slaty deposit contained in veins or disseminated in triassic shales and limestones. Some hepatic cinnabar occurs and also *korallenerz* or coral ore, which contains calcium phosphate (Phillips, *l.c.* 329; Lipold, Oesterr. Zeitsch. 1882, 30, 84). The mines were discovered in 1490 and have been in the hands of the Government since 1580. The ore varies in grade from *stahlerz*, containing 75 p.c. mercury, down to ores containing 0·2 p.c., the average being about 1·1 p.c.

At Monte Amiata, cinnabar occurs as segregations in Eocene formations. These deposits were exploited by the ancient Etruscans and again in the Middle Ages. The present operations were begun at Siele in 1846. The average amount of quicksilver contained in the ores was 0·8 p.c. in 1908. The output has risen from 173 tons in 1898 to 1303 tons in 1920 (Spirek, Zeitsch. prakt. Geol. 1897, 369; Schnabel and Louis' Metallurgy, 2nd ed. ii. 335; C. de Castro, Le Miniere di Mercurio del Monte Amiata; Quicksilver, 1913–1919).

At Nikitowka, the ore consists of sandstone of carboniferous age impregnated with cinnabar. In 1906, the yield of mercury was only 0·28 p.c. and the production fell from 616 tons of mercury in 1897 to 47 tons in 1908. The deposits were worked by the ancient Greeks, and after a lapse of 2000 years operations were begun again in 1886 (Schnabel and Louis, *l.c.*), but have been trifling in extent since 1912.

In California cinnabar occurs disseminated through a zone of slates, serpentine, sandstones, and limestones of Cretaceous and Jurassic age. Some rich ore occurs, especially where serpentine and sandstone are in contact, but the average yield is now under 0·4 p.c., although it was 36 p.c. in 1850 with a similar output. The deposits were known to the Indians, who used the cinnabar as paint, but the mines were first worked systematically in 1845. The most important mines are New Idria and New Almaden, but the latter now yields very little, being almost exhausted.

Mercury also occurs as a sulphide in ores of other metals. The *mercurial fahlore* (*see* FAHLORE) of Hungary contains up to 17 p.c. of

mercury. At Kotterbach this fahlore occurs in spathic iron ores (Schnabel and Louis, *l.c.* ii. 438). According to Bellingrodt (Chem. Zeit. 1886, 10, 1039), zinc blende roasted at Oberhausen contains 0·2 p.c. of mercury which is extracted as a by-product. Zinc ore is also treated for mercury at the Taghit mine, Algeria (Min. Ind. for 1902, 11, 548). At Nipissing, Cobalt, Ontario, silver ore occurs containing from 2–5 lbs. mercury per ton, chiefly in the form of native amalgam (Eng. and Ming. Jour. Dec. 7, 1912, 1078).

Extraction from ores. There are two methods of extracting mercury from cinnabar suitable for use on a large scale :—

1. By heating cinnabar in air, the action being represented by the equation

$$HgS+O_2=Hg+SO_2$$

2. By heating cinnabar with lime or iron, air being excluded. The chemical action may be represented by the equations

$$4HgS+4CaO=4Hg+3CaS+CaSO_4$$
$$HgS+Fe=Hg+FeS$$

In each of these cases, the temperature necessary for the reaction is higher than the boiling-point of mercury, so that the latter is volatilised and has to be condensed. In the air roasting process, the mercurial vapours are mixed with a large volume of sulphur dioxide, nitrogen, carbon dioxide, and other gases, and condensation is difficult. Nevertheless, the roasting process is now generally used, partly owing to the high cost of retorting with lime or iron, which prohibits the use of that method for poor ores, but mainly on account of the injury to the health of the workmen by the concentrated mercury vapour which they inhale when the retorts are emptied.

Some of the difficulties of treating cinnabar by the roasting process are as follows :—

1. The amount of mercury in the ores is small, sometimes only 0·2 or 0·3 p.c., and part of this is obstinately retained by the residues, necessitating long-continued treatment at a red heat.

2. The mercurial vapours readily penetrate the brickwork of the furnace and condensers. This is checked by keeping the pressure of the gases inside the furnace and condensers slightly below the outside atmospheric pressure by means of a fan placed at the outlet. By this device also the workmen are protected from the mercury vapours. The exhaust must not be excessive or the retention of the mercury in the condensers would not be complete. The furnaces are now always covered with iron plates, so that penetration of the masonry by mercury occasions only a temporary loss.

3. Liquid mercury penetrates the furnace bottoms. According to Spirek, over 1000 centners of mercury have been recovered from the foundations of furnaces at Idria. To prevent ultimate loss, furnaces stand on iron plates with upturned edges, draining to a little sump where the mercury may collect.

4. The gases from the furnace are acid, owing to the presence in them of SO_2 and SO_3. The condensed water accordingly attacks iron condensers, whilst most other metals, such as copper, would form amalgams with the condensed mercury. Stoneware, glass, and wood, as well as iron are used in the construction of condensers.

5. *Stupp* or mercurial soot is formed, consisting of finely divided mercury together with mercury sulphate, and chloride, and sooty products of the fuel and the bituminous and other constituents of the ore. The soot accumulates in the condensers and is treated subsequently by special processes. At Monte Amiata, it contains 70 or 80 p.c. of all the mercury recovered. Although inconvenient if formed in very large quantities, however, soot is useful when amounting to about 1 p.c. of the ore treated, as it assists the condensed mercury (*quicksilver-mist* or *quicksilver-foam*) to settle in the condensers and dust chambers and reduces the vapour loss by forming a dry crust over the liquid quicksilver.

According to Christy (Trans. Amer. Inst. Ming. Eng. 1884, 13, 547 ; 1885, 14, 206), the issuing gases are saturated with mercury vapour at New Almaden, and the loss as vapour can be calculated from the vapour pressure of mercury at the temperature of the gases. According to Spirek, however (Min. Ind. for 1897, 6, 571), the gases at Monte Amiata had a saturation of only 30–45 p.c., owing to the action of the stupp. In any case, it is clear that the temperature and volume of the issuing gases should be kept as low as possible.

The mist loss, due to fine particles of mercury being carried away mechanically in the effluent gases, depends on the method of condensation and the velocity of the gaseous current. It is usually from 2–2½ times the vapour loss.

According to Duschak and Schuette (Ming. and Sci. Press, Sept. 7, 1918, 315 ; Technical Paper No. 209, U.S. Bureau of Mines) the losses in the stack-gas at two mines in California were as follows in grammes of mercury per cubic metre of gas :—

	New Idria		
	Old plant	New plant	Oceanic
Total loss . .	0·029	0·085	0·047
Vapour loss . .	—	0·052	0·034
Mist loss (by diff.) .	—	0·033	0·013

The total losses in the issuing gases were about 1 p.c. of the mercury in the ore at the new condensing plant at New Idria and 1·3 p.c. at the Oceanic. The gas leaving the old condenser system at New Idria was only half saturated with mercury vapour. The loss in the effluent condenser water was about one-third of the loss in the gases at New Idria but was negligible at the Oceanic. The loss due to absorption of mercury by porous materials used in the construction of the condenser system may be much greater than the fume loss.

The total losses of mercury, which, according to Schnabel, formerly amounted to 50 p.c. or more, have now been reduced to 5 p.c. or even less of the mercury present in the ores, in spite of the great fall in the richness of the ores treated. This reduction of loss is partly due to the labours of the metallurgists at Idria since 1870, the names of Exeli, Langer, Czermak, Spirek, Novak, and others being associated with improvements in the methods of treatment. Much progress is also due to the work of the Italians at Monte Amiata, and especially of the Americans (Scott and others) in California.

Ores are not usually finely crushed for the roasting process, and they are seldom prepared for reduction by means of concentration in water. For ten years the ore at the Cornacchino mine, Monte Amiata, was dressed, with the production of a concentrate containing 25 or 30 p.c. of mercury, and tailing assaying from 0·6–1 p.c. of mercury which was thrown on the dump. The tailing was subsequently treated at a profit in the continuous fine ore roasters and concentration has been discarded (Mineral Industry for 1897, 6, 569).

In 1914, however, several concentrating plants were at work in California on ores which were too poor for treatment in furnaces without being dressed previously. W. W. Bradley has shown on an experimental scale (Quicksilver Resources of California, 1917) that certain friable ores with crystalline cinnabar give high recoveries with water concentration on tables. Slimed cinnabar is lost but can be recovered by flotation, using a mixture of turpentine and petroleum. A combination of the two methods of concentration is therefore indicated. Bradley also found that mercury ores could be treated by leaching with alkaline sulphide (Na_2S and NaOH). These methods have not yet passed the experimental stage.

Types of furnaces. A number of different furnaces have been used for the treatment of mercury ore in the course of the last 100 years. In the discontinuous shaft furnace (Aludel and Idria furnaces) the ore in the form of lumps, or fines made into balls, was piled in a shaft on a perforated arch or grate and heated by the products of combustion of a fire placed below. Shaft furnaces working continuously (Exeli, Langer, and Knox furnaces) succeeded, in which there was no grate to support the ore. The heating gases entered the shaft at the side some distance from the bottom. In a more recent type of continuous shaft furnace for treating coarse ore (Hähner, Valalta, Novak, and Spirek furnaces) there is no external fire, the ore being charged in mixed with charcoal.

In fine-ore shelf furnaces (Hüttner and Scott, Livermore, Czermak, and Czermak-Spirek furnaces) the ore passes down over a series of sloping shelves and is heated by the gases from an external fire. These furnaces are more economical than the coarse-ore furnaces and are in wide use. Reverberatory furnaces (Alberti, Exeli ironclad reverberatory, Czermak-Spirek reverberatory) are used in certain cases. Lastly there are the retort furnaces.

A more detailed description of some of these furnaces is appended.

Aludel or Bustamente furnace.—This old-fashioned form of furnace was still in use at Almaden in 1907 and is probably not yet entirely discarded. It is an intermittent shaft furnace, designed by Barba in Peru and introduced into Almaden by Bustamente in 1646. One form of Aludel furnace using wood as fuel is shown in elevation and plan in Figs. 1 and 2, and another and later form with a grate for coal is Figs. 3 and 4. In Fig. 1, *a* is the fire-door, *b* the fire-place, *c* a perforated brick arch above which is the circular distillation chamber, 4 feet 3 inches in diameter in the smaller furnaces, and 6 feet 6 inches in the larger. The ores are first charged in through the opening *d*, which is afterwards bricked up and charging is completed through the door in the top arch. The total height of

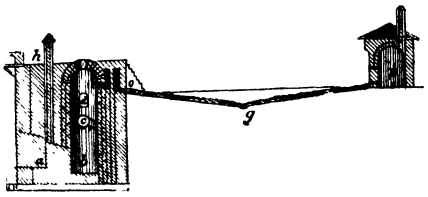

FIG. 1.

the cylindrical shaft is from 20–26 feet. On the arch *c* is placed 2000 kilos. of quartz or of poor ore in large pieces, so that the flames rise through them readily. This is covered with 10–14 tons of ore, beginning with ore of medium quality (*requiebro*, containing from 7–15 p.c. of mercury). Upon this is charged the poorer

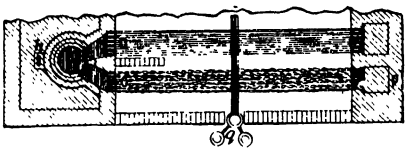

FIG. 2.

ores (*china*, containing about 1 p.c. of mercury), then the rich ore (*metal* containing over 15 p.c. of mercury), and lastly small ore of mixed quality (*vasisco*) made into balls.

The furnace is then closed and the charging doors luted up, and the aludels are luted together in position. These are pear-shaped

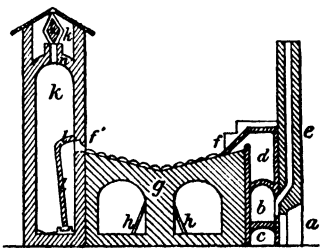

FIG. 3.

clay condensers, 18 inches long, glazed on the outside, and so shaped that the narrow end of each fits into the wider end of the next following one. They are arranged in 12 parallel rows each containing 40–45 aludels, lying in grooves on a sloping roof, *ff*, Figs. 3 and 4. The aludels communicate with condensing chambers *k*,

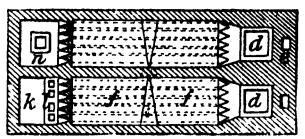

FIG. 4.

Figs. 3 and 4, *p*, Fig. 1. The products of combustion from the fire pass in part through the flue *h*, Fig. 1, *e*, Fig. 3, but mainly through the

bed of ore. The mercurial vapours, sulphur dioxide, and the products of combustion of the fuel pass through the aludels where partial condensation takes place and into the chamber *k*, Figs. 3 and 4, passing below the partition *l*. The condensed mercury in part drains out of the aludels into cast-iron pans situated below (*q*, Fig. 2). In the coal furnace shown in Fig. 3, the mercury drains from the aludels at *g*, through the wooden pipes, *h*, to cisterns filled with water.

The fire is maintained for 10 or 12 hours, thus heating the column of ore sufficiently to enable the cinnabar, pyrites, and bituminous matter to burn in the current of air, which is raised to a temperature of 200°–300° by passing through the layer of quartz before it reaches the ore. The ores burn for 44 hours, a period during which the first aludel reaches a temperature of 245°–260°, and the last aludel one of 29° somewhat later (Kuss, Ann. des Mines, 1877, 13, 39; 1878, 15, 524). The furnace is then opened and the residues allowed to cool for 18 hours, after which they are withdrawn and the furnace recharged.

The aludels are cleaned out once in one or two months, according to position, and the soot collected and prepared for re-treatment. The losses of mercury, according to Langer (Berg. u. Hüttnm. Jahrb. Berg-Akad. 1879) amounted in 1879 to an average of 20 p.c. (*See* also Moreau, Le Génie Civil, 1884, 380; Eng. and Ming. Jour. 1881, 32, 335.)

Idrian furnace.—The aludel furnaces were introduced at Idria about 1750, but were soon altered into the form known as Idrian furnaces, in which the condensing apparatus consists of large brick chambers in place of aludels. These furnaces gave higher percentage losses than aludel furnaces but were worked more cheaply. They were discarded at Idria in 1870. (*See* Schnabel and Louis, *l.c.* ii. 352.) For description of older methods of ore treatment at Idria, *see* Mitter (Vortrag auf dem Bergmannstag zu Klagenfurt, 1893); also Agricola (De re Metallica, Lib. ix. 1556).

Exeli furnace.—The introduction of shaft furnaces fired continuously marked a great advance on the older forms. One of the earliest of these was the Exeli furnace, built at Idria in 1872 (Das K. K. Quecksilber bergwerk Idria in Krain, Vienna, 1881; Schnabel and Louis, *l.c.* 358), and introduced by Randol at New Almaden in 1874 (Egleston, *l.c.* ii. 857). It was surrounded by three external fireplaces and cased in wrought iron to prevent loss of mercury. It was afterwards altered by bricking up the fireplaces and charging charcoal with the ore at the top of the furnace. For the *Langer furnace*, *see* Schnabel and Louis, *l.c.* ii 365, and for the *Knox furnace*, *see* Egleston, *l.c.* ii. 841.

Novak furnace.—This is a good example of a continuously working shaft furnace in which the ore and fuel come into direct contact. It is suitable for coarse ore in cases where charcoal can be obtained cheaply. The earliest shaft furnace of the kind was the Hähner furnace, used at Idria from 1849 to 1852 (Schnabel and Louis, *l.c.* ii. 407). It was replaced by the Valalta furnace (Berg. u. Hüttmn., Ztg. 1864, 284; 1868, 32; Eng. and Mng. Jour. 1872, 14, Nos. 11 and 12). The Novak furnace was introduced at Idria in 1892. One of these furnaces is shown in elevation and plan in Figs. 5 and 6, but three furnaces are united in a single block. The outer walls are cased in iron plates. The shaft *a* is rectangular, 7 metres in height and 2 metres by 2·4 metres in cross section at its widest part. There are four openings, *b*, *b*, for the removal of the residues. The brick shaft stands on a cast-iron plate, *c*, supported by legs and standing on a brick foundation, accessible also from below at *d*. Any loss of mercury in the foundations is

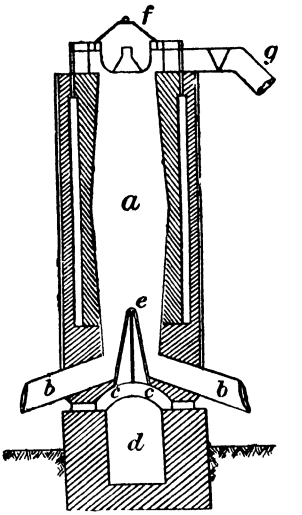

FIG. 5.

thus prevented. The roof-shaped ridge *e*, in the bottom of the furnace, is pierced with many small holes for the supply of air. The charging hopper *f* is fitted with a water-joint and the pipe *g* leads to the condensers. Poor ore in lumps not smaller than 0·67 inch mesh and pressed soot are treated, one ton of ore together with 16 p.c. of its weight of charcoal being charged into the furnace every 2 hours. The condensers are of the usual Czermak type, *see* Fig. 11. The production of soot amounts to 0·5 p.c and the loss of mercury to 7 or 8 p.c. With furnaces of

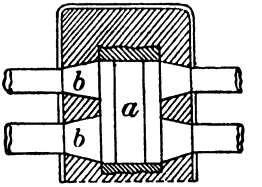

FIG. 6.

this type the formation of soot is much less than in the fine ore furnaces about to be described.

The modern Czermak-Spirek shaft furnaces used at Siele, Monte Amiata, in which the loss is only 2 or 3 p.c. of mercury, are described in the Mineral Industry for 1901, 10, 559. (*See* also Spirek, Sixth Internat. Cong. of Appl. Chem. Rome, 1906.)

Hüttner and Scott furnace (Schnabel and Louis, *l.c.* ii. 372; Egleston, *l.c.* ii. 864). This furnace was introduced at the New Almaden

mines, California, in 1875, and was the earliest of the shelf furnaces, which are especially suitable for treating fine ore. At New Almaden the small ore of less than 1·2 inch cube was called *tierras*, and the larger ore of between 1·2 inch and 2·3 inch cube, was known as *granzitas*. These materials were treated in separate furnaces built on the same principle, with a large number of inclined shelves sloping at an angle of 45° in alternately opposite directions, upon which the fine ore slides down, filling up the spaces between the shelves. The products of combustion of the fire pass horizontally between the under side of the shelves on each tier and the surface of the ore resting on the shelves of the next tier below. The ore is thus heated and roasted, and is finally discharged at the bottom of the furnace.

One of the newer forms of this furnace was built by Newcomb at Oat Hill, California, in 1898 (Mineral Industry, 7, 583). Fig. 7 is a

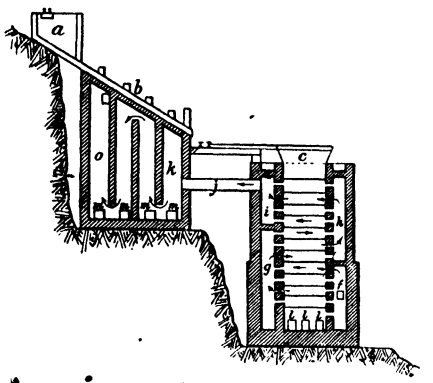

FIG. 7.

vertical section through the furnace and the first section of the condensers; and Fig. 8 is a front view, with the furnace in section and the condensers partly in elevation. Fig. 9 is a horizontal section of the furnace on A, B, Fig. 8.

The ore is passed through 1·5 inch gratings

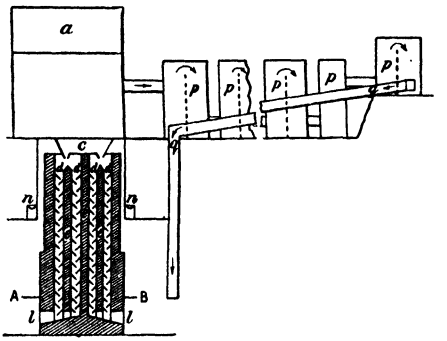

FIG. 8.

before entering the ore-bin *a*, Figs. 7 and 8, whence it passes over a drying platform *b*, placed above the condenser, and is discharged into a hopper, *c*. The hopper is kept full of ore which acts as a seal when a slot is opened and some ore let fall into the furnace. Two tons of ore are thus charged in at intervals of one hour.

The furnace is of brick, 22 feet by 16 feet, and 37 feet high, outside measurements. The roasting chamber is divided into four compartments, *d*, Figs. 8 and 9, by three vertical partitions, *e*, and in each compartment is a series of 24 sloping shelves (*see* Fig. 8) consisting of fire clay tiles which allow the ore to slide down in a zig-zag path. The ore piles up on the shelves bridging over the 6-inch spaces between them, so that the products of combustion from the fire-box, *f*, Figs. 7 and 9, cannot rise vertically in the shaft but pass horizontally under the shelves from *f* to *g*, thence from *g* to *h*, following the course indicated by the arrows, and finally from *h* to *i*, whence they escape by two cast iron exit pipes *j*, to the condenser *k*.

FIG. 9.

The spent ore is discharged by being raked, at intervals of 15 minutes, through the openings *l*, *l*, which are placed 5 feet below the level of the fire-grate, so as to enable the ore to be cooled before it is withdrawn. The furnace holds 40 tons of ore, so that the ore remains under treatment about 20 hours. The fuel used is 2½ cords of wood in 24 hours. The temperature is kept as low as possible, a cherry-red heat being aimed at, and hardly a trace of cinnabar is found in the material discharged.

The condensers are of brick, with cemented floors sloping down to the discharge apertures *m*, *m*, Fig. 7, whence the metal runs to the quicksilver troughs *n*, *n*, Fig. 8. Very little mercury is condensed in the first compartment *k*, but the amount increases up to the last compartment *o* of the first condenser. After this, in passing through the remaining six brick condensers *p*, *p*, Fig. 8, the amount of mercury recovered decreases. The fumes next pass into the wooden flue condenser *q*, Fig. 8, eventually being discharged into the open air through a vertical flue in which an exhaust fan is placed. The length of travel in the condensers is 400 feet. About 30 p.c. of the total yield of mercury is obtained from the soot. The loss of mercury is estimated at about 5 p.c., and the labour required is 4 men per shift with a fifth during the day to attend to the soot-pan.

In California, the Scott furnaces are in general use, the ore being only crushed to 2 or 2½ inches diameter, so that the fine-grinding evil is avoided. Shaft furnaces appear to have been discarded in California, as less advantageous than the shelf furnaces.

Multiple-hearth mechanically-stirred furnaces have also been in use in California, and it is claimed that they are less costly to build and operate. However, they require more skilled labour and more frequent repairs involving delay, and have fallen into disuse. Rotary furnaces of the cement-kiln type were introduced at the New Idria Mine in 1918 and proved highly successful. Wet ores could be treated without being dried, but ores containing a large amount of sulphur or an excessive amount of fines were less amenable in the rotary furnace, and are considered more suitable to the Scott furnaces (Eng. and Mng. Jour. 1919, 107, 86).

Czermak-Spirek continuous roasting furnace

(Mineral Industry for 1897, 6, 572). This furnace is a modification of the Czermak furnace introduced at Idria in 1886 (*see* Schnabel and Louis, *l.c.* ii. 388). It is on the same principle as the Scott furnace, and is similar in being suitable for the treatment of fine ore.

It consists of a rectangular chamber of iron, with two fireplaces, one at each end. The fires are lighted alternately, only one being at work at any given time. The products of combustion pass into a wide flue or combustion chamber extending longitudinally in the middle line of the furnace near its base. Hot air from iron pipes used to cool the ore just before it is discharged is used for combustion, and an excess of air is supplied.

The ore is fed from above upon **V**-shaped tiles, with the apex upward, ranged in parallel lines, in such a way that the apex of each tile is opposite the space between two tiles in the layer next above (*see* Fig. 10). The ore slips

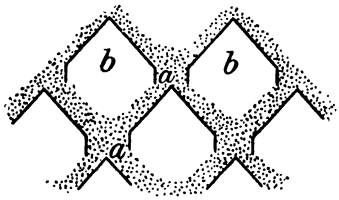

FIG. 10.

down the tiles and completely fills the space *a* between two successive layers of tiles. When part of the residues are withdrawn from the bottom of the furnace, there is a general subsidence of ore extending to the top. There is a regular system of oval openings in the sides of the furnace provided with movable covers, through which iron bars may be introduced to dislodge the sintered ore in case of necessity. The **V**-shaped tiles are supported on longitudinal walls made of perforated bricks.

The products of combustion and hot air from the combustion chamber circulate through the furnace by the passages *b*, between the tiles and the ore and pass out at the top of the furnace through cast-iron pipes into the condensers. The temperatures in the furnace are as follows: ore on discharge, 100°; air supplied for combustion, after being used to cool the roasted ore before it is discharged, 300°–360°; combustion chamber, 800°–900°; in the first tier of tiles of the roasting zone, 700°–800°; in the fourth and highest tier, 360°–400°; in the passage to the condenser, 260°–360°.

The condensers are of the usual Czermak pattern, consisting of cast-iron pipes of elliptical section (*a*, Fig. 11). In positions where the temperature is below 100° so that the acid vapours are condensed, the iron is lined with cement to avoid corrosion of the iron. Glazed stoneware is also used instead of cast iron. These condensers are cooled with water. The lower part *b* of the condensers is sometimes constructed of wood, and dips for about two inches into water contained in lined cast-iron or wooden boxes, *c*. The flue leading from the furnace is shown at *d*. The vapours escape into the wooden flue *e*. The large furnaces have two sets of condensers which can be cleaned alternately without stopping the work of the furnace. From the condensers, the vapours

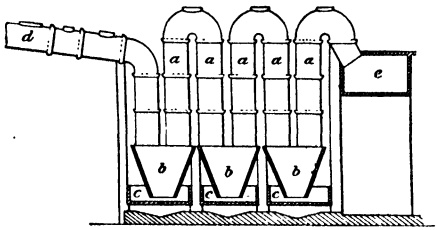

FIG. 11.

pass into flat wooden flues, or dust chambers, in which a poor soot is collected.

The pressure of the vapours within the furnace and condensers is kept below atmospheric pressure by means of a fan which provides an exhaust equivalent, according to Spirek, to a water column of about 4 mm. at the outlet or 1 mm. at the junction between the furnace and the condensers.

The capacity of the furnace depends on the nature of the ore, and in the case of the largest sized furnace at Siele varies from 16–26 tons per day. The ore remains in the furnace from 41–68 hours, and is shifted by the withdrawal of a portion every 2 or 3 hours. The ore is roasted at a bright red heat until the last trace of mercury has been driven off. The condensation is also very good, about 90 p.c. of the mercury and soot collecting in the first 3 **U**-tubes, within a length of 4 metres. The greater part of the metal, and in the case of low-grade ores the whole of it, remains in the soot, and is recovered in part in soot presses, or by rubbing on an inclined surface and in part by redistilling the soot in a small continuous roaster of the same pattern. At Monte Amiata, the average loss of mercury with these roasters is 4 or 5 p.c., after the impregnation of the wooden condensers is completed. Two workmen per shift are sufficient to attend to this furnace, one on the charging floor, the other as fireman.

These furnaces are in use at Monte Amiata, Idria, Almaden, and elsewhere.

Reverberatory furnaces are used for the treatment of fine ore which yields too much flue dust when treated in shelf furnaces, and also for coarse ore which decrepitates or sinters readily.

The first reverberatory was employed by

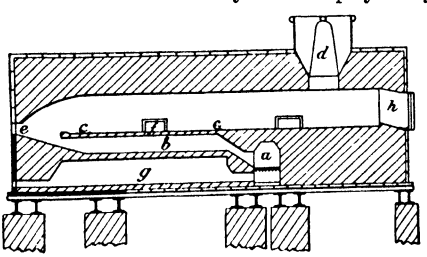

FIG. 12.

Alberti at Idria in 1842, and the latest form is the Czermak-Spirek long-bedded calciner introduced in 1888 and shown in Figs. 12 and 13.

Two furnaces are placed side by side in one block and stand on a dish of riveted sheet-iron. The fire-grate *a* extends across almost the whole width of the furnace. The flame traverses the flue *b* under the bed of the hearth and then passes over the tiled hearth *c*, which is 5½ metres

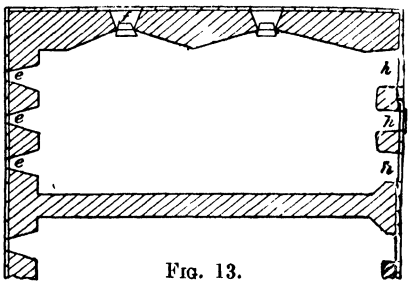

Fig. 13.

long and 2·4 metres wide. The charging hopper is at *d*, and there are five working doors at *e* and *f*. The residues are withdrawn every 2½ hours through the door *f* into the receptacle *g*. The gases and vapours pass through the openings *h* into Czermak condensers of the usual pattern.

These furnaces treat 6·6 tons of poor ore and soot in 24 hours with a consumption of 148 cubic feet of wood per 10 tons of ore. The production of soot amounts to 1·9 p.c. and the loss of mercury to 8 or 9 p.c. (Schnabel and Louis, *l.c.* ii. 402).

For the description of a similar reverberatory furnace designed by Spirek for the treatment of mercury-lead ores, *see* Mineral Industry for 1902, 11, 548.

Retort furnaces were used for a time at Idria, Monte Amiata, and California, but are probably no longer in use in any part of the world except, according to Schnabel, at Littai, in Carniola. The ore is mixed with lime or iron and heated in cast-iron or clay retorts, which are pear-shaped or cylindrical in shape, and usually contain from 1–5 cwt. of ore. The method is suitable only for rich ore or soot, but even for such material the process gives no better results than the air-roasting process, and apart from cost, it has the disadvantage of producing concentrated vapours of mercury which have injurious effects on the workmen.

At Littai (Schnabel and Louis, *l.c.* ii. 421), cast-iron retorts are used, taking a charge of 2 cwt. of ore. The ore contains 2 or 3 p.c. of mercury, and 5 or 6 p.c. of lime is added. The retorting lasts 6 hours and the loss of mercury is stated to amount to from 5–6 p.c.

Soot or *Stupp*, the deposit on the walls of the condensers, consists of finely divided mercury and compounds of mercury, together with carbon, tarry matters, and ash from the fuel and dust from the ore, amounting in all, according to Spirek, to about 1 p.c. of the ore at Monte Amiata. The composition of soot varies largely. One sample from the condenser of a Czermak furnace was found to contain:

Metallic mercury	22·01 p.c.
Mercury as cinnabar . . .	6·75 ,,
Mercury as sulphates, chlorides, &c.	3·04 ,,
Total mercury . .	31·80 ,,

(*See* Schnabel and Louis, *l.c.* ii. 425, where many analyses are given.)

The soot is usually treated mechanically to separate part of the mercury contained in it. It may be worked with hoes on an inclined surface until no more mercury flows off, as at Almaden (Berg u. Hüttnm. Jahrb. der K. K. Montanlehranstalten, 27, 46). When rubbed with lime, more mercury is separated.

At Idria and Monte Amiata, Exeli stupp presses are used. These are iron pans fitted with vertical knives fastened to the bottom. Revolving arms carrying similar knives stir the soot and press it against the stationary knives. Lime is added little by little to the extent of from 17–30 p.c. of the soot during the course of the operation, which occupies one or two hours in the case of rich material. When the soot is stirred and pressed, mercury separates from it and flows away through small openings in the bottom of the pan.

The soot residues after treatment still contain 10 p.c. or more of mercury and are treated mixed with ore in the same furnace as before, or mixed with other rich materials in similar furnaces of small size, or more rarely in retorts. Formerly where coarse ore furnaces were in use, the soot residues were moulded into bricks and treated with the ores.

Purification. Impure mercury is recognised by the fact that globules are pear-shaped with tails, instead of spherical, when made to run down a sloping surface, and may even leave a trail behind them on paper. Mechanical impurities are removed by squeezing through chamois leather or by filtering through punctured blotting paper.

Retorting at a low temperature with a cover of charcoal and lime will remove most of the impurities. Oxidisable impurities are best removed by the passage of a stream of air through the mercury, which is covered with dilute nitric or sulphuric acid. The base metals are rapidly oxidised by the air and dissolved by the acid (*cf.* Harries, Zeitsch. angew. Chem. 1921, 34, 359). Small quantities of impurities may be removed merely by digesting or shaking mercury with dilute nitric acid.

Mercury is kept in a glass or stoneware vessel under a layer of dilute nitric acid of sp.gr 1·1 and drawn off as required by a stopcock at the bottom and washed with water before use.

Properties. Mercury is a silver-white liquid metal with a slight bluish tinge. In thin films it transmits violet light (Melsens). Its sp.gr. at 0° is 13·59545 when compared with water at 4° (Volkmann, Thiesen and Scheel). At −38·85°, (Balfour Stewart), −38·87° (Wilhelm), −38·89° (Henning), it solidifies, contracting considerably and forming a tin-white, soft, malleable and ductile metal of sp.gr. 14·193 at its melting-point (Mallet, Phil. Mag. 1877, [v.] 4, 145). Its density in the liquid state at the same temperature is 13·690 (Vicentini and Omodei). Its electric conductivity is $1·063 \times 10^4$ at 0° (Dewar and Fleming); and its thermal conductivity K at 0° is 0·0148 (H. F. Weber). For thermal expansion *v.* Callendar and Moss, Phil. Trans 1911, 211 A, 1; Chappius, Bureau Int. Poids et Mes. Mem. 1917, 16.

It is volatile at ordinary temperatures and even at −44° (Merget); its b.p. is 357·25° at

760 mm. pressure (Regnault), 356·7° (Heycock and Lamplough), forming a colourless vapour. (For its vapour pressures from 40°–512°, *see* Ramsay and Young, Chem. Soc. Trans. 1886, 49, 37.) According to Brönsted and Hevesy a partial separation of isotopes of mercury may be made by evaporating the metal at low pressures and condensing the evaporated atoms on a cooled surface. The density difference found between the heaviest and lightest mercury amounts to 0·49 p.c., corresponding with a difference of 0·1 unit in the atomic weight (Zeitsch. physikal. Chem. 1921, 99, 189). Its critical temperature is 1172° (abs.), and pressure 180 atm. (van Laar); 1077° and 420 atm. (Ariès, Compt. rend. 1918, 166, 334), 1723° (abs.), and 1042 atm. (Weber).

It is unaltered in air, oxygen, nitrous and nitric oxides, carbon dioxide, &c., at ordinary temperatures. When heated to about 350°, it becomes gradually converted into the red oxide, HgO, which is decomposed below a red heat.

Mercury is not acted on by HCl, and is almost unaffected by dilute H_2SO_4, although dissolved by hot strong H_2SO_4. It is dissolved even by cold dilute HNO_3, and is rapidly attacked by hot or concentrated nitric acid. It is also dissolved by aqua regia.

Neutral and acid solutions of ferric chloride are reduced when shaken with mercury. Under similar conditions titanic acid is not reduced. Solutions of potassium ferricyanide, chromate, ammonium molybdate, sodium vanadate, and potassium antimonate when acidified with hydrochloric acid are reduced on shaking with mercury.

When agitated with oils, turpentine, &c., or triturated with grease, fats, sulphur, certain sulphides, arsenides, &c., mercury is subdivided into minute globules, not easily reunited. This is known as the flouring, sickening, or deadening of mercury and is the cause of losses in the extraction of silver and gold from their ores by amalgamation. The coalescence of floured mercury can be effected with some loss by the action of nitric acid.

Vapours of mercury have a poisonous effect ('salivation') on the animal system. Among the remedies are cleanliness, fresh air, acid foods, and moderation in the use of alcohol. The use of potassium iodide is also recommended.

Uses. Mercury is used in the extraction of gold and silver from their ores, for the manufacture of vermilion (*v. infra*), and of fulminates, in medicine, in dentistry, and in the manufacture of barometers, thermometers, and of other scientific apparatus. The metal and its amalgams are used in small quantities for a variety of other purposes.

The consumption of mercury in silver-milling was formerly very large when the pan amalgamation process was in wide use. In treating the ores of the Comstock lode, for example, 7 lbs. of mercury was formerly lost in the treatment of a ton of ore. In modern stamp-battery practice on gold ores, the loss is only 0·2 or 0·3 oz. of mercury per ton of ore. The development of the cyanide process and the abandonment of the patio and pan amalgamation processes have caused a reduction in the amount of mercury required in the extraction of silver ores. Its consumption in the manufacture of fulminates was very great during the war, and paint for ships' bottoms is also stated to consume large and increasing amounts.

The *production* of mercury during the years 1918–1920 in tons was as follows (*see* Quicksilver, 1913–1919, Imperial Mineral Resources Bureau, 1922):—

	1918	1919	1920
Austria	413	1	1
Hungary	83	—	—
Italy	1021	831	1303
Mexico	161	117	75
Spain	558	1207	848
United States	1101	717	438
China (exports)	289	79	45
Total	3626	2951	2709

Mercury is transported in wrought-iron flasks or bottles closed by screw stoppers. The weight of mercury in a Spanish flask is 34·507 kg. or 76 lbs. It was formerly 76·5 lbs. but in California was reduced to 75 lbs. in 1904. In England the price is quoted per flask of 75 lb. The old sheepskin bag used to contain 55 lbs.

T. K. R.

Mercury sols can be prepared by various methods—mechanical, thermal, and electrical. When mercury is forced in a fine stream into solutions of gelatin and potassium nitrate, definite mercury sols are produced, or when mercury is shaken with very dilute solutions (10^{-5}N) of ammonia, ammonium sulphate, ammonium chloride, calcium citrate, tartaric acid, potassium tartrate or gelatin, or by passing hot mercury vapour directly into water. They have varying colours, from grey to yellowish-brown and reddish-brown (Nordhund, Diss. Upsala, 1918, 1).

Compounds of Mercury.

Mercury forms two series of salts: the *mercuric* compounds, in which the metal is divalent, and the *mercurous* compounds, in which it is apparently monovalent.

The *mercuric salts* are often obtained when excess of acid acts on metallic mercury. Reducing agents convert them into mercurous salts, which may be further reduced to metallic mercury. The soluble salts are extremely poisonous and are acid to litmus.

The *mercurous salts* are produced when an acid acts on excess of mercury, or by the reduction of mercuric compounds. In solution they readily dissociate into metallic mercury and a mercuric salt (Hada, Chem. Soc. Trans. 1896, 1667). This reaction is reversible and ends with the establishment of equilibrium between the mercurous and mercuric ions present (Abel, Zeitsch. anorg. Chem. 1891, 26, 361).

Mercury forms three oxides, *mercurous oxide*, *mercuric oxide*, and *mercuric peroxide*.

Mercurous oxide Hg_2O is obtained as a

[1] The production of Austria is included in that of Italy in 1919 and 1920, as Idria is now in Italian territory.

blackish-brown powder by the addition of alkalis to a solution of mercurous salt, or by triturating a solution of alkali with calomel. It is washed, dried spontaneously, and kept in the dark. By the action of light or of a gentle heat it is decomposed into the red oxide and mercury, and it combines with oxygen at 100° (Colson, Compt. rend. 1899, 128, 1104). It may be obtained in colloidal solution by treating the aqueous solution of mercurous salt with alkali salts of the albinic acids in presence of alkali hydroxide or carbonate (Hofmann, D. R. P. 185599, 1905; J. Soc. Chem. Ind. 1907, 1254).

Mercurous hydroxide does not exist at the ordinary temperature, but is obtained as a bright yellow precipitate by the action of alcoholic potash on alcoholic mercurous nitrate at −42° (Bird, Amer. Chem. J. 8, 826).

Mercuric oxide, *Red oxide of mercury*, *Red precipitate*, HgO. This oxide is slowly produced when the metal is heated in air to near the boiling-point. It may be obtained pure by pouring a boiling solution of mercuric chloride into an excess of boiling potassium carbonate solution and boiling till the precipitate is of the right colour (Dufau, J. Pharm. Chim. 1902, 16, 439). It is usually prepared by heating the nitrate until nitrous fumes cease to be evolved, but not sufficiently to decompose the oxide itself. When prepared slowly on the large scale the oxide is obtained in fine brick-red crystalline plates of sp.gr. 11·163 (Playfair and Joule).

By precipitating a mercuric salt with cold potash, the oxide is obtained as an orange-yellow powder of the same composition, but more easily acted on by reagents. With oxalic acid it produces the oxalate, whilst the crystalline oxide is not so affected. When heated with mercuric chloride solution it rapidly forms an oxychloride; the crystalline form is only slowly so converted. The amorphous oxide is also more easily decomposed by heat. It was formerly considered by many chemists that the red and yellow oxides differed only in the size of the particles (*see e.g.* Ostwald, Zeitsch. physikal. Chem. 1900, 34, 495; Schick, *ibid.* 1902, 42, 155). Schoch, however, has shown (Amer. Chem. J. 29, 319) that the crystalline form of the red is different from that of the yellow oxide, that the dissociation pressure of the yellow oxide at 300° is considerably greater than that of the red oxide, and that when heated at 250° it is converted into the red oxide with partial decomposition.

Mercuric oxide is a powerful poison. It dissolves in about 20,000 parts of water at 25° or about 2200 parts at 100° (Schick, *l.c.*). It is slightly soluble in solutions of sodium hydroxide (Fuseya, J. Amer. Chem. Soc. 1920, 42, 368). When heated it becomes bright red, and finally nearly black, but regains its colour on cooling. A superficial change of colour from bright red to brownish-red is produced when the red oxide is exposed to light. When strongly heated, it is decomposed into mercury and oxygen. By this reaction, oxygen was first prepared by Priestley.

When heated with zinc, tin, or antimony filings, the oxide is reduced to metal with incandescence. When added to fused sodium the action is still more intense. The mixture with sulphur explodes violently when heated. Mixed with phosphorus it detonates when struck. At a red heat it is converted by chlorine into mercuric chloride, with liberation of oxygen. It dissolves in fused potash with formation of a double oxide, without evolution of gas.

Mercuric oxide is frequently used as an oxidising agent in chemical operations.

A colloidal solution of mercuric oxide is obtained when mercuric chloride solution is treated with the sodium salts of protalbinic or lysalbinic acids and caustic soda. A yellow solution is obtained which can be purified by dialysis and then gives on evaporation *in vacuó* at 40° red-brown plates of the stable hydrosol (Paal, Ber. 1902, 35, 2219).

Mercury peroxide HgO_2 is formed in small quantities during the catalytic decomposition of hydrogen peroxide by metallic mercury (Antropoff, Zeitsch. Elektrochem. 1906, 12, 585), and is prepared by the interaction of alcoholic mercuric chloride, hydrogen peroxide, and alcoholic potash (Pellini, Atti. R. Accad. Lincei, 1907, [v.] 16, ii. 408). Either method yields the anhydrous peroxide as an amorphous, brick-red powder, which is fairly stable in dry air. It is slowly decomposed by water, and with acids yields a mercuric salt and hydrogen peroxide: with hydrochloric acid chlorine is liberated.

Mercuric sulphide HgS occurs native as *cinnabar*, which is the principal source of the mercury of commerce. Cinnabar is found, granular or massive, in sub-transparent rhombohedral crystals which cause circular polarisation of transmitted light. It has a cochineal-red colour and gives a scarlet streak.

Mercuric sulphide exists in three different crystalline forms: (1) cinnabar δ-HgS, sp.gr. 8·176, readily prepared by digesting any form of mercuric sulphide with a solution of alkali sulphide; (2) metacinnabarite (black and cubic) α′-HgS, sp.gr. 7·60, precipitated from dilute acid solutions of mercuric salts by sodium thiosulphate; and (3) β′-HgS, sp.gr. 7·20, obtained as a fine crystalline powder from more concentrated neutral solutions of mercuric salts with sodium thiosulphate. Cinnabar is the stable form of mercuric sulphide at all temperatures up to its sublimation point, about 580° (Allen and Crenshaw, Amer. J. Sci. 1912, [iv.] 34, 341). Mercuric sulphide fuses at 1450° in an atmosphere of nitrogen under 120 atm. pressure, forming a matt steel-grey solid which becomes red when rubbed (Tiede and Schleede, Ber. 1920, 53, 1717).

The black sulphide is produced by the action of hydrogen sulphide on solutions of mercuric salts, or by triturating or heating mercury with sulphur. Thus prepared it was formerly used in medicine under the name of *Æthiops mineral.* It occurs native in California (Moore, J. pr. Chem. 1870, [ii.] 2, 319).

Under the name of *vermilion*, the red variety is prepared on the large scale and used as a pigment. Native cinnabar cannot be so used because of impurities which affect the colour. Vermilion is prepared both by *dry* and *wet* processes.

Dry processes.—These all depend on the preparation of the black sulphide, usually by the combination of mercury and sulphur, and its subsequent conversion into the red variety by a process of sublimation. The following

method was formerly largely used in secret in Holland. 1080 lbs. of mercury and 150 lbs. of powdered sifted sulphur are moderately heated in an iron pan with constant stirring, and the black *æthiops* obtained is cooled and powdered. This is introduced in charges of about 25 lbs. four times an hour into long subliming pots of refractory clay, each holding about 410 lbs., heated from below to about two-thirds of their height. As each charge is added it ignites, and a long flame escapes from the pot; when this has subsided, the pot is covered with an iron plate. The operation occupies about 36 hours. The pots are cooled and broken, and the vermilion, which is principally in the upper portions, is ground with water between stones, sifted, elutriated, and dried.

It is said that if 1 part of antimonious sulphide be added to the mixture of sulphur and mercury before sublimation, and the vermilion be digested with potassium sulphide, an improved pigment is obtained which contains no antimony.

At Idria, a mixture of 8 lbs. sulphur and 42 lbs. mercury is placed in a well-bound cask, which is rotated for some hours until the contents consist of a uniform brownish powder.

A number of vertical, cast-iron cylindrical retorts heated to dull redness are charged with the mixture, and immediately covered. When crackling has ceased the covers are replaced by stoneware necks, each connected with a tube and receiver. The fire is then increased to drive the whole of the sulphide from the retort.

When cooled the necks are taken off, and the cake of vermilion removed. That nearest the retort is best, whilst that in the receiver contains free sulphur, and is resublimed with a fresh charge. The cakes are broken, ground with water, boiled with sodium hydroxide solution, washed and dried.

The Chinese vermilion is celebrated for its fine colour, which inclines to carmine. It is said to be prepared as follows:—

About half a bottle (38 lbs.) of mercury and 17½ lbs. of sulphur are mixed in an iron pan, about 25 inches wide and 7 or 8 inches deep, and heated by charcoal. When melted, it is stirred with an iron spatula, and the remainder of the mercury is gradually added. When the metal has disappeared the mass is removed from the fire, cooled by the addition of a little water, rapidly stirred, and coarsely powdered. The reddish or black semicrystalline powder, which contains free mercury and sulphur, is placed in a fixed iron pan, and covered with porcelain tiles 8 inches diameter (many of which are broken), arranged in the shape of a dome. The whole is covered by a pan 4 inches less in diameter than the fixed one, to which it is luted by clay, leaving four holes in the luting for the escape of gases. The charcoal fire is then lighted and kept fiercely burning for 18 hours; blue flames are seen burning round the holes, showing loss of sulphur and of mercury. The fires are then allowed to die out and the pans to cool. Most of the vermilion is found adherent to the porcelain, and is removed. That attached to the iron is inferior, and is made with the other waste into cakes with alum and glue water, dried, and resublimed. The sulphide on the porcelain is blood-red and crystalline. It is powdered and ground with water in a hand-mill between stones, and washed into a vessel. At the close of a day's work a solution of alum and glue (1 ounce of each to 1 gallon of solution) is well stirred with the powder, and the whole is allowed to stand until morning. The glue tends to lengthen the period of deposition, and to render the stratification into the various qualities more perfect. The alum is said to improve the colour. The liquid is decanted, and the upper portions of the deposit are set aside. The lower parts are reground and treated as before, the grinding being sometimes repeated several times. The fine vermilion is stirred in water and settled, and the water is decanted. The residue is dried in the open air, powdered, sifted through muslin, and packed in papers holding about 1⅓ ounce each (*v.* Chem. News, 1884, 50, 77; J. Soc. Chem. Ind. 1882, 1, 195). It is used for making Chinese red-ink—for painting on porcelain and wood and colouring candles and paper. Most of the numerous temples throughout China are painted red, and everything lucky and pleasant among the Chinese is of vermilion colour (J. Soc. Chem. Ind. 1890, 9, 1047).

Wet processes.—The processes most used depend on the action of alkaline sulphides on the amorphous mercury sulphide. The temperature adopted largely influences the colour.

The action of these sulphides is attributed by Ditte (Compt. rend. 98, 1380) to the alternate production and decomposition of a double sulphide of mercury and alkali. In the case of potassium sulphide the compound $K_2S{\cdot}5HgS$ is first produced, and is decomposed at about 45° (the temperature generally employed), with deposition of the *red crystalline* mercuric sulphide, whilst the liberated alkaline sulphide dissolves a further amount of the more readily attacked amorphous sulphide, and again forms the double sulphide, which is again decomposed as before.

In order to prepare a polysulphide free from hyposulphite (which is said to have an injurious effect on the colour), potassium sulphate is converted into sulphide by ignition with carbon. The mass is extracted with water, and boiled with sulphur out of contact with air.

Of this strong solution 2½ kilos. is digested and agitated with 1 kilo. sulphur and 5 kilos. mercury at a gentle heat. The mixture gradually becomes heated, and in about 2 hours acquires a greenish-brown colour. After a further period of 2 hours it becomes of a rich brown, and is allowed to cool to 50°, and is maintained at that temperature for 3 or 4 days with frequent agitation. A fine-coloured vermilion gradually settles down; it is washed with potash, then with dilute nitric acid, and finally with water (Firmenich, Dingl. poly. J. 1864, 172, 370).

According to Liebig, a fine vermilion is produced by immersing recently precipitated *white precipitate* in a solution of ammonium polysulphide. The mixture at first produced is black, but when heated to about 45° gradually acquires a fine colour resembling that of Chinese vermilion. It may be digested with potash, and washed to improve the colour.

Hausmann (Ber. 1874, 7, 1746) adds excess of dilute ammonia to a solution of mercuric chloride, and dissolves the precipitated *mercuric*

ammonium chloride in a slight excess of sodium hyposulphite. On warming to 70° or 80° the vermilion begins to precipitate. The heat is continued until the mass has become pasty, the sulphide is then separated as usual. The above temperature and the presence of the ammonia and ammonium chloride are said to be essential.

One of the best processes is that of Brunner (Pogg. Ann. 1828, 15, 593). A mixture of 100 parts mercury with 38 parts sulphur (flowers) is triturated for some hours, mixed with a solution of 25 parts potash in 150 parts water, and digested at a temperature below 45°, keeping the liquid at constant volume by adding water.

After 2 or 3 hours it becomes brownish, and then gradually brightens. The temperature must be carefully regulated and the volume kept constant, or the precipitate loses its pulverulent character and becomes inferior in colour. At the proper point, usually after about 8 hours, the heating is stopped and the contents are washed as quickly as possible, as the further action of the potash would produce a brown colour. It is lixiviated to separate any black sulphide, and dried.

The method of Gauthier Bouchard is strongly recommended. Concentrated ammonia solution is saturated with sulphuretted hydrogen, and 400 c.c. of the solution is digested in a stone bottle with flowers of sulphur, with production of a solution of ammonium sulphide of sp.gr. 1 034. This is mixed with 200 grams of sulphur and 1000 grams of mercury (as pure as possible), agitated well in a closed vessel for about 7 hours, and finally heated for 3 or 4 hours to 50°. The liquid is decanted and the residue is washed with water, followed by dilute nitric acid and finally by water.

The chief difficulty in all these methods is to free the vermilion from alkaline sulphides and sulphur, the presence of which is detrimental to the colour of the product. Picton and Linder therefore recommend (Eng. Pat. 5120, 1892) that the black sulphide, produced by one of the usual methods, be suspended in water and treated with a stream of hydrogen sulphide gas until it dissolves. This solution is then heated in a closed vessel to 160°–170° for several hours, when a very pure vermilion is deposited.

Vermilion is adulterated with red lead, red ochre, chrome red, red oxide of iron, and frequently with gypsum. These all remain on volatilisation of the vermilion in a glass tube. Dragon's blood, if present, gives a characteristic odour on heating; it also dissolves in alcohol with a red colour. Chinese vermilion usually contains a little glue, which is not, however, an adulteration. Mercuric sulphide is occasionally present in vulcanised caoutchouc (Frank and Jacobsohn, Gummi. Zeit. 1909, 23, 1046).

The sp.gr. of red mercuric sulphide is 8·12; that of the black sulphide is 7·5.

Mercuric sulphide when heated in the air is decomposed with production of the metal and sulphur, which is at once oxidised to sulphur dioxide. With lime, alkaline carbonates, or metals such as iron, copper, and tin, it is reduced with formation of alkaline or metallic sulphide. When heated with litharge both lead and mercury are reduced, the oxygen and sulphur combining, and passing off as sulphur dioxide.

If boiled in water with powdered zinc, metallic mercury is liberated. A similar but slower action occurs with copper.

Concentrated nitric acid has no action except after prolonged heating. It is then converted—especially if freshly precipitated—into a white insoluble compound containing both sulphide and nitrate of mercury. It dissolves easily in *aqua regia* and in cold concentrated hydriodic acid. Barium sulphide readily dissolves it.

The solubility of mercuric sulphide in solutions of alkali sulphides has been investigated by Knox (*v.* Abegg's Handbuch der anorg. Chem. Bd. 2, Abt. 2, s. 633; and Trans. Faraday Soc. 1908, 4, 29). The black sulphide is more soluble than the red sulphide and the amount of each dissolved per mol. of sodium sulphide increases with dilution. The compound Na_2HgS_2 exists in the solution, but when evaporated over sulphuric acid it deposits yellow crystals of the composition

$$2Na_2S,5HgS,3H_2O$$

The solubility of the sulphides in water is very small, $K_{25} = 0{\cdot}01 - 0{\cdot}02 \times 10^{-6}$ (Name, Zeitsch. anorg. Chem. 1904, 39, 108).

Mercuric sulphide can be obtained in colloidal solution by washing the precipitated sulphide with a solution of hydrogen sulphide (Winssinger, Bull. Soc. chim. [ii.] 49, 452; Linder and Picton, Chem. Soc. Trans. 1892, 61, 123; *see* also Picton, *ibid.* 139). By saturating with hydrogen sulphide a solution of 12 grams mercuric cyanide in 100 of water, a deep brown solution is obtained which when dialysed gives an unstable hydrosol. If, however, the hydrocyanic acid is distilled off *in vacuô* an oily stable hydrosol is obtained (Lottermoser, J. pr. Chem. 1907, [ii.] 75, 293).

Mercuric sulphoxychloride $[3(SHgCl),HgO]_2$ a white granular powder obtained by the action of diacetylthiocarbamide, diphenylthiocarbamide, and allylthiocarbimide on aqueous solutions of mercuric chloride (Ray and Sen, Chem. Soc. Trans. 1919, 552).

Mercurous sulphide Hg_2S is not known.

Mercurous chloride, *Calomel* Hg_2Cl_2, occurs native in small quantities as *horn-quicksilver*, crystallising in rhombic prisms. Artificially prepared calomel has been known from early times, and was used in the 16th century as a medicine under the names *Aquila alba*, or *Draco mitigatus*.

Mercurous chloride is formed by the union of its elements.

It may be prepared by addition of an alkaline chloride to a solution of mercurous nitrate or other mercurous salt. The precipitate is washed well to remove the alkaline chloride, which if allowed to remain would render the calomel slightly soluble. It may be prepared on the large scale by mixing 17 parts of corrosive sublimate with a little alcohol or water to prevent the escape of irritating fumes, and rubbing in 13 parts of mercury until *deadened*. The mixture is then sublimed in glass flasks, in the upper portion of which the calomel condenses as a solid, translucent, fibrous cake. The flasks are broken and the cake is removed, ground to a powder, washed repeatedly with boiling water to remove mercuric chloride, and dried. The powder has usually a slight yellowish tinge.

It is also prepared from the sulphate; 1 kilo. of mercury is mixed with 1·5 kilos. of concentrated sulphuric acid in an iron boiler, gently heated until the fumes of sulphur dioxide cease to escape, and evaporated to dryness. It is then mixed with 1 kilo. of mercury and 1½ kilos of common salt until *deadened*, and is sublimed as usual.

Instead of condensing the calomel in a cake, the vapours may be led into chambers containing air or steam, in which it falls as a very fine powder, which requires no grinding. Sometimes the distillation is conducted in an iron tube connected with the condenser.

At Apothecaries' Hall, the proportions used are 62 parts of mercury sulphate, 40½ parts of mercury, and 34 parts of common salts.

The Japanese have long manufactured a very pure calomel, absolutely free from mercuric chloride, called '*keifun*' (light powder). Balls of porous earth and salt, soaked in 'bittern' (mother liquor of concentrated sea-water), are heated in iron pots lined with earth, each containing a little metallic mercury. Hydrochloric acid is formed from the magnesium chloride in the bittern, and the mercury distils into the closely fitting but unattached clay covers of the pots. Air enters by diffusion and the following reaction takes place:

$$4Hg+4HCl+O_2=2Hg_2Cl_2+2H_2O$$

by which calomel is formed at a temperature below its subliming point and fills the cover with a network of micaceous particles (Divers, J. Soc. Chem. Ind. 1894, 13, 108).

In preparing calomel by the wet way, 9 parts of mercury are digested in 8 parts of nitric acid (sp.gr. 1·2) with the aid of heat towards the end, until no more dissolves. The decanted solution is mixed with a boiling solution containing 8 parts of common salt in 64 parts of water and a few drops of hydrochloric acid. The precipitate is *well* washed with water. This form is said to be more effective for medicinal purposes than that prepared in the dry way.

Calomel is also produced by the action of reducing agents upon solutions of mercuric chloride.

Calomel may be obtained in a light voluminous form, which is 3 times as bulky as the samples prepared either by sublimation or by the usual precipitation methods, if the following prodecure is adopted. Three solutions are prepared containing: (1) 11·5 grms. of mercuric chloride and 10 drops of hydrochloric acid in 100 c.c. of water; (2) 6 grms. of sodium bicarbonate and 10 grms. of dextrose in 80 c.c. of water; (3) 7·5 grms. of crystalline magnesium chloride in 20 c.c. of water. Solutions (2) and (3) are mixed and added to (1). After the reaction has finished the mixture is heated on a water-bath until no more carbon dioxide is evolved, and the finely divided precipitate is collected and washed with cold water. In this form the calomel is stated to have much greater germicidal properties when used in prophylactic ointments or antisyphilitic injections than in the form as usually prepared (Duret, Ann. Inst. Pasteur. 1919, 33, 174; J. Soc. Chem. Ind. 1919, 338 A).

Calomel is a white, tasteless powder, of sp.gr. 6·56–7·41, crystallising in four-sided prisms terminating in pyramids. When heated it volatilises without previous fusion, giving a colourless vapour of sp.gr. 8·21 (air=1). This appears to indicate a molecular constitution HgCl, but Smith and Menzies (J. Amer. Chem. Soc. 1910, 32, 1541) have shown by quantitative measurements of vapour pressures that calomel vapour, even when saturated, is completely dissociated into mercury and mercuric chloride, and contains no molecules of the type HgCl or Hg_2Cl_2. The results also show that calomel is soluble in mercury and its molecular weight in that solution at 360°–400° corresponds to the monomolecular formula, HgCl. The boiling-point of calomel is 382·5° (For methods used *v.* S. and M. *ibid.* 32, 1419; *cp.* also Harris and V. Meyer, Ber. 1894, 27, 1482.) Baker states (Chem. Soc. Trans. 1900, 646) that perfectly dry mercurous chloride can be vaporised without dissociation and then has a v.d. corresponding to the formula Hg_2Cl_2. Further, by cryoscopic measurements, Beckmann has shown that mercurous chloride dissolved in fused mercuric chloride has the formula Hg_2Cl_2 (Zeitsch. anorg. Chem. 1907, 55, 175).

By conductivity measurements, the solubility of calomel in water has been found to be about 0·4 mgm. per litre at 20° (Ley and Heimbucher, Zeitsch. Elektrochem. 1904, 10, 301).

By treatment with alkalis and alkaline carbonates it is converted into mercurous oxide; ammonia converts it into 'black precipitate' NH_2Hg_2Cl. By digestion with ammonium chloride it is partially decomposed, mercuric chloride passing into solution and metallic mercury remaining undissolved (Richards and Archibald, Zeitsch. physikal. Chem. 1902, 40, 385). Hydrochloric acid or sodium chloride acts less rapidly. The prolonged action of steam, hot water, or hot air has a similar effect.

Calomel is largely used in medicine. The usual adulterations or impurities are corrosive sublimate, ammonium and sodium chlorides, lead and calcium carbonates and barium sulphate. The last three may be distinguished by their non-volatility, the others by their solubility in water or alcohol. According to Bonnewyn, if the calomel be shaken with a little alcohol the presence of even $\frac{1}{5000}$ part of corrosive sublimate can be detected by the black deposit produced on a knife-blade inserted into the solution.

Mercuric chloride, *Corrosive sublimate* $HgCl_2$. Mercury is converted into this salt when acted on by chlorine or *aqua regia*.

On the large scale it is prepared by distilling mercuric sulphate with common salt. Mercury is gently heated with concentrated sulphuric acid in an iron boiler until sulphur dioxide ceases to be evolved. The whole of the metal having dissolved, a slight excess of sulphuric acid is added to ensure the absence of mercurous sulphate, and a portion is tested by the addition of sodium chloride. If a precipitate of calomel falls, more acid is added. The mixture is evaporated and thoroughly dried. 20 parts of the sulphate is mixed intimately with 8 parts of sodium chloride and 1 part of manganese dioxide (to minimise the production of calomel) and introduced into glass subliming pots which are placed on iron plates, surrounded by sand to the necks and gently heated to remove moisture,

which passes, through hoods placed over the necks, into a flue.

The moisture being removed, the hoods are replaced by small inverted conical condensers. Sufficient sand is then removed to uncover the upper half of the flasks, and the heat is increased until the whole has sublimed. The heat is finally raised sufficiently to render the sublimate coherent, but not to melt it. When cooled, the upper half of the flask is cracked away and the cake of sublimate is removed. On the lower part of the cake is frequently found a small quantity of the less volatile *calomel*; this is removed and added to a subsequent sublimation.

Wagner (Dingl. poly. J. 186. 135) recommends for the preparation on the large scale the decomposition of *turpeth mineral* (*v. Mercuric sulphate*) with hydrochloric acid. Mercuric chloride is thus obtained in a solution of sulphuric acid containing excess of mercuric oxide and is removed by crystallisation:

$$HgSO_4 \cdot 2HgO + 2HCl = HgCl_2 + H_2SO_4 + 2HgO$$

For the crude salt, he precipitates mercuric oxide by the addition of sodium hydroxide to mercuric nitrate and digests the precipitate with crude magnesium chloride (the mother-liquor from *carnallite*). Where the presence of potassium chloride is not injurious the carnallite itself may be used, in which case the crystals obtained on evaporation contain $KCl,HgCl_2,H_2O$.

Mercuric chloride occurs as a white, satiny, translucent mass, sp.gr. 5·403; or, when crystallised from solutions, as needles or four-sided prisms, belonging to the rhombic system (Mitscherlich, Pogg. Ann. 1833, 28, 118; Luczizky, Zeitsch. Kryst. Min. 1909, 46, 297). It fuses at 288° (Carnelley) and boils at 303° (Carnelley and Williams), giving a vapour of sp.gr. 9·8, corresponding to the normal molecular weight. The vapour condenses in triclinic crystals (Von Lang, Wien. Akad. Ber. 1862, 45, 119). The relations between the vapour pressures and the molecular volumes of the mercuric halides have been examined by Prideaux (Chem. Soc. Trans. 1910, 97, 2032).

100 parts of water dissolve at 10° 6·57 parts, and at 100° 53·96 parts of the salt. The solution is acid to test paper and gradually deposits calomel on exposure to light. Mercuric chloride is soluble in 3 parts of cold alcohol and in about 1·2 parts of boiling alcohol. It is soluble in 4 parts of cold ether and can be extracted from aqueous solution by this solvent. In aqueous solution, mercuric chloride undergoes electrolytic dissociation only to a very slight degree (Grotrian, Wied. Annalen, 1883, 18, 177; Luther, Zeitsch. physikal. Chem. 1904, 47, 107), but it is partially hydrolysed (Ley, Ber. 1897, 30. 2192). Sulphuric acid precipitates it from aqueous solution (Viard, Compt. rend. 1902, 135, 242), but it dissolves in the strong acid and in nitric acid without decomposition. Aqueous solutions of mercuric chloride decompose in the dark to form mercuric oxide, chlorine, and hydrochloric acid, or in the light to form only mercurous chloride and the acid (Verda, Chem. Zentr. 1907, i. 1392). Mercuric chloride is volatile with steam and the salt can be recognised in the vapour from its solutions by chemical tests, or by its action on a photographic plate (Kof and Haehn, Arch. Pharm. 1907, 245, 529; Zeitsch. physikal. Chem. 1907, 60, 367). The dry salt or its solution is easily reduced, first to calomel, and finally to metallic mercury, by arsenic, zinc, tin, &c.; or by stannous chloride, oxalic acid, hydrazine sulphate, or other reducing agents (*v. e.g.* de Coninck and Dautry, Bull. Acad. roy. Belg. 1908, 55).

Corrosive sublimate has a sharp, metallic taste, and is extremely poisonous. The best antidotes are egg-white, with which it forms an insoluble compound, or, in order of efficacy, sodium thiosulphate ('hypo'), hydrogen sulphide, sodium iodide, sodium bromide, and sodium chloride (Raimondi, Chem. Zentr. 1907, ii. 1807). It is used in medicine both internally and externally, especially in cases of syphilis, and in surgery as an antiseptic in the form of dilute solutions (usually 1 : 100) and in gauzes and lint. (For the estimation of mercuric chloride in surgical dressing-materials, *see* Utz, Pharm. Post. 39, 785.) It is also used in preserving anatomical specimens and samples of milk, syrups, &c., for analysis.

Mercuric chloride forms numerous double salts and additive compounds. With the alkali chlorides it forms the compounds $KCl \cdot HgCl_2,H_2O$;

$$2KCl \cdot HgCl_2,H_2O; \quad KCl \cdot 2HgCl_2,2H_2O$$

$2NaCl \cdot HgCl_2$; $NaCl \cdot HgCl_2,2H_2O$, and many others. Of the double salts with ammonium chloride only $HgCl_2 \cdot 2NH_4Cl,H_2O$ can be crystallised from water, but others are formed (Meerburgh, Zeitsch. anorg. Chem. 1908, 59, 136). To the formation of such compounds is due the increased solubility of mercuric chloride in solutions of alkali chlorides and in hydrochloric acid. In many cases, these solutions contain complex anions in which mercury is present (*v.* Shenill, Zeitsch. physikal. Chem. 1903, 43, 705). It forms additive compounds with hydrocarbons, alcohols, and ketones, aromatic nitro derivatives (Mascarelli, Atti. R. Accad. Lincei, 1908, [v.] 17, i. 29), and with alkaloids. The latter compounds are frequently used in the purification of the alkaloids.

A series of *mercury oxychlorides* can be obtained from mercuric chloride by boiling its solution with mercuric oxide or by the action of potassium hydrogen carbonate or calcium carbonate upon it (Tarugi, Gazz. chim. ital. 1901, 31, ii. 313; Arctowski, Zeitsch. anorg. Chem. 1896, 12, 353; Driot, Compt. rend. 1911, 152, 958). $2HgCl_2 \cdot HgO$ crystallises in red monoclinic needles; $HgCl_2 \cdot HgO$ amorphous yellow powder; $HgCl_2 \cdot 2HgO$ is a black crystalline precipitate, and $HgCl_2 \cdot 3HgO$ occurs in glistening yellow scales as the mineral *kleinite* (Sachs, Sitzungsber. K. Akad. Wiss. Berlin, 1905, 1091). Hewitt states that when caustic soda solution diffuses into a solution of mercuric chloride and sodium chloride, very dark red crystals of the formula $Hg_6O_5Cl_2$ are produced (Chem. Soc. Proc. 1907, 23, 10; *v.* also Buttle and Hewitt, Chem. Soc. Trans. 1908, 93, 1405).

Mercurous bromide Hg_2Br_2 is obtained as a white precipitate by adding a soluble bromide to a solution of a mercurous salt, or by the prolonged action of bromine water on the metal. It crystallises from mercurous nitrate solution in white, pearly, tetragonal leaflets. sp.gr. 7·037, and is nearly insoluble in water. At 340°–350° it sublimes without decomposition.

Mercuric bromide $HgBr_2$ is formed from its elements with evolution of heat (Nernst, Zeitsch. physikal. Chem. 1888, 2, 29; Varet, Compt. rend. 120, 620), and is produced by dissolving mercuric oxide in hydrobromic acid. Cold water dissolves 0·4 p.c. and boiling water 2·5 p.c. of the salt, and on cooling it crystallises out in anhydrous glistening scales. From alcohol it crystallises in white rhombic prisms. Mercuric bromide melts at 244° (Carnelly and Williams, Chem. Soc. Trans. 1880, 127) (235° is given for m.p. by Guinchant, Compt. rend. 1909, 149, 479). Like the chloride it is decomposed by boiling with water, *oxybromides* being formed (Fischer and Wartenburgh, Chem. Zeit. 1902, 26, 966).

It is occasionally administered in medicine instead of mercuric chloride, usually by hypodermic injection of a solution of the soluble compounds with sodium chloride $HgBr_2 \cdot 2NaCl$ or bromide $HgBr_2 \cdot 2NaBr$ (Vicario, J. Pharm. Chim. 1907, [vi.] 26).

A double bromide of mercury and potassium has been used as a disinfectant (Cooke, Eng. Pat. 1530, 1905).

Mercurous iodide Hg_2I_2 is a green insoluble powder employed medicinally. It is prepared by triturating a mixture of 5 parts iodine and 8 parts mercury, moistened with alcohol; or by precipitation of a mercurous salt with potassium iodide. A purer product, obtained by boiling excess of iodine with a solution of mercurous nitrate containing nitric acid, crystallises in transparent, yellow, tetragonal plates, blackened by light. When heated it becomes first yellow, then red and finally garnet-red, and on cooling passes through the same colour changes in reverse order. It begins to sublime at about 190° and at 290° melts with decomposition (Stroman, Ber. 1887, 20, 2818; François, J. Pharm. Chim. 1899, [vi.] 10, 16; Compt. rend. 1895, 121, 888; 1896, 122, 190). It dissolves slightly in various oils. The best solvent is castor oil, of which 100 parts dissolves 2 parts of the iodide.

Mercuric iodide HgI_2. A mixture of 5 parts iodine and 4 parts mercury is moistened with a little alcohol, triturated, and sublimed. Dublanc pours 1 kilo. of alcohol upon 100 grams of mercury and adds 124 grams of iodine in 10 successive portions, triturating each time until the alcohol becomes colourless. The last 4 grams usually produce a permanent colour. The precipitate is then washed with alcohol and dried.

In the wet way, which is the best, a solution of 10 parts potassium iodide is added to a solution of 8 parts mercuric chloride, and the precipitate, which is salmon-coloured at first but soon becomes red and crystalline, is washed. A slight excess of either the chloride or iodide will redissolve a portion of the precipitate.

Mercuric iodide may be obtained in comparatively large crystals by the action of a mercuric salt on ethyl or methyl iodides (Bodroux, Compt. rend. 130, 1622); by the action of these iodides on the metal a very pure product may be obtained (Neogi, Chem. Soc. Abstr. 1907, ii. 772).

Mercuric iodide is dimorphous, existing in a red and a yellow form. The *red* variety is produced by the above methods of preparation. It crystallises from hot potassium iodide, alcohol, or nitric acid in tetragonal prisms and pyramids (Luczizky, Zeitsch. Kryst. Min. 1909, 46, 297), and is soluble in many organic solvents (Beckmann and Stock, Zeitsch. physikal. Chem. 1895, 17, 130). Its sp.gr. is 6·26. When heated to 127° it changes into the *yellow* modification with absorption of heat (Guinchant, Compt. rend. 1907, 145, 68). If further heated it remains yellow up to 190°, but slowly becomes red again, the colour deepening continuously between 180° and 255·5° when it melts (Rodwell, Phil. Trans. 1882, 173, 1125; Smits and Bokhorst, Zeitsch. physikal. Chem. 1915, 89, 365). Observations made with large crystals of yellow mercuric iodide show that the gradual development of the orange colour with rise of temperature is not accompanied by any change in crystalline form. This fact points to the formation of mixed rhombic crystals containing both yellow and red modifications. There are apparently two isomeric forms of mercuric iodide (α and β), the red and yellow modifications being mixed crystals containing the two forms in different proportions (Smits, Proc. K. Akad. Wetensch, Amsterdam, 1917, 19, 703). The yellow form volatilises without decomposition, the vapour density corresponding to the formula HgI_2. By cooling the liquid or condensing the vapour (Gernez, Compt. rend. 1899, 128, 1516), the yellow modification is obtained in rhombic prisms of sp.gr. 6·06 which retain their form and colour when cooled to the ordinary temperature, but slowly (or immediately on rubbing) pass into the red variety. Nevertheless the yellow form may be kept at the ordinary temperature for many years (Gernez, Compt. rend. 1909, 148, 1015), and it separates from nearly all organic solvents in this form, though it is only stable above 126° (Kastle and Clark, Amer. Chem. J. 1899, 22, 473; Kastle and Reed, *ibid.* 1902, 27, 209; Gernez, Compt. rend. 1903, 136, 889; 129·5° Reinders, Zeitsch. physikal. Chem. 1900, 32, 507). If mercuric iodide is heated at about 300°–500° in a long glass tube connected with a vessel in which the pressure can suddenly be decreased from 1 to $\frac{1}{10}$th atmosphere it condenses as *colourless* snow which becomes pink and ultimately red (Tamman, Zeitsch. anorg. Chem. 1920, 109, 213). 1 litre of absolute alcohol at 18° dissolves 11·18 grams of the salt; 80 p.c. alcohol dissolves only 2·86 grams. It is almost insoluble in water; 1 litre at 17·5° dissolves 0·0403 gram (Bourgoin, Bull. Soc. chim. [ii.] 42, 620).

In potassium or other alkaline iodide, it dissolves freely with formation of a double iodide.

The solution in potassium iodide is a more powerful antiseptic than mercuric chloride. It has been employed in the preparation of an antiseptic soap (Thomson, J. Soc. Chem. Ind. 1888, 192). An alkaline solution of mercuric iodide in potassium iodide is employed as a delicate test for ammonia and its compounds, being known as *Nessler's solution*.

In mercuric chloride it dissolves readily, forming a double chloride and iodide.

Mercuric iodide forms a very large number of double salts (*v.* Duboin, Ann. Chim. Phys. 1909, [viii.] 16, 258). With alkali iodides and ether it forms both crystalline and liquid compounds, *e.g.* $KHgI_3 \cdot 3Et_2O$, and $KHgI_3 \cdot 4Et_2O$ (Marsh. Chem. Soc. Trans. 1910. 2297).

Mercuric iodide is much used in photography as an intensifier, a solution in sodium sulphite containing the proportions, $HgI_2 : Na_2SO_3$: water : : 1 : 10 : 100, being the best. For details *see* Lumière Bros. and Seyewetz (Monit. Scient. 1899, 13, 782; J. Soc. Chem. Ind. 1899, 1155).

Mercurous fluoride Hg_2F_2, produced by the action of hydrofluoric acid on the carbonate or of silver fluoride on calomel (Finkener, Pogg. Ann. 110, 142), is a yellow crystalline powder, hydrolysed by hot water and blackened by light.

Mercuric fluoride $HgF_2,2H_2O$, prepared by dissolving mercuric oxide in aqueous hydrofluoric acid (Finkener, Pogg. Ann. 110, 628) is a white crystalline salt. It is decomposed in air at 50° forming an *oxyfluoride* HgF(OH); and in dilute aqueous solution is completely hydrolysed, but without formation of oxyfluorides (Jaeger, Zeitsch. anorg. Chem. 1901, 27, 22; Cox, *ibid.* 1904, 40, 146).

Anhydrous mercuric fluoride may be prepared by heating mercurous fluoride in dry chlorine at 275°, or in dry bromine at 400°, or by heating mercurous fluoride at 450° under 10 mm. pressure. Transparent octahedral crystals, m.p. 645°, b.p. 650° (estimated). On exposure to air hydrogen fluoride is evolved and mercuric oxyfluoride and ultimately mercuric oxide are formed.

Mercuric chlorofluoride Hg_2ClF, a pale yellow substance, formed by passing dry chlorine over mercurous fluoride at 120° (Ruff and Bahlau, Ber. 1918, 51, 1752).

Mercurous sulphate $Hg_2(SO_4)_2$ is prepared by dissolving 2 parts mercury in 3 parts sulphuric acid with the aid of a gentle heat; or by the addition of sulphuric acid to a solution of mercurous nitrate; or by the electrolysis of sulphuric acid with a mercury anode (Hulett, Zeitsch. physikal. Chem. 1904, 49, 494). It is a white crystalline salt which with water yields first the basic salt $Hg_2SO_4 \cdot Hg_2O,H_2O$, and finally the oxide.

Mercurous sulphate is used in the standard cells of Clark and Weston.

Mercuric sulphate $HgSO_4$ is prepared by dissolving mercury in strong sulphuric acid with the aid of heat, or mercuric oxide in dilute sulphuric acid. Its preparation has been described under *Mercuric chloride*.

From its solution in sulphuric acid it crystallises in small, silvery, stellate plates. When strongly heated, it becomes reduced to mercurous sulphate with evolution of oxygen, mercury, and sulphur dioxide.

It is soluble in sodium chloride solution. When heated with water it produces a yellow basic sulphate $HgSO_4 \cdot 2HgO$, which turns red when heated, known as *turpeth* or *turbith mineral*, which is soluble in 2000 parts of cold and 600 parts of hot water. Turpeth appears to be the only basic sulphate which can exist in equilibrium with water at 25° (Cox, Zeitsch. anorg. Chem. 1904, 40, 165; Hoitsema, Zeitsch. physikal. Chem. 1895, 17, 651: Guinchant, Bull. Soc. chim. 1896, [iii.] 15, 555). A thiobasic mercuric sulphate, $4HgO \cdot 2HgS \cdot 3SO_3,4H_2O$, has been described by Estrup (Zeitsch. anorg. Chem. 1909, 62, 168).

Nitrates. Several nitrates of mercury are known. When excess of mercury is dissolved in a cold mixture of 1 part nitric acid and 4 parts water, the *mercurous* salt is formed. If the acid be sufficiently strong to effervesce, or be used in excess, or if the mixture be heated, *mercuric* nitrate is produced.

Mercurous nitrate $Hg_2(NO_3)_2$ forms monoclinic tables containing 2 molecules of water. They effloresce and become anhydrous in dry air and when heated to 70° melt to a clear liquid of sp.gr. 4·3 (Retgers, Jahrb. Min.-1896, ii. 183). The pure salt is immediately decomposed by water with formation of a basic nitrate, and when it is boiled with water mercury is volatilised and may be condensed in globules (Hada, Chem. Soc Trans. 1896, 1667). Several basic nitrates are known (*v.* Cox, Zeitsch. anorg. Chem. 1904, 40, 174).

Mercuric nitrate $Hg(NO_3)_2$ is produced by boiling mercury with nitric acid until the solution no longer gives a precipitate with sodium chloride. Large crystals containing

$$2Hg(NO_3)_2,H_2O$$

separate on concentration.

The action of water at 25° on mercuric nitrate produces a basic salt, $Hg(NO_3)_2 \cdot 2HgO$, as a heavy white powder, which is decomposed on further treatment with water yielding the oxide (Cox, Zeitsch. anorg. Chem. 1904, 40, 159).

Mercurous nitrite $Hg_2(NO_2)_2$ is produced by the action of dilute nitric acid upon mercury and forms yellow needles which are partially decomposed by water. Dilute nitric acid slowly converts it into mercurous nitrate, and when heated it decomposes yielding nitric oxide, mercurous nitrate, mercury, and mercuric oxide (Rây, Zeitsch. anorg. Chem. 1896, 12, 365; Chem. Soc. Trans. 1897, 337; Rây and Sen, *ibid.* 1903, 491). The pure salt has sp.gr. 5·925 (Rây, Chem. Soc. Trans. 1908, 999).

Mercuric nitrite $Hg(NO_2)_2$ is obtained by the action of mercuric chloride on silver nitrite or by the decomposition of mercurous nitrate by water (Rây, Chem. Soc. Proc. 20, 57; Chem. Soc. Trans. 1897, 71, 337).

Mercuric hyponitrite HgN_2O_2, formed by the action of sodium hyponitrite on mercuric nitrite, is a buff-coloured powder which decomposes spontaneously into nitric oxide and mercurous hyponitrite (Divers, Chem. Soc. Trans. 1899, 119; *see also* Rây, *ibid.* 1907, 1404, 2031; Rây and Gañguli, *ibid.* 1399).

Mercury nitride N_2Hg_3 is produced as a brown powder by the action of potassamide on mercuric bromide in liquid ammonia solution. When dry it is very explosive (*v.* Franklin, Zeitsch. anorg. Chem. 1905, 46, 1).

Mercury acetylide (*mercury carbide*)

$$ClHg\,HC : CHCl$$

prepared by passing acetylene into a solution of mercuric oxide in ammonium hydrate and carbonate, is a heavy white powder, which is explosive (*v.* Plimpton and Travers, Chem. Soc. Trans. 1894, 264). For the action of acetylene on solutions of mercuric chloride and acetate, *see* Burkard and Travers (Chem. Soc. Trans. 1902, 81, 1271); Biltz and Mumm (Ber. 1904, 37, 4417), and Brame (Chem. Soc. Trans. 1905, 427). Chapman and Jenkins (*idem.* 1919, 115, 847). An acetylide containing twice the amount of acetylene, and having the constitution

$$CHCl : CH \cdot Hg \cdot CH : CHCl$$

has been prepared by Jenkins (Chem. Soc. Trans 1921, 119, 747).

Mercuric cyanide $Hg(CN)_2$ is prepared by boiling a solution of 1 part potassium ferrocyanide and 2 parts mercuric sulphate in 7 parts water:

$$2K_4Fe(CN)_6+7HgSO_4 = 6Hg(CN)_2+4K_2SO_4+Fe_2(SO_4)_3+Hg$$

It may also be prepared by adding 31 grams sodium cyanide dissolved in 50 c.c. water to 90 grams mercuric sulphate. Heat is evolved and the whole solidifies to a mass of granular mercuric cyanide which is extracted with boiling alcohol and finally recrystallised from water (Rupp and Goy, Apoth. Zeit. 1908, 23, 374).

It crystallises in white needles or tetragonal prisms soluble in 8 parts of cold water, insoluble in absolute alcohol. When ignited, it decomposes with evolution of cyanogen.

In aqueous solution mercuric cyanide only undergoes ionic dissociation to a very small extent, and therefore does not exhibit all the usual reactions of mercuric salts. For example, with potassium iodide it yields, not mercuric iodide, but a complex salt $Hg(CN)_2{\cdot}HgI_2{\cdot}2KCN$ (Rupp and Goy, Arch. Pharm. 1909, 247, 100). It is decomposed with formation of hydrocyanic acid by hydrochloric, hydrobromic, and hydriodic acids, or by sulphuretted hydrogen, but not by dilute sulphuric or nitric acids.

The aqueous solution readily dissolves mercuric oxide forming the basic salt $Hg(CN)_2{\cdot}HgO$, which is used as an antiseptic under the name of *mercuric oxycyanide* (Holdermann, Arch. Pharm. 1905, 243, 600; 1906, 244, 133; Rupp, *ibid.* 1906, 244, 1; Jones, Pharm. J. 1920, 105, 87). The pure salt is dangerous to handle and may occasion explosions.

Mercuric thiocyanate $Hg(CNS)_2$ is prepared by the addition of an excess of mercuric chloride to a solution of ammonium thiocyanate. It forms a white crystalline precipitate which burns freely when ignited with evolution of mercurial vapours, and forms a most voluminous ash.

It is occasionally made into a thick paste with gum and worked into pilules which when dried are sold as *Pharaoh's serpent's eggs*.

It is soluble in a solution of ammonium thiocyanate, and this solution, under the trade-name 'Agfa,' is used as an intensifier for photographic negatives (Eberhard, Photo. Mittheil, 1901, 38, 15; J. Soc. Chem. Ind. 1901, 387).

Ammoniacal Compounds of Mercury.

Very many of these compounds have been described, but little is known as to their constitution because the ordinary methods for the determination of molecular weight are not applicable to them.

It is probable that there exist substitution products of ammonia of the type $(OHg_2)NH_2{\cdot}X'$ (*amino-mercuric compounds*); substitution products of ammonium compounds of the type

$$NHg_2X'{\cdot}H_2O$$

mercuri-ammonium compounds); and additive compounds of ammonia and mercuric salts. (*See* Rammelsberg, J. pr. Chem. 1888 [ii.] 38, 558; Barfoed, *ibid.* 1889, [ii.] 39, 201; Pesci, Gazz. chim. ital. 1891, 21, 569; Zeitsch. anorg. Chem. 1899, 21, 301; *see also* Hofmann and Marburg, Annalen, 1899, 305, 198; Zeitsch. anorg. Chem. 1900, 23, 126; Franklin, J. Amer. Chem. Soc. 1907, 29, 35).

Millon's base has the empirical formula $H_5O_3NHg_2$, and is regarded as *dihydroxydimercuriammonium hydroxide* $(HO{\cdot}Hg)_2:NH_2{\cdot}OH$, or as dimercuriammonium hydroxide

$$NHg_2{\cdot}OH{\cdot}2H_2O$$

It is formed as a pale yellow powder when mercuric oxide is gently warmed with dilute ammonia. It deflagrates when heated.

Salts of Millon's base are formed by digesting the base with dilute acids, or by adding ammonia to solutions of mercuric salts of oxyacids. Anhydrous salts of the formula NHg_2X' have been obtained but are probably not true derivatives of Millon's base, but amino compounds of the type $Hg:N{\cdot}HgX'$ (Franklin, Zeitsch. anorg. Chem. 1905, 46, 1; *see also* François, Compt. rend. 1900, 130, 332, and 1022).

The iodide of Millon's base $(OHg)_2NH_2{\cdot}I$ (*oxydimercuriammonium iodide*) is formed by adding ammonia to a solution of mercuric potassium iodide (Nessler's solution, *v.* Analysis), or by the action of excess of ammonia on mercuric iodide. It is a brown powder, fusible without decomposition.

Amino-mercuric chloride, *Infusible white precipitate* $H_2N{\cdot}HgCl$ (Hofmann and Marburg; Franklin; Saha and Choudhury, Zeitsch. anorg. Chem. 1914, 86, 225), is prepared by the addition of ammonia to a solution of mercuric chloride. For medicinal purposes 1 ounce of mercuric chloride is dissolved in 3 quarts of water, and to the cool solution 8 fluid ounces of concentrated ammonia is added with frequent agitation, and the precipitate is washed and dried.

It is a white, inodorous, highly poisonous powder, totally volatile on heating to 360°, slightly soluble in boiling water, easily soluble in nitric, hydrochloric and sulphuric acids, insoluble in alcohol.

An analogous compound derived from ethylamine, $NH(C_2H_5)HgCl$, is known.

By digesting infusible white precipitate with nearly saturated solutions of ammonium chloride containing varying amounts of mercuric chloride, compounds of the formula $3HgCl_2{\cdot}2NH_3$ or of $HgCl_2{\cdot}2NH_3$ separate out. By using solutions nearly saturated with mercuric chloride and adding variable small amounts of ammonium chloride $HgCl_2{\cdot}NH_2{\cdot}HgCl$ is formed (Strömholm) (Holmes, Chem. Soc. Trans. 1918, 113, 74).

Fusible white precipitate $Hg(NH_3)_2Cl_2$ is produced by boiling the above compound with ammonium chloride solution, and form crusts of small regular dodecahedra.

Mercury Salts of Organic Acids.

Mercurous formate $Hg_2(HCO_2)_2$, obtained by adding sodium formate to mercurous nitrate solution, forms white leaflets soluble in 250 parts of water at 17°. When boiled with water it is reduced to metallic mercury (Liebig, Annalen, 3, 207).

Mercuric formate $Hg(HCO_2)_2$, obtained by solution of yellow mercuric oxide in dilute formic acid, slowly changes to mercurous formate with liberation of formic acid and carbon dioxide (Varet, Compt. rend. 1905, 140, 1641).

Mercurous acetate $Hg_2(CH_3{\cdot}CO_2)_2$ forms white leaflets, more stable than the formate, soluble in 133 parts of water at 12°–15° (Lefort, Annalen, 56, 247).

Mercuric acetate $Hg(CH_3{\cdot}CO_2)_2$ also forms white leaflets soluble in 2·75 parts of water at 19° and in 1 part at 100°. The aqueous solution is acid, and on warming, the salt is largely hydrolysed. Both these salts are used in medicine for the treatment of skin diseases.

Mercuric benzoate is obtained by precipitation from sodium benzoate and a mercuric salt; it cannot be recrystallised from water, as it is very slightly soluble, and undergoes partial hydrolysis.

Mercuric oleate and **stearate**, prepared by double decomposition, are used in pharmacy (Dott, Chemist and Druggist, 1909, 74, 785).

Mercurous oxalate $Hg_2C_2O_4$ is a white salt, very slightly soluble in water, insoluble in excess of oxalate (Schäfer and Abegg, Zeitsch. anorg. Chem. 1905, 45, 299). It has been used in gelatin emulsions for phototype printing (Castellani, Phot. Korr. 1906, 43, 281; J. Soc. Chem. Ind. 1906, 827).

Mercuric oxalate HgC_2O_4 is also sparingly soluble in water, but forms soluble double salts with many oxalates. In solution it is quantitatively reduced to mercurous oxalate by the action of light (Roloff, Zeitsch. physikal. Chem. 1894, 13, 324). This reaction is made use of in *Eder's mercury oxalate photometer* (*v.* Abegg, Zeitsch. Elektrochem. 1903, 9, 569). The sensitiveness of the solution to light is increased by the fluoresceins and their sodium salts (Jodlbauer and Tappeiner, Ber. 1905, 38, 2602).

Mercuric fulminate $(C:N{\cdot}O)_2Hg,\frac{1}{2}H_2O$ is prepared by adding 17 parts of alcohol (90 p.c.) to a cold solution of 3 parts of mercury in 36 parts of nitric acid (sp.gr. 1·34), contained in a large flask. The mixture froths and turns black, and a very violent reaction takes place which is moderated by the addition of another 17 parts of alcohol. On the large scale the reaction is carried out by mixing in large glass balloons 1 part of mercury, 10 parts of nitric acid (sp.gr. 1·33), and alcohol (sp.gr. 0·833) in the proportion of 1 litre to each kilo. of acid. The reaction generally begins spontaneously and is allowed to proceed by itself (Beckmann, Ber. 1886, 19, 993; Lobry de Bruyn, *ibid.* 1370) (*v.* FULMINIC ACID).

On cooling the solution produced by either method, mercuric fulminate crystallises in shining white or grey-coloured prisms, sp.gr. 4·42. It is insoluble in cold water, but fairly soluble in hot water and in aqueous ammonia (*v.* Steiner, Ber. 1876, 9, 779).

Pure mercury fulminate is unacted upon by potassium permanganate, and the presence and amount of unsaturated impurities in the salt may be determined by its behaviour towards permanganate (Rathsburg, Ber. 1821, 54 [B], 3185).

Mercuric fulminate explodes violently on percussion or when treated with sulphuric acid, and is much used as a detonator (*v.* EXPLOSIVES); but when ignited with a flame it burns with a reddish flame yielding carbon monoxide, nitrogen, and mercury.

Mercuric Azide HgN_6 may be obtained by mixing concentrated solutions of sodium azide and mercuric nitrate, when mercuric azide is precipitated as a powdery mass which can be purified by solution and crystallisation. It is highly explosive. Although it has the same molecular weight as mercuric fulminate and develops the same volume of gas on detonation, its 'brisance' is twenty to thirty times as great (*cf.* Stettbacher, Zeitsch. ges. Schiess. u. Sprengstoffw. 1920, 15, 211). *See* EXPLOSIVES.

Mercury gallate, prepared by triturating 37·6 grams gallic acid and 21·6 grams yellow mercuric oxide in 25 c.c. of water, is used therapeutically as an antisyphilitic (Brousse and Gay, Compt. rend. 1893, 117, 284).

Mercury tannate is prepared by triturating mercurous nitrate (20 grams) with tannin (12 grams), and is also used in medicine (Zdarek, J. Pharm. d'Anvers, 58, 98).

Mercuric *p*-phenolsulphonate is used medicinally under the name '*hydrargyrol*,' and its compound with ammonium tartrate is similarly used and known as '*asterol*.'

ORGANIC MERCURY DERIVATIVES.

Mercury can replace hydrogen in most organic compounds, and the substances so formed fall into two broad classes: (*a*) those in which mercury is attached to carbon, and (*b*) those in which it is attached directly to nitrogen. Generally, compounds of class (*a*) are non-electrolytes and in general chemical properties resemble the parent compounds. Compounds of class (*b*) are usually less stable and in solution show the reactions of the mercuric ion.

Mercury Derivatives of Aliphatic Compounds.

Mercury alkyl derivatives are of two classes:

(1) Monalkyl derivatives

$$X{\cdot}Hg{\cdot}C_nH_{2n+1}(X=Cl,Br,I,\text{ etc.})$$

(2) Dialkyl derivatives $Hg(C_nH_{2n+1})_2$.

(1) *Monalkyl mercury compounds* are prepared:

(*a*) By the action of mercury on alkyl iodides in sunlight.

(*b*) By the action of halogens, haloid acids, or mercury halides on the dialkyl derivatives.

The halogen compounds are usually colourless crystalline solids, which have a definite melting-point and can be sublimed and distilled in steam. Treated with moist silver oxide they yield hydroxy compounds which are thick liquids, soluble in water and alcohol, strongly basic in character and forming series of salts.

Methyl mercuric iodide $CH_3{\cdot}HgI$, forms colourless crystals, m.p. 143°, which sublime when heated (Frankland, Annalen, 85, 361).

Ethyl mercuric chloride $C_2H_5{\cdot}HgCl$ forms pearly leaflets, sp.gr. 3·48, subliming at 40° (Dünhaupt, Annalen, 92, 379; *see also* Buckton *ibid.* 112, 221).

Ethyl mercuric hydroxide $C_2H_5{\cdot}HgOH$, produced by the action of moist silver oxide on the preceding compound, is a viscous caustic liquid which gives rise to a number of salts.

(2) *Mercury dialkyls* are prepared:

(*a*) By the action of sodium amalgam on alkyl iodides in presence of ethyl acetate (Frankland, Annalen, 130, 105).

(*b*) By the action of potassium cyanide on mercury alkyl iodides.

(c) By treating zinc alkyls with mercuric chloride or an alkyl mercuric chloride (*v. also* Buckton, *ibid.* 108, 103).

They are colourless heavy liquids, unchanged by air or water at the ordinary temperature. They have a peculiar faint odour, and are extremely poisonous (*v.* Hepp, Ber. 1887, Ref. 798). When heated in air they burn.

Mercury dimethyl $Hg(CH_3)_2$ has b.p. 93°–96° and sp.gr. 3·07. Hydrochloric acid converts it into mercuric chloride (Seidel, J. pr. Chem. [ii.] 29, 134).

Mercury diethyl $Hg(C_2H_5)_2$ has b.p. 159°, sp.gr. 2·44. Mixed mercury alkyls of the type $CH_3{\cdot}Hg{\cdot}C_2H_5$, have not been obtained (Frankland, Annalen, 111, 57; Buckton, *ibid.* 109, 222).

(For an account of the many known aliphatic compounds containing mercury, *see* Beilstein's Handbuch der Org. Chem. Bd. i. 1524–1526; suppl. i. 854).

Mercuriethylene-diamine sulphate

$$Hg(CH_2{\cdot}NH_2)_2{\cdot}H_2SO_4$$

mixed with a molecular proportion of ethylene diamine is used as an antiseptic under the trade name '*sublamin.*' It does not precipitate soap, or coagulate albumen, and has a greater germicidal and a less toxic action, weight for weight, than mercuric chloride (Scordo, Chem. Soc. Abstr. 1907, ii. 713; Pesci, Gazz. chim. ital. 1909, 39, i. 143).

Mercury Derivatives of Aromatic Compounds.

Aryl mercuric compounds are formed with an ease comparable with that of sulphonation or nitration and the metal enters the usual position in the molecule (except in the case of benzoic acid, *v.i.*). They are usually prepared by boiling the aryl compounds with mercuric chloride solution. When acted on by stannous chloride in alkaline solution they yield mercury and mercury aryls of the type HgR_2 (Dimroth, Chem. Zentr. 1901, i. 449).

Mercury diphenyl $Hg(C_6H_5)_2$ is prepared by heating bromobenzene, mercuric chloride, and metallic sodium in benzene (Michaelis and Reese, Ber. 1882, 2876); or by heating bromobenzene with an equal volume of xylene, a little ethyl acetate and excess of sodium amalgam (Aronheim, Annalen, 194, 145). It is also obtained by the action of mercuric chloride on an ethereal solution of magnesium phenylbromide (Pfeiffer and Truskier, Ber. 1904, 37, 1125). It crystallises from benzene in white needles or rhombic prisms, m.p. 125°–126°, is easily volatile and gives a vapour irritating to the eyes. Mercury diphenyl has a therapeutic action equal to that of the fatty compounds, but it is less poisonous (Louise and Moutier, Compt. rend. 1905, 140, 1703).

Phenyl-mercuric chloride $C_6H_5{\cdot}HgCl$, made by the action of chlorine on mercury diphenyl, forms small white rhombic prisms, m.p. 250° (Dreher and Otto, Annalen, 154, 93).

Phenyl-mercuric hydroxide $C_6H_5{\cdot}HgOH$ is a strongly caustic liquid and forms numerous salts (Otto, Ber. 1885, 246).

Mercury di-tolyls, di-xylyls, di-naphthyls, &c., are known, and each forms similar series of compounds.

o- and *p-Hydroxyphenyl mercurioxides* and *hydroxy-phenylene-dimercuryoxides* are present in the so-called '**mercury phenate,**' the *hydrargyrum carbolicum*—of the pharmacopœias (Dimroth, Ber. 1902, 35, 2853). This is obtained by precipitating a solution of mercuric chloride with sodium phenate (Merck, Apoth. Zeit. 1889, 4, 651; Andres, Pharm. Zeitsch. Russe, 27, 625), and is used medicinally in the treatment of syphilis.

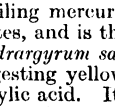
o-Hydroxymercuribenzoic anhydride

$$C_6H_4{<}\begin{matrix}Hg\\CO\end{matrix}{>}O$$

is the chief constituent of the '**mercury benzoate**' used medicinally. It is prepared by digesting freshly precipitated mercuric oxide with benzoic acid and water and is formed by the action of dilute acids on the salts of *o-hydroxymercuribenzoic acid* $C_6H_4{<}\begin{matrix}Hg{\cdot}OH\\CO{\cdot}OH\end{matrix}$.

o-Mercuridibenzoic acid $Hg:(C_6H_4{\cdot}COOH)_2$ is also known (Pesci, Atti. R. Accad. Lincei, [v] 10, i. 413).

Anhydro-o-hydroxymercurisalicylic acid



is produced by boiling mercury salicylate with water for 15 minutes, and is therefore the main constituent of '*hydrargyrum salicylicum,*' which is prepared by digesting yellow mercuric oxide with aqueous salicylic acid. It is much used in the treatment of syphilis (Buroni, Gazz. chim. ital. 32, ii. 307; Dimroth, Ber. 35, 2872; *see also* Larin, Chem. Zeit. Rep. 1901, 25, 193).

(For further details of mercury aromatic compounds and a complete bibliography, *v.* Beilstein, Handbuch der Org. Chem. Bd. iv. 1703–1713; suppl. iv. 1208–1218.

MERGAL. Trade name for a combination of mercury cholate and albumin tannate.

MERIODIN. *Meriodin* is a trade name for mercury diiodo-para-phenolsulphonate; it is also known as '**mercury sozoiodol.**' It is a caustic, and has been used as an antisyphilitic. It is an orange-yellow powder, soluble in sodium chloride solution, but insoluble in water or alcohol. It is employed in parasitic and syphilitic skin diseases, and as a dusting powder in intertrigo, leg ulcers, &c. '*Anogon,* a mixed mercurous and mercuric compound of diiodophenol sulphonic acid ('Sozoiodol'), is also called Meriodin.'

MERLUSAN. Trade name for a mercury compound of tyrosine.

MEROCHINOL. Trade name for mercury hydroxyquinoline sulphonate.

MESCAL BUTTONS *v.* MEZCALINE.

MESITITE. A member of the calcite group of minerals intermediate in composition between magnesite and chalybite. Rather than having the definite molecular composition $2MgCO_3{\cdot}FeCO_3$ assigned to it by Breithaupt, it is an isomorphous mixture of 50–70 p.c. $MgCO_3$ and 50–30 p.c. $FeCO_3$, grading on the one side through breunnerite into magnesite, and on the other through pistomesite and sideroplesite into chalybite. Sp.gr. 3·3–3·45. It occurs as well-developed pale yellow, rhombohedral crystals in the iron mines at Traversella in Piedmont, and as sparry

masses in the Styrian magnesite (breunnerite) deposits. L. J. S.

MESITOL *v.* PHENOL AND ITS HOMOLOGUES.

MESITYLENE *v.* CUMENES.

MESORCINOL *v.* PHENOL AND ITS HOMOLOGUES.

MESOTAN. Trade name for a yellowish oily liquid, $OH{\cdot}C_6H_4{\cdot}CO{\cdot}OCH_2{\cdot}OCH_3$, obtained by treating sodium salicylate with monochlordimethyl ether (*v.* SYNTHETIC DRUGS).

MESO-THORIUM *v.* RADIOACTIVITY and THORIUM.

MESOXALDIALDEHYDE *v.* KETONES.

MESOXALIC ACID *v.* KETONES.

META-ARABIC ACID *v.* GUMS.

METACETONE. By heating sugar with lime Fremy obtained a substance, b.p. 84°, to which he gave the name *metacetone* and the formula $C_6H_{10}O$. Fischer and Laycock find that this body is in reality a mixture of *propylaldehyde*, *dimethylfurfuran*, a third substance with the properties of a hydrocarbon, and a number of other lower and higher boiling homologues. Fischer and Laycock distilled 100 kilos. of sugar and 300 kilos. of burnt lime, and collected the distillate in fractions. Fraction *a*, distilling below 65°, combined partly with phenylhydrazine, yielding the phenylhydrazone of propylaldehyde. The distillate boiling at 25°–45°, consisted of furfuran, and that boiling at 45°–65° is probably methylfurfuran. Fraction *b*, distilling at 65°–115°, was treated like fraction *a*, phenylhydrazine being added, and the product distilled. The distillate consisted of a hydrocarbon and a substance which dissolved on heating with dilute hydrochloric acid to 170°, forming acetonylacetone, and which is probably dimethylfurfuran. The residue, which combined with phenylhydrazine is the phenylhydrazone of propylaldehyde. The fraction boiling above 115° is a complex mixture, consisting of higher homologues of furfuran and aldehydes, which could be removed with sodium bisulphite.

Fischer and Laycock have investigated wood tar, and found that this likewise contains propylaldehyde and dimethylfurfuran (Ber. 1889, 22, 101).

METACETONIC ACID *v.* PROPIONIC ACID.

METAHEWETTITE *v.* HEWETTITE.

METALDEHYDE *v.* ALDEHYDE.

METALLIC SOAPS *v.* SOAPS.

METALLOGRAPHY deals with the internal structure and constitution of metals and their alloys. The science is a comparatively young one, dating back only to 1864, when Sorby (Proc. Sheffield Lit. Phil. Soc. 1864) first applied the microscope to the study of metals and established the close analogy which exists between the internal structure of metals and of rocks. Sorby's pioneer work, however, remained neglected for a long time, and the microscopic study of metals and alloys was revived independently in Germany by Martens (A. Martens, Zeitsch. Ver. deut. Ing. 1878, 22, 11) and in France by Osmond (F. Osmond and J. Werth, Compt. rend. 1885, 100, 450). Since then the subject has developed rapidly, and now numbers many enthusiastic workers, among whom may be mentioned in England the late Roberts-Austen, Arnold and Stead; in France Osmond, Le Chatelier, Charpy, and Guillet; and in Germany Heyn, Wüst, Friedrich, and Tammann.

The metallographic study of metals and alloys is carried out by both microscopical and physical means, the most important of the latter being the thermal or pyrometric study of the behaviour of these bodies on heating and cooling. Other physical methods, such as measurements of thermal expansion, electrical resistance, solution potential, and many other quantities have also been employed. The pyrometric method is, however, at present far the most fruitful and important, and in the present article attention will be almost entirely confined to this one among the physical methods just referred to. In the majority of metallographic researches the pyrometer and the microscope are practically the only instruments used.

The pyrometric study of metals and alloys consists in observing the phenomena which occur in the heating or cooling of the substance between the ordinary or even an artificially lowered temperature, and a high temperature at which the metal or alloy is completely molten. The phenomena in question arise from the fact that when the substance undergoes either a change of state, an allotropic or polymorphic transformation, or a chemical reaction, these changes are almost universally accompanied by an absorption or an evolution of heat. A familiar example is found in the freezing of water to form ice, a process which is accompanied by the evolution of a very large amount of heat, viz. the latent heat of fusion of the water. If the cooling process of a body liable to such changes is followed with a suitable instrument for measuring temperatures, and the rate of cooling be observed it is found that the occurrence of a heat-evolution at any stage of the cooling process results in a retardation, and sometimes even in an entire cessation of the cooling process—the heat evolved by the transformation of the substance for a time balances the loss of heat due to radiation, condition, &c., and keeps the temperature stationary. For this reason the temperatures at which such changes occur are frequently referred to as 'arrest-points' in the cooling (or heating) 'curves' of the body in question. In the case of metals, these curves are obtained by means of a pyrometer, and generally some form of time-observation which enables the observer to record the rate of cooling over the whole range of temperatures involved. Such observations are most simply represented by plotting them in a curve having the temperature of the metal as ordinate and the time as abscissa, such a curve being known as a 'time-temperature' cooling (or heating) curve; on such a curve the arrest-points are shown as more or less marked flattenings of the curve (Fig. 1). If it is desired to plot such a curve on a large scale—and in practice the temperature range involved may be as much as 1000°—this mode of plotting is found cumbersome, and it is preferable to plot the observations in the form of an 'inverse rate' curve. The ordinates of this curve are again the temperatures of the metal, but the abscissæ are the time-intervals occupied by each successive decrement (or increment) of the temperature of the metal. Thus, during the steady cooling

preceding the commencement of solidification, each fall in temperature of 3° might occupy, for example, 12 seconds; then the 3° interval including the commencement of freezing might occupy a time of 120 seconds, the next following fall of 3° might occupy 40 seconds, and the following one as little as 10 seconds; in the inverse-rate curve these observed intervals would be plotted against the mean temperature of each 3° interval. In these curves, uniform rates of cooling are represented by vertical lines, while arrest-points appear in the form of more or less sharp peaks, whose areas approximately represent the quantity of heat evolved by the transformation in question (W. Rosenhain, Observations on Recalescence Curves, Proc. Phys. Soc. London, 1908, 21, 180; *see* Fig. 2). Both types of curves represent observations of time and temperature; in another method of working, the temperature of a uniformly cooling body, such as a piece of pure platinum or porcelain, is used as one of the elements of the curve. Against the actual temperature of the cooling piece of metal is plotted the difference between its temperature and that of the neutral comparison body just mentioned; this method —known as the 'differential' or difference method of Roberts-Austen has the advantage of extreme delicacy, but it is somewhat more laborious and requires more skill on the part of the observer in manipulating the apparatus, while it is also limited to the observation of heat-evolutions occurring at temperatures at which the metal in question remains solid. For all these methods of taking cooling or heating curves, the temperature observations are usually made by means of a thermo-couple whose E.M.F. is measured in some convenient way. The most widespread method of making this measurement is by reading the deflection of a galvanometer, usually of the moving-coil type, but this method has serious disadvantages, and for cases where any considerable accuracy is required the electro-motive force of the couple should be measured accurately by means of some suitable form of potentiometer (W. Rosenhain, The Metallographic Investigation of Alloys, Journ. Inst. Metals, 1909, i. 200; Observations on Recalescence Curves, Proc. Phys. Soc. London, 1908, 21, 180). The neglect of this condition has rendered a large amount of metallographic investigation unreliable.

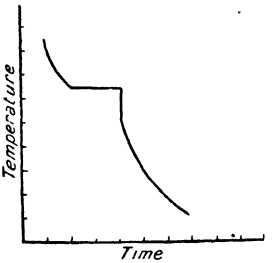


FIG. 1.

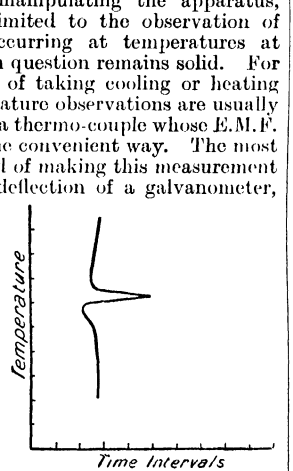

FIG. 2.

Recently, important improvements have been introduced in the methods of taking thermal curves of metals and alloys. So long as the specimens under observation were allowed to follow the 'natural' behaviour of the furnace during heating and cooling, the rate of change of temperature was always much more rapid at the lower end of the temperature scale during heating and at the upper end during cooling, simply because a furnace rises most rapidly in temperature when heating first begins and cools most rapidly while it is still very hot, *i.e.* when cooling commences. This large variation in the rates of heating and cooling within the course of a single curve results in several disadvantages. First, since the maximum rate of heating or cooling must not become excessively rapid, the lower rates which occur at the opposite ends of the curves becomes excessively slow, so that the total time occupied in taking the curve is much prolonged. Further, heat-evolutions or absorptions observed in those parts of the curves taken at a very slow rate are not readily comparable with those observed while the specimen is being heated or cooled at a more normal rate. One way of overcoming this difficulty consists in devising a furnace which can be heated and cooled at a uniform rate throughout the range of temperature required. This can be done by electrical means, but involves the use of a type of furnace which is thermally very inefficient, since the total heat-capacity of the furnace must be kept low if its temperature is to follow the rate of electrical energy supply without material regard to the ordinary laws of cooling. The method has, however, been very successfully employed by Burgess and Crowe at the Bureau of Standards in Washington (Burgess and Crowe, Bulletin, Amer. Inst. Mining Eng. 1913, 2537–2591; also Scientific Papers, No. 213, U.S.A. Bureau of Standards, 1914). Another method, which has been worked out and adopted at the National Physical Laboratory, avoids any attempt to control the rate of cooling or heating of a furnace, but utilises a furnace consisting of a long tube which is kept hot at one end and cold at the other; the specimen under observation is moved along this tube by mechanical means at a constant rate and is thus heated or cooled at a correspondingly constant rate. These 'gradient furnaces' have given very good results, and they have the considerable advantage that the rate of heating or cooling can be varied at will so as to suit different purposes (Rosenhain, Some Appliances for Metallographic Research, Journ. Inst. Metals, 1915, [xiii.] 1, 160–192).

Much attention has also been given to methods of recording thermal curves. In some respects, photographic records are advantageous, particularly on the ground that they are autographic and to some extent free from personal error; they have, however, the grave objection that the scale which can be employed is necessarily limited to relatively small dimensions so that no great degree of sensitiveness can be reached. For that reason, for the most accurate and delicate work, photographic methods are now largely discarded, and observations are taken by eye and recorded by means of a chronograph. If this is done by means of an ordinary drum or tape chronograph, the subsequent labour of reading off and plotting

the observations becomes very great and a certain possibility of error arises. Both these difficulties have been overcome by a special type of 'Plotting Chronograph' (*see* Rosenhain, Some Appliances for Metallographic Research, as above). This instrument, from the tapping of a key by the observer, plots directly and automatically the inverse-rate thermal curve on a very open scale and in a manner which largely eliminates the risk of undetected errors or observation.

The cooling-curves of metals and alloys, taken from a temperature at which the metal is liquid downwards, always show as the highest arrest-point the initial 'freezing-point' of the metal; below this temperature, at which the liquid metal first begins to deposit solid crystals, the cooling-curves may show from one up to four or five further arrest-points, even in simple alloys containing two metals only. In studying such a 'binary' system of alloys, the arrest-points on the cooling-curve of each alloy are generally plotted as points on a diagram in which the concentration of the alloy is used as abscissa and the temperatures as ordinates, the result being a temperature-concentration diagram. If properly completed in such a manner as to indicate all the conditions in which alloys of the two metals can exist in equilibrium at all possible temperatures and concentrations, this diagram is termed the 'equilibrium diagram' of the binary system in question. As a rule, however, the mere plotting of observed arrest-points in the cooling-curves of a series of alloys is not enough to allow such a diagram to be drawn, the evidence of the microscope and of other physical methods being often required to allow of the correct interpretation of the arrest-points observed. The first and simplest line of such an equilibrium diagram is that known as the 'liquidus'; this is the boundary of the region in which the alloys are completely liquid; immediately below the 'liquidus' the alloys in general consist of a mixture of liquid with solid crystals, although in some cases the range of temperature over which such a mixture occurs is very short—in pure bodies, consisting entirely of one chemical entity (pure element or pure compound) the whole process of solidification occurs at a single definite temperature and no region of mixed solid and liquid exists. The liquidus line of the equilibrium diagram can, as a rule, be drawn definitely from pyrometric observations alone, although exceptions occur in the case of pairs of metals possessing either limited miscibility in the liquid state or where the formation of a definite compound takes place slowly in the liquid metal. In other cases, small breaks of continuity in the liquidus curve cannot be definitely located by pyrometric observations alone.

The process of solidification which follows, in any given alloy, upon the commencement of freezing at the temperature of the 'liquidus' curve depends, in the first place, upon the position of the alloy in the binary system to which it belongs and also upon the type which that system follows. The type depends again upon the manner in which the two component metals undergo mutual mixture, solution, combination, or separation during freezing and melting. A large number of these types can be distinguished, but only the most important can be mentioned here. The first and simplest type are those alloys in which the two metals, when they have reached their final equilibrium in the solid state, retain the condition of intimate mixture in which they existed in the liquid state at a higher temperature. In the language of metallography, two such metals form an unbroken series of solid solutions. In their final condition such alloys resemble pure metals in being built up of an aggregate of crystals which are all alike in composition and properties. In the cooling and freezing process, however, the alloys of such a series differ markedly from pure metals in showing at times a very wide range of temperature over which the freezing process is distributed. The equilibrium diagram of such a system of alloys is shown in Fig. 3, the line ACB representing the liquidus or line of commencing freezing, and ASB representing the line of complete solidification or 'solidus.' At temperatures lying between these two lines the alloys consist of a definite proportion of solid crystals in equilibrium with liquid alloy, but it is important to notice that the compositions of the crystals and of the liquid in equilibrium with them are not identical.

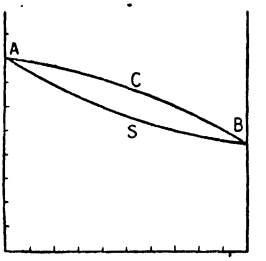

FIG. 3.

The opposite extreme to the type of alloys just described is found in those groups where the component metals are completely, or almost completely, immiscible in the solid state. A typical equilibrium diagram of this type is shown in Fig. 4, where the liquidus curve is represented by the lines ACB, forming a more or less deep **V**; the addition of the metal A to the metal B lowers the temperature of initial freezing, and this lowering is continued with increasing additions of B. Similarly successive additions of A lower the initial freezing temperature of B until a concentration is attained where the two branches of the liquidus curve meet at the point C, which represents the freezing-point of the most fusible alloy of the series. This alloy, both in the free state and when it occurs as a constituent of alloys of different composition, is known as the 'eutectic' alloy of the series, or more briefly as 'the eutectic' (Guthrie, Phil. Mag. 1884, [v.] 17, 462). This eutectic alloy shares with the pure metals and with pure inter-metallic compounds the property of undergoing complete solidification at one temperature instead of showing a 'freezing range.' The solidification of any alloy of intermediate composition, such as that represented by the line

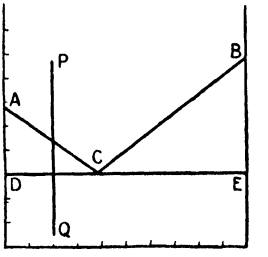

FIG. 4.

PQ, may be described as follows: when the cooling alloy reaches the temperature at which the lines PQ and AC intersect, solid crystals begin to separate, but these are crystals of the metal A. As a result of this separation, the residual liquid metal or 'mother liquor' becomes enriched in B; the residual liquid is now, in fact, an alloy lying further to the right than the line PQ. As the temperature falls, the temperature of initial freezing of this richer alloy is reached and a further quantity of solid A is separated, again increasing the concentration of B in the liquid. This process is continued until the concentration of the point C, and its temperature, are simultaneously reached. At that point the residual liquid has the composition of the eutectic alloy and solidifies as such. The alloy thus becomes completely solid on reaching the temperature of the line DE, which is usually called the eutectic line—this line (CE) is, therefore, in this case, the 'solidus' of the system, since it forms the boundary of the region of completely solid alloys. An alloy such as PQ, at all temperatures below that of DE consists of an agglomerate of crystals of the metal A embedded in a matrix of the eutectic alloy; if the composition of the alloy is such that the line PQ lies close to A, then the crystals of A in the solid alloy will be large and numerous, and little eutectic will be present, while, as the point C is approached, the proportion of eutectic increases. On the other side of C, the alloys consist of crystals of B embedded in the eutectic, and these crystals increase in amount as we move from C to B. Actual examples of binary alloys strictly following this simple type are rare, if indeed they exist at all; so far as at present known the alloys of lead and antimony approximate closely to this type (Antimony-Lead, Gautier, Recherches sur la fusibilité des alliages metalliques, Bulletin de la Soc. d'Encouragement, 1896; Gold-Thallium, Levin, Zeitsch. anorg. Chem. 1905, 45, 31). The great majority of alloys, however, belong to a type which is intermediate between the two extremes which have just been described; this intermediate type consists of alloys in which the two component metals are mutually soluble in the solid state to a limited extent. The typical equilibrium diagram of this class is given in Fig. 5 The liquidus is very similar to that of type II., a eutectic point being again evident at C, but the eutectic line DE no longer crosses the whole width of the diagram. Alloys from O and F and from H to G behave as regards solidification exactly like alloys of type I., forming homogeneous crystalline aggregates which consist of only a single constituent. Alloys from F to G, however, behave like members of type II., but with the difference that the substance which commences to crystallise when these alloys reach the temperature of the line AC is not pure A, but a solid solution of B in A, or, if the alloy lies to the right of C, the crystals consist of a solid solution of A in B.

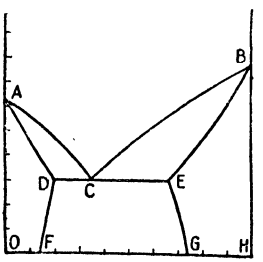

FIG. 5.

A considerable number of further types of binary series of alloys can be distinguished, but it is not possible to deal with these fully here. The only other class which need be mentioned are those in which a definite inter-metallic compound is formed. A typical equilibrium diagram of such a series is shown in Fig. 6, where the liquidus curve ACPDB shows a maximum (P) and two minima or eutectic points, C and D. The occurrence of a maximum in the curve of initial freezing, such as that shown at P, is a definite indication of the existence of an intermetallic compound, although the presence of such compounds is not always shown in this way. The simplest way of regarding an equilibrium diagram of the type shown in Fig. 6, is to suppose it divided into two separate diagrams by the vertical line through P, the one half being thus a diagram of the alloys of A with the compound metal P, and the other half representing the alloys of B with P. In the diagram as drawn, the left-hand half then becomes a diagram of type II., while the right-hand half falls under type III. It should be mentioned, however, that in actual alloys the formation of the compound P may not take place quite completely, and the alloys may in reality contain some free B as well as A and P—the system thus becomes practically one of three components, to which reference is made below.

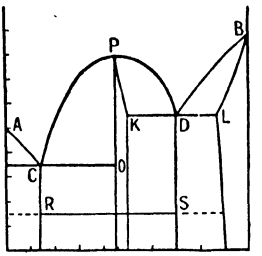

FIG. 6.

Equilibrium diagrams frequently contain lines other than those forming parts of the 'liquidus' and 'solidus' curves; these lines represent the occurrence of transformations or chemical reactions within the metal, frequently at temperatures well below those at which the alloys are completely solid. These changes are represented on the cooling curves by heat evolutions or absorptions, which are sometimes so faint as to escape detection by any but the most sensitive instruments, while in other cases they rival the freezing-point in intensity. These heat evolutions may represent either:

(1) An allotropic change in a pure metal or in the pure metal forming the basis of a solid solution or existing in the form of crystals in a eutectiferous alloy.

(2) A polymorphic change in an intermetallic compound.

(3) A chemical reaction resulting in the formation or the decomposition of a compound or of a solid solution.

Two or more of these changes may occur together. An example of such a change is indicated in an imaginary case by the line RS in Fig. 6, which is supposed to represent the decomposition of the compound P. It will be seen that the line extends over the whole range of composition in which the compound P can exist, either as free crystals or as a constituent

of the eutectics in which it occurs. As a rule, however, it is difficult, and sometimes impossible, to find any evidence—either pyrometric or otherwise—for the occurrence of such changes in alloys where the compound in question exists only as a constituent of a eutectic; the line of transformation is therefore shown as a full line only between the points R and S, where the compound exists in the form of primary crystals, and as a dotted line over the rest of the range of its existence. The interpretation of such a line of arrest-points in an equilibrium diagram will, as a rule, be based principally upon microscopic evidence, and this also applies to several of the other facts tacitly implied in such a diagram as that of Fig. 6; but before passing on to consider the microscopic study of alloys, certain other lines of pyrometric evidence must be mentioned.

The most important of these is the determination of the end-points of a series of arrest-points, and of the point of maximum intensity of such a series. The first of these is important for fixing the position of such points as D and E in Fig. 5, and O, K, and L in Fig. 6. Points D, E, K, and L serve to fix the limits of solid solubility of the metals and compounds in one another, while the point O assists in determining the exact composition of the compound P, since the maximum in the liquidus curve is not always very sharply marked. Probably the best method of determining the end-point of such a series of arrests consists in observing, by means of the most delicate pyrometric apparatus available, large samples of the alloys cooling at a slow rate, but it is also necessary in such cases to secure the complete equilibrium of the alloy at a temperature just above that of the arrest to be observed. For this purpose it is necessary, in some cases, to maintain the specimens of alloy at a definite, more or less high, temperature for prolonged periods—sometimes up to several weeks—and then to take the observations of cooling without having allowed the specimens to cool down intermediately (Rosenhain and Archbutt, Aluminium-Zinc Alloys, Phil. Trans. 1911, A, 211). The exact end-point found, however, will always lie a little short of the true end-point. For this reason a method of extrapolation is often employed. If the quantities of heat evolved at such a series of arrest-points were measured, the measurements being reduced to quantities of heat per gramme of alloy, then a curve could be plotted with concentration as abscissæ and quantities of heat evolved as ordinates. Provided that the measurements were strictly accurate, such a curve would simply be a straight line running from the concentration at which the heat-evolution was largest down to the two end-points of the series; even if not observed very close to these end-points, the line could be continued until it cut the axis, and this intersection would indicate the true end-point of the heat-evolutions. In practice this method is frequently applied, especially by Tammann and his school (Tammann, Zeitsch. anorg. Chem. 1903, 37, 303), both for the determination of end-points and of maxima of heat-evolutions; but unfortunately it is not possible to make the measurements of the quantities of heat evolved with any great degree of accuracy. The determination of the duration of the arrest itself or of the area of the peak of the inverse-rate cooling curves is usually employed, and it has been shown that this is only a rough approximation; the variation of specific heat with concentration of the alloys also affects the shape of these intensity curves, so that very great care is required in employing this method, which has more than once led to erroneous results (W. Rosenhain, The Metallographic Investigation of Alloys. Journ. Inst. Metals, 1909, i. 200; Observations on Recalescence Curves, Proc. Phys. Soc. London, 1908, 21, 180; Rosenhain and Tucker, Lead-Tin Alloys, Phil. Trans. 1908, A, 89; Rosenhain and Archbutt, Aluminium-Zinc Alloys, Phil. Trans. 1911, A, 211).

The above account of the pyrometric study of alloys and its diagrammatic representation has so far dealt only with alloys consisting of two component metals; in practice, however, alloys frequently contain three or more metals. Unfortunately the difficulty of making a complete metallographic study of a system of alloys increases very rapidly with the number of component metals; for fifty determinations required for the elucidation of a binary system of alloys, 1250 would be required for a system of three metals, while no attempt at the complete systematic study of a quaternary system (of four metals) has yet been made, but for corresponding completeness over 30,000 determinations would be needed. In the case of a ternary system (of three metals) it is still possible to employ graphic representation. The concentrations of a system of ternary alloys may be plotted in the form of an equilateral triangle, each corner representing one of the pure component metals; each side of the triangle then represents one of the three limiting binary systems, while the position of any point within the triangle represents the composition of an alloy of a ternary system, on the principle of trilinear co-ordinates. Upon this equilateral triangle as a base, the 'equilibrium diagram' can be erected as a three-dimensional model, ordinates representing temperature being erected upon each point of the area of the triangle. A few such equilibrium models of ternary systems have been more or less completely determined (Lead-Tin-Bismuth, G. Charpy, Compt. rend. 1898, 126, 1569; E. S. Shepherd, J. Phys. Chem. 1902, 6, 519; Lead-Cadmium-Mercury, E. Jänecke, Zeitsch. physikal. Chem. 1901, 60, 399; Magnesium-Lead-Tin, A. von Vegesack, Zeitsch. anorg. Chem. 1901, 54, 367; Aluminium-Copper-Manganese, Rosenhain and Lantsberry, Ninth Report to the Alloys Research Committee, Proc. Inst. Mech. Eng. 1910), but the field is still largely unexplored. It is interesting to note, however, that very few tri-metallic compounds have yet been discovered.

The microscopic study of metals is always carried out by looking at suitably prepared surfaces illuminated by reflected light; the thin sections employed in petrography cannot be used in the case of metals, as these are too opaque for such a purpose. The preparation of a suitable surface for examination by reflected light consists in three distinct processes, viz. the cutting and grinding of a small flat area, the fine-polishing of this surface in order to remove physical irregularities, and the treatment of this polished surface in such a manner as to indicate

the nature of the structure of the metal beneath. The cutting and grinding process, in the first place, consists in preparing an area, as nearly flat as possible, which may range in size from a few square millimetres to several square centimetres—but the difficulty of the subsequent operations increases rapidly with the area to be treated, so that it is preferable to examine several small specimens rather than one very large one. The initial rough cutting and grinding is followed by some process of fine grinding, generally by the use of carefully graded abrasives, each stage reducing the depth of the scratches left on the surface.

The grinding operation is followed by that of fine-polishing. The purpose of this process differs essentially from that of the ordinary polishing process, the object of which is solely the production of the most brilliant surface; in most ordinary polishing processes this is largely accomplished by a species of 'burnishing' action, in which there is much surface flow of the metal, the previously existing scratches being largely 'smeared over' and filled up. For metallographic purposes this action should be avoided as far as possible, since scratches or holes thus hidden immediately become conspicuous under subsequent treatment (etching). It follows that for this work the entire processes of cutting, grinding, and polishing, should be conducted as gently as possible, particularly in the case of the softer metals. For polishing purposes a material which acts as an exceedingly fine abrasive is indeed more preferable to one which, though more rapid in action, tends to cause flow. The polishing materials most widely used consist of the oxides of such metals as aluminium, magnesium, and iron, alumina being probably the best.

A perfectly polished metallic specimen shows, under the microscope, a featureless surface, which will appear either uniformly bright or uniformly dark, according as the light falling upon it is or is not reflected into the objective of the microscope. In order to obtain a sectional view of the structure of the metal it is necessary to employ some method of 'etching.' As a rule, this consists in exposing the specimen to the action of some reagent, such as a weak acid, which gradually dissolves the metal. It is found that this solution does not take place uniformly over the surface of the metal, and that, in fact, it differentiates clearly and consistently the various constituents of metals and alloys. In the case of pure metals and of certain alloys which consist of a single constituent or phase, the etching agent cannot, of course, act by differentiating two or more distinct constituents; but in that case a differentiation occurs between the different crystals of the same constituent, the rate of attack being apparently dependent upon the orientation of the particular section of the crystal exposed to the solvent. Such a 'homogeneous' metal consists, in fact, of an aggregate of minute crystals which have grown together in such a manner that the boundary of each crystal is determined not by the natural symmetrical surfaces commonly associated with the term 'crystal,' but by the surfaces of mutual interference of adjacent crystals—each crystal has grown until checked by meeting its neighbour. In section such a structure exhibits a network of roughly polygonal areas, and the etching reagents employed in metallography attack these various areas at different rates, thus producing both differences of level and varieties of surface texture which readily reveal the arrangement of the constituent crystals. In the case of alloys possessing a duplex or more complex structure, although each of the constituents is still built up of such aggregated crystals, the differences of solubility between the various constituents are very much greater than those between adjacent crystals of the same constituent. Consequently the resulting surface pattern generally shows all those areas which represent sections of crystals of one of the constituents as comparatively deeply etched or eroded, while those corresponding to the other constituent remain practically untouched. In duplex alloys, therefore, etching reveals the distribution of the constituents rather than the crystal structure of any of them.

The specimens of metal thus prepared can be examined by means of almost any good ordinary microscope if it is provided with certain special accessories, but for the greatest convenience and for more refined purposes it is desirable to employ one or other of the specially designed 'metallurgical' microscopes. Two general types of such instruments have been evolved for this special purpose. In the one type, which is generally used by British workers, the ordinary arrangement of the microscope is adhered to, but the stage is provided with a focussing movement, while the body-tube is provided with one of the devices known as 'vertical illuminators.' In the most highly specialised instrument of this kind (Rosenhain, On an Improved Form of Metallurgical Microscope, Journ. R. Microscopical Soc. 1906) the body-tube is entirely fixed to the limb and all the focussing, both coarse and fine, is done by movements of the stage; further, the illuminating arrangements are made integral with the main tube of the instrument, while in other microscopes they are removable and are only screwed on at the lower end of the tube. The function of the 'vertical illuminator' is simply that of sending a beam of light down the tube of the microscope in such a way as to fall upon the back lens of the objective, and then, after being concentrated by the objective, to fall upon the specimen and to illuminate the portion of the surface which is under examination. Such a vertical illuminator consists essentially of a reflector, which may be a thin disc of glass or an opaque reflector or a totally reflecting prism so placed as to cover one-half or less than one-half of the aperture of the objective. The path of the light-rays in both cases is shown diagrammatically in Fig. 7. It will be seen that under this mode of illumination the light falls upon the surface of the specimen in a direction more or less parallel to the optical axis of the microscope, and as this is sometimes placed vertically, this mode of illumination has received the name of 'vertical illumination,' although 'normal illumination' is a more rational term, since the light remains normal to the surface of the specimen whatever the position of the microscope. Under this mode of illumination it is evident that flat, bright surfaces will appear light, while sloping surfaces, or areas rendered rough so as to scatter the light which falls upon

them, will appear dark—since the light reflected from such regions will be more or less completely

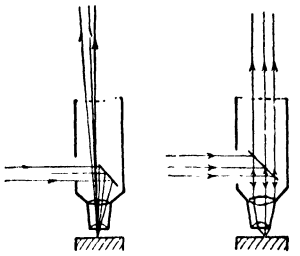

FIG. 7.

thrown outside the aperture of the objective of the microscope. With lenses of moderate power, which leave a certain amount of space between the lens and the specimen, the surface under examination may be illuminated directly by a beam of light falling obliquely upon the surface of the specimen, in the manner indicated in Fig. 8. With such lighting, plane polished surfaces will appear dark, while those with a suitable slope and those roughened so as to scatter the incident light, will appear more or less bright; the consequence is that in many respects the image as seen by 'oblique illumination' bears to that seen by 'normal illumination' a relationship like that of a photographic negative to its positive. Oblique illumination, however, is much more searching, particularly as regards minute holes and scratches, while it also tends to reveal the natural colours of the various constituents much more definitely than normal light. On the other hand, its application is generally limited to magnifications not much greater than 200 diameters, while normal illumination is readily employed with the highest powers of the microscope.

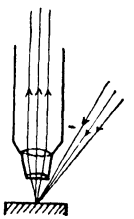

FIG. 8.

The use of the vertical illuminator, whether as a permanent or a more or less temporary attachment to the microscope, entails a special arrangement of the source of light. Whether this be an ordinary lamp or some more or less elaborate optical system, it must be so placed that the light coming from it enters the aperture of the illuminator at the desired angle. This requires a definite relative position of the source of light and the illuminator itself. In any ordinary microscope where focussing is done by moving the tube of the instrument, the position of the illuminator will vary with every adjustment of the focus, and this would entail corresponding re-adjustment of the source of light. By using a focussing stage and leaving the body-tube with the illuminator attached to it in a fixed position, this difficulty is overcome, and this arrangement is the essential feature of the majority of metallurgical microscopes. For certain purposes, of course, special provision for taking large and heavy specimens, for complete rotation of the specimens, and for other special requirements is desirable and can be obtained.

The second type of metallurgical microscope originated with H. le Chatelier (Le Chatelier, Étude des Alliages, 1901, 421), and its use is widely extended in France and Germany. The observation tube of this instrument is horizontal, and directly in line with a tube carrying condensing lenses through which light from a suitable source is concentrated upon the specimen. The stage of this instrument is a table provided with a small hole, and the specimen is placed over this hole, polished face downwards. The objective of the microscope faces upwards towards the specimen, and the incoming light as well as the rays forming the image are turned off at right angles by means of two totally reflecting prisms. In its most recent forms this instrument presents many points of great convenience, but it also possesses certain very marked limitations and disadvantages from which the more ordinary type of microscope is free.

The observations of the structures of metals and alloys made by such microscopes are readily recorded by means of photography. If the beam of light employed for illuminating the specimens is made sufficiently powerful, and particularly if the ordinary eyepiece of the microscope is replaced by one of the well-known 'projection eyepieces' now available, the image of the surface under examination can be projected upon a screen, and this image can be made large enough and bright enough to be visible even to an audience of moderate size. Instead of projecting the image upon a large screen it can equally well be focussed upon the ground glass of a suitably placed camera, and there photographed in the ordinary manner. The manipulation requires some experience and skill, particularly when very high magnifications are attempted, but in principle it does not differ materially from ordinary photography, except that the microscope with its system of lenses is used in place of the ordinary camera lens.

The typical micro-structures met with in metals and alloys may now be briefly considered. We have already indicated that a pure metal is an aggregate of minute crystals whose sections, in the form of irregular, more or less polygonal areas, are revealed by etching a polished surface. In such metals as cast lead or tin the crystals are often very large, and can be seen without the aid of the microscope, but in iron and copper they are usually very small and require magnifications ranging from 100 to 400 diameters to be readily observed. Seen under normal illumination, the crystals of iron appear as illustrated in Fig. 9, Plate I.; the same field of view seen under oblique light is shown in Fig. 10, Plate I. The appearance there seen arises from the fact that the etched surface of each crystal is covered with a number of minute facets all similarly oriented over the whole area of the same crystal, but differing in orientation from one crystal to the next. Oblique light falling on a surface thus constituted picks out those areas where the facets are so placed as to reflect the light into the microscope, and these areas accordingly appear bright, while others, situated unfavourably, appear more or less dark. A rotation of the specimen on the stage of the microscope alters these relative positions, and different crystals appear bright in turn.

The description of the typical structure of a pure metal which has just been given applies

equally to the structure of those alloys which consist either entirely of a definite intermetallic compound in a state of purity, or of a homogeneous 'solid solution.' The term 'solid solution'—sometimes called 'mixed crystals'—implies a state of mutual admixture or solution existing in the solid state which is as intimate as the condition of liquid solutions; probably the best interpretation of the conception is to regard the crystals of a solid solution as being built up of molecules of both the solvent and the solute indiscriminately. Where the two metals are completely isomorphous, these composite crystals may be built up of two kinds of molecules indiscriminately in any proportion, and we then have a series of alloys consisting of solid solutions only; in other cases the number of molecules of the solute which can be incorporated in the crystals of the solvent is limited, and in that case there is a limit to the 'solid solubility' of the two metals. While the final condition of a solid solution is thus simply that of an aggregate of homogeneous crystals resembling in appearance and character the structure of a pure metal, this final condition is not at once arrived at during the solidification of such an alloy. The central part of each individual crystal of such a solid solution when first formed contains considerably less of the solute than the liquid alloy from which it is being deposited, and as solidification proceeds this core of relatively dilute solid solution is surrounded by successive layers of more and more concentrated solid solution. Ideally the concentrations of these layers should be continually equalised by diffusion of the solute from the more concentrated to the less concentrated regions, but this is a slow process, and generally remains incomplete during the ordinary cooling of an alloy from fusion. Samples of alloys consisting of a single solid solution when taken from castings which have not been subjected to prolonged annealing, therefore always show traces of the original 'cores' within the polyhedral crystals. An example of this kind in the case of cast brass is shown in Fig. 11, Plate I. When this alloy has been reheated and subjected to such a process as rolling into bars or rods, these 'cores' are obliterated, and a homogeneous polyhedral structure is then found, such as that illustrated in Fig. 12, Plate I.

We may now consider the micro-structure of such an alloy as that represented by the line PQ in Fig. 4. In accordance with the nature of the freezing process of such an alloy, which has already been described, the microscope shows that it consists of two very distinct constituents; as a rule one of these, which represents the crystals of the pure metal A, remains practically unaffected by the etching reagent, while the other, which represents the eutectic, is more or less eroded and darkened. The relation between the two constituents is readily followed if a series of alloys are considered, commencing with one very rich in A and gradually increasing the concentration of B. At first the micro-structure closely resembles that of a pure metal, but the boundaries between adjacent crystals are seen to be thicker than the fine lines observed in pure metals. With a very slightly higher concentration of B the presence of a dark-etching constituent between the crystals of A becomes evident, and as the concentration of B increases the proportion of this dark-etching constituent (the eutectic) increases, while the crystals of A become mere islands. Ultimately, as the concentration of the point C is reached these islands of A disappear entirely, and the whole field is occupied by the eutectic. An example of such a eutectiferous alloy lying midway between the pure metal and the pure eutectic is shown in Fig. 13, Plate I., while the typical structure of a pure eutectic is shown, under much higher magnification, in Fig. 14, Plate I. It will be seen that the 'dark etching' eutectic is not uniformly etched, but itself exhibits a duplex structure, which is frequently found in these bodies, although it is not one of their essential characters. The eutectic, as it crystallises from the residual mother-liquor along the eutectic lines, such as DE, Fig. 4, is really the product of the simultaneous crystallisation of both the constituents, and we thus generally find it with a laminated structure consisting of alternating layers of the two constituents. It was formerly thought that these were simply minute independent crystals deposited side by side, but later research has shown that most eutectics crystallise in the form of the predominating constituent, the crystals of the one metal being forced into the interstices of the other, the whole arrangement frequently adopting the spherulitic form (Rosenhain and Tucker, Lead-Tin Alloys, Phil. Trans. 1908, A, 89).

The great majority of alloys exhibit in their micro-structures varieties of the three types illustrated and described above, but in a certain number of cases special structures are met with.

In the course of metallographic investigations it is frequently necessary to adopt special methods for determining the exact temperature at which the solidification of a given alloy is completed. For various reasons it has been found that the best available method of making this determination is by a process of quenching small pieces of the alloy from a series of suitably chosen temperatures. By the micro-structure of the quenched specimen it is then possible to determine whether the alloy contained any liquid at the moment of quenching. The rationale of this process lies in the fact that while that part of the alloy which was solid at the instant of quenching had solidified slowly, and had, therefore, been allowed to form relatively large crystals, any liquid metal present when the specimen was suddenly cooled would be forced to solidify very rapidly and would, therefore, form extremely minute crystals. Thus in a series of specimens quenched from successively higher temperatures, it is found that the resulting specimens show the ordinary typical and comparatively large-scale structure of the alloy until the quenching temperature exceeds a certain limit, but that beyond that point small areas of very minute crystals are found. It may then be concluded that the limiting temperature in question is that of the final solidification of the alloy. The first traces of 'liquid' in such specimens appear as minute dots or 'fusion spots,' but with slightly higher temperatures the original solid crystals of the alloy are seen to be embedded in a matrix which had obviously been fluid at the moment of quenching.

When such a quenching process is employed for locating one of the lines of an equilibrium diagram, it is of great importance that the exact temperature of the specimen at the moment of quenching should be accurately known, and that the small specimens should be protected from oxidation as far as possible during the progress of the experiment in order to avoid changes of composition and structure. In all earlier investigations quenching was carried out by heating the specimens in a small furnace, and when the desired temperature had been attained, withdrawing them by means of a rod or wire and quickly throwing them into water or other quenching fluid. More recently an apparatus has been devised (Rosenhain, The Metallurgical and Chemical Laboratories in the National Physical Laboratory, Journ. Iron and Steel Inst. 1908, I.) in which the specimen is heated electrically while contained in an exhausted tube made of fused silica; when the desired temperature has been reached, water is admitted into this exhausted tube through a wide-bore tap, and the powerful stream of water, driven by the pressure of the atmosphere, quenches the specimen, and carries it out of the furnace with it; the quenching is thus carried out very rapidly at an accurately known temperature, and without any exposure to the atmosphere.

Apart from the processes of solidification, a great many metals and alloys undergo transformations which are frequently accompanied by thermal phenomena shown on the cooling-curves, and, as a rule, these transformations are accompanied by more or less striking changes in microstructures. In the case of pure metals these changes occurring at temperatures below that of solidification are generally regarded as being 'allotropic'; in the case of alloys, however, these transformations or 'inversions' may arise from a variety of causes, such as the formation or decomposition of a compound, an allotropic change in one of the components resulting in the rejection of the other component from solid solution, or the rejection from solid solution of a phase the limit of solubility of which has been reached owing to a variation of solid solubility with temperature. Typical examples of these and similar changes are met with in such systems of alloys as iron-carbon, copper-tin, copper-zinc, copper-aluminium, aluminium-zinc, and others, and some of these will be referred to in connection with the equilibrium diagrams of these systems.

The equilibrium diagrams and general metallography of some of the more important alloys will now be briefly described. Among alloys forming uninterrupted series of solid solutions (type 1. above) perhaps the most important are the iron-manganese and the copper-nickel series, whilst iron-nickel and copper-manganese probably also belong to this type. The equilibrium diagram of the copper-nickel series is given in Fig. 15, these alloys being important on account of their electrical uses (resistance alloys) and also as forming the basis of such industrially important metals as '*Nickel silver*' and Monel metal. Cupro-nickel is also very extensively used in the production of rifle-bullet envelopes. The diagram is of the simplest type, and the micro-structures met with in the alloys are correspondingly simple—in the cast alloys some core-formation is visible, but in the worked materials, such as sheet or wire, complete homogeneity is attained, the resulting structure being very similar to that of brass (*see* Fig. 12, Plate I.), but usually on a more minute scale.

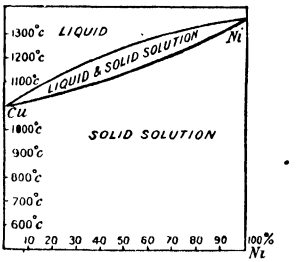

FIG. 15.

A characteristic example of another type of equilibrium diagram is that of the alloys of lead and tin, which are important on account of their use as solder, pewter, &c., and also because they form the basis of important ternary and quaternary alloys such as certain anti-friction alloys and type-metal. The diagram given in Fig. 16 (Rosenhain and Tucker, Lead-Tin Alloys, Phil. Trans. 1908, A, 89) shows the typical V-shaped liquidus with a long eutectic line running up to, or very nearly up to, the tin end of the series, but stopping some little distance (at about 18 p.c. of tin) from the lead end. Formerly the line was supposed to run up to the lead end also, but this was an error arising from the fact that these alloys take up their equilibrium condition very slowly, so that alloys cooled from fusion in the ordinary way show eutectic practically up to the lead end; this, however, disappears on prolonged heating of the alloys at a temperature near 170°. Below the solidus this diagram shows a line indicating an inversion occurring in the alloys from 18 to 63 p.c. of tin at a temperature of 150°, but with lower tin-contents the temperature at which this change occurs falls rapidly, and the inversion

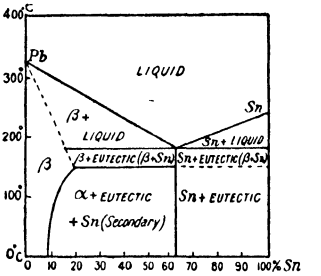

FIG. 16.

cannot be traced at all at concentrations of less than 8 p.c. of tin. This inversion is accompanied by a partial rejection of the tin from solid solution, and involves a change of density.

As typical of a comparatively simple system exhibiting a maximum in the liquidus corresponding to a definite compound, the alloys of silicon and magnesium may be taken (Vogel, Zeitsch. anorg. Chem. 1909, 61, 46–53). These alloys are of some importance in the case of certain aluminium alloys in which both silicon and magnesium are present. The constitutional diagram of these alloys, as far as it is at present known, is given in Fig. 17. The liquidus

has four branches: Si–I. corresponding to the commencement of the deposition of silicon containing but little magnesium in solid solution, I.–II. and II.–III. both corresponding to the deposition of crystals of the compound Mg_2Si, and III.–Mg corresponding to the commence-

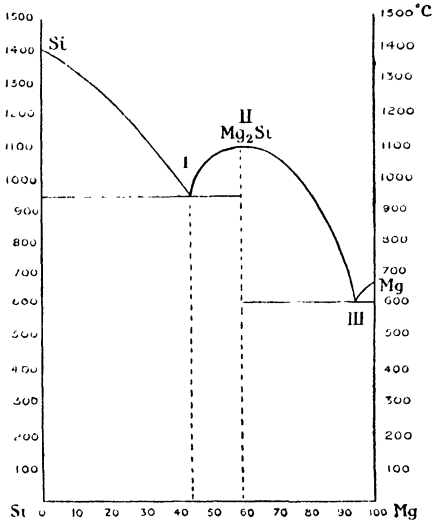

FIG. 17.

ment of crystallisation of magnesium containing only a small amount of silicon in solid solution. The diagram further shows the existence of two distinct and well-defined eutectics, one composed of silicon and the compound Mg_2Si, and the other of magnesium and the compound. The diagram as drawn does not indicate the solubility of any of the three phases in one another, but it is very probable that when the system has been more fully studied, distinct ranges of solubility, resulting in the formation of solid solutions, will be found. In such a system the micro-structures of the alloys correspond very clearly with the indications of the diagram. Thus the alloys corresponding to the branch Mg–III. of the liquidus show crystals of magnesium embedded in the Mg–Mg_2Si eutectic; those corresponding to the branch III.–II. show crystals of Mg_2Si embedded in the same eutectic, and correspondingly for the two remaining branches. Alloys of the exact composition of the compound Mg_2Si or, at least, exact within the limits of solid solubility which may exist, exhibit the structure of a simple homogeneous crystalline aggregate. In this connection it is, however, interesting to note that inter-metallic compounds such as the body Mg_2Si are almost always exceedingly brittle bodies, even when their constituent metals are soft and ductile. Compounds of copper with such metals as tin and aluminium form striking examples of this fact. It follows that in those binary alloys where a definite intermetallic compound is formed, over a considerable range of composition on either side of this compound the alloys are usually so brittle that they cannot be used for any technical purpose; this removes the greater part of the ranges of most binary systems from all practical usefulness, and in fact it is found that industrially useful alloys rarely contain much more than 15 p.c. of substances other than the predominating metal. The only real exceptions to this rule are to be found in the alloys of zinc with such metals as copper and aluminium; apparently the addition of zinc can be pushed much further without producing serious brittleness than is the case with any other metal, and industrially useful alloys containing over 40 p.c. of zinc are well known. The alloys of lead and tin furnish another example, but in their case practical utility does not depend upon mechanical strength; similarly in certain anti-friction or bearing metals large proportions of added elements are sometimes employed, but these alloys are intended to meet special requirements and a considerable degree of brittleness is permissible.

Probably the most widely used of all non-ferrous alloys are those of copper and zinc, which include the whole series of 'brasses,' although in many industrial varieties of brass other metals besides copper and zinc are met with in varying proportions. It should perhaps be mentioned here that a considerable degree of confusion has arisen in connection with the terms 'brass' and 'bronze' which have been used very loosely or even indiscriminately. The matter has, however, been dealt with by a Nomenclature Committee of the Institute of Metals, in whose Report (Journ. Inst. Metals, 1914, i. 45–55) these terms have been authoritatively defined. 'Brass,' used alone, denotes an alloy of zinc and copper in which copper preponderates; 'bronze' similarly denotes an alloy of tin and copper in which copper preponderates, while the presence of a third metal in the alloy is to be indicated by a prefix such as 'tin-brass' or 'phosphor-bronze.'

The equilibrium diagram of the zinc-copper alloys, as worked out by Shepherd (Copper-Zinc Alloys, E. S. Shepherd, J. Phys. Chem. 1904, 8, 421), and modified in accordance with the

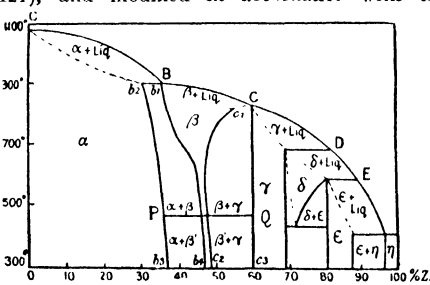

FIG. 18.

work of Carpenter and Edwards (Copper-Zinc Alloys, H. C. H. Carpenter and C. A. Edwards, Journ. Inst. Metals, v. 1911), is given in Fig. 18. In this diagram each of the six Greek letters indicates a definite phase; according to Shepherd these are all solid solutions, but it appears probable that each of these solid solutions owes its separate existence to some definite compound associated with it—there is some evidence for the existence of the two compounds Cu_2Zn and Cu_2Zn_3. It will not be necessary to discuss the whole of this diagram in detail, since the industrially important alloys consist either of pure α, or a mixture of α and β, and in special cases of either pure β or of β with a little γ; in accordance

with what has been stated above in general terms, the β phase is decidedly harder and stronger, but also much more brittle than the α phase, while the γ phase is very brittle, and at the same time weaker than the β body. As indicated by the diagram, alloys containing up to 37 p.c. of zinc, when solidified and in equilibrium, consist of the pure α phase; this is a ductile body whose characteristics closely resemble those of copper itself, but with increasing zinc-content the strength increases while the ductility diminishes slightly. The micro-structure of these alloys closely resembles that of copper; in the cast state they consist of the usual aggregate of roughly polygonal crystals, similar to those illustrated in Fig. 11, Plate I.; as these alloys, however, consist of solid solutions of considerable concentration, they show a strong tendency towards the formation of dendritic 'cores,' as described above. In brass as ordinarily cast this structure is very prominent, and tends to obliterate the ordinary polygonal structure so far as to suggest to the observer, at first sight, that he is dealing with a truly duplex alloy. Annealing, however, entirely removes this appearance from the micro-structure, and leaves the alloys perfectly homogeneous; if the annealing has been accompanied by or associated with mechanical work, the disappearance of the 'cores' is accompanied by the formation of numberless 'twinned' crystals which indicate their presence on the micro-sections by the appearance of crystals with rectilinear edges and crossed, by one or more parallel bands showing a distinct orientation, as shown in Fig. 12, Plate I. These structures, it may be added, are also characteristic of the α body met with in other alloys of copper, such as those with tin, aluminium, manganese, &c., although in each class of alloys the range of existence of the α phase may be widely different—thus in the copper-aluminium series the range of the pure α phase is only slightly over 7 p.c.

It will be seen that in the equilibrium diagram of the copper-zinc series the region of the pure α phase is bounded on the right by the curved line b_2b_3; immediately to the right of this line lies the region in which the alloys consist of a mixture of the α and β phases. If we consider the cooling from fusion of an alloy containing, for instance, 34 p.c. of zinc, we see that it will begin to solidify at a temperature of about 915°, depositing α crystals until the temperature of the line b_2b_1 is reached at about 880°. At that temperature the remaining liquid solidifies in the form of β crystals, which fill up the interstices between the previously deposited α crystals; if quenched from a temperature just below this line, such an alloy is found to exhibit the duplex structure of α and β thus indicated. On further cooling, however, the alloy crosses the line b_2b_3 and passes from the region of mixed α and β into that of pure α. If time enough is allowed to permit of the establishment of full equilibrium, the whole of the β present in the alloy will be transformed into α and the alloy will become homogeneous in accordance with the indications of the diagram; with most ordinary rates of cooling, however, this transformation is not completed, and the alloy retains some of its original β in that condition, remaining in what is known as 'meta-stable equilibrium.' In such a case the tendency for the β phase to undergo transformation is always present, but it is held permanently in check by the internal resistance of the metal to such rearrangements—this resistance being very considerable at low temperatures, but diminishing rapidly when the temperature is raised. All metals and alloys in which a transformation or 'inversion' of any kind has been prevented by rapid (or insufficiently slow) cooling, are thus in a meta-stable state, and the attainment of stable equilibrium only requires a raising of the temperature. Alloys which have been quenched are usually intentionally thrown into a meta-stable condition. In the present case it follows that the rate of cooling, in the first instance, or the subsequent application of heat, as in annealing, will make a very great difference to the character of the alloy and to all its physical and mechanical properties, since in the meta-stable state the relatively hard, strong, but brittle β body is present, while in the annealed state this body is absent.

To the right of the line b_2b_3 we have first the region of α and β, and then, to the right of the line b_1b_4, the region of pure β, while beyond that again is the region of $\beta+\gamma$. The industrially important Muntz metal, containing about 60 p.c. copper and 40 p.c. zinc, lies in the region of $\alpha+\beta$, and accordingly always exhibits a very definite duplex structure which is not removed by annealing, in this respect differing from a typical brass such as that used for condenser tubes, which contains 70 p.c. copper and 30 p.c. zinc, and therefore lies in the region of pure α. Study of the curves of the diagram will at once show that the alloys containing the β body during cooling undergo a decomposition on passing through the temperature of the line b_1b_4 or c_1c_2 respectively, breaking up from pure β into α plus β or β plus γ respectively. These decompositions are also readily prevented by somewhat rapid cooling, so that the final state of the alloys depends a good deal upon the rate at which they have been allowed to cool from fusion or from subsequent heating.

Some reference is required to the horizontal line in this diagram, running from P to Q through the entire region of the alloys in which the β phase occurs. This line represents a series of heat-evolutions, which, originally observed by Roberts-Austen (Roberts-Austen, Fourth Report to the Alloys Research Committee of the Inst. Mech. Eng. 1897, 31–100), have been redetermined by Carpenter and Edwards (H. C. H. Carpenter and C. A. Edwards, Journ. Inst. Metals, v. 1911). The nature of the change indicated by these arrest-points is not quite clearly established; the authors just named suggest the interpretation that at this temperature the β phase undergoes decomposition into α and γ, and they quote some microscopical and mechanical evidence in support of this view. There are, however, serious difficulties in the way of this explanation, and the writer prefers to regard the change, for the present, as a transformation in the β phase, and this view has been confirmed by the work of Hudson on vanadium-brass (Hudson, Journ. Inst. Metals, 1914, 1); the critical points in question, however, appear to be of some importance in the thermal treatment of brass.

Before leaving the metallography of the zinc-copper alloys the effect of heat-treatment on the micro-structure of these metals must be mentioned. It has been shown that even at the ordinary temperature the crystals of brass which have previously undergone severe mechanical distortion undergo a gradual re-arrangement, resulting in the formation of larger crystals of normal shape (E. Cohen, Revue général des Sciences, Paris, 1910); at higher temperatures this recrystallisation is decidedly rapid, the size of the resulting crystals depending upon both the highest temperature reached and on the duration of heating, although at each temperature there appears to be a limiting size of crystal structure, which is gradually attained, but is not exceeded on prolonged heating at that temperature. For practical purposes the scale of crystal structure is important, because it is a universal law in metals and alloys that increasing size of crystals brings with it decrease in strength and increase in brittleness or fragility. It follows that in brass, as in most other metals, prolonged heating, or heating to an excessive temperature, tends to injure the metal, which becomes 'overheated,' and if the heating is very excessive, may become 'burnt,' a stage where the injury to the internal structure has become so severe that it cannot be eradicated by any treatment short of re-melting.

The influence of the most frequent impurities on brass has received much attention, both from the mechanical point of view and from that of the effect on the micro-structure. A very frequent, and in many respects injurious, impurity is lead. This metal apparently does not remain in solid solution in the α body of the copper-zinc series, and in all ordinary brasses, therefore, appears as a distinct micro-constituent whose presence can be recognised, in the form of minute dark globules, which are readily seen before the specimen is etched, when present to the extent of not less than 0·2 p.c. When the specimens are etched in the more usual manner by means of ferric chloride solution, these minute dark specks are no longer very conspicuous; on the other hand, their presence can be made very obvious by etching the specimens with concentrated nitric acid, applied in the form of a single drop, and immediately washed off in a rapid current of water. This reagent develops a more or less deep and irregular pit in the surface at the spots previously occupied by lead globules, and the etched specimen accordingly appears to be deeply pitted. It may be mentioned that the presence of lead—at all events when present in quantities exceeding 0·40 p.c.—tends to produce 'pitting' by corrosion of the brass around the lead globules, a process which frequently leads to the rapid failure of such objects as condenser tubes, &c. The method of etching a polished specimen with strong nitric acid mentioned above thus furnishes an approximate guide to the probable behaviour of such metal—a brass which pits deeply under such etching is likely to pit rapidly in service. It should, however, be mentioned that these minute lead globules are not the only impurities which cause pitting under the action of strong nitric acid, minute globules of oxide behave in the same manner, although their appearance before etching is different from that of the lead particles. It has, further, been shown that the presence of 2 p.c. of lead may be an advantage in condenser tubes from the point of view of resistance to corrosion (Second Report to the Corrosion Committee of the Institute of Metals, Journ. Inst. Metals, 1913, ii. 13–118). Lead is also intentionally added to brass when specially good machining properties are required.

With regard to other impurities, it may be stated generally that the less injurious or non-injurious ones are rarely if ever visible as distinct constituents under the microscope; in fact, the question whether a given impurity is injurious or not is very largely a question of whether it does or does not form a distinct micro-constituent. Thus arsenic (in small amounts), nickel, silver, &c., all remain in solid solution in the α body—some of these, indeed, as well as manganese and tin and iron are deliberately added to certain 'special' brasses in order to obtain valuable ternary alloys. The constitution of these ternary alloys has not yet been studied sufficiently to make it possible to discuss their metallography in detail, although much work has been done on them (*see* L. Guillet, Alliages Métalliques, ch. x.).

The alloys of copper and tin constitute one of the most complex of the binary series, but

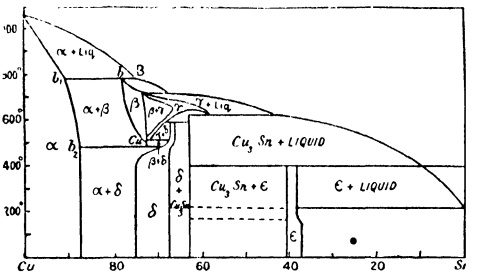

FIG. 19.

their constitution has been exhaustively studied and the results are embodied in the diagram reproduced in Fig. 19. Space does not permit of a full description and discussion of this diagram (Heycock and Neville, Phil. Trans. 1903, 202, A, 1; Giolitti and Tavanti, Gazz. chim. ital. 1908, 38, ii. 209; Shepherd and Blough, J. Phys. Chem. 1906, 10, 630; J. L. Haughton (Journ. Inst. of Metals, 1915, xiii. 1, 222–248), and attention must again be confined to that end of the series which embraces the industrially useful alloys, which, with the exception of 'speculum metal,' contain less than 14 p.c. of tin.

The industrially most important alloys are included among those which begin to solidify along the branch AB of the liquidus; these alloys begin to solidify by the deposition of crystals of the α body, which is a simple solid solution of tin in copper. These alloys which contain more copper than the concentration indicated by the abscissa of the point b_1 (about 92 p.c. of copper) completely solidify in the α form and undergo no further changes on cooling to the ordinary temperature. This α body of the tin-copper series is, it may be remarked, somewhat similar in character to the corresponding body of the zinc-copper and aluminium-copper series, *i.e.* a tough ductile

body of gradually increasing strength and hardness as the proportion of the added element is increased; there is, however, a marked difference between the three series as regards the relative influence of various proportions of the added element—the concentration of the point corresponding to b_1 in Fig. 19 being in the zinc-copper series approximately 70 p.c. of copper. This may be expressed by saying that the effect of 7 or 8 p.c. of tin is equivalent to that of 30 p.c. of zinc. It is interesting to note that this relatively feeble action of zinc is met with in other alloys of this metal.

Alloys still belonging to the group represented by the line AB, but containing more than about 8 p.c. of tin, do not solidify completely until they reach the temperature of the line $b_1 b_B$ (just below 800°), and at that temperature the remaining liquid solidifies in the form of the β constituent. In the field $bb_1b_2c_4$ the alloys thus consist of a mixture of the two phases α and β, but if they are cooled sufficiently slowly, the β body disappears entirely. In the case of alloys lying between 92 and 87 p.c. of copper, the cooling alloy crosses the line b_1b_2, which is exactly analogous to the corresponding line b_2b_3 of the zinc-copper diagram; on crossing this line the β body disappears and the alloys again consist entirely of α. Since in these as in all similar alloys, the β body is much more brittle than the α, this transformation has a powerful effect on the mechanical properties of the alloys. A still more important change takes place in the alloys containing rather less than 87 p.c. of copper; in these, along the line b_2c_4 the β body is transformed into the δ phase, and this phase is considerably harder and very much more brittle than the β phase. When these alloys are slowly cooled in the ordinary course, these transformations occur only to a limited extent, and the resulting structure shows a mixture of transformed and unchanged constituents, while the mechanical properties are also intermediate. By quenching the alloys containing less than

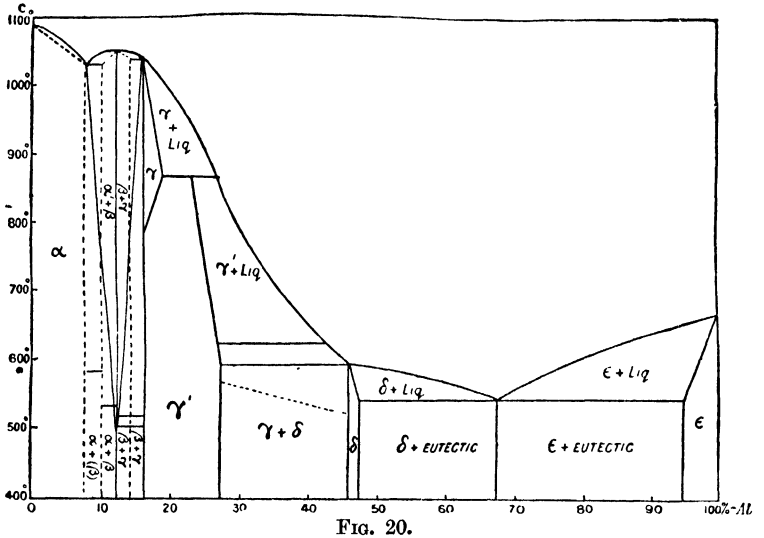

FIG. 20.

87 p.c. of copper from a temperature just above the line b_2c_4, however, the $\beta=\delta$ change can be entirely prevented, very much to the advantage of the strength and ductility of the alloys.

Tin-copper alloys to which other metals or metalloids have been added include a number of important 'special bronzes,' many of which are known under trade names. Among the special bronzes, the class of alloys known as 'phosphor bronze' are perhaps the most important. The addition of phosphorus to copper-tin alloys is usually made in the form of either phosphor-copper or phosphor-tin alloys previously prepared. The quantity of phosphorus introduced varies according to the purpose for which the alloy is intended. In a great many cases the object of adding the phosphorus is simply to free the metal from oxide of tin, which is apt to occur in ordinary bronze in the form of small angular crystals the presence of which reduces the strength and ductility of the alloy. Phosphorus thus added merely as a de-oxidising agent passes almost completely into the slag, and mere traces are found in the resulting 'phosphor bronze.' In other cases it is desired to retain a certain amount of phosphorus, probably in the form of the hard and brittle compound Cu_3P in the resulting alloy, in order to increase its hardness and to give it the special properties desired in a bearing metal—properties which are obtained by alloys consisting of crystals of a hard brittle constituent embedded in a soft and comparatively plastic matrix. The constitution of the copper-tin phosphorus alloys has been studied to some extent, but the reader must refer to the original paper of Hudson and Law (Hudson and Law, A Contribution to the Study of Phosphor-Bronze, Journ. Inst. Metals, iii. 1910, 1, 161) for further details.

The alloys of copper with aluminium (aluminium bronzes) can only be very briefly considered here. The equilibrium diagram, as given by Carpenter and Edwards (Carpenter and Edwards, Eighth Report to the Alloys Research Committee of the Inst. Mech. Eng. 1906), is reproduced in Fig. 20. Again, industrially useful alloys are only found near the extreme ends of the series,

but in this case the light alloys of aluminium containing up to 12 p.c. of copper are of importance, as well as the heavy alloys rich in copper (89 p.c. copper and over). The remarkable properties of these alloys and of others directly derived from them have been closely studied (Carpenter and Edwards, Eighth Report to the Alloys Research Committee of the Inst. Mech. Eng. 1906; Rosenhain and Lantsberry, Ninth Report to the Alloys Research Committee of the Inst. Mech. Eng. 1910). From the point of view of constitution and micro-structure, the copper-aluminium series is closely related to the copper-zinc and copper-tin series. Near the copper end of the series we have again an α body consisting of a solid solution of aluminium in copper and gradually increasing in strength and hardness with increasing content of aluminium, but with the important difference that the degree of combined strength and ductility obtainable by the aid of aluminium is much greater than that found in either of the two other series named. An additional property of very great value is the high resistance of these alloys to corrosion. In the copper-aluminium series we again have a β body, which is hard and comparatively brittle, while great brittleness, rendering the alloys industrially useless, appears with the occurrence of the third phase of the series.

The micro-structures of all the copper alloys which have been described above are very similar. Those alloys which consist of the α constituent alone show a structure closely resembling that of pure copper, already illustrated in the case of brass in Figs. 11 and 12, Plate I. Where the β phase is present, etching usually does not reveal the crystal boundaries of the α phase at all, the β constituent being merely darkened and eroded. A typical example from the aluminium-copper series is given in Fig. 21, Plate II. It should be remembered that the scale of this micro-structure will depend, in any given alloy, upon the heat treatment which the metal has received; prolonged heating, especially at high temperatures, produces a coarse structure, and this coarsening of the micro-structure is accompanied by a degradation of the mechanical properties.

The alloys of aluminium have acquired a considerable degree of importance which later developments tend to increase. Only a few of the most important ones can be discussed here. The alloys of aluminium with copper have already been mentioned; their constitution is represented by the right-hand side of the diagram of Fig. 20. It has been found that aluminium possesses a small, but not definitely ascertained power of dissolving copper in the solid state; at concentrations above 5 p.c., however, the copper forms a eutectic alloy with aluminium, the copper being present in this eutectic in the form of the definite compound $CuAl_2$, which—like almost all inter-metallic compounds—is a hard and brittle body. Alloys of aluminium containing as much as 3 and 4 p.c. of copper contain small quantities of this eutectic, and as a consequence they are harder and stronger, but also far less ductile than pure aluminium. When the copper content exceeds 4 p.c. the degree of brittleness becomes too great for many purposes, and the alloys can no longer be rolled into bars or sheets, even when hot.

The alloys of aluminium with manganese have not been studied sufficiently for the construction of a complete equilibrium diagram, but sufficient is known of their constitution to state that in the alloys near the aluminium end of the series, manganese is present in the form of the hard, brittle compound Al_3Mn, and additions of more than 2 p.c. appear to be injurious. Alloys containing from 30 to 60 p.c. of manganese have the curious property of disintegrating spontaneously; a cast ingot of such an alloy, whilst hard and sound when first solidified, breaks down spontaneously into a fine crystalline powder, in some cases in the course of a few hours. This process is not accompanied by any considerable oxidation, and appears to be the result of a polymorphic change of the compound Al_3Mn. Similar spontaneous disintegration occurs in certain other alloys of aluminium, notably those of iron, but in certain cases this change is permanently inhibited if an ingot of the alloy is forged or otherwise worked soon after casting. Certain other, more complex, alloys of aluminium exhibit a process of spontaneous change leading to gradual weakening in the course of several years, so that aluminium alloys should only be employed after a careful study of the properties of the particular combination in question. As regards many of the better-known alloys of aluminium, such as those with copper, copper-manganese, and zinc, this study has already been carried out, so that reliance can be placed on these materials.

The structure and constitution of ternary alloys of aluminium with both copper and manganese has been studied (Rosenhain and Lantsberry, Ninth Report to the Alloys Research Committee of the Inst. Mech. Eng. 1910), but the matter cannot be dealt with here. An interesting development from the alloys of this group is represented by the material known as 'Duralumin,' a patented alloy of aluminium with copper, manganese, and a small amount (about $\frac{1}{2}$ p.c.) of magnesium. Treated in the ordinary manner this alloy is very similar in properties to the simple aluminium-copper alloys, but after heating to a definite temperature lying in the neighbourhood of 400° the alloy undergoes an ageing process occupying 8–10 hours, in the course of which it increases nearly 100 p.c. in strength and hardness without a corresponding loss of ductility. The metallographic explanation of this phenomenon has not, as yet, been arrived at.

The alloys of aluminium with zinc, and derivatives of these alloys, have received much attention (Rosenhain and Archbutt, Aluminium-Zinc Alloys, *v. supra*). The equilibrium diagram of the aluminium-zinc series is given in Fig. 22. Owing to the fact that zinc is soluble in solid aluminium up to a considerable concentration (exceeding 40 p.c.) a considerable range of these alloys is industrially useful, and even the more brittle members of this series may be of practical utility as casting alloys on account of their comparative lightness and cheapness. The liquidus curve of the aluminium-zinc series is given by the line ABCD (Fig. 22). Along AB a solid solution of zinc in aluminium begins to crystallise; up to about 40 p.c. of zinc the solidification is completed in this form (the γ phase) along the curved

solidus Ab_1. The break in the liquidus at B, however, indicates that beyond this point the liquid alloys deposit a new phase (β), which is probably the definite compound Al_2Zn_3; along the line Bb_2b_1 this compound is formed by a reaction between the solid γ phase already present and the residual liquid; since the solid crystals become encased in sheaths of the compound, the completion of this reaction is very slow, and in fact only takes place when the alloys are annealed for several hours at a temperature just below that of the line Bb_1. At the point b_2 the alloy possesses the composition of the compound, and the whole of the solid solution reacts with the whole of the residual liquid to form the compound; to the right of b_2 there is an excess of the original solid solution, and this forms an unbroken series of solid solutions with the compound—*i.e.* the compound and aluminium are mutually soluble in all proportions. To the left of the point b_2 there is an excess of liquid, and this solidifies as the eutectic of zinc and the compound along the line d_1c_1. The compound (β) is, however, again decomposed—throughout the entire range of its existence, even in the state of solid solution—on reaching the temperature of the line EFG (256°), when it breaks up into its constituents, viz. the α and γ phases, which are simply saturated solid solutions of aluminium in zinc and *vice versâ*. An interesting feature of this decomposition, however, is that the two products arrange themselves in the form of fine laminæ closely resembling the typical structure of a eutectic alloy, but on a much smaller scale. This phenomenon presents a striking analogy to the formation of 'pearlite' in steel (*v. infra*), and is of importance because of its rarity. • How far this decomposition occurs in those alloys of most industrial importance (viz. those containing less than 30 p.c. of zinc) is not yet definitely known, but it is probable that the phenomena in question affect the behaviour of these alloys on heating and cooling.

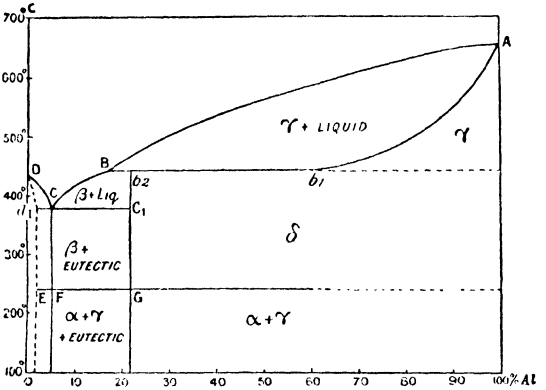

FIG. 22.

Iron and Steel. The iron-carbon system is, from the metallographic point of view, one of the most complex groups of alloys; although a range of only 5 or 6 p.c. of carbon-content is to be studied, since alloys richer in carbon cannot at present be prepared, and although probably a larger amount of investigation has been expended on these alloys than on any other system, it cannot be said that their metallography is as well understood as that of such alloys as copper-zinc or copper-tin. The reason probably lies in the difficulty of studying the constitution of these alloys at high temperatures—difficulties which are due to the rapidity with which they undergo oxidation at high temperatures, and the rapidity with which many of them undergo transformations on cooling through certain temperatures. Quenching such alloys fails to maintain them entirely in the condition which it is desired to study, and a series of complex transition products are accordingly met with, which vary in character according to the exact circumstances, and have consequently given rise to much controversy. The metallography of the iron-carbon series will be described from the standpoint of the so-called 'allotropic theory,' which is now almost universally accepted, but it is desirable to mention the fact that somewhat divergent views are held in some quarters; these divergences, however, affect only the interpretation and not the actual facts of iron and steel metallography.

The equilibrium diagram of the iron-carbon series, somewhat modified from that originally drawn up by Roozeboom (Roberts-Austen, Fifth Report to the Alloys Research Committee of the Inst. Mech. Eng. 1890; Roozeboom, Zeitsch. physikal. Chem. 1900, 34, 437; Goerens, Erstarrungs und Erkättungsvorgäuge bei Eisenkohlenstofflegierungen Halle, 1907; Carpenter and Keeling, Journ. Iron and Steel Inst. 1904, I) is shown in Fig. 23. It should be remarked at once, however, that this diagram represents what is not in reality a diagram of completely stable conditions; the stable equilibria are indicated by the dotted lines in the diagram, and will be dealt with later, but the meta-stable equilibria represented by the full lines occur with such persistence, especially in the alloys containing less than 2 p.c. of carbon, that they are of greater interest and importance than the conditions of true stability, which are met with in practice only in the case of cast iron and pig irons generally.

The liquidus curve of the iron-carbon alloys, within the limits open to investigation, consists of two branches, AB and BC, the former representing the commencement of solidification of a solid solution of carbon or of iron carbide in iron; the branch BC as drawn in Fig. 23 represents the solidification of carbide of iron (or 'cementite'). This branch of the curve probably tends to a definite maximum at a concentration corresponding to the formula Fe_3C, but this portion of the curve cannot be pursued up to that point, principally because with these high concentrations of carbon the stable system, in which iron carbide or cementite has no place, tends to predominate, and the liquidus curve becomes that representing the separation of graphite according to the dotted line B'C'. Along the line b_1BC_1 the eutectic of the solid solution (AB) and of cementite (C) separates, while the

curved solidus line Ab_1 represents the completion of solidification of the alloys containing up to 2·2 p.c. of carbon. The position of this line has been determined by Gutowsky by means of

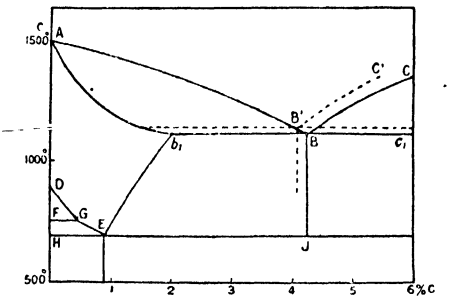

FIG. 23.

quenching experiments (Gutowsky, Metallurgie, 1909, 6, 512), and it is of considerable practical importance since it indicates a superior limit above which steel may not be heated without permanent injury due to 'burning'—steel which has been heated to the point of incipient fusion (*i.e.* above the line Ab_1) appears to be permanently spoilt in such a way as to be unfit for any use except re-melting. It may be added that even at considerably lower temperatures steel may be rendered weak and brittle, but if the injury has not gone too far the quality of the metal can be restored by suitable treatment.

To understand the lower portion of the diagram of Fig. 23, *i.e.* the portion comprising the lines DE, Eb_1, FG, and HEJ, we must first consider the transformations undergone by pure iron in cooling from a temperature above 900° down to the ordinary temperature. The cooling-curve of electrolytic iron nearly free from impurities is shown in Fig. 24. At or near the temperature of 900° there is the first arrest-point in the cooling-curve; then the cooling proceeds regularly down to a temperature of 750° (point F in Fig. 23), where there is a second arrest-point which sometimes exhibits a double peak; if even a trace of carbon is present there is a third very slight arrest-point at or about 700°, and after that the iron cools normally. The interpretation to be placed on these arrest-points is that at the temperatures in question the iron undergoes a transformation or rearrangement of its constituent atoms, which liberates a considerable quantity of latent heat, thus producing the arrest of cooling. These transformations or atomic rearrangements are analogous to similar phenomena observed in

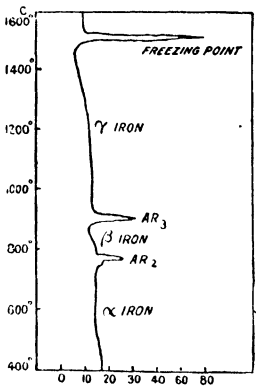

FIG. 24.

such elements as sulphur, selenium, &c., and are described as 'allotropic' transformations. In the case of iron, the form which is stable—in pure iron—at temperatures above 900° is called γ iron, and the arrest-point which indicates the transformation of γ iron is called Ar_3 on cooling and Ac_3 on heating (Osmond, Journ. Iron and Steel Inst. 1890, 1). The form of iron which exists between this arrest-point and the next (Ar_2–Ac_2) is called β iron, while the form which exists below Ar_2, down to the ordinary temperature, is called α iron. No marked difference in crystalline form has as yet been demonstrated between the three allotropic modifications of iron, but the point Ac_2 coincides with the disappearance of magnetic permeability on heating and Ar_2 with its re-appearance on cooling, so that β and γ iron are generally regarded as being non-magnetic. It has also been shown that the transition of nearly pure iron from the α into the β form is accompanied by a slight but definite increase in hardness and tensile strength, while a strongly-marked and sudden increase in strength occurs when the iron passes into the γ state (Rosenhain and Humfrey, The Crystalline Structure of Iron at High Temperatures, Proc. Roy. Soc. 1910; Rosenhain and Humfrey, Journ. Iron & Steel Inst. 1913, i. 219–271), and it is also known that the allotropic transformations are accompanied by sudden changes in volume. It further follows from the equilibrium diagram of Fig. 23 that while γ iron can hold carbon or carbide of iron in solid solution to a considerable extent, both β and α iron have little or no power of dissolving carbon or carbide of iron.

The area ADEb_1 of the diagram of Fig. 23 thus represents a region in which the alloys consist of a solid solution of carbon or more probably carbide of iron in γ iron. On cooling, this solid solution behaves very much like a liquid solution of two metals; along the line DG crystals of β iron are deposited, leaving the solid solution richer in carbon; along the line GE this process is continued except that the crystals which separate are now α iron; along the line Eb_1, on the other hand, crystals of cementite (carbide of iron) are deposited, leaving the residual solid solution poorer in carbon than it previously had been. If we follow the cooling of a steel containing from 0 to about 0·45 p.c. carbon, we find it passing first through the line DG, and then commencing to deposit crystals of β iron; these crystals increase in quantity until the line FG is crossed, when the whole of the β iron is transformed into α iron, and the quantity of this α iron now continues to increase, the carbon becoming more and more concentrated in the residual solid solution. This concentration continues in such a way that at any instant if a horizontal line be drawn representing the temperature of the alloy, then the abscissa of the point where this line crosses the line DGE indicates the concentration of the residual solid solution. Accordingly, when the steel has reached the temperature of the line HEJ, the residual solid solution has at the same time reached both the concentration and the temperature of the point E. This point, and, indeed, the whole line HEJ, corresponds closely to the eutectic line of a simple system of eutectiferous alloy, such as the line DE of Fig. 4. At

the temperature of the line HEJ the remaining γ iron of the residual solid solution undergoes transformation into α iron, and rejects the carbide which it held in solution up to that temperature; the result is that the residual solid solution breaks up into two phases, viz. α iron and cementite, giving rise to a regular laminated eutectic-like structure, which is called a 'eutectoid.' The micro-constituent corresponding to this decomposition is called 'pearlite,' from the pearly appearance which its laminated character gives it under certain conditions of illumination. The α iron, on the other hand, which has previously separated, is known micrographically as 'ferrite,' since it is practically pure iron. The microscopical appearance of pure ferrite has already been illustrated in Figs. 9 and 10, Plate I.; Fig. 25, Plate II. shows the structure of a very mild steel, containing about 0·15 p.c. carbon and consisting of ferrite (light) and pearlite (dark). Fig. 26, Plate II. shows the 'eutectoid' structure of pearlite more highly magnified.

Alloys lying between the concentrations of points E (0·9 p.c. C), and b_1 (2 p.c. C) undergo a somewhat similar series of changes, but here it is cementite which separates out at all temperatures below the line Eb_1, while the residual solid solution is lowered in carbon content until the temperature of the line EJ, and the concentration of the point E are again simultaneously reached. The alloys of this group accordingly consist, when slowly cooled, of crystals of cementite embedded in the eutectoid pearlite.

Alloys lying to the right of the point b_1, so far as they follow the equilibria of the cementite system at all, consist, immediately below the line Eb_1, of crystals of the solid solution of cementite in γ iron embedded in a true eutectic of cementite and solid solution. The subsequent behaviour of these alloys is similar to that of the group just previously described, the solid solution behaves exactly like that of an alloy having the concentration b_1, the additional cementite remaining unchanged throughout. After slow cooling through the line EJ these alloys consist of two kinds of cementite, viz. that derived from the original eutectic solidification and that deposited by the solid solution during cooling, the latter being embedded in pearlite.

The constitution of the iron-carbon alloys at high temperatures, as indicated by the equilibrium diagram, is of special importance, owing to the wide use in the arts and industries of the process of hardening steel by quenching. It has already been explained that the effect of quenching is to inhibit the occurrence of those changes which take place in the metal in the course of normally slow cooling; this inhibition may be more or less complete according to the vigour of the quenching process employed. A very rapid cooling, as by quenching in water or even in iced brine, prevents the transformations more completely than more moderate rates of cooling caused by plunging the hot steel into oil or mercury (Benedicks, Journ. Iron and Steel Inst. 1908, ii. 152).

The iron-carbon alloys in the region ADGEb_1 of the diagram consist, as has already been stated, of a homogeneous solid solution of carbide of iron in γ iron. This solid solution, so far as it is known in micro-sections, has received the name of 'austenite.' In the case of certain alloy steels containing considerable proportions of such elements as nickel or manganese, this austenite solid solution remains stable down to the ordinary temperature, or may be retained by moderate quenching. In pure carbon steels it is never preserved unchanged by quenching, but it has been observed by etching steel surfaces at a temperature of over 1100° by means of hydrogen chloride acting in an atmosphere of hydrogen (Baykoff, Révue de Métallurgie, 1910). In quenched carbon steels, austenite is only met with if the carbon content is over 1 p.c., the quenching temperature over 1000°, and the quenching a vigorous one. Even then the austenite is always accompanied by some of the transition products which are intermediate between the unaltered solid solution (austenite) and the normal final decomposition product, pearlite. Among these transition products, three definite stages are observed. The first of these is the constituent known as 'martensite.' This always accompanies austenite in severely quenched carbon steels, and appears in the form of jagged areas showing a minute structure of fine interlacing needles or laminæ, generally crossing at angles approaching 60°. An example of the austenite-martensite structure of severely quenched carbon steels is shown in Fig. 27, Plate II. In the case of steels of lower carbon content, this constituent, martensite, may appear entirely without austenite, and it may occupy the entire area of the specimen. A photograph of a typical martensite structure is shown in Fig. 28, Plate II. This constituent is the hardest body met with in carbon steels; it is distinctly harder than austenite, but while austenite appears to be non-magnetic, martensite is distinctly magnetic, and it is, in fact, this constituent to which the large coercive force of hardened steel is due. The nature of martensite has been much discussed, but a rational view appears to be that the acicular structure arises from a partial decomposition of the austenite along the cleavage planes of its crystals, the whole process, however, being complicated by the changes in volume which accompany the allotropic transformations of iron.

The γ iron of austenite tends, on cooling, to undergo transformation into α iron. In the course of this transformation the iron probably passes through the β condition, even when the composition of the steel is such that the β iron would have no range of stable existence during slow cooling. As there is some evidence to show that β iron is harder than α iron, the view has been widely held that the hardness of martensite, *i.e.* of hardened steel, is due to the retention in it of a considerable quantity of meta-stable, hard β iron. The difficulty of accounting for the magnetic properties of hardened steel on this theory was met by the hypothesis that the non-magnetic properties of β iron above Ac_2 are the result, not of any inherent non-magnetic quality of β iron, but arise from a large temperature-coefficient of magnetic properties in this form of iron—so that, retained forcibly down to the ordinary temperature, β iron might prove to be sufficiently magnetic to account for the relatively low permeability met with in hardened steel. As simpler explanations have been put forward,

however, the 'β iron' theory of hardening in steel has lost ground very considerably in recent years.

The simplest and most logical explanation of the phenomena of hardening in quenched steel is based on what has come to be known as the 'amorphous theory' of metals. This theory is based on the hypothesis, first put forward by Beilby (Beilby, numerous papers; *see* The Hard and Soft State in Solids, Faraday Soc. June, 1904, and same title, Journ. Inst. Metals, 1911, 2 [vi.]) that metals, while ordinarily crystalline, may under certain conditions exist in a non-crystalline or amorphous state in which their properties resemble those of hard, brittle vitreous bodies such as glass or fused silica. (For a full statement of the theory, *see* Rosenhain, Metals, Crystalline and Amorphous, Engineering, Sept. 1913.) Such amorphous metal never exists in considerable masses, but is formed as the result of mechanical disturbance of crystalline arrangement (*see* below) or remains as a very thin residual layer where adjacent growing crystals meet, acting—in the latter case—as an inter-crystalline cement holding the crystals together. The strength and hardness of this cementing layer accounts for the fact that in pure metals the crystal junctions are stronger than the crystals themselves, so that the metal becomes stronger and harder the greater the number of junctions, *i.e.* the smaller the scale of the crystal structure. In the extreme case, where the crystals themselves are little more than incipient nuclei, we should have the maximum amount of junction area and—according to the amorphous theory—the largest amount of hard, amorphous metal, so that the metal would attain its maximum hardness in that condition. Now this is precisely the condition which may be expected to arise during the quenching of steel. The transformation from γ iron to α iron takes place, during slow cooling, by the development of a number of small α crystals which grow larger and absorb more and more of the γ iron. When cooling becomes very rapid, however, there is no time for the growth of these α crystals, and in these circumstances a very much larger number of α nuclei would come into existence, but each would remain little more than a nucleus, surrounded by its layer of amorphous cement. The fullest hardness would thus be attained if the rate of cooling and other conditions were such that the whole volume of the steel was finally occupied by these minute or incipient α crystals merely separated from one another by films of amorphous metal. In any actual case, however, the size of the developed α crystals, and the number of nuclei formed, would vary even in different parts of a single original γ crystal, thus giving rise to the acicular structure of martensite, which is undoubtedly related to the crystalline planes of the austenite from which it is derived. On this theory, the hardness of quenched steel is ascribed to the presence in it of a relatively large amount of amorphous metal, thus correlating the hardness obtained by quenching with the hardness produced by plastic deformation ('cold work') and with the hardness of such substances as glass. It is interesting to note that both quench-hardened and work-hardened metals are softened by tempering and annealing, and that when hardness of either kind is extreme it is liable to undergo slight changes even at the ordinary temperature ('ageing'). Finally, it may be pointed out that the magnetic properties of hardened steel are readily accounted for by the 'amorphous' theory; the nuclear crystals of α iron are the seat of permeability and 'remanence,' while the high coercive force or magnetic hardness is due to the fact that the magnetic atoms (or molecules) of α iron lie tightly embedded in the hard and unyielding amorphous cement which hinders re-arrangement of any kind, whether under the action of mechanical forces (hardness) or under the action of magnetic forces ('coercivity').

Even if we may regard the amorphous theory as adequately explaining the phenomenon of hardening in quenched steel, other factors undoubtedly play an important part. Thus, the volume-changes which are known to accompany the transformations of iron from the γ to the α state produce powerful internal stresses in quenched steel, which frequently lead to distressing failures in the shape of 'hardening cracks' or, in less severe cases, to distortion. These internal stresses may play a part in the hardening process, although this part is probably confined to facilitating the production or retention of amorphous metal. Thus Carpenter and Edwards (Carpenter and Edwards, The Hardening of Metals, Journ. Iron and Steel Inst. 1914, i. 138-191) ascribe the hardness of quenched steel to the presence of amorphous iron, but consider that this is formed as the result of mechanical deformation by multiple twinning (*see* below) of which they believe that the micro-structure of martensite bears evidence. McCance (A. McCance, The Theory of Hardening, Journ. Iron and Steel Inst. 1914, i. 192-205) goes still further and ascribes the hardness of steel, without reference to amorphous metal, to a state of 'inter-strain' set up within the material by quenching.

It is further evident that carbon must play a vitally important part in the whole phenomena of hardening since they do not occur to any very considerable extent in the absence of that element.

Carbon is said to act as a species of 'brake' on the allotropic transformations, and the nature of its action may be understood when it is considered that the transformation of pure iron from one allotropic form to another merely involves a rearrangement of the atoms within the crystal. While the γ iron contains dissolved carbide of iron, however, the allotropic change of the iron involves the expulsion of the carbide from solution, and, for completion, its rejection from the crystals of iron. This rejection involves a transfer of the carbide molecules across distances which are very large compared with molecular dimensions, and it is not difficult to understand that such a transfer occupies time, and that it is, therefore, more or less readily inhibited by the action of quenching.

In the case of martensite the rejection of the carbide from its state of solution in the γ iron of the austenite has only just begun, and the carbide probably exists in a separated form only on the cleavage planes of the original γ iron crystals. When the rate of cooling has been somewhat slower, however, the rejection

of the carbide, as well as the allotropic transformation of the iron itself, are allowed to go somewhat further, and as a result a further transition product is found in the micro-sections. This is the dark-etching body known as 'troostite,' found in oil-hardened steels, and particularly in those quenched at the temperature of the thermal transformation. In this constituent the rejection of the carbide is practically complete, but the carbide is in a state of extremely fine division, according to some views, indeed, in a state of 'colloidal solution' or suspension in the iron (Benedicks, Journ. Iron and Steel Inst. 1905, ii. 352, and 1908, ii. 217). In troostite it appears probable that while some γ iron is still present and a considerable amount of hard amorphous iron is present as cement surrounding the minute α crystals, yet these crystals have had time to grow to a certain extent, with the result that steel containing troostite is distinctly softer than that consisting entirely of martensite. When the quenching or tempering is so adjusted that the whole of the γ iron has just disappeared, the proportion of troostite would attain its maximum, this being the state of tempered steel called 'osmondite,' by Heyn (Heyn and Bauer, Journ. Iron and Steel Inst. 1909, i. 109). Further tempering, or still slower cooling, leads to the appearance of a further transition product, which is not very sharply differentiated from troostite on the one hand, and from pearlite on the other. This is known as 'sorbite.' Here almost the whole of the iron has reached the α stage, and the carbide has begun to segregate into masses which are at first too minute to be seen under the microscope; but with further tempering, or less vigorous cooling, the segregation of the carbide reaches the point where it can be resolved under the microscope into granular or laminated pearlite. Steel containing sorbite is not really hard in the ordinary sense, although it possesses distinctly greater hardness and tensile strength than the same steel in the pearlitic state. Rail and other comparatively low-carbon steel is sometimes so treated as to render the carbonaceous constituent sorbitic, and in this condition the steel exhibits specially valuable physical properties.

The hardening of steel may be summarised metallographically as follows:—

Fully hardened steel	=	Martensite or austenite-martensite.
Moderately hardened or slightly tempered	=	Martensite-troostite.
Tempered steel	=	Troostite with either martensite or sorbite.
Slightly hardened or much tempered	=	Sorbite.

A large and increasingly important class of alloys are those produced by the addition of various metals, such as nickel, chromium, manganese, and the rare metals such as vanadium, tungsten, molybdenum, and others, to iron and to certain grades of steel. The metallography of these steels is, however, so complex that it cannot be described here. Broadly speaking, these 'special' steels may be divided into four large classes, the class to which any particular steel belongs being dependent upon the total proportion of alloyed elements present.

The first class of the special steels are those containing relatively small proportions of the added elements; these possess a simple structure of ferrite and pearlite, very similar to that of pure carbon steels, although differing in minor details; their mechanical properties are frequently markedly superior, and notably those containing nickel, chromium, and vanadium are finding much technical application. The great value of the nickel and nickel-chrome steels of this type lies in the fact that by heat-treatment, such as quenching in oil from such a temperature as 820°C. followed by tempering at or near 600°C. they attain excellent physical properties which cannot be obtained in carbon steels. This is partly due to the action of nickel and chromium in not only lowering the critical points of the steel, but in retarding the rate at which the steel undergoes its transformations. This makes it possible to 'quench' satisfactorily with less risk of fracture and to obtain good results from heat-treatment even in large masses of steel which can never be made to cool very rapidly. The second class of the alloy steels show a structure resembling that of martensite; they are hard and practically unworkable, but their existence is utilised in certain special cases, as in the production of case-hardened objects without quenching in the cementation of certain grades of nickel steel. The third class of alloy steels are those containing still larger proportions of alloyed elements, as, for example, a nickel steel containing about 25 p.c. of nickel. They exhibit a simple polyhedral structure, which is that of austenite, but in this case the solid solution contains the alloyed elements as well as the γ iron and carbon. These steels are non-magnetic, and possess remarkable mechanical properties, notably a high degree of ductility combined with great tensile strength. In some cases, however, they possess the peculiar property of being converted into steels of the previous class (martensitic) by mechanical work; such a steel, when first cut by a saw, for instance, is quite soft, but it rapidly hardens under the tool, until it can no longer be cut at all. This property is, however, confined to steels lying near the border-line of the two classes. A further increase in the proportion of the alloyed elements brings the steel into the fourth class, in which the presence of a carbide of the alloyed element can be detected in the micro-structure. For most general purposes such steels are useless, but certain of them are extremely valuable for use as high-speed cutting tools. This highly important type of alloy steels cannot, however, be discussed in detail here. It can only be mentioned that while in ordinary carbon steels the temperature required for tempering, and therefore softening the steel is as low as 400°, these special steels can be made to withstand temperatures as high as a dull red heat without losing their hardness; they are thereby enabled to maintain their cutting edge at speeds which render the tools almost red hot. The manner in which the presence of the alloyed elements effects this behaviour can be approximately understood when it is mentioned that the critical points of an ordinary carbon steel are to some extent displaced, according to the temperature to which the steel has last been heated. The presence of an alloyed element not only itself

displaces the normal position of the critical points—in the case of nickel steels, for example, extending the range of stable existence of γ iron down to the ordinary temperature—but the alloyed element also increases the extent to which the critical points can be displaced by heat treatment. In the case of high-speed tool steels it is found that by heating the steel to a temperature of 1200° or higher (a white heat), and allowing it to cool in a current of air, the critical point on next heating is raised to so high a temperature that a dull red-heat does not affect the 'temper' of the steel.

The micro-structure of steel has so far been described as the result of either 'normally slow cooling' or of quenching. For the steels containing higher proportions of carbon this classification is practically sufficient, but for the class of 'mild' steels containing up to 0·70 p.c. of carbon the effects of quenching need scarcely be considered, except in the case of the 'sorbitic' steel mentioned above. On the other hand, for these steels the temperature and duration of annealing, and the application of work by rolling, pressing, or forging is of vital importance, both to the micro-structure and to the mechanical behaviour of the material. Metallographic methods have cleared up the greater part of this field, but only general results can be mentioned. Thus it may be taken as a fundamental fact that coarse and well-defined micro-structures imply undesirable mechanical properties, especially as regards behaviour to shock, while a fine, close structure offers the best prospect of good quality in the metal. It is, however, a universal tendency of crystals forming an aggregate such as iron or steel, to grow; *i.e.* certain of the constituent crystals of the aggregate tend to increase in size at the expense of their neighbours. In the case of such comparatively 'refractory' metals as iron or steel, this growth of crystals is *nil*, or exceedingly slow at ordinary temperatures, although in the case of lead (Ewing and Rosenhain, The Crystalline Structure of Metals, second paper, Phil. Trans. A, 1900) and brass (*see* L. Guillet, Alliages Métalliques, ch. x.), such growth takes place measurably even without the application of heat. When iron or steel is heated, however, the tendency for crystal growth rapidly asserts itself, and, indeed, it is to this process of growth, or of 're-crystallisation,' that we owe the power of annealing or softening metal which has been rendered hard and brittle by the application of cold work. In the case of steel, when the temperature of the upper critical point is passed (on heating) the transformation occurs at a number of centres which behave as centres of crystallisation, and a new system of crystals begins to grow from each of these centres, although to some extent the new set of crystals tends to follow the outlines of those previously in existence. With rising temperature the rate of crystal growth increases, and the ultimate size of structure attained is thus a function of both the time of heating and of the temperature attained. When steel which has been thus heated is allowed to cool slowly, although there is a distinct tendency for re-arrangement to occur on passing through the critical points, yet the coarse structure is very apt to persist, and if the heating has been carried too far we have a coarse, weak structure typical of 'overheated' steel. To some extent this coarse structure may be removed by heating the steel for some time to a temperature just above the upper critical point, and then cooling it somewhat rapidly through the critical point down to the ordinary temperature. A more effective method, however, consists in exposing the steel to hot working (rolling, forging, &c.). This process deforms the existing crystals in a manner described below, and these deformed crystals are unstable, *i.e.* crystal growth starts afresh in them, and can no longer follow the previous outlines; the result is an entirely new and much more minute system of crystals. The exact analogue of this process has been watched, in the case of lead, taking place at the ordinary temperature.

For the mere removal of the hardening effects of 'cold work' annealing temperatures between 600°C. and 700°C. are frequently used, particularly as these are found to leave the steel softer than higher annealing temperatures. The use of these temperatures, however, entails serious disadvantages. The very soft state of the steel when thus annealed is due to a very low elastic limit which—in very low carbon steels—approximates to that of annealed pure iron. The reason is that annealing in the temperature range just below the critical point, Ac, has the effect of allowing the lamellæ of cementite which exist in the pearlite to separate and to form small granules or globules, which—on prolonged annealing—coalesce into larger globules. In this form, divorced from its former close union with the ferrite, the cementite can no longer exert its stiffening and strengthening effect on the surrounding ferrite, and the steel is reduced to the state of iron in which globules of cementite are uselessly embedded. Such over-softened steel can, however, readily be brought into a very satisfactory condition by 'normalising' it, *i.e.* heating to 900°C. followed by cooling in air.

Another class of phenomenon sometimes occurs in very mild steel when annealed at these low temperatures after mechanical deformation ('cold work'). This is known as 'grain growth' (*see* Sauveur, Note on the Crystalline Growth of Ferrite below its Thermal Critical Range. Proc. of the International Ass. for Testing Materials, Sixth Congress, 1912, ii.; Chappell, Journ. Iron and Steel Inst 1914, i. 460; Rosenhain and Hanson, (Journ Iron and Steel Inst. 1918, i. 313). It consists in a very rapid development of large, coarse ferrite crystals. This development occurs most freely in ferrite free from all carbon, as it exists in pure iron or in steel containing little or no carbon. Even in steels containing as much as 0·3 p.c. of carbon, however, bands or 'ghosts' are often found in which no carbon is present, and in these grain-growth of a dangerous kind may occur. Here also the evil can be completely cured by normalising at 900°C.

Cast iron, Pig iron. The equilibrium diagram and constitution of iron-carbon alloys has so far been discussed only in reference to alloys containing less than 2 p.c. of carbon, and usually known under the name of 'steel.' The alloys richer in carbon must now be dealt with; these are met with industrially in the shape of a large variety of cast and pig irons, but it must be

remembered that while the better kinds of steel consist essentially of almost pure iron-carbon alloys, the cast and pig irons generally contain very considerable proportions of impurities, such as silicon, sulphur, phosphorus, &c. In addition, a large number of these higher-carbon alloys differ essentially from steel by containing carbon in the form of graphite. The equilibrium diagram of the iron-carbon system given in Fig. 23 represents, as has already been mentioned, what is in reality a meta-stable condition of the iron-carbon system; if sufficient time at a suitable temperature be allowed it is probable that carbide of iron would decompose completely into iron and graphite. Apparently it is also possible for free carbon (graphite) to separate as primary crystals from the molten iron-carbon alloys containing over 4·3 p.c. of carbon. If it is true—as seems probable—that in the liquid alloys the carbon is dissolved in the form of only slightly dissociated carbide, then in these high-carbon alloys the carbide (cementite) in certain conditions, and notably in the presence of silicon and in the absence of manganese, is liable to undergo decomposition at a temperature near that of incipient solidification, one of the products of decomposition being graphite, which thus appears as a solid phase in the shape of crystals separating from the liquid. The equilibrium diagram of this ultimately stable system (Fig. 23, dotted lines) thus contains the liquidus branch corresponding to the separation of the γ iron solid solution, but this is carried to a eutectic point differing slightly from the γ iron-cementite eutectic, and corresponding to a γ iron-graphite eutectic; below the temperature of this eutectic the alloys are completely solid, and to the left of the eutectic-point (B) consist of γ iron embedded in the graphite eutectic, while to the right of the point B they should consist of primary graphite crystals embedded in the eutectic; owing to the low density of the graphite, however, this substance does not remain embedded in the liquid metal from which it is separated, but floats to the surface in the form of 'kish.' On further cooling the behaviour of these alloys should theoretically lead to the complete decomposition of all the cementite, including that contained in the γ iron solid solution, but the exact circumstances in which such decomposition occurs are not fully ascertained. The lower part of the dotted-line diagram of Fig. 23 has not, therefore, been filled in.

In practice certain varieties of cast and pig iron tend to follow the system of solidification just indicated, but they rarely, if ever, do so completely; whilst, if the rate of cooling is rapid, and especially if the iron contains little silicon and much manganese, the decomposition of the cementite is more or less completely prevented, and the iron cools with the formation of little or no graphite, forming what is known as 'white iron'; iron which contains much graphite and little cementite is known as 'grey,' whilst intermediate varieties are known as 'mottled.'

Microscopically, all varieties of iron may, in accordance with the above, be regarded as mixtures of steel with a certain amount of graphite. The 'steel' portion will have the characteristic structure of an iron-carbon alloy whose carbon content corresponds to the amount of 'combined' carbon, *i.e.* of undecomposed cementite, present in the iron. Thus an iron containing, for instance, 0·5 p.c. of combined carbon, together with 3 p.c. of graphite (total carbon 3·5 p.c.), will show a structure of ferrite and pearlite corresponding to that of a 0·5 p.c carbon steel, together with a considerable amount of graphite. A typical example of the micro-structure of a 'grey' iron of this type is shown in Fig. 29, Plate II., but the presence of impurities, particularly of phosphorus, very materially affects the appearance of such micro-structures, since the phosphorus forms, with the iron, a definite compound Fe_3P, and this compound forms with the iron a well-defined and characteristic eutectic, which may be mistaken for pearlite under the microscope. This phosphide eutectic can, however, be readily distinguished from pearlite by exposing the specimen to a moderate degree of heat which causes a slight surface oxidation, and in consequence a differential tinting of the various constituents.

Increasing total carbon-content, with constant amount of combined carbon, merely causes an increase in the amount of graphite found in the micro-sections; an increase in the proportion of combined carbon, however, causes the 'steel' portion of the iron to move up the carbon-scale, first producing an increase of the amount of pearlite, and finally the appearance of cementite in place of ferrite. In the case of 'white' irons produced by chilling high-carbon cast iron, the graphite disappears entirely, and the resulting micro-structure consists entirely of cementite and pearlite, together with the constituents due to impurities. As regards mechanical properties, it is obvious that the presence of plates of graphite, destroying the continuity of the 'steel' matrix, largely reduces the strength of the material as compared with a steel of equal combined carbon; on the other hand, the iron will be 'soft' or 'hard,' according to the micro-structure of the 'steel' matrix, an iron containing ferrite and pearlite will be much softer and less brittle than an iron containing cementite and pearlite. These latter constituents are responsible for the great hardness of 'chill' iron castings.

For certain purposes castings are treated in such a manner as to be deprived of their graphite content more or less completely by a process known as the production of 'malleable' castings. This process consists in heating or annealing the castings for a considerable time, generally while packed in an oxidising material, such as iron oxide. To a considerable extent decarburisation occurs, while much of the combined carbon is deposited in the form of a very finely divided graphite known as 'temper carbon.' The softening effect of the process depends partly upon the actual removal of carbon by oxidation and partly upon the effect produced by prolonged heating upon the arrangement of the graphite which remains in the metal. While in ordinary castings it is present in the form of plates and veins, in 'malleable' castings it is found in small nodules and patches which do not affect the strength and ductility of the material to anything like so great an extent.

A converse process, for producing surface hardness in articles made of iron or mild steel

is that known as 'case hardening.' In this process the iron or steel is heated for a considerable time in contact with carbonaceous matter, preferably also containing nitrogenous matter. The iron takes up carbon and forms a hard external layer rich in carbon, which, therefore, has the power of being hardened by quenching. Micro-sections of case-hardened articles readily show the depth and nature of the hard 'case,' and the structure of the underlying softer and tougher material.

Deformation, fracture, and fatigue in metals. Microscopic metallography has made it possible to determine the mechanism by which metals undergo plastic deformation, and incidentally to explain the mode of fracture under tension, shock, and 'fatigue.' It has already been indicated that when a piece of metal is forced to change its shape, as by hammering, rolling, pressing, &c., the component crystals of the metal also undergo a corresponding change of shape, although subsequently if the temperature is high enough to permit of sufficient molecular mobility in the particular metal in question, the crystals tend to rearrange themselves into more normally shaped forms. If a bar of metal be forcibly stretched, the constituent crystals will be found to be stretched also. Thus cold-rolled iron shows the structure illustrated in Fig. 30, Plate II., where the ferrite crystals are seen to be lenticular in section in place of the normal polyhedral shape. The manner in which metallic crystals undergo such changes of shape becomes evident if a surface of a specimen of metal is prepared for microscopic examination (*i.e.* polished) before the piece of metal is subjected to the change of shape. The crystals which, before deformation, appeared as practically featureless polygonal areas, after the application of the strain, are seen to be cross-hatched by systems of fine lines. In the case of highly plastic metals, such as lead or copper, the lines are seen to be characteristically straight and regular, while in the harder metals, such as iron, the lines appear more or less branched and curved. It has been possible, however, to observe the formation of these lines in iron at high temperatures (up to 1100°) (Rosenhain and Humfrey, The Crystalline Structure of Iron at High Temperatures, Proc. Roy. Soc. 1910), and in those circumstances they are as straight and regular as those of copper. The typical appearance of these lines is shown in Fig. 31, Plate II. Their nature has been elucidated by a long series of experiments, including the preparation of transverse sections of specimens of metal upon which the lines had previously been developed. The conclusion arrived at is that they are in reality minute steps in the surface arising from the fact that the adjacent portions of the crystal have slipped over one another along the cleavage or gliding planes of the crystal. It may be accepted as abundantly proved that the polygonal grains seen in the micro-sections of metals are true crystals, possessing all the essential features of crystals as regards the regular and symmetrical arrangement of the constituent molecules, although these crystals have grown together into an aggregate without allowing the individual members to develop their characteristic external shape. These crystals, however, may be regarded as built up of minute elements or groups, much as a stack of bricks is built up of individual bricks. It has been shown (Ewing and Rosenhain, The Crystalline Structure of Metals, Bakerian Lecture, Phil. Trans. A, 1899; Rosenhain, Deformation and Fracture in Iron and Steel, Journ. Iron and Steel Inst. 1906, I.; Rosenhain and Humfrey, The Crystalline Structure of Iron at High Temperatures, Proc. Roy. Soc. 1910) that these crystal 'bricks' or units are themselves never deformed or changed in shape (excepting the temporary 'elastic' deformations which are left out of consideration here), and that the crystals which are built up of these units accommodate themselves to changes of shape imposed upon them by allowing the 'bricks' to slide over one another along at least three sets of gliding planes. Where these planes of slip reach the surface of a crystal forming part of the previously polished face of the specimen, the result is the formation of a minute step in the surface, and the short sloping surface of such a step, when viewed by 'normal' light, appears as a fine dark line. Illumination by oblique light, on the other hand, shows the lines shining brightly against the dark background whenever the short sloping surfaces are turned so as to face the incident light. On account of their mode of formation these lines have been called 'slip bands.'

In certain metals, notably in copper and its α alloys, and also in lead and many other plastic metals and alloys, the process of deformation by slip as just described is also accompanied by what is known as 'mechanical twinning.' In this process a certain portion of the crystal, in order to accommodate itself to the circumstances created by the application of plastic strain, swings over into an entirely new orientation, which is, however, definitely related by crystallographic laws to the orientation of the parent crystal; this process usually occurs in a series of parallel bands. The presence of crystals showing regular alternating bands of similar orientation is always an evidence of 'twinning,' and since twinned crystals rarely occur in cast metals, this feature is generally evidence of the application of work to the specimen in which it appears. Where deformation by slip and by mechanical twinning occur together, the slip-bands change their direction on passing the edge of the twinned area, and a stair-like shape of the bands results.

The process of deformation by slip obviously implies that the metal retains its truly crystalline character after it has undergone a permanent change of shape, and it is found that, unless the amount of deformation has been very large, this is actually the case.

A further series of phenomena must, however, be considered; these relate to the changes which occur in the structure of the crystal at and in the immediate neighbourhood of the surfaces upon which slip has taken place. It has been shown that when the surface of a piece of metal is rubbed or polished (G. T. Beilby, The Hard and Soft State in Metals, Phil. Mag. 1904; G. T. Beilby, Hurter Memorial Lecture, J. Soc. Chem. Ind. 15, 1903), some of the molecules or atoms in the surface layer of the metal are torn away from their crystalline arrangement, and are left upon the surface in a state

of relative freedom, which allows them to behave in a manner resembling a thin film of viscous liquid. It is by the spreading out of such a film under the action of pressure and of polishing media, that polished surfaces are formed. The material of this thin surface film, however, is no longer in the crystalline condition; its condition resembles that of an exceedingly viscous liquid, and is therefore to be regarded as being truly 'amorphous,' and it has been shown that in this amorphous condition, although temporarily mobile, the material is much harder and also much more brittle than the same substance in the crystalline state. Now in the interior of the crystals of a metal which undergoes deformation by slip, metal surfaces move over one another under very considerable pressures, and it follows that an action very similar to that which occurs upon a surface which is being polished will take place on every gliding plane; *i.e.* a thin layer of atoms will be disturbed from their normal position in the crystalline arrangement, and a layer of temporarily mobile, amorphous material will be formed. Now it has been shown that if this layer is thin, the directive forces of the adjacent crystalline systems are sufficient to cause the disturbed atoms to reassume the orientation of the system, and in that case the surface on which slip has taken place may be said to have 'healed up.' On the other hand, two different cases may occur. In the first case the process of slip may be carried so far that the disturbed layer becomes too thick to allow of complete and almost immediate recrystallisation, and then each surface of slip remains as a species of 'scar' within the metal, taking the form of a thin layer of hard, amorphous material. The presence of these hard layers tends to render the metal both harder and stronger, but also more brittle, and it is well known that this is the universal result of the application of cold work or plastic deformation to ductile metals. If the process of plastic deformation is carried to an extreme, as in the hammering of thin metal foil, a large proportion of the metal may ultimately be present in the amorphous condition; but this condition is unstable, and a very moderate amount of heating is sufficient to induce recrystallisation. This stage, however, is only reached in special circumstances; more usually the application of stress results first in a certain amount of plastic deformation (by slip), followed by a local and rapid deformation—also by slip—which culminates in fracture at some point where the amount of slip has carried the adjacent parts of a crystal out of contact. The fracture resulting from such a mode of breaking has a fine silky fibrous appearance, owing to the fact that all the minute surfaces of slip along which fracture has occurred are inclined at small angles to the direction of stress, but the metal has remained essentially crystalline; indeed, apart from non-metallic inclusions, such as the 'cinder' in wrought iron, there is no true 'fibrous' structure or condition in metals.

The second class of circumstances which do not permit of the immediate re-crystallisation of the layer of disturbed atoms, which are formed on surfaces of slip arise when the stress which has produced a small amount of slip is reversed; such a reversal of the stress will, if it comes soon after the first occurrence of the slip, cause the reversal of the slip itself, and the layer of disturbed atoms will still be in the mobile condition, and will serve as a species of lubricant to facilitate the return slip. At the same time, the reverse motion will produce an increase in the number of disturbed atoms, and the disturbed layer will grow in thickness with each reversal. After a large number of such reversals of stress some of this disturbed material will be forced—in its temporarily mobile state—out of the space between the adjacent sections of the crystal, and what was before a surface slip will thus become an actual fissure, which spreads rapidly through the whole mass. The resulting fracture will show comparatively large bright facets representing the planes on which slip has occurred, so that the fracture will have a 'crystalline' appearance, although the metal itself is neither more nor less crystalline than it was at the beginning. The view that metals 'become crystalline' under alternating stresses or under vibration is thus entirely without foundation. It should be said that the explanation of the manner in which metals fracture under 'fatigue,' *i.e.* under the repeated alternation of stresses which would fail to fracture the material at a single prolonged application, as it has been given here is no longer to be regarded as of a speculative character, since every point in the explanation has been definitely observed and verified by several independent observers (Ewing and Humfrey, The Fracture of Metals under Repeated Alternations of Stress, Phil. Trans. A, 1903, 200; Stanton and Bairstow, The Resistance of Iron and Steel to Reversals of Direct Stress, Proc. Inst. C.E. 1907).

The conception of the part which amorphous metal plays in the whole mechanism of the cohesion of crystalline aggregates in general, and of metals in particular, has in recent years received considerable extension by the development of what has come to be known as the 'Amorphous Cement' theory (Rosenhain and Ewen, Intercrystalline Cohesion in Metals, Journ. Inst. Metals, 1912, [viii.] 2, 149–185; same authors and title, Second Paper, Journ. Inst. Metals, 1913, [x.] 2, 119–149; Rosenhain and Humfrey, The Tenacity, Deformation, and Fracture of Mild Steel at High Temperatures, Journ. Iron and Steel Inst. 1913, [i.] 219–271; Bengough, A Study of the Properties of Alloys at High Temperatures, Journ. Inst. Metals, 1912, [vii.] 2). According to this view, when a metal solidifies from fusion, or undergoes recrystallisation in the solid state, the crystals grow outward from their respective centres or nuclei, ultimately limiting each other by approaching to contact; actual contact between adjacent crystals, however, only occurs at a few points, a small residuum of the metal being retained in the amorphous or under-cooled liquid condition filling the minute interstices between adjacent crystals and acting as an amorphous cement, whose relatively great strength and hardness accounts for the special strength which is known to reside in the intercrystalline boundaries in pure metals. That such a residue of uncrystallised materials should remain in the crystal junctions is ascribed to the counterbalancing effect of opposed

crystalline orienting forces emanating from the two adjacent crystals, but considerable difference of opinion exists, even among the supporters of the theory, as to the probable thickness of these hypothetical layers of amorphous cement. Although at first put forward essentially as a working hypothesis to account for certain special facts, so large a volume of evidence has since been brought forward in support of the theory that considerable importance must now be attached to it, particularly as it is found that this conception brings together under a single, simple explanation a very wide range of otherwise apparently unconnected facts, such as the modes of fracture of metals both at the ordinary temperatures and at temperatures near their melting-points, their behaviour *in vacuó*, and the action of certain gases on metals.

The methods of metallography, although they have so far been described largely from the point of view of affording a clearer insight into the nature and constitution of metals and alloys, are also capable of direct practical applications. These applications include, in the first place, the control of metallurgical operations, particularly of the temperatures employed in thermal and mechanical treatment of all kinds and the investigation of new alloys. There is also an important field of usefulness for these methods, and more especially for the microscopic examination of metals in conjunction with exhaustive mechanical tests, in the investigation of cases of failure or breakage either under test or in service, including such questions as apparently mysterious fractures, unduly rapid wear or corrosion and similar problems. Although it would be too much to claim that metallographic methods are always capable of finding the correct solution of problems of this class, a great deal of light can often be thrown upon the causes which have led to the failure, and, in many instances, the true cause of failure can be discovered. A considerable number of such investigations have been described (W. Rosenhain, The Study of Breakages, Engineering, Sept. 1908; W. Rosenhain and D. Hanson, A Cause of Brittleness in Mild Steel Boiler Plates, Journ. Iron and Steel Inst. 1918, I.), but the greater number are—for obvious reasons—never allowed to reach the public. It is, however, to be borne in mind that it is largely by the investigation of cases of unexpected breakage or other failure that fresh knowledge on the properties of our engineering materials can be obtained. In a number of actual cases it has been found that the metal had been damaged by modes of treatment which had been regarded as harmless. Metallography is therefore a science which has not only placed in the hands of metallurgists a mass of valuable and detailed knowledge of the internal structure and constitution of metals and alloys, but it has also furnished them with methods of investigation which are probably destined to elucidate many of the still 'mysterious' features in the behaviour of the materials of engineering. W. R.

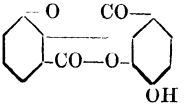
METANIL YELLOW *v.* AZO- COLOURING MATTERS.

METANILIC ACID $NH_2C_6H_4SO_3H$ Prepared by sulphonating nitrobenzene and reducing the nitrobenzene sulphonic acid by iron turnings, neutralising with milk of lime, filtering, and evaporating. Used for making metanil yellow.

METARABIN *v.* GUMS.

METAXYLORCINOL *v.* PHENOL AND ITS HOMOLOGUES.

METELLAGIC ACID. Metellagic acid $C_{14}H_6O_8$ is prepared by the oxidation of *m*-hydroxybenzoic acid with potassium persulphate and sulphuric acid. It crystallises from pyridine in colourless prismatic needles, and when distilled with zinc dust gives fluorene. The acetyl derivative $C_{14}H_6O_8(C_2H_3O)$, colourless needles, melts at 269°–271°. According to Perkin and Nicrenstein (Chem. Soc. Trans. 87, 1425), metellagic is related to ellagic acid, and possesses the following constitution:



METHACETIN. *p*-Methoxy-acetanilide

An antipyretic and analgesic.

METHAL *v. Spermaceti*, art. WAXES.

METHANE. *Methyl hydride* (*v.* METHYL COMPOUNDS).

METHOXYBENZENE. *See* ANISOLE.

***p*-METHOXYBENZENEDIAZO CYANIDES** *v.* DIAZO- COMPOUNDS.

METHOZIN. A synoym for antipyrine.

METHYL, CH_3, is a univalent, compound radicle, not known in the free state. The compound C_2H_6 discovered by Frankland and Kolbe (Chem. Soc. Trans. 1, 60) was called methyl, and believed to be the free base, and even when its molecule was recognised as dimethyl $(CH_3)_2$, it was at first thought to be distinct from ethane, the gas obtained by Frankland from ethyl iodide by heating with zinc and water. It was, however, proved to be identical with that body by Schorlemmer (Chem. Soc. Trans. 17, 262).

METHYL COMPOUNDS.

Methyl acetate *v. Alkyl acetates*, art. ACETIC ACID.

Methyl alcohol CH_3OH. *Methyl hydrate*, *hydroxymethane*, *wood spirit*, *pyroxylic spirit*, *wood naphtha*, 'Columbian spirit,' 'Colonial spirit,' 'Manhattan spirits,' 'kakol' (proprietary names in U.S.A.); 'green wood spirits' and 'standard wood spirits' in Canada, 'prospirit' in Germany (Ger. *Holzgeist*). B.p. 64·56°/760 mm. (J. Gyr, Ber. 1908, 4322); 64·96° (corr.) (Thorpe and Rodger); sp.gr. 0·796472 at 15°/15° (Klason and Norlin, Chem. Soc. Abstr. 1906, i. 821; Gyr, Ber. 1908, 4322; Doroschewsky and Roschdestvensky, Chem. Soc. Abstr. 1909, i. 868); 0·81000 at 0°/4° (Young and Fortey, Chem. Soc. Trans. 1902, 735); m.p. −94·9° (Ladenburg and Krugel); H.C.=170·6 (Stohmann, Kleber, and Langbein, J. pr. Chem. [ii.] 40, 341); H.F.=61·4 (S., K., and L.).

Boyle found that the liquid obtained by distilling wood contained two constituents, an acid portion and a neutral spirit. Various conjectures were made as to the nature of this

'spirit,' the first investigation of which was made by Dumas and Peligot in 1834 (Ann. Chim. 58, 5; 61, 193). They gave it the name 'methyl alcohol' (*μέθυ*, wine; *ὕλη*, wood).

Formation.—By the dry distillation of wood, of beet-sugar molasses (Vincent, Bull. Soc. chim. [ii.] 27, 148), or of calcium formate (Paternò and Lieben, Annalen, 167, 293; Friedel and Silva, J. 1873, 526). Methyl alcohol occurs in the free state and as methyl esters in plants (Gutzeit, Maquenne, Geuther), forming various essential oils. It is also recovered from the waste water of the steamed wood pulp in paper manufacture, by allowing the liquors to concentrate through repeated use and subsequently distilling (Alkier, Eng. Pat. 1514, 1890). According to Takahashi, Gunke, and Yamazaki (J. Amer. Chem. Soc. 1917, 39, 27231), most fermented drinks contain small quantities of methyl alcohol.

Preparation.—Methyl alcohol is prepared on the large scale from the distillate from wood, which contains various tarry matters, acetic acid, and the methyl alcohol. The distillates from the wood are allowed to stand for some time, when the tarry, resinous, and oily matters precipitate; the supernatant liquid is then filtered through gravel into another vessel, from which it is either distilled at once or after previous neutralisation with lime. The distillation is effected in the first case in copper stills, and heat is applied by coils of copper pipes conveying steam; in the second case boilers of sheet iron are employed, and the heat applied by the direct fire.

The distillate is then purified by repeated redistillations from caustic lime, and lastly, from a little sulphuric acid (in order to remove NH_3 and amines). In some cases chalk is used instead of lime, and sometimes chalk and sodium bicarbonate.

The distillation is carried on in copper stills heated by steam coils, or the retorts are guarded by iron jackets, and heated over the fire. The crude spirit thus obtained is colourless, and its sp.gr. varies from 0·87 to 0·82.

The disagreeable-smelling constituents are sometimes got rid of by Wildsmith's process, which consists in the application of oxidising agents, *e.g.* potassium dichromate, aided by the action of light, to the crude spirit, by which means the hydrocarbons, &c., are destroyed, and a colourless, almost odourless, liquid obtained.

The usual yield of pyroxylic spirit is from 1 to 3 gallons from each ton of wood distilled, but the quantity depends upon the kind of wood employed, and also upon the proper regulation of the temperature during distillation. The best yields are obtained by using a mixture of oak, beech, and hornbeam (Barillot, Compt. rend. 122, 469).

In the United States birch, beech, maple, oak, elm, and alder are used, together with sawdust and wood-waste. The wood is seasoned for 1 to 2 years and cut into lengths of 50 inches, which are distilled in iron retorts at 200°–260° (*see* WOOD, DESTRUCTIVE DITILLATION).

Large quantities of methyl alcohol are now made by the distillation of vinasse (residues obtained by the evaporation of the spent wash in the preparation of ordinary alcohol from beet-sugar molasses). The distillate contains ammoniacal compounds, methylamine, methyl cyanide, and methyl alcohol. After neutralising with sulphuric acid the mixture is evaporated, the vapours being condensed; these contain methyl cyanide and methyl alcohol; the former is decomposed by rectification over lime, and the distillate, which contains dilute methyl alcohol, is dehydrated by means of lime. Methyl alcohol is also formed in the manufacture of wood pulp and from waste esparto liquors.

Commercial wood spirit contains very variable proportions of the pure alcohol, from as low as 35 p.c. to as high as 95 p.c. It contains acetone, methyl acetate, and formate, allyl alcohol, aldehyde, methylamine, and often various empyreumatic bodies; these have considerable influence, not only upon its density, but also upon its solvent powers for shellac and other resins. The 'tailings' contain furfural, methyl-ethyl ketone, and allyl acetate with small quantities of paraxanthine. The crude alcohol has a sp.gr. of 0·796–0·875 at 15·5°. The purest spirit is always preferred for use in lamps as a fuel, but for the use of the varnish-makers and polishers some of the impurer varieties, containing essential oils, &c., are sometimes chosen.

The following process for the production of methyl alcohol from wood is patented by F. J. Root (U.S. Pat. 713552, 1902). In the destructive distillation, a pressure is maintained in the apparatus slightly lower than that of the atmosphere. The readily condensable gases are condensed in primary condensers, whilst the gases which are not readily condensable are mixed with a definite proportion of steam and the acids thus set free are recovered in a secondary condenser. The degree of vacuum and the supply of steam required for mixing with the less condensable gases are obtained by means of a steam exhauster situated beyond the primary condensers. This exhauster is regulated automatically by the volume and tension of the gases generated so that both functions are kept constant. The introduction of superheated air, containing only a little oxygen and a good deal of steam, which increases the yield of volatile products in the ordinary destructive distillation, is patented by Zwillinger (Eng. Pat. 18823, 1889).

A variant of the ordinary method of destructive distillation of wood consists in first adding strong sulphuric acid. 100 kilos. of wood, containing 35 p.c. of moisture, with 20 kilos. of strong sulphuric acid on distillation up to 160° and rectifying the distillate, yield wood alcohol 3 kilos., acetic acid 7 kilos., oil of turpentine 2 kilos., and 40 kilos. of wood charcoal of good quality (Orljavacer, Chem. Fabrik, Fr. Pat. 357432, 1905).

Hofer and Moest find that a good yield of methyl alcohol is obtained by the electrolysis of sodium acetate solution containing sodium chlorate (Annalen, 323, 284; D. R. P. 138442, 1901).

The conversion of methane, which often occurs in large quantities near oilfields, into methyl alcohol or other commercially useful articles, is a problem which is still undergoing investigation. Lance and Elworthy (Eng. Pat 7297, 1906) claim the use of hydrogen peroxide (with or without ferrous sulphate or monopersulphuric acid) and monopersulphuric acid

alone. Von Unruh has utilised atmospheric air as an oxidising agent with bark as a catalyst, but in this case methyl alcohol is the subsidiary product, the oxidation proceeding further and producing formaldehyde chiefly. 24 litres of methane by this process, when mixed with 180 litres of air at 45°, yield in the apparatus described 1565 grams of formaldehyde in 12 hours (U.S. Pat. 891753, 1907; *see also* Hausmann & Co., D. R. P. 214155, 1906).

Attempts have been made to chlorinate natural methane under the action of light and to hydrolyse the methyl chloride produced to methyl alcohol, but without economic success (*cf.* Walter, D. R. P. 222919; Bedford, J. Ind. Eng. Chem. 1916, 10, 1090). Methyl chloride can be completely converted to methyl acetate by passing it over porous sodium acetate at about 295° and into methyl alcohol by passing it over slaked lime at 300°.

Purification.—According to a method patented by Piper and Rotten of Berlin (D. R. P. 36827, 1886), the wood spirit is first distilled with lime and then by fractional distillation; the acetone is thus reduced to 1 or 2 p.c. To remove the remaining acetone the spirit is heated to boiling (with reflux condenser), and dry chlorine is passed into it; portions are tested from time to time by distilling, and testing the distillate for acetone by the iodoform reaction (*see also* Rotten, J. Soc. Chem. Ind. 1901, 604). Treatment with bleaching powder is also sometimes adopted. When this reaction is no longer given the passage of the chlorine is stopped, and the methyl alcohol separated by fractional distillation from the high boiling chlorinated acetone, and purified by distillation over lime from traces of chlorine. The methyl alcohol thus obtained is perfectly free from acetone; the chloracetone can be reconverted into acetone by reducing agents. Methyl alcohol purified in this way invariably contains some chlorinated impurities, which may be removed by heating under a reflux condenser with lime.

In order to obtain pure methyl alcohol, the oxalic or formic ester is prepared, and then decomposed by heating with water (Wöhler, Annalen, 81, 376), or ammonia (Grodzki and Krämer, Ber. 7, 1494). Methyl benzoate when heated with a solution of 1 part sodium hydroxide in 5 parts of water yields methyl alcohol (Carius, Annalen, 110, 210). Pure methyl alcohol may be prepared by treating 10 parts of commercial wood spirit with 1 part of iodine, and then adding caustic soda until the colour of the iodine disappears, and distilling (Regnault and Villejean, Bull. Soc. chim. [ii.] 42, 255). 100 c.c. of the crude spirit are digested with 150 grams of solid caustic soda, and afterwards distilled, 500 grams of oxalic acid are mixed with 200 c.c. of sulphuric acid, and then 400 c.c. of the purified alcohol are added, and the mixture is heated on the water-bath; the crystals of methyl oxalate are dried by pressure and saponified by heating with water at 70°. The distillate is then dehydrated by means of baryta, lime, and anhydrous copper sulphate (Dittmar and Fawsitt, Trans. Roy. Soc. Edin. 33, 509). Apparatus for the purification of wood spirit is best constructed of aluminium or an aluminium alloy free from copper. Copper heavily coated with tin, or iron or copper lined with earthenware may also be used with connecting pipes of earthenware. Air should be excluded as completely as possible, as this oxidises the methyl alcohol to formaldehyde, acetaldehyde, and methylal, the reaction being readily catalysed by copper vessels. Aldehyde resin is likely to form in the still if the alkaline reagent has been added to the crude wood spirit (P. Pikos, J. Soc. Chem. Ind. 1909, 1118).

The following is a continuous method of preparing pure concentrated wood spirit. The crude spirit is distilled and the vapours passed first through lime water, then warm concentrated alkali solution (15°–20° Beaumé), afterwards washed with stearic or other fatty acid, and finally with alkali again. This treatment removes all aldehydic resins, higher alcohols, ketones, &c. (J. Farkas, D. R. P. 166360, 1904).

The purest anhydrous methyl alcohol is prepared from the best acetone-free commercial article by first heating for some time with freshly burnt lime, then leaving in contact with ignited potassium carbonate for some weeks, and finally distilling several times from metallic calcium. The most accurate criterion of dryness is the esterification constant which, for the anhydrous alcohol and phenyl acetic acid, is 3·556. One-twentieth of a p.c. of water by volume lowers this to about 0·532 and ordinary pure dry methyl alcohol from methyl oxalate is often as low as 0·465 (J. Gyr, Ber. 1908, 4322).

Other processes are patented by Rosenerans (U.S. Pat. 793542, 1905); Chute (U.S. Pat. 824906, 1906); Schmidt (U.S. Pat. 885183, 1908); and Christiansen (U.S. Pat. 1302011, 1919).

Detection and estimation.—The recognition of methyl alcohol itself is a somewhat difficult matter but its oxidation products, formaldehyde and formic acid, are more readily characterised. Of its compounds, the most characteristic is the *oxalate*, which is a crystalline solid melting at 54°. Mulliken and Scudder (Amer. Chem. J. 1899, 21, 266; 1900, 24, 444; J. Amer. Chem. Soc. 1905, 892), Barbet and Jandrier (Chem. Soc. Abstr. 1898, ii. 265), Jandrier (Chem. Zentr. 1899, i. 1296), Leach and Lythgoe (J. Amer. Chem. Soc. 1905, 964), Scudder and Riggs (*ibid.* 1906, 1202), Franz Utz (Chem. Zentr. 1905, ii. 1467), Hinkel (Analyst, 1908, 417), Voisenet (Bull. Soc. chim. 1906, [iii.] 35, 748), Trillat (Compt. rend. 1899, 127, 232), Vorisek (J. Soc. Chem. Ind. 1909, 823), Pieszczek (Pharm. Zeit. 1913, 58, 850), Denigès (Compt. rend. 1910, 150, 530, 831), Bono (Chem. Zeit. 1912, 36, 1171), Mannich and Geilmann (Arch. Pharm. 1916, 254, 50), Wolff (Chem. Zeit. 1919, 43, 555), Ehman (Amer. J. Pharm. 1919, 91, 594), Simmonds (Analyst, 1912, 37, 16), Jones (*ibid.* 1915, 40, 221), Gettler (J. Biol. Chem. 1920, 42, 311), and others have all made contributions to the question of the most reliable test for methyl in the presence of ethyl alcohol (*cf.* Simmonds, Alcohol, Macmillan & Co., 1919). As an outcome, the following official test of the U.S. Pharmacopœia has been adopted for quantities of 2 p.c. and upwards: the liquid is diluted so as to contain about 10 p.c. total alcohols. About 3 c.c. is oxidised by plunging a red hot copper spiral five or six times into it while it is kept from boiling away by being surrounded by a beaker of cold water. It is then filtered and

boiled till free from the smell of acetaldehyde. After cooling, 1 drop of 0·5 p.c. resorcinol is added and sulphuric acid poured into the test tube so as to form a layer. It is allowed to stand for 3 minutes and gently rotated. If no rose-red ring appears, methyl alcohol is below 2 p.c. Quantities from 2 p.c. down to 0·1 p.c. may be detected by fractionating 50 c.c. three times through a good fractionating head. The first two distillations should proceed till about 35 and 20 c.c. respectively in the case of a strong spirit, or 20 and 10 c.c. with a weak one, have passed over. The first 3 c.c. of the third distillation is tested as above.

The detection of methyl alcohol in the presence of formaldehyde necessitates first the removal of the formaldehyde. This may be done in several ways. Gnehm and Kaufler (Chem. Soc. Abstr. 1904, ii. 520; 1905, ii. 209) recommend combining it with sodium sulphanilate. Stritar (*ibid.* 1904, ii. 686) uses ammonia. Bamberger (*ibid.* 786) prefers sodium hydrogen sulphite. The best reagent for this purpose is probably potassium cyanide, as proposed by Leffmann (Chem. Zentr. 1905, ii. 1467). The methyl alcohol is subsequently distilled off and estimated by the sp.gr. of the distillate. *See also* Duyk (Chem. Soc. Abstr. 1902, ii. 110) and Blank and Finkenbeiner (Ber. 1906, 1326).

A review of the various methods of detecting methyl alcohol in presence of ethyl alcohol is given by Simmonds, 'Alcohol,' Macmillan & Co., which also contains a description of the process of Denigès, as modified by Simmonds, and adopted in the Government Laboratory, London. The book contains a useful bibliography on the subject. Chaplin has also described a modification of Denigès' method, which is claimed to increase its sensitiveness and to avoid false reactions (Analyst, 1921, 375). The solution to be tested is diluted until it contains 5 p.c. of total alcohols; 5 c.c. of this solution are then mixed with 0·3 c.c. of 85 p.c. phosphoric acid, and 2 c.c. of 3 p.c. potassium permanganate solution are added. When the permanganate is decomposed completely (about 10 minutes) 1 c.c. of 10 p.c. oxalic solution is added, followed, after 2 minutes, by 1 c.c. of concentrated sulphuric acid and 5 c.c. of Schiff's reagent. If a blue or violet coloration does not appear after 10 minutes (any coloration due to acetaldehyde will have disappeared in this time) there is present less than 0·2 p.c. of methyl alcohol in the mixed alcohols.

Table showing percentage of methyl alcohol in aqueous solutions at 15° (*Klason and Norlin, Arkiv för Kemi Mineralogi och Geologi, vol.* 2, *No.* 27).

A table published by Doroschewsky and Roschdeslvensky (J. Russ. Phys. Chem. Soc. 1900, 41, 977) differs in no essential particular from the above table.

For the estimation of methyl alcohol, in the absence of other materials than water, a reference to the table of sp.gr. is the most rapid method, but Zeisel's well-known methyl iodide method is very reliable. The latter is only interfered with by acetal or ethyl alcohol. In the presence of ethyl alcohol the most accurate method is that due to Thorpe and Holmes (Chem. Soc. Trans. 1904, 1), depending on the fact that when oxidised with dichromate and sulphuric acid, ethyl alcohol gives rise to acetic acid and a minute quantity (about 0·5 p.c.) of carbon dioxide, whilst methyl alcohol is completely oxidised, under the stipulated conditions, to carbon dioxide and water. The process is as follows: the sample is mixed with water in such proportion that 50 c.c. of the mixture shall contain not more than 1 gram of methyl alcohol, and in the presence of ethyl alcohol not more than 4 grams of the mixed alcohols. Fifty c.c. of this mixture are then introduced into the oxidation flask, 20 grams of potassium dichromate, and 80 c.c. of dilute sulphuric acid (1 : 4) added, and the mixture allowed to remain for 18 hours. A further quantity of 10 grams of potassium dichromate and 50 c.c. of sulphuric acid mixed with an equal volume of water are now added and the contents of the flask heated to boiling for about 10 minutes. The carbon dioxide is swept out by a current of air and collected in weighed soda-

lime tubes. When ethyl alcohol is present, a subtractive correction of 0·1 gram of carbon dioxide for each gram of ethyl alcohol must be made This method is of great convenience in determining the adulteration of tinctures and other medicinal preparations by methylated spirits.

Other substances yielding carbon dioxide in these circumstances are allyl alcohol, methyl acetate, and acetone. Ether and pyridine do not affect the estimation.

Properties.—A colourless liquid with an odour like that of ethyl alcohol; miscible with water in all proportions, and with contraction and evolution of heat (*v.* table). It burns with a blue flame. It possesses, like ethyl alcohol, remarkable solvent powers, dissolving most substances which are soluble in ethyl alcohol; consequently it may be used in many cases instead of that liquid.

Methyl alcohol, like strong ethyl alcohol, is a toxic substance, its poisonous nature being attributed to its conversion into formaldehyde (Bösscken and Waterman). For a bibliography of the literature relating to the toxicity of methyl alcohol, *see* Morson (J. Soc. Chem. Ind. 1918, 26, T). According to Langgaard (Chem. Zentr. 1912, ii. 1382) methyl alcohol is more poisonous than ethyl alcohol when taken in repeated small quantities, but ethyl alcohol is much more dangerous when taken in a single large dose.

Its vapour pressure at various temperatures is given in the following table (Dittmar and Fawsitt):—

Temperature	Vapour pressure	Temperature	Vapour pressure
°C.	mm.	°C.	mm.
0°	29·7	40°	259·4
5°	40·2	45°	327·3
10°	53·8	50°	409·4
15°	71·4	55°	507·7
20°	94·0	60°	624·3
25°	122·7	65°	761·1
30°	158·9	64·96°	760·0
35°	203·9		

A similar table, ranging from 0° to 240°, has been published by Young (Scient. Proc. Roy. Dublin Soc. 1910, 440).

Anhydrous copper sulphate is slightly soluble in absolute methyl alcohol, yielding a bluish-green solution, hence it cannot be used as a test of the freedom of methyl alcohol from water (Kelpl, J. pr. Chem. [ii.] 25, 526). This blue solution deposits crystals of $CuSO_4,2CH_3OH$ (Forcrand, Compt. rend. 102, 551). Hydrated copper sulphate dissolves to the extent of 11·5 p.c. at 0° and the solution on standing deposits green rosettes of crystals having the composition $3CuSO_4{\cdot}CuO,4CH_3OH$ (Auger, *ibid.* 142, 1272). Methyl alcohol combines with many salts in a manner similar to water of crystallisation, *e.g.* $LiCl,3CH_3OH$; $MgCl_2,6CH_3OH$; $CaCl_2,4CH_3OH$, six-sided tables, decomposed by water, may be heated to 100° without decomposition (Kane, Phil. Mag. [iii.] 10, 45). A compound with barium oxide, $BaO,2CH_3OH,2H_2O$, is obtained in brilliant prisms, when BaO is dissolved in aqueous methyl alcohol, and the liquid evaporated at the ordinary temperature (Forcrand, Compt. rend. 102, 1557).

When passed over heated zinc, methyl alcohol yields carbon monoxide, hydrogen, and a small quantity of methane (Jahn, Ber. 13, 983). In contact with heated copper it is decomposed into formaldehyde and hydrogen. A large proportion of the formaldehyde is polymerised to methyl formate, whilst another portion is resolved into carbon monoxide (Mannich and Geilmann, Ber. 1916, 49, 585). At higher temperatures (1150°) it is completely resolved into carbon monoxide and hydrogen, the decomposition taking place in two stages which proceed simultaneously. In the first stage formaldehyde and hydrogen are formed, and the formaldehyde is then decomposed, giving carbon monoxide and hydrogen (Peytral, Compt. rend. 1917, 165, 703). By the action of zinc chloride, hydrocarbons C_nH_{2n+2} are the chief products, also some hexamethyl benzene (Le Bel and Greene, J. 1878, 388). By electrolysis in presence of sulphuric acid, *methylal* $CH_2(OCH_3)_2$ is produced (Renard, Ann. Chim. Phys. [v.] 17, 290).

Methyl alcohol is not decomposed by *bacterium aceti*. Potassium or sodium liberates hydrogen and forms a methoxide; sodium methoxide $NaCH_3O$ combines at 160° with carbon monoxide to form sodium acetate.

Magnesium dissolves in methyl alcohol on gently heating, forming magnesium methoxide, which separates in pointed prisms from solutions containing about 6 grams in 40 of alcohol, or as an amorphous powder from more concentrated solutions. The crystals contain 3 molecules of methyl alcohol and effloresce rapidly. Bromine converts it into bromoform and magnesium bromide. Magnesium nitride reacts energetically with methyl alcohol forming trimethylamine, according to the equation:

$$Mg_3N_2+6CH_3OH = 3Mg(OH)OCH_3+NH_3+N(CH_3)_3$$

(Szarvasy, Ber. 1897, 305, 806).

Chlorine acts on methyl alcohol readily if moist. In diffused daylight at 99·5° the chief product is formaldehyde, which probably results through the intermediate formation of chloromethyl alcohol CH_2ClOH, and dichloromethyl ether $(CH_2Cl)_2O$. The latter may actually be isolated. Carbon dioxide and carbon monoxide and also methyl chloride are continuously evolved during the reaction. If the alcohol is diluted with water the reaction proceeds with explosive violence. Bromine has but little action, but in sunlight at 130°–150° methyl bromide is formed, mixed with carbon monoxide and dioxide and formic acid if the bromine is not in excess.

Iodine is even more inert, but at 180°–200° hydrogen iodide, carbon dioxide, and methyl iodide are formed. The chief bulk of the alcohol is converted into methyl ether, which is also readily produced by heating the alcohol in sealed tubes with 5 p.c. of iodine (André Brochet, Compt. rend. 121, 130).

Cold methyl alcohol absorbs one molecular proportion of boron trifluoride forming *boron methoxy difluoride* $BF_2{\cdot}OCH_3$, crystallising in prisms melting at 41·5° and boiling at 87°.

Sodium methoxide (1 mol.) readily converts this compound into *boron dimethoxy fluoride*

$$BF(OCH_3)_2$$

which is a colourless mobile liquid fuming in air, burning with a green flame, and boiling at 53°. It has a sp.gr. of 1·053 at 0°. Sodium methoxide changes this into *methyl borate* $B(OCH_3)_3$. Methyl borate boils at 55°–56° and has sp.gr. 0·919 at 0°. It burns with a green flame and is readily decomposed by moist air or water.

There is also formed by the action of boron trifluoride on methyl alcohol a molecular compound with methyl ether, $BF_3,O(CH_3)_2$. It boils at 126°–127° and dissociates at a slightly higher temperature. In addition an acid product of still higher boiling-point is produced to a small extent (V. Gasselin, Ann. Chim. [vii.] 3, 5).

The catalytic oxidation of methyl alcohol to formaldehyde is the subject of several papers by E. Orloff (J. Soc. Chem. Ind. 1908, 139, 419, 1176). Ozone oxidises methyl alcohol to formaldehyde very readily in 50 p.c. aqueous solution (Harries, Ber. 1903, 1933).

White phosphorus, when heated with methyl alcohol (1 mol.) for some hours at at least 250°, produces tetramethyl phosphonium hydroxide and, in addition, phosphines and phosphoric acid (J. Berthaud, Compt. rend. 143, 1166).

Methyl alcohol decomposes diazonium salts, forming, with benzene diazonium nitrate, anisole, *o*-nitrophenol, and 2 : 4-dinitrophenol. If water is present, *p*-nitrophenol is also formed. The alkoxy derivative only is produced from diazobenzenesulphate. Sodium methoxide in solution in methyl alcohol produces benzene and diphenyl (Beeson, Amer. Chem. J. 16, 235).

Impurities.—The impurities of commercial wood spirit are small quantities of aldehyde, dimethylacetal, allyl alcohol, acetone, methylethyl ketone, higher ketones, and chloroform.

Acetone is the most objectionable, especially when the alcohol is to be used in the preparation of aniline colours. In order to estimate the amount of acetone 1 c.c. of the wood spirit is mixed with 10 c.c. of a double normal solution of soda, and 10 c.c. of a double normal solution of iodine are added with constant shaking, and then 10 c.c. of absolute ether. The ethereal layer is then measured, an aliquot portion taken and evaporated on a watch-glass and the residual iodoform weighed. The weight of the iodoform (calculated to the total volume of ethereal solution) multiplied by 0·28 gives the amount of acetone in 1 c.c. of wood spirit (Kramer, Ber. 1880, 1002).

According to Messenger (Ber. 21, 3366), this method gives too high results if the quantity of acetone be small. The following method and details are due to Milan and Stritar (Zeitsch. anal. Chem. 1904, 387). *Crude wood spirit :* 5 c.c. are diluted to 500 c.c. and 5 c.c. of this mixture are submitted to Zeisel's process. The weight of silver iodide multiplied by 272·9 gives grams of methyl alcohol per 100 c.c. *Aqueous wood spirit* containing under 10 p.c. methyl alcohol: 10 c.c. are diluted to 50 c.c. and shaken for ½ hour with 0·5 gram of charcoal, filtered, washed, and diluted to 100 c.c. and estimated as above. *Crude pyroligneous acid :* 50 c.c. are neutralised with sodium carbonate made up to 250 c.c. and filtered. 100 c.c. are then made strongly alkaline and distilled till 50 c.c. have collected. The distillate is treated with charcoal, &c., as above. The shaking with charcoal removes guaiacol and other phenol ethers, but the estimation is invalidated by the presence of acetal, methyl acetate, and allyl alcohol. A correction for these may be made by determining the iodine number and esterification number of the sample.

Methyl benzoate $C_6H_5{\cdot}COO{\cdot}CH_3$. Prepared by heating a mixture of benzoic acid, methyl alcohol, and sulphuric acid. A colourless liquid, of aromatic smell; b.p. 198·6°; sp.gr. 1·0942 at 15°/15°. Known as 'Niobe oil,' and used in perfumery.

Methyl boride $B(CH_3)_3$, *bormethyl, trimethylborine,* V.D. 1·9108 (calc.=1·9314), a gas obtained from methyl borate by the action of zinc methyl (Frankland and Duppa, Annalen, 124, 129); has an intensely disagreeable smell, ignites spontaneously in the air; can be liquefied by a pressure of three atmospheres at 10°. Caustic potash absorbs the gas and yields, on evaporation, a viscid residue of $B(CH_3)_3{\cdot}KOH$. Ammonia forms a compound $B(CH_3)_3{\cdot}NH_3$, which can be crystallised from ether in large crystals; m.p. 56°; b.p. 110°.

Methyl bromide CH_3Br, *bromomethane*; b.p. 4·5° (corr.) (Perkin, Chem. Soc. Trans. 1884, 454); sp.gr. 1·73306 at 0·8°/0·8°.

Preparation.—By heating the cacodyl compound $As(CH_3)_2(OH)_2Br$ (Bunsen, Annalen, 46, 44); from methyl alcohol, bromine, and phosphorus (Pierre, Ann. Chim. [iii.] 15, 373). 133 grams red phosphorus, 800 grams methyl alcohol, are mixed in a retort, the mixture heated to the boiling-point, and 800 grams of bromine are gradually added; after some hours the mixture is distilled (Merrill, J. pr. Chem. [ii.] 18, 293; Steinkopf and Schwen, I. prakt. Chem. 1921, 102, 363). By dropping methyl sulphate into hydrobromic acid at 45°–50°, or better into a concentrated solution of an alkali bromide slightly acidified with sulphuric acid, at 30°–35° (Boulin and Simon, Compt. rend. 1920, 170, 595). By the action of hydrogen bromide, or potassium bromide and sulphuric acid, on methyl alcohol (Taboury, Bull. Soc. chim. 1911, [iv.] 9, 124; Bygden, J. pr. Chem. 1911, [ii.] 83, 421).

Methyl bromide is a colourless mobile liquid with a smell resembling that of chloroform, unites with water to form a crystalline hydrate $CH_3Br,20H_2O$ (?) which is decomposed at 4° (Merrill)

For brominated compounds of methyl bromide, *v. Methylene bromide,* art. BROMOFORM; and *Carbon tetrabromide,* art. CARBON.

Methyl chloride CH_3Cl, *chloromethane*; b.p. −23·73° (Regnault); −21° (Berthelot); −23° (Vincent and Delachanal); sp.gr. 0·99145 at −23°; 0·95231 at 0° (Vincent and Delachanal, Bull. Soc. chim. [ii.] 31, 11). Vap. press. at 0°= 2·48 atmospheres, at 15°=4·11, at 30°=6·50 (Vincent and Delachanal). For compressibility, *see* Bodareu, Atti R. Accad. Lincei, 1914, [v.] 1, 491.

Preparation.—From methyl alcohol, common salt and sulphuric acid (Dumas and Peligot, Annalen, 15, 17); from methane and chlorine (Berthelot, Ann. Chim. [iii.] 52, 97); by heating

the cacodyl compounds $As(CH_3)_2(OH)_2Cl$ or $As(CH_3)_2Cl$ (Bunsen, Annalen, 46, 44).

On the large scale by the dry distillation of 'vinasses' from beetroot. The methylamine is saturated with hydrochloric acid and concentrated, then heated to 260°-300°, when methyl chloride together with mono- and trimethylamine is evolved; the bases are removed by means of hydrochloric acid and the methyl chloride dried over calcium chloride and condensed by pressure in wrought-iron cylinders (Vincent and Delachanal, Bull. Soc. chim. [ii.] 31, 11; J. 1878, 1135). One part of melted zinc chloride is dissolved in two parts methyl alcohol and hydrogen chloride led into the mixture (Groves, Chem. Soc. Trans. 1874, 641).

Methyl chloride is obtained from methane by the action of carbonyl chloride at high temperatures:

$$CH_4+COCl_2=CH_3Cl+CO+HCl$$

The mixed gases which should contain a slight excess of methane are led over a catalyst capable of acting as a chlorine carrier or of accelerating the reaction by surface condensation (Hochstetter, D. R. P. 292089; J. Soc. Chem. Ind. 1916, 35, 867).

It may also be obtained by heating methyl sulphate with stannic chloride. At low temperatures the substances react with the intermediate formation of the methosulphate of stannyl chloride:

$$SnCl_4+2Me_2SO_4=2MeCl+SnCl_2(SO_4Me)_2$$

a white amorphous solid, decomposed at higher temperatures, giving stannic sulphate and methyl chloride (Boulin and Simon, Compt. rend. 1919, 169, 618).

It may also be prepared by dropping methyl sulphate into hydrochloric acid (D. 1·112) at about 50°:

$$Me_2SO_4+HCl=MeHSO_4+MeCl$$

(Boulin and Simon, *ibid.* 1920, 170, 595).

For observations on the chlorination of methane, *v.* Pfeifer, Mauthner, and Reitlinger, J. pr Chem. 1919, [ii.] 99, 239.

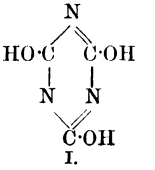
Properties.—Methyl chloride is a colourless gas with ethereal odour, and burns, when ignited in air, with a greenish flame. One part of water dissolves 4 volumes of methyl chloride; 1 of absolute alcohol, 35 volumes; and 1 of acetic acid, 40 volumes (Berthelot). The neutral solution is not precipitated by silver nitrate. With water at temperatures below 7·3° at 760 mm. it forms a solid hydrate $CH_3Cl,6H_2O$ (de Forcrand and Villard, Compt. rend. 106, 1402; Villard, Ann. Chim. [vii.] 11, 377). With chlorine in sunlight it yields methylene chloride (CH_2Cl_2), chloroform ($CHCl_3$), and finally carbon tetrachloride CCl_4 (*q.v.* art. CARBON); the chlorination can also be effected by leading a mixture of chlorine and methyl chloride over animal charcoal at 250°-350°.

Methyl chloride forms with bromine methylene bromide, bromoform and carbon tetrabromide (Damoiseau, J. 1881, 376).

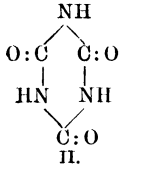
Methyl chloride is extensively used in the preparation of various coal-tar colours and also as a means of producing cold. By its evaporation a temperature of −23° is produced, or if the evaporation be accelerated by blowing in air −55° is easily reached, and since its vapour is non-poisonous, its superiority to liquid sulphur dioxide for this purpose is evident.

Methyl *iso*cyanate $CH_3{\cdot}N:CO$, *methyl carbimide*; b.p. 43°-45° (Gautier, Annalen, 1497, 313). Formed by the distillation of a mixture of 1 part of potassium cyanate with 2 parts of potassium methyl sulphate (Wurtz, Ann. Chim. [iii.] 42, 43); also by the action of diazomethane on nitro-urea (Degner and von Pechmann, Ber. 1897, 649). A liquid with intensely suffocating smell, converted by dry ammonia into methyl-urea $NH(CH_3)CO{\cdot}NH_2$ which forms prisms soluble in water. Water converts it into dimethyl-urea $NH(CH_3)CO{\cdot}NHCH_3$ with evolution of carbon dioxide.

Methyl cyanurates. Monomethyl, dimethyl, and trimethyl derivatives of both normal (I.) and *iso*cyanuric (II.) acids are known.



I.



II.

Normal trimethyl cyanurate $(NCOCH_3)_3$ is prepared from sodium methoxide and cyanogen chloride (Hofmann and Olshausen, Ber. 1870, 271). From dry sodium methoxide and cyanogen bromide (Ponomarew, *ibid.* 1885, 3264; Klason, J. pr. Chem. [ii.] 33, 131). Soluble in ether and water and crystallises in trimetric prisms melting at 135° and boiling at 265°. On long boiling it changes into the isomeride, melting at 175° (trimethyl *iso*cyanurate).

Normal dimethyl cyanurate $C_3N_3(OH)(OC_3H)_2$ results by heating 2 grams sodium in 15 grams absolute methyl alcohol and 15 grams normal trimethyl cyanurate to 100° for 1½ hours and decomposing the sodium salt with acetic acid (Hofmann, Ber. 1886, 2067). It forms small six-sided leaves soluble in alcohol and water but not ether. It softens at 165°-170° and decomposes on further heating into dimethyl *iso*cyanurate, m.p. 222°, and also trimethyl *iso*cyanurate, m.p. 175°.

Trimethyl isocyanurate $C_3O_3N_3(CH)_3$ is produced together with the normal trimethyl ester from silver cyanurate and methyl iodide (Ponomarew, Ber. 1885, 3271); also from the silver salt of the dimethyl derivative and methyl iodide (Hofmann, *ibid.* 1886, 2096); also by the interaction of cyanuric acid and diazomethane (Palazzo and Scelsi, Gazz. chim. ital. 1908, 38, i. 659). Monoclinic prisms melting at 175°-176° and boiling at 274°. Soluble in alcohol but not in water.

Dimethyl isocyanurate $(CH_3)_2H(CNO)_3$ is obtained by the dry distillation of methyl acetyl urea (Hofmann, Ber. 1881, 2069); also from the normal dimethyl derivative (*v. supra*). Monoclinic, thin leaves from water melting at 222°.

Monomethyl isocyanurate

$$(CH_3)H_2N_3C_3O_3,H_2O$$

is prepared by heating nitrosocarbonyldimethylurea with water (Fischer and Frank, Ber. 1897, 2615). It forms thin leaves, readily dehydrated at 100°, melting at 296°-297°, and has an unpleasant odour. On methylation the trimethyl derivative is produced.

Mixed derivatives have been prepared by Hantzsch and Bauer (Ber. 1905, 38, 1005). The di-o-mono-N- derivative, m.p. 105°, is prepared by the interaction of silver cyanate and methyl iodide below 0°. The mono-o-di-N- derivative, m.p. 118°, is prepared from silver cyanurate and methyl iodide at low temperatures.

Methyl cyanide $CH_3{\cdot}CN$, *acetonitrile*; b.p. 81·6°; sp.gr. 0·8052 at 0°, 0·7891 at 15° (Vincent and Delachanal, Bull. Soc. chim. [ii.] 33, 405). H.C. at 18°=312·14 (Thomsen, Th. 4, 128) =291·6 (Berthelot and Petit, Compt. rend. 108, 1217).

From ammonium acetate and phosphorus pentoxide (Dumas, Compt. rend. 25, 383); from acetamide and phosphorus pentoxide; by distillation of potassium methyl sulphate with potassium cyanide (Dumas, Malaguti, and Leblanc, Annalen, 64, 333); in heating cyanacetic acid at 165° (Van 't Hoff, Ber. 1874, 1382); also by heating dimethyl sulphate with potassium cyanide (Walden, Ber. 40, 3214); by passing vapour of anhydrous acetic acid mixed with ammonia through a tube filled with pumice containing a deposit of alumina and heated to 500°. It is also formed by the action of prussic acid on diazomethane (von Pechmann, *ibid.* 1895, 857); and by pouring acetic acid over magnesium nitride (Emmerling, *ibid.* 1896, 1635).

Preparation.—A mixture of 5 molecules of acetamide and 1 molecule of phosphorus pentasulphide is distilled, the product washed with caustic soda and digested with lead oxide (Henry, Annalen, 152, 149). By long heating of a mixture of acetamide and glacial acetic acid under a reflux condenser (Demarçay, Bull. Soc. chim. [ii.] 33, 456).

Acetonitrile is a colourless liquid with a pleasant ethereal smell, miscible with water, from which it separates on the addition of common salt. It burns in air with a peach-blossom flame; with acetic acid at 200° it produces diacetamide. It is miscible with methyl alcohol or with ethyl alcohol, and its b.p. is lowered by such admixture—a liquid containing 80 p.c. wood spirit and 20 p.c. acetonitrile has the lowest b.p. (63·7°), whilst, in the case of ethyl alcohol, a mixture of 56 p.c. spirits of wine and 44 p.c. acetonitrile boils at 72·6° (Vincent and Delachanal, Bull. Soc. chim. [ii.] 33, 405). It combines easily with dry hydrobromic or hydriodic acids, more difficultly with hydrochloric acid (Gautier, Annalen, 142, 291); by passing hydrogen chloride into a cooled mixture of acetonitrile and acetic acid, acetyl chloride and acetamide result (Colson, Bull. Soc. chim. [iii.] 17, 57). $CH_3CN{\cdot}2HBr$ forms crystals melting at 47°–50° (Engler, Annalen, 149, 306). Bromine combines with acetonitrile at 100° to form a compound—$CH_2Br{\cdot}CN{\cdot}HBr$—crystallising in prisms which melt at 65°, and are decomposed by moist air, forming ammonium bromide, acetic acid, and dibromodiacetamide (Engler, Annalen, 133, 137; 142, 69). Sulphur trioxide produces the compound $(CH_3CN)_32SO_3$, which crystallises and dissolves in water, but not in organic solvents. By precipitating its aqueous solution with alcohol and ether crystals of the composition $(CH_3CN)_3(SO_3)_2,H_2O$ are obtained (Eitner, Ber. 1893, 2834).

By the action of sodium upon methyl cyanide, methane and an oily substance $C_4H_6N_2$ soluble in ether (Holtzwart, J. pr. Chem. [ii.] 38, 343), sodium cyanide, and *cyanmethine* $C_6H_9N_3$ are obtained (Baeyer, Ber. 1869, 319). This is best obtained by heating 6 parts methyl cyanide with 1 part of sodium under a pressure of 100 mm., distilling off the excess of methyl cyanide and crystallising the residue from alcohol (Meyer, J. pr. Chem. [ii.] 27, 153). It forms monoclinic crystals (m.p. 180°–181°), which dissolve in 0·64 part of water or 5·25 parts of alcohol at 18°. Cyanmethine unites with many acids, *e.g.* $C_6H_9N_3.HCl$, needles soluble in water; b.p. 200°–250° $(C_6H_9N_3)_2H_2SO_4$, crystallises with difficulty. It also forms chlorine and bromine derivatives (Baeyer, Ber. 4, 176). Treated with aluminium and cold sodium hydroxide solution (15 p.c.) acetonitrile gives a 75 p.c. yield of ethylamine (Ferrer, Anal. Fis. Quim. 1914, 12, 239).

Substitution products of acetonitrile.

Chloracetonitrile $CH_2Cl{\cdot}CN$, from chloracetamide and phosphorus pentoxide (Bisschopinck, Ber. 6, 732); the reaction is better carried out in a vacuum (Scholl, *ibid.* 1896, 2417). A liquid; b.p. 123°–124°, sp.gr. 1·204 at 11·2°, 1·193 at 20° (Engler, *ibid.* 1873, 1003).

Dichloracetonitrile $CHCl_2{\cdot}CN$; b.p. 112°–113°; sp.gr. 1·374 at 11·4° (Bisschopinck, Ber. 6, 732).

Trichloracetonitrile $CCl_3{\cdot}CN$; b.p. 83°–84°, sp.gr. 1·439 at 12·2°. From trichloracetamide and phosphorus pentoxide (Bisschopinck, Ber. 6, 732). By action of chlorine upon acetonitrile in presence of iodine (Beckurts, *ibid.* 1876, 1594).

Bromacetonitrile $CH_2Br{\cdot}CN$, and *dibromacetonitrile* $CHBr_2{\cdot}CN$, m.p. 142°, are also known (*v.* Engler, Annalen, 142, 69, and Van 't Hoff, Ber. 1874, 1571; also Henry, Compt. rend. 103, 413).

Iodacetonitrile $CH_2I{\cdot}CN$; b.p. 186°–187°; sp.gr. 2·3065 at 12°; from chloracetonitrile and sodium iodide in alcoholic solution (Henry, Compt. rend. 103, 413).

Nitroacetonitrile $CH_2(NO_2)CN$ *v.* FULMINIC ACID.

Dinitroacetonitrile $CH(NO_2)_2CN$, a syrupy liquid obtained by the action of sulphuric acid upon the ammonia compound $CH(NO_2)_2CN{\cdot}NH_3$. This compound is obtained by the reduction of an ethereal solution of trinitroacetonitrile by means of dry sulphuretted hydrogen:

$$C(NO_2)_3CN+4H_2S=CH(NO_2)_2CN{\cdot}NH_3+2H_2O+4S$$

(Schischkoff, Annalen, 101, 215; 119, 249; 104, 250).

Trinitroacetonitrile $C(NO_2)_3CN$, a solid, m.p. 41·5°; explodes when heated to 220°. Formed by the action of a mixture of fuming nitric and sulphuric acids upon sodium fulminate (Schischkoff, Ann. Chim. [iii.] 49, 310). Soluble in ether, but decomposed by alcohol, water, or alkalis.

Methyl *iso*cyanide $CH_3{\cdot}NC$, *iso-acetonitrile, methyl carbylamine*; b.p. 59·6°; sp.gr. 0·7557 at 14° (Gautier, Annalen, 152, 222). From methyl iodide and 2 molecules of silver cyanide at 130° (Gautier, Compt. rend. 65, 468); also from chloroform, methylamine, and alcoholic potash (Hofmann). It is also formed in small quantity when potassium methyl sulphate is distilled with potassium cyanide.

Methyl *iso*cyanide is a liquid with a very unpleasant smell; soluble in 10 parts of water at 15°; forms crystalline salts with acids.

Methyl fluoride CH_3F. A gas, sp.gr. (H=1) 17·38, calc.=17·05 (Collie, Chem. Soc. Trans. 1889, 110). Obtained from potassium methyl sulphate and potassium fluoride (Dumas and Péligot, Annalen, 15, 59); by the action of heat upon tetramethyl ammonium fluoride (Collie); from a mixture of methyl iodide and silver fluoride (Moissan and Meslans, Compt. rend. 107, 1153; Chem. Soc. Trans. 1889, 364). Liquefied by a pressure of 30 atmospheres at ordinary temperatures; slightly soluble in water, more so in methyl alcohol. It is very stable; critical temp. 44·9°; pressure 47123 mm. (Collie). For the physical constants of methyl fluoride, *see* Moles and Batuecas, J. Chim. Phys. 1919, 17, 537. Chlorine in sunlight displaces hydrogen and forms CH_2ClF, a gas soluble in water and of sp.gr. 34·18 (calc.=34·25).

Methyl formamide $H{\cdot}CO{\cdot}NH(CH_3)$; b.p. 180°–185° (Gautier, J. 1869, 618); 190° (Linnemann, J. 1869, 601); sp.gr. 1·011 at 19°. A thick oily liquid soluble in water and alcohol, insoluble in ether, formed by the distillation of methylamine formate.

Methyl formate $H{\cdot}CO{\cdot}OCH_3$; b.p. 32°–32·5° (corr.) (Perkin, Chem. Soc. Trans. 1884, 491); Volhard, Annalen, 176, 133). Sp.gr. 0·98239 at 15°/15°.

Preparation.—130 parts of methyl alcohol saturated with hydrogen chloride are gradually poured upon 100 parts of calcium formate; the mixture is then digested for some time, and finally distilled (Volhard, Annalen, 176, 133). A mixture of equivalent proportions of sodium formate, hydrochloric acid, and wood spirit may be used (Bardy and Bordet, Ann. Chim. [v.] 16, 561). Wood spirit is digested with formic acid, sp.gr. 1·22, and distilled; the distillate is then dehydrated by means of phosphorus pentoxide.

Methyl formate is a colourless liquid with a characteristic smell; its vapour is decomposed at a red heat, forming carbon monoxide and methyl alcohol. Chlorine in presence of sunlight yields *trichloro-methyl chloroformate* $Cl{\cdot}CO{\cdot}OCCl_3$, b.p. 127·5°–128°, sp.gr. 1·6525 at 14°, which, when heated at 340°–350°, yields carbonyl chloride $COCl_2$ (Hentschel, J. pr. Chem. [ii.] 36, 99). If the action be stopped at an earlier stage, a compound $C_4H_3Cl_5O_4$, b.p. 108°–109°, sp.gr. 1·4741 at 27°/27°, is formed. In the absence of sunlight, chloroformic ester $Cl{\cdot}COOCH_3$ is produced immediately (Hentschel, J. pr. Chem. [ii.] 36, 213; *cf.* Grignard, Rivat, and Ed. Urbain, Compt. rend. 1919, 169, 1074, and 1143).

Methyl-*cyclo*-hexanone *v. Ketones.*

Methyl hydrate *v. Methyl alcohol.*

Methyl hydride, Methane, *marsh gas,* CH_4; sp.gr. 0·559 (air=1); b.p.=−164·0° at 736·6 mm. (Olszewski, Ann. Chim. [ii.] 31, 58); sp.gr. of liquid=0·415 (O.); critical temp. 82·85; critical pressure, 45·6 atm.; critical density, 0·1623 (Cardoso). H.F.p.=21,750 cals.; H.F.v.=21,170 cals.; H.C.p. 2=11,930 cals. (Thomsen, Th. 4, 50): H.C.p.=213,500 cals. (Berthelot, Ann. Chim. [v.] 23, 179). 1 vol. of water at $t°$ absorbs $0{\cdot}05449-0{\cdot}001807t+0{\cdot}00001028t^2$ vols. of marsh gas; 1 vol. of alcohol at $t°$, $0{\cdot}522586-0{\cdot}0028655t+0000142t^2$ vols. (Bunsen).

Marsh gas is emitted from the surface of the ground in many parts of the world, notably in Italy, North America, and in the vicinity of the Caspian Sea. It is formed by the putrefaction of vegetable matter under water, and hence occurs in marshy places. It is evolved in large quantities from the mud volcanoes of Sicily, Italy, and the Crimea. It also occurs in the coal measures, and, in small quantities, in the gases of the human intestines (Ruge, J. 1862, 528), and in the breath of calves and sheep (Reiset, J. 1863, 638).

It is formed by the putrefaction of cellulose. According to Hoppe-Seyler, this is due to the action of a fungus (*Amylobacterium*, Van Tieghem, Compt. rend. 88, 205), and cellulose (sterilised filter-paper was used) is converted into a non-reducing sugar $C_6H_{12}O_6$, which splits up into $3CO_2$ and $3CH_4$; this action is stopped by a temperature above 60°.

Marsh gas is also produced by the destructive distillation of carbonaceous matter—*e.g.* wood or coal—and hence occurs, to the extent of about 40 p.c. by volume, in coal gas.

It can be obtained from chloroform or carbon tetrachloride by passing the vapour, mixed with hydrogen, through a hot tube, or by heating with copper, potassium iodide, and water (Berthelot, J. 1857, 267). Also by passing a mixture of the vapour of carbon disulphide and sulphuretted hydrogen over heated copper or iron (Berthelot, Ann. Chim. [iii.] 53, 69). Also by the action of the silent electrical discharge upon a mixture of hydrogen and carbon monoxide (Brodie, Proc. Roy. Soc. 21, 245), and by the direct combination of carbon and hydrogen at 1200° (Bone and Jerdan, Chem. Soc. Trans. 1897, 42; Bone and Coward, *ibid.* 1908, 1975), and also by the action of water on aluminium carbide (Moissan, Bull. Soc. chim. [iii.] 11, 1012; 15, 1285).

Carbon dioxide mixed with hydrogen is converted into methane when heated in presence of nickel as a catalyst:

$$CO_2+4H_2=CH_4+2H_2O$$

The reaction begins at 230°, and is rapid and nearly complete between 300° and 400°. By passing the product of the reaction through caustic soda, to free it from unchanged carbon dioxide, and condensing it by liquid air to free it from hydrogen, pure methane may be obtained.

It is also formed by the direct reduction of carbon monoxide by hydrogen in presence of nickel: $CO+3H_2=CH_4+H_2O$. The reaction begins at 180° and proceeds rapidly at 230°–250°. If the gases are mixed in theoretical proportions the methane is obtained almost pure. At temperatures above 250° part of the carbon monoxide is converted into carbon dioxide and carbon: $2CO \rightleftarrows C+CO_2$, owing to the specific action of the nickel at these temperatures.

This last is a simple method of obtaining methane free from admixed gases. For details, *see* Harger, Colliery Guardian, March, 1913; Campbell and Parker, Chem. Soc. Trans. 1913, 103, 1292.

These methods of preparing an industrial gas rich in methane, of high calorific power, and suitable for incandescent lighting, have

been covered by patents. *See* Henderson's Catalysis in Industrial Chemistry, Longmans.

Preparation.—By heating potassium acetate with caustic potash

$$KC_2H_3O_2+KOH=K_2CO_3+CH_4$$

Sodium acetate and a mixture of equal volumes of calcined soda and powdered lime are heated in an iron or copper vessel (Schorlemmer, Chem. News, 29, 7), hydrogen and ethylene are also produced in this reaction (Kolbe); the latter may be removed by means of sulphuric acid.

It can also be obtained by the action of the copper-zinc couple upon a mixture of equal volumes of alcohol and methyl iodide (Gladstone and Tribe, Chem. Soc. Trans. 1884, 154). Methane is also obtained by the decomposition of zinc methyl with alcohol or water.

Properties.—Methane is colourless and odourless, and forms an explosive mixture with air ('firedamp'). In mixtures of methane and air containing from 5 to 9·2 p.c. of methane the decomposition is $CH_4+2O_2=CO_2+2H_2O$, but with larger quantities, in addition to carbon dioxide and water, hydrogen and carbon monoxide are formed. It is very stable, and is not affected by phosphorus pentoxide or antimony pentachloride, or even by strong nitric acid. Dry chlorine has no action in the dark, but in sunlight the mixture explodes; in diffused daylight chloro substitution derivatives are formed, viz. methyl chloride, methylene dichloride, chloroform, and carbon tetrachloride. For observations on the chlorination of methane, *v.* Pfeifer, Mauthner, and Reitlinger, J. pr. Chem. 1919, [ii.] 99, 239; Whiston, Chem. Soc. Trans. 1920, 183. When passed through a hot tube, a small portion is converted into naphthalene. At higher temperatures it is more or less dissociated in amount dependent on the temperature, and the amount and nature of the heated surface (Bone and Coward; Campbell and Slater). It is very gradually absorbed by cold fuming sulphuric acid (Worstall, J. Amer. Chem. Soc. 1899, 246). It may be oxidised to methyl alcohol and formaldehyde (*see Methyl alcohol*).

It forms a hydrate with water at −2° or −3° under a pressure of 30 atmospheres. Tension of dissociation at 0°=27·5 atmospheres; crit. temp.=21·5° (Villard, Compt. rend. 107, 295).

Methyl iodide CH_3I; b.p. 42·3° (corr.) (Perkin, Chem. Soc. Trans. 1884, 459); 42·9° (corr.) (Thorpe and Rodger, Phil. Trans. 1894, A, 11, 464); sp.gr. 2·28517 at 15°/15° (P.); 2·2677 at 15° (Bardy and Bordet, Ann. Chim. [v.] 16, 569). Formed by the action of phosphorus and iodine upon methyl alcohol (Dumas and Péligot, Annalen, 15, 30).

Preparation.—In a similar manner to that of ethyl iodide (*q.v.*). 35 parts methyl alcohol, 100 parts iodine, and 10 parts of phosphorus are the proportions usually employed. These substances are allowed to remain in contact for some hours; the methyl iodide is then distilled off, washed with dilute caustic soda solution, and dried by means of calcium chloride. The preparation from an iodide of an alkali or alkaline earth by the action of methyl sulphate is patented by Weinland and Schmidt (D. R. P. 175209, 1905). A yield of 94 p.c. is obtained by dissolving yellow phosphorus in methyl iodide, and adding iodine to the liquid, and slowly dropping methyl alcohol into the cooled mixture (Walker and Johnson, Chem. Soc. Trans. 1905, 1595).

It forms a colourless liquid which turns brown on exposure to light owing to the liberation of iodine. It is extensively used in the preparation of various aniline colours owing to the ease with which it undergoes decomposition; it thus affords a ready means of introducing the methyl group into other compounds.

Methyl nitrate CH_3NO_3; b.p. 65°; sp.gr. 1·2167 at 15°/15° (Perkin, Chem. Soc. Trans. 1884, 682).

Preparation.—200 c.c. pure wood spirit are distilled with 40 grams urea nitrate and 150 c.c. pure nitric acid (sp.gr. 1·31) until two-thirds have distilled off; to the residue 170 c.c. of methyl alcohol and 130 c.c. nitric acid are added, again distilled, and then 150 c.c. methyl alcohol, 110 c.c. nitric acid, and 10 grams urea nitrate are added to the residue, and distillation again continued (C. Lea, J. 1862, 387).

Can also be prepared by mixing methyl alcohol and sulphuric acid, and adding 2 parts of this liquid to a mixture of 1 part nitric acid and 2 parts sulphuric acid. The distillate is washed with potassium carbonate solution. Delépine recommends the following. A mixture of 50 c.c. strong sulphuric acid and 150 c.c. methyl alcohol cooled to 12° are carefully added to a mixture of 100 c.c. strong sulphuric acid and 150 c.c. nitric acid (36°), cooled to 12°, so that the temperature does not rise above 15°. Afterwards the whole is shaken with 100 c.c. strong sulphuric acid. After a few minutes' standing the ester is separated off (Bull. Soc. chim. [iii.] 13, 1044).

Methyl nitrate is a colourless liquid with a pleasant smell; explodes when heated to 150°, or by percussion.

Methyl nitrite CH_3NO_2; b.p. −12°; sp.gr. of liquid 0·991 at 15°/. A gas, prepared by treating 1 molecule methyl alcohol with 1 molecule *iso*amyl nitrite (Bertoni, Gazz. chim. ital. 12, 438). Also by the action of nitric acid upon copper (or arsenious acid) and methyl alcohol, or by the action of nitric acid upon brucine (Strecker, Annalen, 91, 76).

Methyl oxalate $(CH_3)_2C_2O_4$; m.p. 54°; b.p. 163·3° (corr.) (Weger, Annalen, 221, 86). Oxalic acid (dried at 100°) is mixed with boiling methyl alcohol, and on cooling the crystals separate out (Erlenmeyer, J. 1874, 572).

Forms monoclinic plates, which, by action of chlorine yield, first, an oily liquid of the composition $C_2O_4(CHCl_2)_2$ (Malaguti, Annalen, 32, 49), and by prolonged action in sunlight, a body $C_2O_4(CCl_3)_2$, which crystallises in leaflets (Cahours, *ibid.* 64, 313).

Methyl hydrogen oxalate $H(CH_3)C_2O_4$. When oxalic ethyl ester is treated in methyl alcoholic solution with potassium methoxide, potassium methyl oxalate is thrown out in the form of fine leaves (Salomon, Ber. 8, 1509). Methyl hydrogen oxalate is a solid of low melting-point which boils at 108°–109°/ 12 mm. (Anschütz and Schönfeld, Ber. 19, 1442).

Methyl oxide, Dimethyl ether $(CH_3)_2O$; b.p −23·65° (Regnault, J. 1863, 70); −21° (Berthelot); sp.gr. (air=1) 1·617.

Formed by heating methyl alcohol with sulphuric acid (Dumas and Péligot, Ann. Chim. [ii.] 58, 19), or with boron trioxide (Ebelmen, *ibid.* [iii.] 16, 138; Annalen, 57, 328).

1·3 parts of wood alcohol are mixed with 2 parts of sulphuric acid, and heated to 140°. The gas evolved is passed into strong sulphuric acid, which absorbs 600 times its volume; the gas is then set free by diluting the acid with an equal volume of water (Erlenmeyer and Kriechbaumer, Ber. 1874, 699).

Methyl ether is a colourless gas with a pleasant odour; 1 vol. of water at 18° absorbs 37 volumes of the gas (Dumas and Péligot). It unites with hydrochloric acid to form a compound $(CH_3)_2O{\cdot}HCl$, which boils at 2° (Friedel, Bull. Soc. chim. [ii.] 24, 160, 241).

Chlorine Substitution Products.

Chloromethyl ether $CH_2Cl{\cdot}O{\cdot}CH_3$; b.p. 59·5° at 759 mm.; formed by bringing together, in diffused daylight, chlorine and excess of methyl oxide (Friedel, Bull. Soc. chim. [ii.] 28, 171). It is decomposed by water into hydrochloric acid, trioxymethylene $(CH_2O)_3$ and methyl alcohol.

Dichloromethyl ether $(CH_2{\cdot}Cl)_2O$; b.p. 105°; sp.gr. 1·315 at 20°; formed by the action of chlorine upon methyl oxide (Regnault, Annalen, 34, 31).

Tetrachloromethyl ether $(CHCl_2)_2O$; b.p. 130°; sp.gr. 1·606 at 20° (Regnault).

Perchloromethyl ether $(CCl_3)_2O$; b.p. 100° (with decomposition); sp.gr. = 1·597; by the action of chlorine upon methyl oxide in sunlight (Regnault). Decomposed by heat, yielding carbon tetrachloride and carbonyl chloride. (*See also* de Sonay, Ber. 1894, Ref. 337.)

Methyl phosphates.

1. *Normal methyl phosphate* $(CH_3)_3PO_4$; b.p. 197·2° (corr.); sp.gr. 1·2378 at 0° (Weger, Annalen, 221, 89). From methyl iodide and silver phosphate (Hall, Chem. Soc. Trans. 51, 754).

2. *Dimethyl phosphoric acid* $(CH_3)_2HPO_4$; a syrupy liquid, produced when phosphoryl chloride $POCl_3$ is dropped into methyl alcohol (Schiff, Annalen, 102, 234). The salts are very soluble in water.

3. *Monomethyl phosphoric acid* $CH_3H_2PO_4$ is produced when methyl alcohol is dropped into phosphoryl chloride (Schiff, Annalen, 102, 337).

Methyl phosphites.

Monomethyl phosphite $CH_3H_2PO_3$, a syrupy liquid formed by the action of phosphorus trichloride upon methyl alcohol (Schiff, Annalen, 103, 164). It is miscible with ether, and forms salts which are amorphous, and are decomposed by water into methyl alcohol and phosphites.

Trimethyl phosphite $P(OCH_3)_3$ is a liquid boiling with partial decomposition at 185°. It is prepared by the action of phosphorus trichloride on sodium methoxide. Sp.gr. 1·1785 at 15° (Jaehne, Annalen, 256, 281).

Methyl salicylate $C_6H_4(OH){\cdot}COO{\cdot}CH_3$. Is the chief constituent of oil of winter-green. Obtained by distilling a mixture of salicylic acid, methyl alcohol, and sulphuric acid. B.p. 222·2°; sp.gr. 1·189 at 15°/15°. Used in perfumery and pharmacy.

Methyl sulphates.

1. *Hydrogen methyl sulphate, methyl sulphuric acid* CH_3HSO_4. The free acid is an oily body, which remains liquid at −30°. Obtained from methyl alcohol and sulphuric acid (Dumas and Péligot, Annalen, 15, 40), or from methyl alcohol and chlorosulphonic acid in the cold (Claesson, J. pr. Chem. [ii.] 19, 240).

Preparation.—One part of methyl alcohol is mixed with two parts of concentrated sulphuric acid, allowed to stand in a warm place for some hours, diluted with water and neutralised with barium carbonate, filtered and the barium precipitated by the proper quantity of sulphuric acid. Methyl sulphuric acid forms salts with the metals, which are soluble and readily crystallise. On distillation it decomposes into dimethyl sulphate and sulphuric acid (Claesson).

Chloride of methyl sulphuric acid CH_3SO_3Cl. *Methyl chlorosulphonate* is obtained by dropping methyl alcohol into sulphuryl chloride in molecular proportions (Behrend, J. pr. Chem. [ii.] 15, 32), or by passing sulphur dioxide into methyl hypochlorite (Sandmeyer, Ber. 1886, 861), or by the action of chlorosulphonic acid on methyl hydrogen sulphate or on methyl sulphate (Levaillant and Simon, Compt. rend. 1919, 169, 140–234). It is an oily liquid with pungent smell; decomposed by water into methyl sulphuric and hydrochloric acids.

The same products may be obtained by treating methyl alcohol with sulphur dioxide and chlorine in the proportion of 1 molecule of each of the gases to 2 molecules of the alcohol (Boake and Durrans, Eng Pat. 119250). Methyl chlorosulphonate boils at 42°/16 mm.; 134°–135°/760 mm; D^{15} 1·492; n_D^{17} 1·414.

2. *Dimethyl sulphate* $(CH_3)_2SO_4$; b.p. 188°; sp.gr. 1·33344 at 15° (Perkin, Chem. Soc. Trans. 1886, 785). By distilling wood spirit with 8 or 10 parts of sulphuric acid (Dumas and Péligot, Ann. Chim. [iii.] 58, 54) or by distilling anhydrous methyl sulphuric acid, best *in vacuo* (Claesson, J. pr. Chem. [ii.] 19, 244). Methyl sulphate is prepared by bringing together methyl alcohol (27 grams) and chlorosulphonic acid (100 grams) at −10° and then distilling the mixture under 20 mm. pressure at 140°. The yield is 80–83 p.c. theoretical. Fuming sulphuric acid gives a yield of only 42 p.c. (D. R. P. 113239). By adding 4 parts of 60 p.c. oleum to 1 part of methyl alcohol cooled to −18° and subsequently distilling the mixture under reduced pressure, a yield of 90 p.c. of the theoretical amount is obtained. The Société Anonyme des Produits Chimiques de Fontaines in Lyon-Monplaisir uses practically the same process with carbon tetrachloride as a diluent (D. R. P. 193830). By treating cooled methyl alcohol with chlorine and sulphur dioxide (Durrans, U.S. Pat. 1317648). Haworth and Irvine (Eng. Pat. 122498) combine dry dimethyl ether and sulphur trioxide in presence of a solvent which may conveniently consist of methyl sulphate itself. The yield of dimethyl sulphate by the action of sulphuric acid on methyl alcohol increases within limits with increase in the molecular proportion of sulphuric acid. The complete reaction appears to be a balance of three reactions:

$$H_2SO_4 + CH_3{\cdot}OH \rightleftarrows CH_3{\cdot}HSO_4 + H_2O$$

$$2CH_3{\cdot}HSO_4 \rightleftarrows H_2SO_4 + (CH_3)_2SO_4$$

$$CH_3{\cdot}HSO_4 + CH_3{\cdot}OH = H_2SO_4 + (CH_3)_2O$$

In order to obtain the best yield of dimethyl sulphate it is necessary to avoid the presence of water or of excess of methyl alcohol (Guyot and Simon, Compt. rend. 1919, 169, 655). It is extensively used as a methylating agent for aromatic amines, the reaction being:

$$Me_2SO_4+2R\cdot NH_2=RNH_2\cdot MeHSO_4+R\cdot NHMe$$

(Ullmann, Annalen, 327, 103), *cf.* however, Claesson and Lundvall (Ber. 13, 1699). Quinoline and quinaldine are both quantitatively converted into their ammonium bases by treatment with methyl sulphate in benzene solution (Ullmann, *l.c.*). It is also a very convenient reagent for esterifying acids (Carl Graebe, *ibid.* 344, 244). On distillation under reduced pressure of the products obtained by the action of methyl sulphate on alcoholic solutions of sodium penta-, tetra-, or tri-sulphide *methyl trisulphide*, Me_2S_3, has been obtained by Strecker (Ber. 1908, 1105. *Cp.* also Klason, Chem. Soc. Abstr. 1888, 356). A colourless liquid with an odour like that of peppermint.

Methyl sulphides.

1. *Hydrogen methyl sulphide, methyl mercaptan, methyl sulphydrate*, CH_3SH (Gregory, Annalen, 15, 239); b.p. 5·8° at 752 mm. (Klason, Ber. 20, 3407); $\alpha°=0·894$. By heating potassium hydrogen sulphide with potassium methyl sulphate (Dumas and Péligot), or by acting upon *s*-methyl-*iso* thiocarbamide sulphate (prepared by warming an aqueous solution of thiocarbamide with methyl sulphate) with dilute sodium hydroxide solution, when it is converted into cyanamide and methyl mercaptan (Arndt, Ber. 1921, 54, B, 2236). It is a colourless liquid with a disagreeable odour and forms a crystalline hydrate with water. By the action of chlorine upon carbon disulphide containing a little iodine, *Perchloromethyl mercaptan* CCl_3ClS, a liquid (b.p. 146°–148° corr.; sp.gr. 0°1·712 at 12·8°) is obtained (Rathke, Annalen, 167, 195). This substance is decomposed by heating to 200° into carbon tetrachloride and sulphur chloride.

2. *Dimethyl sulphide* $(CH_3)_2S$; b.p. 37·1°–37·3° at 754·7 mm. (Beckmann, J. pr. Chem. [ii.] 17, 453); b.p. 37·2° at 758 mm. (Klason, Ber. 20, 3407); 37·52° (corr.); sp.gr. 0·8702 at 0°/4° (Thorpe and Rodger). Sp.gr. 0·845 at 21° (Regnault, Annalen, 34, 26). From potassium sulphide and methyl chloride (Regnault, Ann. Chim. [ii.] 71, 391).

Preparation.—500 c.c. methyl alcohol are treated with 750 c.c. sulphuric acid, and a solution of 2·75 kilos. sodium carbonate (crystals) is added, and the solution concentrated until the sodium sulphate crystallises out. To the solution of sodium methyl sulphate 500 grams of potash dissolved in water and half saturated with sulphuretted hydrogen are added. The yield is about 150 grams (Klason, Ber. 1887, 3407; Chem. Soc. Trans. 1888, 356). Methyl sulphide is a colourless liquid with an unpleasant smell. It combines directly with chlorine to form oily substitution products $(CH_2Cl)_2S$, $(CHCl_2)_2S$, and $(CCl_3)_2S$ (Riche, Ann. Chim. [iii.] 43, 283). Bromine unites with it to form a crystalline bromide $(CH_3)_2SBr_2$ (Cahours, Annalen, 135, 355). It also forms many crystalline compounds with various salts, *e.g.*

$$(CH_3)_2S\cdot HgCl_2$$

$2(CH_3)_2S\cdot PtCl_4$), &c. (Loir, Ann. Chim. [iii.] 39, 448; 54, 42). It combines at ordinary temperatures with methyl iodide to form *trimethyl sulphine iodide* $(CH_3)_3SI$, which crystallises in prisms.

By the action of moist silver oxide upon this compound there is formed *trimethyl sulphine hydroxide* $(CH_3)_3S\cdot OH$, an oily liquid which possesses strongly basic properties and forms characteristic salts with the acids. Sulphuretted hydrogen reacts with the base, yielding the *hydrosulphide* $[(CH_3)_3S]SH$, which on treating with one molecular proportion of the hydroxide yields the *normal sulphide* $[(CH_3)_3S]_2S$, which resembles in its reactions the sulphides of the alkalis (Brown and Blackie, Chem. News, 37, 130; 39, 51).

Methyl trisulphide $(CH_3)_2S_3$ has been prepared by Strecker (*see* above *Dimethyl sulphate*).

Methyl sulphite $(CH_3)_2SO_3$ or $SO(OCH_3)_2$; b.p. 121·5°; sp.gr. 1·0456 at 16·2°/4°. Obtained from methyl alcohol and sulphur chloride S_2Cl_2 (Carius, Annalen, 110, 209; 111, 96). Is isomeric with ethyl sulphurous acid $OH\cdot SO\cdot OC_2H_5$, and ethyl sulphonic acid $C_2H_5SO_2\cdot OH$.

Methyl chlorosulphinate $Cl\cdot SO_2\cdot CH_3$ is formed when well cooled methyl alcohol is mixed with thionyl chloride. It boils at 19°/13 mm. or 102°/755 mm. with decomposition into sulphur dioxide and methyl chloride. Is readily decomposed by water into sulphur dioxide, hydrogen chloride, and methyl alcohol (Stähler and Schirm, Ber. 1911, 44, 319).

Methyl sulphonic acid $CH_3SO_2\cdot OH$, a syrupy liquid decomposed at about 130°. By the action of nitric acid upon methyl thiocyanate or disulphide (Muspratt, Annalen, 65, 261). Also by heating methyl iodide with sodium sulphite solution to 120° (Collmann, *ibid.* 148, 105), and by the reduction of trichloromethane sulphonic acid (Kolbe, *ibid* 54, 174), and also by the action of chloride of lime on methyl thiocyanate (de Coninck, Compt. rend. 126, 828). It forms stable crystalline salts which are very soluble in cold water but almost insoluble in alcohol. The potassium compound $CH_3\cdot SO_2\cdot OK$, is decomposed by heating with caustic potash—

$$CH_3\cdot SO_2OK+3KOH=3H_2+K_2CO_3+K_2SO_3$$

(Berthelot, J. 1869, 336).

For the reactions of *methyl disulphonic acid* (methionic acid), and its applications in syntheses, *see* Schroeter and collaborators (Annalen, 1919, 418, 161; Chem. Soc. Abstr. 1919, i. 516).

Methyl sulphonic chloride $CH_3\cdot SO_2Cl$; b.p. 150°–153° (Carius); 160° (Nithack); sp.gr. 1·51 (Gowan, J. pr. Chem. [ii.] 30, 281). By the action of phosphorus pentachloride upon methyl sulphonic acid (Carius, Annalen, 114, 142). It is not acted upon by sulphuretted hydrogen or potassium cyanide in alcoholic solution. Ammonia forms an amide

$$CH_3\cdot SO_2\cdot NH_2$$

which crystallises in long prisms (Gowan, *l.c.*, also Chem. Soc. Trans. 48, 367).

Chloromethyl sulphonic acid $CH_2Cl\cdot SO_2\cdot OH$, an acid syrup obtained by the action of nascent hydrogen upon trichloromethyl sulphonic acid (Kolbe, Annalen, 54, 168).

Dichloromethyl sulphonic acid $CHCl_2\cdot SO_2\cdot OH$, an unstable body formed by the action of zinc upon trichloromethyl sulphonic acid (Kolbe, Annalen, 54, 164); also by heating chloroform

with a solution of potassium sulphite to 180° (Strecker, *ibid.* 148, 92). The *chloride*

$CHCl_2 \cdot SO_2Cl$

(b.p. 170°–180°, sp.gr. 1·71) is formed by the action of phosphorus pentachloride upon the acid (Gowan, J. pr. Chem. [ii.] 30, 399), or by reducing, by means of sulphur dioxide or stannous chloride, trichloromethyl sulphonic chloride (Kolbe).

Trichloromethyl sulphonic acid

$CCl_3 \cdot SO_2 \cdot OH, H_2O$

m.p. 130°. The free acid is obtained from the chloride by treatment with baryta, and precipitation of the dissolved barium by means of sulphuric acid, the excess of sulphuric acid is then removed by means of lead carbonate and excess of lead by means of sulphuretted hydrogen (Gowan, J. pr. Chem. [ii.] 30, 284).

It forms small prisms which are very stable and insoluble in water, but soluble in alcohol or ether. It has strong acid properties and is not affected by nitric acid, aqua regia, or chromic trioxide.

Trichloromethyl sulphonic chloride $CCl_3 \cdot SO_2Cl$ (m.p. 135°, b.p. 170°) forms camphorlike crystals, and is obtained by the action of moist chlorine upon carbon disulphide (Berzelius and Marcet, Gilbert's Annalen, 48, 161). Bassett (Chem. News, 54, 79) recommends the following process: 100 grams of powdered potassium chlorate, 200 c.c. hydrochloric acid, 400 c.c. water, and 50 c.c. carbon disulphide are mixed together and allowed to stand for some days until the carbon disulphide becomes solid; the white solid is then removed by filtration and washed; the yield is 63 grams. It is very stable and reacts with difficulty or not at all with aromatic amines. With secondary and tertiary organic bases it yields colouring matters. It also oxidises leuco bases and their sulphonic acids to colouring matters (Espenschied, D. R. P. 14621).

Methyl thiocyanate $CH_3 \cdot S \cdot CN$; b.p. 132·9 at 757·2 mm.; sp.gr. 1·088 at 0° (Pierre, J. 1851, 51). H.C.=398·95 cals. (Thomsen, Th. 4, 196). By heating methyl sulphide with cyanogen bromide to 100° (Cahours, J. 1875, 257). By distilling a concentrated solution of equal parts of potassium thiocyanate and calcium methyl sulphate (Cahours, Annalen, 61, 95). Calcium methyl sulphate may be replaced with advantage by methyl sulphate in theoretical proportions.

If heated to 180°–185° it is partially converted into the *iso*thiocyanate. By the action of chlorine in daylight cyanuric chloride $Cl_3(CN)_3$, thiocarbonyl chloride $CSCl_2$, and thiocarbonyl tetrachloride $CSCl_4$ are obtained (James, Chem. Soc. Trans. 51, 272). By heating with methyl iodide to 100° trimethyl sulphine iodide $(CH_3)_3SI$ is produced (Cahours, J. 1875, 257).

Methyl *iso*thiocyanate $CH_3 \cdot NCS$, *methyl mustard oil*; m.p. 34°; b.p. 119° (Hofmann, Ber. 1, 172). By heating the silver salt of methyl thiocarbamic acid $CS(NH \cdot CH_3)SH$ with water. This acid is formed by the action of carbon disulphide upon methylamine. Methyl mustard oil forms white crystals which have a smell resembling that of horse-radish.

Methyl selenide $(CH_3)_2Se$; b.p. 58·2°. Obtained by distilling a solution of sodium selenide (prepared from phosphorus pentaselenide and caustic soda) with potassium methyl sulphate (Jackson, Annalen, 179, 1). A disagreeably smelling liquid; with platinum tetrachloride forms a yellow compound $2(CH_3)_2Se \cdot PtCl_4$, soluble in alcohol. It also unites with chlorine and bromine $(CH_3)_2SeCl_2$, m.p. 59·5°; $(CH_3)_2SeBr_2$, m.p. 82°.

Methyl diselenide $(CH_3)_2Se_2$, a heavy, reddish yellow liquid with very unpleasant odour, formed when potassium diselenide is heated with potassium methyl sulphate (Wöhler and Dean, Annalen, 97, 5; Rathke, *ibid.* 152, 211).

Methylamines.

These are compounds with strongly marked basic properties, derived from ammonia by the replacement of one, two, or three atoms of hydrogen by an equal number of methyl groups.

Methylamine $(CH_3)NH_2$, *monomethylamine*; b.p. −6° to −5·5° at 768·35 mm.; crit. temp. 156·9°; crit. press. 73·6 atm. (Berthoud); sp.gr. 0·699 at −10·8° (Hofmann, Ber. 22, 699).

Occurrence.—In the oil yielded by the dry distillation of bone (Anderson, Annalen, 88, 44). In the plants *Mercurialis annua* (Linn.) and *M. perennis* (Linn.) (Reichardt, J. 1865, 457). In herring brine (Tollens, Zeitsch. Chem. 1866, 516) and in the products of the putrefaction of fish. In crude wood spirit (Commaille, J. 1873, 686; Vincent, Ann. Chim. [v.] 1, 444). In the products of the dry distillation of the residues from beet-sugar 'vinasses' (Duvillier and Buisine, Ann. Chim. [v.] 23, 317).

In the products of distillation of bran with lye (Laycock, Chem. News, 1898, 78, 210, 233). In the products yielded by the decomposition of fibrin by *streptococci* (Emmerling, Ber. 1897, 30, 1863).

Formation.—By the action of caustic potash upon methyl *iso*-cyanate or *iso*-cyanurate (Wurtz, Ann. Chim. [iii.] 30, 443). From ammonia and methyl iodide (Hofmann, Phil. Trans. 1851, 381) or methyl nitrate (C. Lea, Chem. News, 6, 46; Juncadella, Compt. rend. 48, 342). By heating wood spirit with sal ammoniac to 300° (Berthelot, Ann. Chim. [iii.] 38, 69).

If a solution of formaldehyde and ammonium chloride is heated, the former, whether present in excess or not, acts on the trimethylene triamine first formed and yields methylamine in theoretical quantity. If the ammonium chloride is in large excess, the amine is very pure; if the aldehyde is in large excess, trimethylamine is the final product (Plöchl, Ber. 21, 2117; Brocket and Cambier, Compt. rend. 1895, 120, 557; Eschweiler, Ber. 1905, 38, 880; Koeppen, Ber. 1905, 38, 882; Knudsen, Ber. 1914, 47, 2694; Werner, Chem. Soc. Trans. 1917, 111, 844; Jones and Wheatley, J. Amer. Chem. Soc. 1918, 40, 1411).

Chloropicrin treated with iron filings and acetic acid (Geisse, Ann. 1859, 109, 282) or tin and hydrochloric acid (Wallach, *ibid.* 1877, 184, 51) yields monomethylamine:

$CCl_3 \cdot NO_2 + 12H = CH_3 \cdot NH_2 + 3HCl + 2H_2O$

(*cf.* Frankland, Challenger and Nicholls, Chem. Soc. Trans. 1919, 159).

Methylamines are produced by heating ammonium methyl sulphates at about 260°, when the yield of methylamine is about 27 p.c.

of the theoretical yield; when a mixture of ammonium methyl sulphate with two equivalents of ammonium benzene sulphonate is heated the yield of methylamine is about 50 p.c. of the theoretical amount (*cf.* Werner, Chem. Soc. Trans. 1914, 105, 2762; Denham and Knapp, *ibid.* 1920, 236). They are also formed by heating methyl alcohol under pressure with a mixture of ammonium chloride and zinc chloride. The yields are 55·0, 7·5, and 1·86 p.c. respectively of mono-, di-, and tri-methylamine, calculated on the weight of the ammonium chloride (Turner and Howard, J. Amer. Chem. Soc. 1920, 42, 2663).

By heating caustic potash with certain alkaloids—*e.g.* morphine, codeïne, creatine, &c. (Wertheim, Annalen, 73, 210; Dessaignes, J. 1855, 331). By the action of chlorine upon caffeïne or theobromine (Rochleder, J. 1850, 435). By the action of nascent hydrogen, from zinc and sulphuric acid, upon hydrocyanic acid (Mendius, Annalen, 121, 139). By passing a stream of hydrogen and hydrocyanic acid gas over platinum black, heated to 110° (Debus, Chem. Soc. Trans. 16, 249).

By the reduction of hexamethylenetetramine with zinc dust and hydrochloric acid (D. R. P. 73812); of formamide with sodium in amyl alcohol solution (Guerbet, Bull. Soc. chim. [iii.] 21, 780); or of nitromethane electrolytically in sulphuric acid solution at 70°–75° (Pierron, *ibid.* 783).

Preparation.—Equal molecules of methyl nitrate and ammonia dissolved in methyl alcohol are heated to 100°. The product is decomposed by caustic soda, and the base combined with hydrochloric acid, the dried chloride is then heated with caustic soda, and the liberated methylamine passed into sulphuric acid, the sulphate is dried at 110° and treated with absolute alcohol in which the di- and tri-methylamine salts are soluble; the insoluble monomethylamine sulphate is then decomposed by potash, and the free methylamine passed into a cooled solution of ethyl oxalate. The resulting di-methyl oxamide is dissolved in hot water, filtered and recrystallised, then decomposed by caustic potash, and the gas passed into absolute alcohol (Duvillier and Buisine, Ann. Chim. [v.] 23, 324; *v.* also Muller, Bull. Soc. chim. [ii.] 42, 202; Chem. Soc. Trans. 48, 501).

It can also be prepared by the interaction of acetamide and bromine in caustic potash solution (Hofmann, Ber. 1882, 15, 765; 1885, 18, 2741; François, Compt. rend. 1908, 147, 680); or by heating formaldehyde with ammonium chloride at 40°–95°.

Methylamine can be prepared electrolytically, cheaply and conveniently, according to the following process: An electrolytic cell, provided with a diaphragm separating the cathode and anode, is filled with a solution of sodium sulphate, and 140 grams hexamethylenetetramine is added. The electrolysis is carried out by means of lead electrodes and a current of 3 amperes per square decimetre. The alkali formed at the cathode is neutralised by the careful addition, drop by drop, of dilute sulphuric acid. The temperature must be kept at about 20°. Methylamine and trimethylamine are thus formed, and can be separated in the ordinary way. Ammonium sulphate can replace the sodium sulphate (D. R. P. 148054; Frdl. 1902–04, 26; *see also* D. R. P. 143197; Frdl. 1902–04, 25).

Commercial methyl sulphate is added in small portions at a time to excess of a 10 p.c. aqueous solution of ammonia at −5°. The product is then added to an excess of a 30 p.c. aqueous solution of sodium hydroxide, and the mixture is distilled, the issuing gas being collected in 20 p.c. hydrochloric acid. The methylamine hydrochloride is separated from the ammonium chloride by fractional crystallisation, and is finally purified by recrystallisation from alcohol (Burmann, Bull. Soc. chim. 1906, [iii.] 35, 801).

According to Bertheaume (*ibid.* 1908, 146, 1215) this method of separation is of very little use (Fleck, J. Amer. Chem. Soc. 1896, 18, 670).

A better method of separating the three amines than the one given above, is to treat the concentrated solution of their hydrochlorides with caustic soda and collect the gas evolved in formaldehyde. The liquid is now treated with an equal weight of caustic potash, whereby the greater part of the trimethylamine is evolved, whilst the methylene derivatives of mono- and di-methylamine remain in solution, and can be fractionated by distillation. The amines are regenerated by boiling the condensation products with alcoholic hydrochloric acid (Delépine, Compt. rend. 1896, 122, 1064; Ann. Chim. 1896, [vii.] 8, 439).

Methylamine may be separated from ammonia by shaking the aqueous mixture of the two substances with yellow mercuric oxide during an hour. The liquor is then decanted and distilled, when pure methylamine is obtained, providing no other nitrogenous bases are present in the impure liquor (François, J. Pharm. Chim. 1907, 25, 517, 523; Compt. rend. 1907, 144, 567; *ibid.* 1908, 147, 428).

To distinguish the three amines from ammonia the solution is neutralised with hydrochloric acid and evaporated to dryness. The residue is dissolved in 95 p.c. alcohol, and 5 c.c. of the solution is heated at 70°–75° with a few grammes of tetrachlorobenzoquinone. If any of the amines are present a violet coloration is produced, whereas ammonia gives no coloration (Tsalapatini, Chem. Zentr. 1908, i. 299). For the detection and estimation of ammonia in the methylamines, *see* François (Compt. rend. 1907, 144, 857). Methylamine can be distinguished from the di- and tri-amines by treatment with Nessler's reagent, with which it gives a yellow precipitate insoluble in excess of water and reagent. The other two amines form a white precipitate, which disappears on addition of water (Delépine, Compt. rend. 1896, 122, 1272).

Properties.—Methylamine is a colourless gas with a strong ammoniacal smell. It is very inflammable and burns with a yellow flame; it is decomposed at a red heat into ammonia, hydrocyanic acid, hydrogen, and marsh gas. It is very soluble in water, 1 volume of water at 12·5° dissolving 1150 volumes and 959 volumes at 25°. The solution behaves like *liquor ammoniæ* and yields crystallisable salts on neutralisation with acids.

Heat of neutralisation with hydrochloric acid =25·9 cals. (Muller, Ann. Chim. 1888, [vi.] 15, 517). For salts of methylamine, which, as

a rule, resemble those of ammonia, *v.* Wurtz, *ibid.* [iii.] 30, 443; Topsoë, J. 1883, 618; Bailey, Chem. Soc. Trans. 45, 692; Petit and Polonowsky, Bull. Soc. chim. [iii.] 9, 1013; Brochet and Cambier, *ibid.* 13, 536; Jarry, Compt. rend. 1897, 124, 964; Cook, Amer. Chem. J. 1899, 22, 437; Ragland, *ibid.* 417; Lenher, J. Amer. Chem. Soc. 1898, 20, 572; Dunstan and Goulding, Chem. Soc. Trans. 1897, 579; Ladenburg, Ber. 1896, 29, 2711; Wende, *ibid.* 2719; Ristenpart, *ibid.* 2530; Partheil and Broich, *ibid.* 1897, 30, 618; Fenner and Tafel, *ibid.* 32, 3228; Delépine, Ann. Chim. [vii.] 8, 461; Compt. rend. 1896, 122, 1272; Hofmann and Marburg, Annalen, 1899, 305, 191; Lang, Chem. Soc. Trans. 1903, 724; Rengade, Compt. rend. 1905, 140, 246; François, *ibid.* 1906, 142, 1199; Litterschild, Arch. Pharm. 1904, 242, 37; Guareschi, Chem. Zentr. 1891, ii. 620; Christensen, J. pr. Chem. [ii.] 45, 356; Gutbier and Woernle, Ber. 1906, 39, 4134.

Methylamine, like ammonia, in aqueous solution precipitates metallic hydroxides from solutions of many salts; but, unlike ammonia, dissolves, when in excess, the hydroxide of aluminium, whereas it fails to dissolve the hydroxides of cadmium, nickel, and cobalt.

When methylamine is oxidised with monopersulphuric acid (Caro's acid), according to Bamberger and Seligman, it undergoes the following changes:

$$CH_3NH_2 \rightarrow CH_3{\cdot}NH{\cdot}OH \rightarrow CH_2{:}NOH \rightarrow \text{either } OH{\cdot}CH{:}NOH \text{ or } CH_2NH{\cdot}OH \rightarrow CH_3NO_2$$

hydrogen cyanide also being formed (Ber. 1902, 35, 4299). Unlike the di- and tri-amines, it is readily decomposed by chromic acid with evolution of nitrogen (Coninck and Combe, Compt. rend. 1898, 127, 1221; 128, 682).

Methylamine interacts with cyanogen chloride in cold ethereal solution forming principally *s*-dimethylguanidine hydrochloride and also methylcyanamide (Kaess and Gruszkiewicz, Ber. 1902, 35, 3598).

It also reacts slowly with sodium phosphate and magnesium sulphate in dilute aqueous solution, forming methylamine magnesium phosphate (François, J. Pharm. Chim. 1908, 28, 86). Neither di- nor tri-methylamines react thus.

Liquid methylamine is a very good solvent for organic compounds, and combines readily with both organic and inorganic compounds, forming addition products (Gibbs, J. Amer. Chem. Soc. 1906, 28, 1395; Hochstetter and Kohn, Monatsh. 1903, 24, 773). For a number of addition products with inorganic substances, *see* Bonnefoi, Compt. rend. 1897, 124, 773; 127, 516; Jarry, *l.c.*; and Ann. Chim. [vii.] 27, 376; Matthews, J. Amer. Chem. Soc. 1898, 20, 826; Lenher, *ibid.* 1900, 23, 486; Moissan, Compt. rend. 128, 26; Lang and Jolliffe, Chem. Soc. Proc. 1903, 147; Ephraim and Weinberg, Ber. 1909, 42, 4447; Ekeley, J. Amer. Chem. Soc. 1909, 31, 664.

In the presence of soil, calcium carbonate and oxygen, methylamine is converted into ammonia, and finally into nitrites and nitrates (Demoussy, Compt. rend. 1898, 126, 253).

Under the influence of the silent electric discharge methylamine evolves nitrogen (Berthelot, *ibid.* 775; *see also* Mixter, Amer. J. Sci. 1898, [iv.] 6, 217).

Methyl chloramine Me·NHCl is obtained by distilling methylamine hydrochloride with sodium hypochlorite (Berg. Compt. rend. 1893, 116, 887). It is a colourless volatile oil with a piquant irritating odour.

Methyl dichloramine $MeNCl_2$ is obtained by leading chlorine into aqueous methylamine (Köhler, Ber. 1878, 12, 771) or by the distillation of methylamine hydrochloride with bleaching powder (Bamberger and Renauld, Ber. 1895, 28, 1683). It is a golden-yellow liquid, b.p. 59°–60°. Similar bromo and iodo compounds are also known (Dehn, J. Amer. Chem. Soc. 1909, 31, 123).

Methyl nitramine MeN_2O_2H is obtained by treating δ-dimethyl dinitro-oxamide with barium hydroxide (Franchimont, Rec. trav. chim. 1894, 13, 313; 321, 331; also v. Pechmann, Ber. 1897, 30, 647). It forms long needles, m.p. 38°, readily soluble in water and in alcohol. On reduction with aluminium amalgam and aqueous alcohol it yields diazomethane, whilst with zinc and hydrochloric acid it is reduced to methylamine, hydrazine and methylhydrazine (Thiele and Meyer, Ber. 1896, 29, 962). When heated with β-naphthol, β-naphthol methyl ether is formed with evolution of nitrogen (Franchimont and Umbgrove, Rec. trav. chim. 1897, 15, 215). It forms a number of metallic salts (Franchimont, *l.c.*; Ley and Kissel, Ber. 1899, 32, 1364). The *potassium* salt $KMeO_2N_2$, m.p. 220°, explodes on heating or on being struck.

Thionylmethylamine MeN:SO is an oil which fumes in air, b.p. 58°-59° (Michaelis and Storbeck, Annalen, 1893, 274, 187). Methylamine derivatives of various aliphatic acids are described by Duden, Bock and Reid (Ber. 1905, 38, 2036); Fosse (Compt. rend. 1906, 143, 914); Tafel and Wassmuth (Ber. 1907, 40, 2831); Benary (Ber. 1909, 42, 3912); Gansser (Zeitsch. physiol. Chem. 1909, 61, 16); Fourneau (Bull. Soc. chim. 1909, [iv.] 5, 229); also D. R. PP. 198306, 1908; 202167, 1909.

Methylaminoanthraquinones are prepared by dissolving a mixture of the desired amino-derivative of anthraquinone and formaldehyde in concentrated sulphuric acid and warming to 55°–60° (D. R. P. 156056, 1905).

α-Methylaminoanthraquinone, m.p. 167°, is obtained by treating α-mononitroanthraquinone with methylamine solution (D. R. P. 144634; Frdl. 1902-04, 201).

1 - Methylaminoanthraquinone - 5 - sulphonic acid $SO_3H{\cdot}C_6H_3{<}^{CO}_{CO}{>}C_6H_3NHMe$, and also the diamino compound

$$NHMe{\cdot}C_6H_3(CO)_2C_6H_3NHMe$$

are formed by treating potassium 1 : 5-anthraquinonedisulphonate with aqueous methylamine at 150°. The potassium salt of the former crystallises from water in violet-brown needles. Other methylamine anthraquinone sulphonic acids are obtained similarly (D. R. P. 186722, 1907).

For other derivatives of methylamine anthraquinone which are used as dyes, *see* D. R. PP. 156759, 164791; Frdl. 1905-07, 293, 280; D. R. PP. 212470, 1909; 220314; Chem. Zentr. 1901, i. 1306).

Methylaminoacetocatechol

$$C_6H_3(OH)_2CO{\cdot}CH_2{\cdot}NHMe$$

is formed by warming gently chloroacetocatechol with an excess of methylamine. It is a white crystalline powder darkening at 200° and decomposing at about 230°. Ferric chloride gives an emerald-green colour (D. R. P. 152814; Dakin, Chem. Soc. Proc. 1905, 154). When reduced and then treated with ammonia, it yields methylamino-*o*-dihydroxyphenylethanol, m.p. 208°, which is an astringent, and has hæmostatic properties (J. Soc. Chem. Ind. 1909, 1005). The ethanol yields a hydrochloride, m.p. 157° (D. R. P. 202169).

Methylaminoquinones are described by Fichter (Annalen, 1908, 361, 363).

2-Methylamino-8-methoxyquinoline crystallises in silver prisms, m.p. 151°, and forms a crystalline nitrosamine, m.p. 180° (Fischer, Ber. 1902, 35, 3674).

Methylaminocamphene has b.p. 202°–203°/756 mm. $[\alpha]_D$+28·7° (Forster and Micklethwait, Chem. Soc. Trans. 1904, 334).

Methylaminocoumarins are described by v. Pechmann and Schaal (Ber. 1899, 32, 3690, 3696); and by Morgan and Micklethwait (Chem. Soc. Trans. 1904, 1238).

Methylaminothiazoles are described by Young and Crookes (Chem. Soc. Trans. 1906, 68).

Uracils by Wheeler and Jamieson (Amer. Chem. J. 1904, 32, 342).

Dimethylamine $(CH_3)_2NH$; b.p. 7·2°–7·3° at 764·1 mm.; crit. temp. 164·6°; crit. press. 52·4 atm. (Berthoud); sp.gr. 0·6865 at −5·8° (Hofmann, Ber. 1889, 22, 699). From methyl iodide and ammonia (Hofmann, J. 1862, 329). In small quantity by distilling the compound of aldehyde ammonia and sulphurous acid with caustic lime (Petersen, Annalen, 1857, 102, 317). In the putrefaction of fishes; occurs in herring brine (Bocklisch, Ber. 18, 87, 1924). Is obtained together with methylamine by the action of methyl alcohol on phospham (*see Methylamine*; also Vidal, Chem. Zentr. 1897, ii. 517).

Preparation.—The product of the action of ammonia upon methyl iodide (consisting of the hydriodides of mono-, di- and tri-methylamine and tetramethylammonium iodide) is treated with alcohol in order to remove the last-mentioned compound. The residue on treatment with caustic potash yields the free bases which can be partially separated by condensation, the more volatile monomethylamine escaping condensation may be received in hydrochloric acid.

The mixture of the free bases is then treated with ethyl oxalate, the trimethylamine remains unacted upon, the dimethylamine is converted into the ethyl ester of dimethyl oxamic acid, whilst the mono- base is converted into dimethyl oxamide. The latter is difficultly soluble in cold water, and is thus separated from the dimethylamine compound, which is then distilled with potash

$$(CH_3)_2N{\cdot}C_2O_2(OC_2H_5)+2KOH = (KO)_2C_2O_2+C_2H_5OH+(CH_3)_2NH$$

The alcoholic solution is neutralised with hydrochloric acid, evaporated to dryness, and decomposed by caustic potash. The hydrochloride of dimethylamine can be freed from admixed ammonium chloride by treatment with chloroform, in which the latter is insoluble (Behrend, Annalen, 1883, 222, 119).

By the reduction of a mixture of formaldehyde and methylamine with zinc-dust and hydrochloric acid (D. R. P. 73812).

Dimethylamine can be obtained by heating thiodimethylamine (185 grammes) with sulphuric acid chlorhydrin (130 grammes), the temperature being raised gradually and the mass finally heated for 2–3 hours at 130°–150°. On cooling the product is shaken with ether to remove benzenethiochloride, and the residue is treated with water, made alkaline, and the dimethylamine is separated by distillation in steam (D. R. P. 105870; Frdl. 1897-1900, 34).

An almost theoretical yield of dimethylamine hydrochloride is obtained by adding powdered nitrosodimethylaniline hydrochloride and a few zinc shavings to a nearly boiling, dilute aqueous solution of sodium hydroxide, the amine being absorbed in concentrated hydrochloric acid contained in a Péligot's U-tube (Menschutkin, J. Russ. Phys. Chem. Soc. 1898, 30, 243; Norris and Laws, Amer. Chem. J. 1898, 20, 54).

The free base can be liberated by treatment with caustic soda.

Properties.—Dimethylamine is a colourless, inflammable liquid with a strong ammoniacal smell. Bromine acts upon an aqueous solution forming dimethylamine hypobromite and bromide $N(CH_3)_2H{\cdot}HBrO$ and $NH(CH_3)_2{\cdot}HBr$; or, if the bromine be in excess, the unstable tribromide $N(CH_3)_2Br_3$, a yellow flocculent precipitate, is obtained (Raschig, Ber. 1885, 18, 2250).

At 0° it combines directly with two atoms of bromine (Remsen and Norris, Amer. Chem. J. 18, 94).

When oxidised with hydrogen peroxide it yields nitrous acid, formaldehyde and formic acid (Dunstan and Goulding, Chem. Soc. Trans. 1899, 1009). With Nessler's reagent, dimethylamine gives a white precipitate.

When heated with hydrogen at 820°–1120°, hydrocyanic acid, methane and ammonia are formed, the relative quantities of the products depending on the quantity of hydrogen present (Voerkelius, Chem. Zeit. 1909, 33, 1025, 1078, 1090).

Dimethylamine forms salts resembling those of ammonia (Topsoë, J. 1883, 618; Delépine, Ann. Chim. [vii.] 8, 459; Norris and Laws, *l.c.*; and 490; Ragland, *l.c.*; Cook, *l.c.*; Jörgensen, Zeitsch. anorg. Chem. 1906, 48, 374).

Dimethylamine dihydrochloride is a white crystalline substance formed by passing dry hydrogen chloride into the base or into the normal hydrochloride (Kaufler and Kunz, Ber. 1909, 42, 385).

Dimethylchloramine Me_2NCl, b.p. 46°/765 mm., is obtained in the same way as the monomethyl derivative, and has similar properties (Berg. *l.c.*). The corresponding bromo derivative has b.p. 64°–66° (Seliwanoff, Ber. 1893, 26, 423; Willstätter and Hottenroth, Ber. 1904, 37. 1775).

Other halogen derivatives are described by Cohn (J. pr. Chem. 1897, [ii.] 56, 345) and Knorr (Ber. 1904, 37, 3504).

Dithiodimethylamine $S_2(NMe_2)_2$ is a reddish-yellow liquid, b.p. 82°–83°/22 mm., 170°–180°/760 mm. (decomp.). It is decomposed by acids into the amine, sulphur, and sulphur dioxide (Michaelis and Luxembourg, Ber. 1895, 28, 165).

Dimethylnitramine $Me_2O_2N_2$ forms bright

colourless needles, whilst the *isonitramine* is a liquid, b.p. 112° (Franchimont and Umbgrove, *l.c.*; Lachman, Amer. Chem. J. 1899, 21, 483; Bamberger, Ber. 1895, 28, 402; Kirpal, *ibid.* 537).

Dimethylamine acetone $NMe_2 \cdot CH_2 \cdot COMe$ is prepared by adding chloracetone to an aqueous 30 p.c. solution of dimethylamine. It is a colourless oil, b.p. 123°, miscible with water, yielding a platinochloride, which forms beautiful crystals, m.p. 176° (decomp.). It also yields a hydrochloride; an aurichloride (m.p. 145°–146°); a methiodide (m.p. 168°); and an oxime, m.p. 99° (Stoermer and Dzimski, Ber. 1895, 28, 2220; 1896, 29, 866).

Methyl dimethylaminoacetate is a volatile oil, boiling at 135°. The corresponding ethyl compound boils at 149°–150°.

Methyl β-dimethylaminopropionate

$$NM_2 \cdot CH_2 \cdot CH_2 \cdot CO_2Me$$

b.p. 154·5°, yields a methiodide, m.p. 191°–192° (decomp.), which, when warmed with alkalis, gives acrylic acid and trimethylamine, whilst with silver oxide it gives β-trimethylpropiobetaine (Willstätter, Ber. 1902, 35, 584).

Methyl-γ-dimethylaminobutyrate has b.p. 171·5°–173°, and yields a crystalline aurichloride and picrate.

Dimethylaminodimethylacetal is a colourless mobile liquid, b.p. 137·5°, which has no reducing properties. Other dimethylamino derivatives of aliphatic acids have also been prepared (Willstätter, Ber. 1902, 35, 1378).

Dimethylamino derivatives of aliphatic hydrocarbons are described by Willstätter (Ber. 1901, 34, 129; Annalen, 1903, 326, 1); Duden and Lemme (Ber. 1902, 35, 1335); Hochstetter and Kohn (Monatsh. 1903, 24, 773); Bouveault (Bull. Soc. chim. 1904, [iii.] 31, 1306, 1322).

A number of methyl and dimethyl aminocarbinol derivatives of the type

$$R_1R_2C(OH)CH_2NR_3R_1$$

(where R_1, R_2=alkyl or aryl groups, R_3= methyl or other alkyl, and R_1=an alkyl group or hydrogen) are obtained by the action of methyl or dimethylamine on an ethylene oxide

$$R_1R_2C\overset{O}{\diagdown\!\!\diagup}CH_2$$

(D. R. P. 199148; Frdl. 1908–10, 975; also D. R. P. 173610; Knorr and Matthes, Ber. 1901, 34, 3482).

These substances, which have valuable anæsthetic properties, and are less toxic than cocaine or eucaine, can also be obtained by treating aminoacetones or esters of amino acids containing a tertiary amino group with magnesium organo compounds of the type $R \cdot Mg \cdot X$ (D. R. PP. 169819, 169746; Frdl. 1905–07, 1029, 1033).

Esters having pronounced soporific properties and a low toxicity are produced by condensing alkyl dimethylaminohydroxy*iso*butyrates with anhydrous chloral (D. R. PP. 203643, 198306, 202167; Frdl. 1908–10, 980, 984, 1000).

For other dimethylamino compounds used in medicine, *see* D. R. PP. 121051, 129967; Frdl. 1900–02, 1219, 1226; J. Soc. Chem. Ind. 1909, 491.

Dimethylaminoparaxanthine known in commerce as *paraxine*, is an energetic diuretic (D. R. P. 156901, 1905) and is decomposed into **2:6-Dioxy-8-dimethylamino-7-methylpurine**, m.p. above 319°, a crystalline substance which can be separated from the urine and has also a strong diuretic action (Forschbach and Weber, Arch. exp. Path. Pharm. 1907, 56, 186).

Dimethylamine reacts in equimolecular proportion with polyhydroxyaromatic compounds forming addition products with an alkaline reaction which can be used for developing in photography without further addition of alkali (D. R. P. 141101; Frdl. 1900–02, 1217).

Dimethylamine is used in the production of a large number of valuable dyestuffs; thus violet to blue dyestuffs are obtained by heating gallocyanine with mono- di- or tri-methylamine (D. R. PP. 57459, 65000: Frdl. 1890–94, 367).

Blue dyes are also obtained by the action of dimethylamine on the dyes of the oxazine series. The substances so obtained differ from the parent dye in giving purer colours and in being stable towards alkalis (D. R. P. 54658; Frdl. 1890–94, 373).

See also Freund and Wirsing, Ber. 1907, 40, 204; D. R. PP. 172079, 161665; the article on AMINES and the various parent dyes.

When dimethylamine is heated with *p*-aminophenol-azo-β-naphthol and formaldehyde, a dark-brown powder is obtained, which is a good dye for tannined cotton (D. R. P. 95546; Frdl. 1897–1900, 555).

3-Dimethylaminoanthraquinone is obtained when dimethylaminobenzoylbenzoic acid (1 part) is heated with concentrated sulphuric acid (10 parts) at 175°–180°. It forms red needles, m.p. 181°. When 12 parts of sulphuric acid is used, and the temperature is kept at 80°, dimethyl-aminoanthranol is formed, but is readily oxidised to the anthraquinol by ferric chloride (Haller and Guyot, Compt. rend. 1898, 126, 1544; D. R. P. 108837).

1-Dimethylamino-5-phenoxyanthraquinone, m.p. 147°–149°, and similar compounds which form important materials for the manufacture of dye-stuffs, have been obtained by treating the corresponding anthraquinone derivative with the desired mono- or di-alkylamine in pyridine solution at 110°–115° (D. R. P. 165728; Frdl. 1905–7, 289).

For other dimethylaminoanthraquinone derivatives, *see* Severin, Compt. rend. 1906, 142, 1274; D. R. PP. 136777, 136778; Frdl. 1900–02, 374; D. R. P. 146691; Frdl. 1902–04; D. R. PP. 146691, 1904; 205096, 1909).

Dimethylamine, when heated with fluorescein chloride or dichlorofluorescein chloride in presence of zinc chloride at 160°–170°, gives derivatives of chloroaminofluoran, whilst at higher temperatures rhodamines are produced (D. R. P. 139727, 1903).

Chloromethyl- and dimethyl-aminofluoran form pink crystals, melting at 168° and 218° respectively.

Dimethylaminocamphor is a colourless oil, b.p. 241°/758 mm. It does not reduce Barreswil's solution, and is only slowly acted on by silver nitrate. It forms a picrate, m.p. 220° (decomp.); hydriodide, m.p. 251° (decomp.); a platinichloride, m.p. 211° (decomp.); and acetate, m.p. 251°, with evolution of gas (Forster, Chem. Soc. Trans. 1905, 240; Rabe and Schneider, Ber. 1908, 41, 872).

5-Dimethylaminouracil

$$NH\langle\begin{matrix}CO\text{——}NH\\CO\cdot C(NMe_2)\end{matrix}\rangle CH$$

is formed by treating 5-bromouracil with dimethylamine, and forms colourless plates, m.p. 297° (decomp.) (Wheeler and Jamieson, Amer. Chem. J. 1904, 32, 342).

Trimethylamine $N(CH_3)_3$; b.p. 3·2°–3·8° at 764·6 mm., sp.gr. 0·662 at −5·2° (Hofmann, Ber. 22, 699; sp.gr. 0·673 at 0° (Bleunard). Does not solidify at −75° under a pressure of 10 mm.; forms a crystalline hydrate with 7 molecules of water, melting at 4·3°. Occurs in certain plants, *e.g. Chenopodium Vulvaria* (Linn.), *Arnica montana* (Linn.), *Rhagodia hastata* (Australian Salt Bush), hawthorn blossom, pear and wild cherry blossom, in ergot (Dessaignes, J. 1857, 481; Walz, J. 1852, 552), in certain lichens such as the *Sticta fuliginosa*, in hops and in cod-liver oil, in bone oil and guano (Zopf, Annalen, 1897, 297, 272). It also occurs in various animal fluids, *e.g.* in calves' blood (Dessaignes), and in human urine (Filippi, Zeitsch. physiol. Chem. 1906, 49, 433). Also in large quantities in herring brine, which owes to it its peculiar smell (Wertheim, J. 1851, 480).

It is also a product of the decomposition of fibrin by *streptococci* (Emmerling, Ber. 30, 1863).

It is obtained by treating methyl iodide with ammonia (Hofmann); by the distillation of tetramethylammonium hydroxide (Hofmann, Annalen, 93, 325); by distillation of narcotine (Wertheim, *ibid.* 73, 208), or codeïne (Anderson, *ibid*, 77, 367), with potash.

By the action of methyl alcohol on magnesium nitride (Szarvasy, Ber. 1897, 30, 305). By the reduction of trimethyloxamine with zinc-dust (Hantzsch and Hilland. Ber. 1898, 31, 2058; Dunstan and Goulding, *l.c.*). By the interaction of hexamethylenetetramine with formaldehyde (Eschweiler, Ber. 1905, 38, 880).

By heating a mixture of ammonium chloride (1 part) and trioxymethylene (2·65 parts) under reflux at 120°–170° (Schmitz, D. R. P. 270260).

By heating a mixture of ammonium chloride and formaldehyde (*cf.* Methylamine). *Cf.* Werner, Chem. Soc. Trans. 1917, 111, 844.

By the putrefaction of yeast or of wheat meal (Hesse, J. 1857, 403). Also by the dry distillation of 'vinasses' from the beetroot sugar manufacture (Vincent, Bull. Soc. chim. [ii.] 27, 150).

Preparation.—The crude methylamine from the distillation of the 'vinasse' is treated with sulphuric acid, the solution evaporated to a syrup and treated with absolute alcohol, the monomethylamine sulphate is thus precipitated. The filtrate is treated with the proper amount—1 molecule for every 2 molecules of primary amine present—of ethyl oxalate, and allowed to stand for 24 hours. The precipitate, consisting of a mixture of di-*iso*butyl oxamide and di-*iso*propyl oxamide, is filtered off and the filtrate distilled; the residue is then decomposed by potash, the free bases received in alcohol, and the alcoholic solution mixed at 0° with ethyl oxalate (1 molecule to each molecule of free base) and allowed to stand for a day. The mixture is then distilled, and the triethylamine obtained pure. The non-volatile residue is made slightly alkaline with milk of lime and evaporated, calcium *iso*propyl oxamate first crystallises out, and then calcium ethyl oxamate. The mother liquor, on addition of alcohol, gives a precipitate of calcium methyl oxamate, whilst calcium dimethyl oxamate remains in solution (Duvillier and Buisine, Ann. Chim. [v.] 23, 299).

A mixture of herring pickle and lime is subjected to distillation, the alkaline distillate is neutralised with hydrochloric acid, evaporated to dryness, and the residue treated with alcohol, which leaves the ammonium chloride undissolved. The solution is evaporated, the residue dissolved in a little water, and redistilled with lime, the vapours being led through an empty bottle to separate less volatile constituents, and then conducted into water or condensed with ice.

50 grammes of ammonium chloride are heated with 440 grams of 40 p.c. formaldehyde solution in an autoclave at 120°–160°.

Trimethylamine can more readily be obtained in a pure state by the distillation of tetramethylammonium hydroxide (Schmidt, Annalen, 1892, 267, 254).

Properties.—Trimethylamine is a volatile liquid with a strong, fish-like smell. It is very soluble in water, and possesses strong basic properties, although it can be displaced from its compounds by either mono- or di-methylamine. It is not acted upon by formaldehyde, and hence it may be determined in presence of ammonia (Budai, Zeitsch. physiol. Chem. 1913, 86, 107).

When heated at 800°–1000° it decomposes almost quantitatively into hydrocyanic acid and methane, whilst at 600°, *tetramethyl hydrazine* is formed (Voerkelius, Chem. Zeit. 1909).

When passed through a hot tube with hydrogen it decomposes, forming dimethyl dimethylene diamine $(CH_2)_2(CH_3)_2N_2$, ammonia, cyanogen, and other products (Romeny, Ber. 11, 835). It forms salts with acids, of which the hydrochloride is of some importance; it has been suggested to employ it in the manufacture of potassium carbonate from potassium chloride by a process analogous to the Solvay ammonia soda process. Ammonia cannot be employed in this process, since ammonium chloride has only about the same solubility as potassium hydrogen carbonate, whilst trimethylamine hydrochloride is very much more soluble.

For a number of salts formed by trimethylamine with inorganic salts, *see* Guareschi, *l.c.*; Christensen, *l.c.*; Ragland, *l.c.*; Cook, *l.c.*; Hofmann and Marburg, *l.c.*; Mylius and Foerster, Ber. 24, 2424; Wiede, *ibid.* 31, 3140; Michael and Hibbert, Annalen, 1909, 364, 64.

Trimethylamine dibromide NMe_3Br_2 is formed by passing dry trimethylamine into ice-cold bromine, or by heating trimethylamine hydrobromide (1 molecule) with a small quantity of hydrogen bromide and bromine (1 molecule). Similar iodine, chlorine, and mixed halogen derivatives have also been obtained (Remsen and Norris, Amer. Chem. J. 1896, 18, 90; *see* also Hantzsch and Graf, Ber. 1905, 38, 2154; Norris, *ibid.* 3904). They are crystalline unstable substances.

For other halogen and halogen acid compounds of trimethylamine, *see* Gabriel and Stelzner, Ber. 1895, 28, 2929; Delépine, Compt. rend. 1896, 122, 272; Ann. Chim. 1896, [vii.] 8, 439; Norris, Amer. Chem. J. 1898, 20, 51; Pictet and Krafft, Bull. Soc. chim. [iii.] 7, 72; Hantzsch, Ber. 1905, 38, 2161; Kaufler and Kunz, *ibid.* 1909, 42, 2482).

Trimethylamine combines with carbon disulphide to form a colourless crystalline compound

$N(CH_3)_3CS_2$, m.p. 125°, which is somewhat unstable; it is soluble in chloroform, and combines with dilute acids, but is decomposed by strong acids into its constituents.

Trimethyloxamine (*Trimethylamine oxide*) $Me_3N{:}O,2H_2O$ forms needle-shaped crystals, m.p. 96°, and is best obtained by the action of hydrogen peroxide on an aqueous solution of trimethylamine (Dunstan and Goulding, Chem. Soc. Trans. 1899, 794, 1005; Mamlock and Wolffenstein, Ber. 1901, 34, 2499).

Trimethylamine, like dimethylamine, enters into the constitution of a number of important dyes. It also yields derivatives which form substances important physiologically; thus it reacts with ethylene oxide forming *choline*

$$Me_3N + \begin{matrix}CH_2\\ |\\ CH_2\end{matrix}\!\!>\!O + H_2O = Me_3N\!<\!\begin{matrix}CH_2\cdot CH_2\cdot OH\\ OH\end{matrix}$$

With monochloracetic acid producing *betaine*

$$Me_3N + ClCH_2\cdot CO_2H = Me_3N\cdot CH_2\cdot CO + HCl$$
$$\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\quad O$$

With ethylene dibromide, to form *neurine*

$$Me_3N + C_2H_4Br_2 = Me_3N\!<\!\begin{matrix}CH_2\cdot CH_2Br\\ Br\end{matrix}$$
$$\xrightarrow{Ag_2O} Me_3N\!<\!\begin{matrix}CH:CH_2\\ OH\end{matrix} + 2AgBr$$

***iso*Crotyltrimethylammonium bromide**

$$CMe_2:CH\cdot NMe_3Br$$

obtained by the interaction of *iso*butylene bromide and trimethylamine, is homologous with neurine bromide, and, like valeryltrimethyl ammonium bromide, closely resembles it in its physiological action. Dibrom*iso*butyl trimethyl ammonium bromide and dibrom*iso*butyltrimethyl ammonium dibromide and other similar compounds have also been prepared (Kleine, Chem. Zentr. 1894, i. 16).

Ethylene bromide reacts with trimethylamine in molecular proportion at 100°, yielding tetramethylammonium bromide, trimethylvinylammonium bromide (neurine bromide), dimethylamine bromide, and other compounds.

Propylene and amylene bromides also react with trimethylamine yielding a number of methylammonium compounds (Kleine, *l.c.*).

Trimethylamine reacts with halogen ketones, forming ketonic bases (Schmidt, Arch. Pharm. 1898, 236, 334).

Trimethylacetonylammonium chloride (*coprine chloride*) $AcCH_2\cdot NMe_3Cl$ is a crystalline substance which gives a platinochloride, yellowish red needles, m.p. 238°–240°; an aurichloride, beautiful yellow needles, m.p. 139·5°; and an oxime, colourless plates, m.p. 212° (Furnée, Arch. Pharm. 1898, 236, 334).

Trimethylacetonylammonium bromide melts at 190°, and at 195° it gives rise to a yellow distillate, and tetramethylammonium bromide (Brendler and Tafel, Ber. 1898, 31, 2683).

For the interaction of trimethylamine with other aliphatic compounds, *see* Malbot, Bull. Soc. chim. [iii.] 6, 845, 709, 711; *ibid.* 7, 213; Duvillier, *ibid.* [iii.] 23, 507; Menozzi and Pantoli, Gazz. chim. ital. 23, ii. 209; Hartmann, Chem. Zentr. 1896, i. 999; André, Compt. rend. 1998, 126, 1107; Benary, Ber. 1908, 41, 2399; D. R. P. 195813; Frdl. 1908-10, 990.

In France and in Russia trimethylamine has been employed successfully in medicine, but English and American doctors have not obtained such good results. For the physiological effects of trimethylamine, *see* Combemale and Brunelle, Compt. rend. Soc. Biol. 1891, 175.

Methylammonium cobaltinitrite

$$(MeNH_3)_3CO(NO_2)_6$$

is prepared by adding to a nearly saturated solution of methylamine hydrochloride, a nearly saturated solution of pure sodium cobaltinitrite. It is a yellow powder, stable when dry, but slowly decomposing in the presence of moisture or on heating. When treated with strong mineral acids it decomposes violently (Cunningham and Perkin, Chem. Soc. Trans. 1909, 1564).

Monomethylammonium hexabromoplatinate $(NH_3Me)_2PtBr_6$ and the corresponding di- and tri-methyl compounds are all crystalline substances (Gutbier and Bauriedel, Ber. 1909, 42, 4243).

Magnesium methylammonium arsenate

$$NH_3Me\cdot MgAsO_4,8H_2O$$

and the trimethylammonium compound

$$NHMe_3\cdot MgAsO_4,6H_2O$$

are white crystalline powders (Brisac, Bull. Soc. chim. 1903, [iii.] 29, 591). Similar methylammonium phosphates have also been prepared (Porcher and Brisac, *ibid.* 587). For other methyl ammonium compounds, *see* Reynolds, Chem. Soc. Trans. 1891, 394; François, Compt. rend. 1905, 140, 1697; Gutbier, Zeitsch. physikal. Chem. 1909, 69, 304.

Tetramethylammonium $N(CH_3)_4$, *tetramethylium*, according to Palmaer (Zeitsch. Elektrochem. 1902, 8, 729) is produced when a solution of tetramethylammonium chloride or hydroxide in liquid ammonia is electrolysed between platinum electrodes, but it could only be observed as giving a transient blue coloration and could not be isolated.

The base, **Tetramethylammonium hydroxide** NMe_4OH is formed as the pentahydrate

$$NMe_4OH,5H_2O$$

m.p. 62°–63°, by the action of a methyl alcohol solution of potassium hydroxide on a similar solution of tetramethyl ammonium chloride. When this hydrate is desiccated it forms a trihydrate, m.p. 59°–60°, and a monohydrate which decomposes at 130°–135° without melting (Walker and Johnson, Chem. Soc. Trans. 1905, 955). The hydroxides are hygroscopic, strongly alkaline, and readily absorb carbon dioxide when exposed to the air. When heated they decompose forming methyl alcohol and trimethylamine. The *iodide* $N(CH_3)_4I$ is the main product of the action of ammonia upon methyl iodide (Hofmann, Proc. Roy. Soc. 1851, 381), or by heating trimethylazonium iodide with methyl iodide at 125°–130° (Harries and Haga, Ber. 31, 59). It forms quadratic prisms soluble in hot water, but only slightly in cold water; sp.gr. 1·84 (Schröder, Ber. 12, 562). Similar chlorine and bromine compounds are also known.

Tetramethylammonium pentaiodide NMe_4I_5, m.p. 126°-127°, is obtained by the action of methyl iodide on nitrogen iodide (Silberrad and Smart, Chem. Soc. Trans. 1906, 173).

Tetramethylammonium forms many salts which have the power of producing crystalline double compounds with many metallic salts (*v.* Topsöe, J. 1883, 619; Risse, Annalen, 107, 223;

Lossen, *ibid.* 181, 374; Ragland, *l.c.*; Prescott, J. Amer. Chem. Soc. 1898, 20, 96; Wiede, *l.c.*; Auld and Hantzsch, Ber. 1905, 38, 2685; Milbauer, Zeitsch. anorg. Chem. 1907, 53, 135; Schmidt, Chem. Zentr. 1907, ii. 1593; Braun, Ber. 1908, 41, 2123; Kaufler and Kunz, *l.c.*).

Tetramethylammonium formate (*Forgenine*) $H{\cdot}CO_2{\cdot}N(CH_3)_4$ is obtained by the action of tetramethylammonium iodide on silver formate. It is a white crystalline, odourless, hygroscopic substance, stable in dry air and in solution, decomposing above 200°, and giving the reactions of formates (Vanzetti, Chem. Zentr. 1906, ii. 1347).

Forgenine is employed in medicine, but in large doses it is toxic, and may even prove fatal (Piccinini, Chem. Zentr. 1907, i. 651).

α-Methyl hydroxylamine $MeO{\cdot}NH_2$ is formed by treating methyl ethyl benzhydroxamate with hydrochloric acid (Lossen and Zanni, Annalen, 1876, 182, 225). The hydrochloride forms prisms, m.p. 149°, and gives an orange-red crystalline platinochloride (Lossen, Ber. 1883, 16, 827; Petraczek, *ibid.* 827).

β-Methyl hydroxylamine $MeNH{\cdot}OH$ is formed by heating benz*syn*aldoxime methyl ether or its nitro derivative with hydrochloric acid (Dittrich, Ber. 1890, 23, 3598; Kjellin, *ibid.* 1893, 26, 2382), but is best prepared by the electrolytic reduction of nitromethane in alcoholic sulphuric acid solution at 15°–20° (Pierron, Bull. Soc. chim. [iii.] 21, 783; *see* also Bamberger, Ber. 1894, 27, 1350; Kirpal, *ibid.* 1882, 25, 1715). It forms long prisms, m.p. 42°, b.p. 62·5°/15 mm., sp.gr. 1·0003 at 20°/4°. It is readily soluble in water and alcohol, decomposes on standing, and is reduced to methylamine by hydriodic acid.

The *hydrochloride* has m.p. 88°–90°; the *picrate* m.p. 128°–130°.

α-Methyl β-ethyl hydroxylamine $NHEtOMe$ is a colourless alkaline liquid, b.p. 60°–61°, readily soluble in water and does not reduce silver nitrate. It forms a hydrochloride and a platinichloride. *β-Methyl α-ethyl hydroxylamine* has b.p. 65°–65·5° and similar properties to the α-methyl β-ethyl compound (Jones, Amer. Chem. J. 1907, 38, 253).

αβ-Dimethylhydroxylamine hydrochloride

$NHMe{\cdot}OMe,HCl$

forms long prismatic needles m.p. 115°–116°. It is volatile at 100°, does not reduce Barreswil's solution or silver nitrate. The platinochloride forms red prismatic crystals which melt at 180° (decomp.). The free base is a colourless volatile liquid, b.p. 42·2°–42·6° (Jones, Amer. Chem. J. 1898, 20, 1).

Methyl hydrazine $CH_3HN{\cdot}NH_2$ is prepared by the reduction of diazomethane with sodium amalgam and alcohol, or by agitating methyl iodide with excess of methylhydrazine in aqueous solution (Pechmann, Ber. 1895, 28, 859; Harries and Haga, *ibid.* 1898, 31, 56). A colourless liquid with ammoniacal smell. The sulphate $NHCH_3{\cdot}NH_2,H_2SO_4$, a crystalline compound, is obtained from methyl hydrazine carbamide which results from the action of nascent hydrogen upon nitroso-methyl carbamide $NH_2{\cdot}CO{\cdot}N(CH_3)NO$ (Brüning, Ber. 21, 1809). The oxalate has m.p. 166°. Methyl hydrazine gives benzoyl and other derivatives (Michaelis and Hadanck, Ber. 1908, 41, 3285).

***as*-Dimethyl hydrazine** $(CH_3)_2N{\cdot}NH_2$; b.p. 62·5° at 717 mm.; sp.gr. 0·801 at 2·2°; b.p. 63·9° at 752·5 mm.; sp.gr. 0·7914 at 22·3°/0° (Brühl, Ber. 1897, 30, 160); from nitroso-dimethylamine and nascent hydrogen (zinc-dust and acetic acid) in alcoholic solution (Renouf, Ber. 1880, 13, 2171), or by the dry distillation of trimethylazonium hydroxide (Harries and Haga, *l.c.* 58). It has a strong ammoniacal smell, and is very soluble in water, alcohol, or ether. It is decomposed by nitrous acid into nitrous oxide and dimethylamine.

The *oxalate* has m.p. 142°–143°. The *cyanide* crystallises in beautiful needles and decomposes at 0°–10° (Peters, Ber. 1906, 39, 2784).

***sym*-Dimethyl hydrazine** $MeNH{\cdot}NHMe$ is obtained by the action of methyl iodide on potassium or lead diformyl hydrazine (Harries and Klamt, Ber. 1895, 28, 504; Harries and Haga, *l.c.* 63), or by boiling the methyl iodide salt of methyl pyrazole with strong potassium hydroxide (Knorr and Köhler, Ber. 1906, 39, 3257; Knorr, *ibid.* 3265). It is a mobile, colourless, fuming liquid, b.p. 81°/747 mm., with the characteristic odour of aliphatic hydrazines. It dissolves in water with evolution of heat, attacks cork, rubber, and the epidermis, and its vapour, when mixed with air, burns with a faintly luminous flame, depositing soot, and is liable to explosion. It is a fairly strong reducing agent, and forms salts with mineral and organic acids. It also forms a semicarbazide and a phenylthiosemicarbazide, m.p. 115°; a dibenzoyl derivative, m.p. 85°; a dimethyl picrazide, m.p. 141°, and other derivatives (Knorr and Köhler, *l.c.*).

Trimethylazonium iodide $NH_2{\cdot}NMe_3I$ is obtained by agitating an aqueous solution of hydrazine hydrate with methyl iodide and caustic potash. It resembles ammonium chloride in crystalline structure, and has m.p. 235° (decomp.). It is converted into hydrochloride when acted on by silver chloride, and into the hydroxide by its interaction with silver oxide (Harries and Haga, *l.c.*).

Tetramethyl tetrazone $(CH_3)_2N{\cdot}N{:}N{\cdot}N(CH_3)_2$, b.p. 130°; a yellow explosive oil, slightly soluble in water. It is a strong base, and its salts are very soluble in water; it reduces silver solution with formation of a mirror (Renouf).

Methylene Compounds.

Methylene CH_2, a dibasic radicle not known in the free state.

Methylene diacetate $CH_2(C_2H_3O_2)_2$. B.p. 170°; from methylene iodide and silver acetate (Butlerow, Annalen, 107, 111); from chlormethyl acetate $C_2H_3O_2{\cdot}CH_2Cl$ and potassium acetate (Henry, Ber. 1873, 739). A liquid decomposed by water at 100° into acetic acid and trioxymethylene.

Methylene bromide CH_2Br_2, *Dibromomethane.* B.p. 96·5°–97·5° corr.; sp.gr. 2·4985 at 15°/15°, 2·47745 at 25°/25° (Perkin, Chem. Soc. Trans. 1884, 520). Obtained by the action of bromine upon methylene iodide under water (Butlerow, Annalen, 111, 251); from methyl bromide and bromine at 250° (Steiner), or by the action aluminium bromide heated to 100° on trioxymethylene (Gustavson).

A liquid which, by the action of water and

excess of lead oxide at 150° gives ethylene glycol (Eltekoff, Ber. 6, 558).

Methylene chloride CH_2Cl_2, *Dichlormethane.* B.p. 41·6° corr.; sp.gr. 1·37777 at 0°/4° (Thorpe, Chem. Soc. Trans. 1880, 195); b.p. 40°; sp.gr. 1·33771 at 15°/15°, 1·32197 at 25°/25° (Perkin, *ibid.* 1884, 527); b.p. 40·41° (corr.) (Thorpe and Rodger). From methane and chlorine after preliminary formation of methyl chloride (Regnault, Annalen, 33, 328); from methylene iodide and chlorine (Butlerow, Annalen, 111, 251).

Preparation.—A mixture of chloroform (1 vol.), zinc, and alcohol (3 vols.) is gradually treated with hydrochloric acid and distilled; the distillate, consisting of chloroform and methylene chloride, is rectified, and the residue boiling above 53° is again treated with zinc (Greene, Chem. News, 50, 75). It may also be prepared by treating methylene iodide under water with chlorine.

Properties.—A colourless liquid with a pleasant smell, resembling that of chloroform. When heated with water to 200°, hydrochloric and formic acids and methyl chloride are produced; the latter, on further heating, forming methyl alcohol and hydrochloric acid. With aqueous ammonia at 140° it forms ammonium chloride, methylamine hydrochloride, and formic acid (André, Compt. rend. 102, 1474). When treated with ammonia, dissolved in methyl alcohol, hexamethylenetetramine is obtained.

Methylene chlorobromide CH_2ClBr, *Chlorobromomethane.* B.p. 68°–69° at 765 mm.; sp.gr. 1·9907 at 19°/19°; V.D.=4·43 (Henry, Compt. rend. 101, 599). Obtained by the action of bromine upon chloriodomethane. A mobile colourless liquid, with agreeable smell. It gives rise when treated with 2 mols. of ammonia in saturated methyl alcohol solution for 2 hours at 60°–70° to hexamethylenetetramine hydrobromide, ammonium chloride, and ammonium bromide.

Methylene chlorofluoride CH_2ClF, *Chlorfluormethane.* A gas, V.D. 34·18 (calc. 34·25). From methyl fluoride and chlorine in sunlight. Is colourless, and slightly soluble in, and slowly decomposed by, water; burns with difficulty in oxygen (Collie, Chem. Soc. Trans. 1889, 112).

Methylene chloroiodide CH_2ClI, *Chloriodomethane.* B.p. 109°–109·5° at 760·4 mm.; sp.gr. 2·444 at 14·5°/14·5°; V.D. 88·14. An oily liquid obtained by the action of iodine monochloride upon methylene iodide (Sakurai, Chem. Soc. Trans. 1885, 198); also by action of iodine in potassium iodide solution upon monomercuric methylene chloriodide (*ibid.* 1882, 362).

Methylene iodide CH_2I_2, *Diiodomethane.* M.p 4°; b.p. 180°, with partial decomposition; sp.gr. 3·3326 at 15°/15° (Perkin, Chem. Soc. Trans. 1896, 1173); M.M. at 15°=18·827 (Perkin, *ibid.* 45, 464). From iodoform and sodium ethoxide (Butlerow, Ann. Chim. [iii.] 53, 313); by heating iodoform either alone or with iodine (Hofmann, Annalen, 115, 267; Dunn, Chem. Soc. Proc. 1910, 116); from chloroform or iodoform and hydriodic acid (Leben, Zeitsch. Chem. 1868, 712). By the action of iodine on diazomethane dissolved in ether (*v.* Pechmann, Ber. 1894, 1889). A yellow liquid which, when heated with water and copper to 100°, yields ethylene (Butlerow, Annalen, 120, 356). With zinc ethyl it forms butane. With silver acetate yields methylene acetate; combines with mercury to form mercuric methylene iodide CH_2I,HgI. It dissolves phosphorus very readily at ordinary temperatures (more than 1 : 1). An attempt to prepare the radicle methylene (CH_2), by heating with silver powder produces carbon, methane and ethane and other products (Sudborough, Chem. Zentr. 1897, ii. 180). Methylene iodide, on account of its high density, is employed in the mixed solutions used for determining the sp.gr. of rocks and minerals by flotation, the usual diluents being benzene or ether.

Methylene oxide CH_2O *v.* FORMALDEHYDE.

Methylene sulphides.

Trimethylene sulphide $(CH_2S)_3$, *Parathioformaldehyde.* B.p. 216°; sublimes without decomposition. Formed by the action of sulphuretted hydrogen upon a solution of formaldehyde. Also by reducing, by means of zinc and hydrochloric acid, carbon disulphide (Girard, Annalen, 100, 306), potassium thiocyanate, or allyl mustard oil (Hofmann, Ber. 1, 176). It also results from the action of potassium sulphide on methylene iodide (Husemann, Annalen, 126, 294; Mansfeld, Ber. 1886, 698). It crystallises from benzene, carbon disulphide, or chloroform in quadratic prisms which are insoluble in water and possess a penetrating odour. It forms crystalline compounds with many salts, *e.g.* $C_3H_6S_3.HgCl_2$, needles, insoluble in water; $2C_3H_6S_3.PtCl_4$, golden-yellow needles.

Metathioformaldehyde $(CH_2S)x$ is formed by leading sulphuretted hydrogen for 10 hours into a boiling solution of hexamethylenetetramine saturated with ammonia (Wohl, Ber. 1886, 2345). The precipitate is purified by washing with water and hydrochloric acid, and by boiling with alcohol and glacial acetic acid. It has a characteristic odour, melts at 175°–176°, is not volatile without decomposition, and does not form salts with mercuric or platinic chlorides.

Methylene hydrogen sulphide $CH_2(HS)_2$, *thiomethylene glycol,* is not known in the free state. The diethyl ether, $CH_2(SC_2H_5)_2$, b.p. 184°, sp.gr. 0·987 at 20°, is obtained by the treatment of sodium mercaptide with methylene iodide (Claesson, J. pr. Chem. [ii.] 15, 176).

Methylene sulphonic acid $CH_2(SO_3H)_2$, *Methane disulphonic acid,* forms very unstable needle-like crystals. Produced in small quantity by the action of sulphur trioxide upon ether (Liebig, Annalen, 13, 35; Strecker, *ibid.* 100, 199); by the oxidation of methylene thiocarbonate (Husemann, *ibid.* 126, 293); from chloroform and potassium sulphite solution at 180° or from iodoform and potassium sulphite at 150° (Strecker, *ibid.* 148, 92).

Preparation—Lactic acid or calcium lactate is heated with fuming sulphuric acid until sulphur dioxide begins to be evolved; the mixture is then neutralised with barium carbonate. It can also be prepared by heating 2 volumes of acetamide with 1 volume of fuming sulphuric acid (Buckton and Hofmann, Annalen, 100, 133). For salts *v.* Hofmann, Strecker, *l.c.*, also Monari (Ber. 1885, 1343).

Hexamethylenetetramine, *hexamethyleneamine, formamine, ammonio-formaldehyde, ammonaldehyde. cystamin, cystogen, formin, metramine, urisol, uritone, urotropine, vesalvine* $(CH_2)_6N_4$, is prepared by the action of ammonia

on trioxymethylene (Butlerow, Annalen, 115, 322); from alcoholic ammonia and methylene chloride at 125° (Höland, *ibid.* 240, 225); or by passing formaldehyde vapour into a concentrated solution of ammonia, evaporating to a syrupy consistency and pouring into alcohol (Wohl, Ber. 1886, 1842). Commercial ammonium carbonate is dissolved in 40 p.c. formaldehyde solution, the solution is evaporated to dryness under reduced pressure and the residue is sublimed *in vacuô*, or recrystallised from absolute alcohol. It forms rhombohedral crystals from alcohol, is insoluble in ether, but readily in water and chloroform. Thioformaldehyde is produced by heating it with hydrogen sulphide. It is precipitated from its aqueous solution by bromine as an orange-red tetrabromide

$$C_6H_{12}N_4Br_4$$

which, when kept over potash, loses two atoms of bromine; the resulting dibromide melts at 198°–200°. This dibromide when boiled with water is decomposed into formaldehyde, water, ammonia, and hexamethylenetetramine. Hexamethylenetetramine is also precipitated from its solutions by mercuric chloride quantitatively. In the presence of ammonium salts it may be estimated by heating it with strong potash, by which it is unaffected, until all ammonia is expelled, then making acid and boiling to decompose the hexamethylene tetramine and subsequently making alkaline and estimating the ammonia in the usual way (Puckner and Hilpert, J. Amer. Chem. Soc. 1908, 1471). The purity of a specimen is readily examined qualitatively by means of Nessler's solution, which shows the presence of ammonia and ammonium salts by the usual yellow colour or brown precipitate, and of formaldehyde by a precipitate of mercury (Wöhlk, Zeitsch. anal. Chem. 1905, 765). Many compounds and derivatives of hexamethylene tetramine have been prepared and patented. The compounds with halogen pyrroles and aromatic sulphuric acids by Stange (Eng. Pat. 4804, 1899); with phenol and phenol mono- and poly- sulphuric acids and their halogen derivatives by the Chemische Fabriken vorm. Weiler-ter-Meer (D. R. P. 124231); basic compounds by Karl Hock (D. R. P. 139394); *cystopurin*, a compound of 1 mol. hexamethylenetetramine and 2 mols. sodium acetate by Bergell and Wülfing (Eng. Pat. 29093, 1906; U.S. Pat. 852993, 1907; Chem. Zentr. 1907, i. 487); the chloral, bromal, and butyl chloral derivatives by Lederer (Eng. Pat. 17693, 1897); the quinate by Wichmann and Gabler (U.S. Pat. 690804, 1902; Zimmermann, Eng. Pat. 14834, 1899); the salicylic acid compound by O. Imray (Eng. Pat. 22481, 1895); a powerfully astringent compound resulting from the condensation with tannin by H. E. Newton (Eng. Pat. 10790, 1898); 'ammonium compounds' by Farbenfabriken vorm. Baeyer & Co. (D. R. P. 164510); the borate by Aktien Gesellschaft für Anilinfabriken (Fr. Pat. 363764, 1906; U.S. Pat. 869636; Eng. Pat. 5039, 1906). In addition the following derivatives have been prepared: salts of inorganic acids and compounds with metallic salts by B. Grützner (Chem. Zentr. 1898, ii. 663); halogen derivatives by Horton (Ber. 1888, 1999), and Höhnel (Chem. Zentr. 1900, i. 409); bromoiodides and chloroiodides by Mouneyrat (Compt. rend. 136, 1472); the chromate by K. A. Hofmann (Ber. 1906, 3181). Quaternary salts have been prepared by Hahn and Walter (Ber. 1921, 54 [B] 1531). The products of decomposition have been studied by Ischidzu and Inouye (Chem. Zentr. 1906, i. 1087), Grassi-Cristaldi; and Di Franco by the catalytic hydrogenation with reduced nickel has obtained trimethylamine, ammonia, and methane (*ibid.* 1907, i. 237).

Methylene tetramethyl diamine

$$CH_2[N(CH_3)_2]_2$$

is prepared from formaldehyde and dimethylamine (Henry). It boils at 85°, and has sp.gr. 0·7491 at 18·7°.

Methylene tetraethyl diamine $CH_2[N(C_2H_5)_2]_2$, b.p. 166°–169° (168° Henry). Formed by the action of trioxymethylene, 6·5 parts, upon diethylamine, 29·2 parts (Kolotoff, J. Russ. Phys. Chem. Soc. 17, 244). It is an unpleasant-smelling liquid, insoluble in water, but very soluble in alcohol; sp.gr. 0·8105 at 18·7° (Henry, Ber. 1893 (Ref.) 934).

Methylene tetrapropyl diamine

$$CH_2[N(C_3H_7)_2]_2$$

boils at 225°–230° with decomposition; sp.gr. 0·8014 at 18° (Henry).

Methylene thiocarbonate CH_2CS_3. A yellowish-white, amorphous powder insoluble in water, almost insoluble in alcohol, ether, or carbon disulphide, obtained by the action of methylene iodide upon sodium thiocarbonate in alcoholic solution (Husemann, Annalen, 126, 292). Is decomposed by ammonia into ammonium thiocyanate and methylene sulphide $(CH_2S)_3$.

Methylene thiocyanate $CH_2(CSN)_2$, m.p. 102°. From methylene iodide and potassium thiocyanate in alcoholic solution (Lermontoff, Ber. 1874, 1282). It forms needles or prisms which are almost insoluble in cold, moderately soluble in warm water, and easily soluble in alcohol or ether. By oxidation, *e.g.* by nitric acid, it yields methylene disulphonic acid.

Dimethylene dimethyl diamine

$$(CH_2)_2N_2(CH_3)_2$$

A crystalline non-volatile body obtained by passing trimethylamine and hydrogen through a heated tube (Romeny, Ber. 1878, 835).

Dimethylene diethyl diamine

$$(CH_2)_2N_2(C_2H_5)_2$$

b.p. 205°–208°. Obtained by heating in a sealed tube a mixture of trioxymethylene with ethylamine (Kolotoff, J. Russ. Phys. Chem. Soc. 17, 231). An oily liquid with an unpleasant odour, soluble in cold water or in alcohol. Is decomposed by hydrochloric acid into trioxymethylene and ethylamine.

β-METHYLADIPIC ACID *v.* PIMELIC ACID.

METHYLAL *v.* SYNTHETIC DRUGS.

METHYLALLOXAN *v.* ALLOXAN.

METHYL ANILINE  NH·CH$_3$. (1) Made by digesting aniline hydrochloride with methyl alcohol in an autoclave at 180°, adding milk of lime and steam-distilling. (2) By heating a mixture of aniline with methyl alcohol in presence of iodine at 220° (Knoll and Co. D. R. P. 250236). (3) By condensing aniline

with formaldehyde and reducing the anhydroformaldehyde aniline $(CH_2:N{\cdot}C_6H_5)_3$ with zinc and sodium hydroxide (Geigy and Co., D. R. P. 75854). (4) By adding formaldehyde (40 p.c. solution) to a mixture of aniline and caustic soda containing zinc dust, heating and steam distilling (Morgan, Eng. Pat. 102834 of 1916). (*Cf.* Frankland, Challenger and Nicholls, Chem. Soc. Trans. 1919, 115, 198).

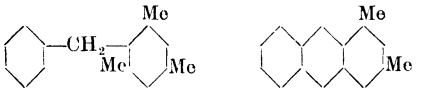
Methylaniline boils at 192°. Sp.gr. 0·976 at 15°. Yields *methylethylaniline* (b.p. 201°) on ethylation (Claus and Howitz, Ber. 1884, 17, 1324.

METHYL-ANTHRACENE AND OTHER ALKYL DERIVATIVES OF ANTHRACENE (*see also* articles on ALOES, COCHINEAL, CHRYSOPHANIC ACID, CASCARA SAGRADA, INDANTHRENE, KERMES, RHUBARB, VAT DYES). In order to obtain the higher homologues of anthracene, it has been found necessary in most cases to resort to synthetical methods, as very few of these substances have been met with in coal tar.

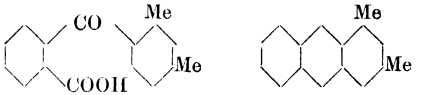
The methods usually employed are the following:—

(1) Elimination of hydrogen from the hydrocarbons of the C_nH_{2n-14}, or C_nH_{2n-16} series, by passing them through red-hot tubes.

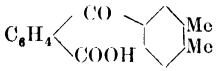
Benzyl mesitylene is thus converted into dimethylanthracene.



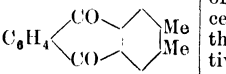
(2) By distilling *o*-ketonic acids with zinc-dust (Gresly, Annalen, 234–238); *m*-xyloyl-*o*-benzoic acid yields *m*-dimethylanthracene,



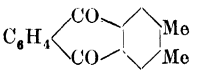
(3) By the action of sulphuric acid on *o*-ketonic acids (at about 125°), and subsequent reduction with zinc-dust and ammonia (Elbs, J. pr. Chem. 1890, 41, 1, &c.).

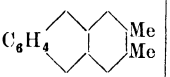


o-Xyloyl-*o*-benzoic acid.



o-Dimethylanthraquinone.

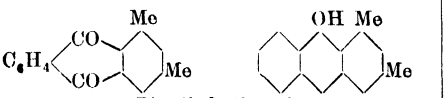




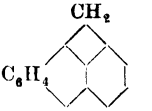
o-Dimethylanthracene.

This reaction cannot be successfully employed in a number of cases where one of the methyl groups is attached to the carbon atom next to the carbonyl group, as under these conditions anthracylene derivatives frequently result (*v.* Elbs, *l.c.* pp. 15–18).

Thus *m*-dimethylanthraquinone, on reduction with zinc dust and ammonia, yields *m*-dimethylanthracylene and not *m*-dimethylanthracene.



m-Dimethylanthranol.

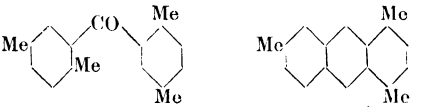


m-Dimethylanthracylene.

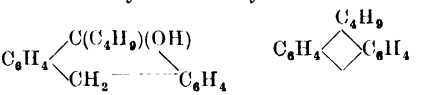
And similarly in a number of other cases.

It should, however, be remarked that the results of a number of Elbs' analyses of these anthracylene derivatives agree only so very approximately that this explanation can scarcely be looked on as completely satisfactory.

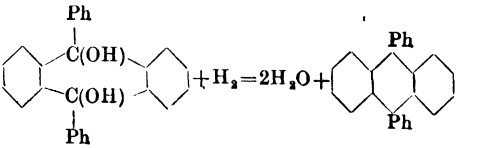
(4) By the prolonged boiling of some ketones. Thus di-*p*-xylyl ketone, when boiled for 6 hours under a reflux condenser yields (1,4,7) trimethylanthracene (Elbs and Olberg, Ber. 19, 409).



(5) The homologues of anthracene of the fromula $C_6H_4(C_2HC_nH_{2n+1})C_6H_4$ are produced by boiling the alkylhydroanthranol with alcohol, hydrochloric acid, or picric acid. Thus *iso*butyl hydranthranol yields *iso*butylanthracene.

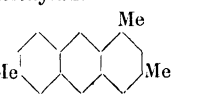


(6) Homologous arylanthracenes substituted in the γ position arise when the carbinols resulting from the action of magnesium aryl halogen compounds on anthraquinone and its derivatives are reduced. Thus diphenyl anthracene results when the corresponding carbinol is treated with zinc and acetic acid.

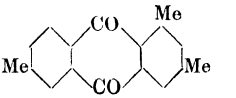


In their properties and reactions the homologues of anthracene behave very similarly to anthracene itself. On oxidation with chromic acid they yield corresponding anthraquinone derivatives, but in most cases the oxidation goes further and converts a portion of the anthraquinone into mono-, di-, or tricarboxylic acid, according to the number of side chains present, thus

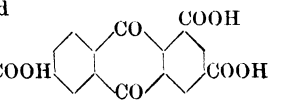
(1,3,6) Trimethylanthracene



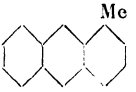
on oxidation yields first trimethylanthraquinone



and ultimately (1,3,6) anthraquinone tricarboxylic acid



α-Methyl anthracene



According to Birukoff (Ber. 20, 2069), α-methyl anthracene may be prepared by the distillation of methyl erythroxy anthraquinone with zinc-dust. O. Fischer and Sapper (J. pr. Chem. 1911, [ii.] 83, 201), obtained only a small yield of the substance in this manner; the main product was anthracene. The best method of preparation, according to these authors, consists in heating 4-chloro-1-methylanthraquinone with zinc-dust at a very low red heat. α-methylanthracene crystallises in long colourless needles, has m.p. 85°–86°, and is much more soluble in most solvents than anthracene or β-methylanthracene. Its solution in alcohol exhibits blue fluorescence. With picric acid, α-methylanthracene forms a compound crystallising in red needles, having m.p. 113°–115°.

9 : 10-*Dihydro*-1-*methylanthracene* is obtained by reduction of α-methylanthracene in boiling amyl alcoholic solution by means of sodium (Fischer and Ziegler, J. pr. Chem. 1912, [ii.] 86, 289). The substance is volatile in steam and crystallises in colourless needles, melting at 30°.

4-*Chloro*-1-*methylanthracene* is obtained on boiling 4-chloro-1-methylanthraquinone with zinc-dust and aqueous ammonia. It melts at 112° and, unlike the corresponding quinone, does not part with halogen on distillation with zinc-dust.

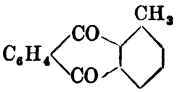
The *picrate* crystallises from benzene in dark red needles, m.p. 118°.

9 : 10-*Dihydro*-4-*chloro*-1-*methylanthracene* (Fischer and Ziegler, *l.c.*) is prepared by reducing 4-chloro-1-methylanthracene with hydrogen iodide in glacial acetic acid solution. It crystallises from methyl alcohol in colourless needles, melting at 47°–48°.

9 : 10-*Dihydro*-9 : 10-*dibromo*-4-*chloromethylanthracene* crystallised in greenish prisms from toluene and is obtained by the addition of bromine to a solution of 4-chloro-1-methylanthracene in carbon disulphide (Fischer and Ziegler, *l.c.*).

1-*Chloro*-4-*methylanthranol* is obtained by reduction of 4-chloro-1-methylanthraquinone by means of hydrogen iodide in boiling acetic acid solution. Bright yellow needles, m.p. 145°–146°, readily soluble in benzene and chloroform, more sparingly so in alcohol (Fischer and Ziegler, *l.c.*).

α-Methyl anthraquinone

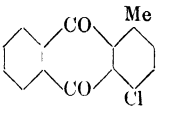


is readily prepared by oxidising α-methylanthracene with chromic acid in acetic acid solution, only small quantities of anthraquinone carboxylic acid being produced.

α-Methylanthraquinone crystallises from dilute acetic acid in small white needles, which, when exposed to light, become reddish-coloured. It melts at 170°–171°, is very readily soluble in alcohol or benzene, but difficultly soluble in glacial acetic acid.

It differs from its 4-hydroxy derivative in that it does not lose its methyl group on distillation with zinc-dust. Since α- and β-methylanthracene are obtained on submitting many natural products to zinc-dust distillation, it is of importance to be able to distinguish between them. α-Methylanthraquinone differs from the corresponding β- compound in turning red on exposure to light. Moreover it is oxidised by dilute nitric acid at 160° to anthraquinone-1-carboxylic acid, which develops a rose coloration when heated with soda lime. Under these conditions anthraquinone-2-carboxylic acid gives a blue colour.

4-*Chloro*-1-*methylanthraquinone*,

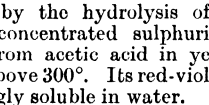


o-(*p*-Chlorotoluoyl) benzoic acid, prepared from *p*-chlorotoluene and phthalic anhydride, is heated at 100° with oleum (20 p.c. SO_3) for one to two hours. The reaction mixture is added to water and the precipitate collected, washed with alkali and crystallised from acetic acid. The yield is 4·4 grams from 5 grams of the acid. The substance crystallises from alcohol in slender yellow needles, melting at 164°, and is very stable to oxidising agents (Heller and Schülke, Ber. 1908, 41, 3635; D. R. P. 211967). A bromo-derivative (M.L.B., D. R. P. 259881) may be prepared in nitrobenzene solution. It melts above 300° and crystallises in orange needles from nitrobenzene. This substance is stated to dye cotton orange from a vat.

4-*Nitro*-1-*methylanthraquinone* (?) is obtained by treating 1-methylanthraquinone with concentrated nitric acid (Fischer and Ziegler, *l.c.*). It crystallises from acetic acid in glistening yellow needles, melting at 252°.

4-*Anilino*-1-*methylanthraquinone* may be prepared by heating 4-chloro-1-methylanthraquinone (2 grams) with aniline (12 grams) and dry sodium acetate (2 grams) at 185° during ten hours. It crystallises from alcohol in reddish-black needles, melting at 144°, and moderately readily soluble in chloroform, acetone and benzene. The corresponding *p*-toluidino-derivative occurs in dark red rods, m.p. 159°–160° (Grünthal and Ruthenberg, Ber. 1912, 45, 796).

2-Hydroxy-1-methylanthraquinone

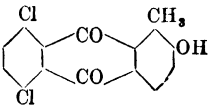


is obtained by the hydrolysis of its methyl ether with concentrated sulphuric acid. It crystallises from acetic acid in yellow needles which melt above 300°. Its red-violet potassium salt is sparingly soluble in water.

Methyl ether. This is the product of the action of sulphuric acid at 155° on 4′-methoxy-5′-methyl-2-benzoylbenzoic acid. It crystallises in canary-yellow needles from methyl alcohol and melts at 184°. The substance is soluble in acetic acid or ethyl alcohol and may be sublimed. It forms a monobromo- derivative, melting at 228°, and when dissolved in fuming nitric

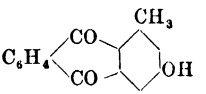
acid, yields a nitro-methoxy-methylanthraquinone which forms canary-yellow needles, melting at 179°. The latter on reduction with stannous chloride in alkaline solution is converted into the corresponding amino compound. This amino-methoxy-methyl anthraquinone separates from methyl alcohol in bright red needles of m.p. 187°. Acetamino-methoxy-methyl anthraquinone crystallises from acetic acid in brown needles, melting at 204°. On energetic nitration, 2-methoxy-1-methylanthraquinone yields a trinitro derivative (Bentley, Gardner and Weizmann, Chem. Soc. Trans. 91, 1626).

5:8-*Dichloro*-2-*hydroxy*-1-*methylanthraquinone*

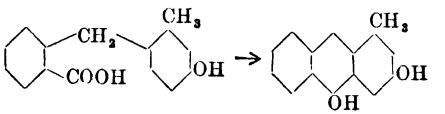


3 : 6 : Dichlorphthalic anhydride condenses with *o*-tolyl methyl ether in presence of aluminium chloride and the product is probably 3 : 6-dichlor-3′-hydroxy-2-*o*-toluoyl benzoic acid. This acid on heating with fuming sulphuric acid and boric acid, is converted to the quinone which separates from acetic acid as a yellow flocculent powder, decomposing at 249°. It should be remarked that in the above methyl hydroxy compounds, the methyl group may have the position 3 (Walsh and Weizmann, Chem. Soc. Trans. 97, 691).

3-Hydroxy-1-methylanthraquinone



This quinone has been synthesised by the following series of operations (Bistrzycki and Yssel de Schepper, Ber. 31, 2975). The condensation of phthalic anhydride and *m*-cresol yields a benzoyl benzoic acid which, on reduction, furnishes 4-hydroxy-2′-methyldiphenylmethane carboxylic acid. This compound, on treatment with sulphuric acid, is changed with loss of the elements of water into 1-methyl-3 : 10-dihydroxyanthracene thus :—

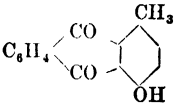


This anthracene derivative crystallises from alcohol in needles melting at 224°. Its diacetate forms microprisms from benzene and melts at 171°–173°. On oxidation with chromic acid in acetic acid solution, this diacetate yields the acetyl derivative of 3-hydroxy-1-methylanthraquinone. The derivative crystallises from alcohol in yellow needles, melting at 130°–135°, and on hydrolysis with alcoholic potash the parent quinone is produced.

3-Hydroxy-1-methylanthraquinone occurs in needles, sublimes at 200° and melts at 299°–300°. It dissolves in ammonia to an orange solution.

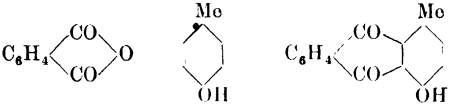
5 : 8 - *Dichloro* - 3 - *methoxy* - 1 - *methylanthraquinone* (Walsh and Weizmann, *l.c.*) is obtained in small yield by treatment of the benzoyl benzoic acid from dichlorphthalic anhydride and *m*-tolyl methyl ether with sulphuric acid. The yellow compound crystallises from acetic acid and decomposes at 236°.

4-Hydroxy-1-methylanthraquinone



(Methyl erythroxyanthraquinone).

is produced when a mixture of phthalic anhydride and *p*-cresol is heated with concentrated sulphuric acid (Birukoff, *l.c.*).



Preparation.—5 parts of phthalic anhydride, 2 parts of *p*-cresol, and 15 parts of concentrated sulphuric acid are heated to 160° for ten minutes, the product poured into water, the precipitate well washed with boiling water, and extracted with boiling dilute caustic potash solution. 4-Hydroxy-1-methylanthraquinone is obtained from the alkaline solution by the addition of hydrochloric acid in yellow flocks, which are readily purified by recrystallisation from glacial acetic acid. The pure substance is thus obtained in beautiful dark-brown needles, melting at 175°.

This quinone may also be obtained by the hydrolysis of its methyl ether, either by means of acetic acid and hydrochloric acid at 100° under pressure or with concentrated sulphuric acid. Further, the condensation of phthalic anhydride and *p*-cresol is well effected by fusion with boric acid. A benzoyl benzoic acid results, and thus, by further treatment with sulphuric acid, yields the quinone (Bentley, Gardner and Weizmann, *l.c.*).

4-Hydroxy-1-methylanthraquinone is almost insoluble in ammonia and sodium carbonate solution, readily soluble in caustic potash solution with a red coloration ; with baryta or lime-water insoluble brick-red lakes are produced. It dissolves in sulphuric acid with an orange-yellow colour, sublimes very easily, and in all its reactions, and also in its absorption spectrum, shows great similarity with erythroxyanthraquinone.

Fusion with potash converts it with difficulty into a colouring matter which is probably α-methylalizarin.

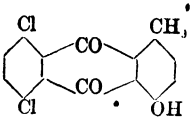
The *acetate* crystallises from acetic acid in yellow needles, which melt at 179°–180°.

Methyl ether. O. Fischer and Sapper (J. pr. Chem. 1911, [ii.], 83, 201) obtained this substance by the action of methyl alcoholic potassium hydroxide at 100° under pressure on 1-methyl-4-chloroanthraquinone. They described it as consisting of yellow needles of m.p. 128° and reddening under the action of light. Bentley, Gardner and Weizmann (*l.c.*) condensed phthalic anhydride with *p*-tolylmethyl ether and so obtained 2′-methoxy-5′-methyl-2-benzoylbenzoic acid. The action of sulphuric acid at 150° on this compound led to the formation of the methyl ether of 4-hydroxy-1-methyl-anthraquinone, described as orange-yellow needles from methyl alcohol, melting at 171°.

3-*Nitro*-4 - *hydroxy* - 1-*methylanthraquinone* (?)

is the product of the nitration of 4-methoxy-1-methylanthraquinone (Fischer and Ziegler, J. pr. Chem. 1912, [ii.] 86, 292). It crystallises in glistening orange prisms from acetic acid and melts at 182°. It may also be obtained from 4-chloro-1-methylanthraquinone by nitration in presence of boric acid (Fischer and Rebsamen, Ber. 1914, 47, 464).

5 : 8-*Dichloro*-4-*hydroxy*-1-*methylanthraquinone*



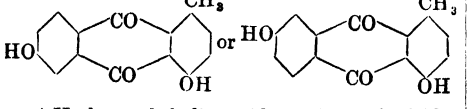
3 : 6 : Dichlorphthalic anhydride was condensed by means of aluminium chloride with *p*-tolyl methyl ether. The resulting 3 : 6 : dichloró-5'-hydroxy-2-toluoyl-benzoic acid was heated with fuming sulphuric acid (10 p.c. SO_3) in presence of boric acid for a few minutes at 130°. The quinone separates from acetic acid in microneedles of m.p. 259°. Its brilliant red solution in concentrated sulphuric acid exhibits purple fluorescence. Its acetyl derivative forms lemon-yellow needles, melting at 181°.

When heated with sodium phenoxide and copper powder, one chlorine atom is replaced by phenoxyl.

2-*Nitro*-3 : 4-*dihydroxy*-1-*methylanthraquinone* is obtained by treating 4-chloro-1-methylanthraquinone with nitric acid first in the cold and then at 60°–70°. It crystallises from acetic acid in red needles, melting at 217°–218°, and yields a diacetyl derivative, yellow needles melting at 188°. The salts are intensely coloured and the potassium salt crystallises in bluish-violet needles. On reduction with stannous chloride and potassium hydroxide the corresponding aminohydroxymethylanthraquinone is obtained. This separates from benzene in dark red needles, melting at 285° (Fischer and Rebsamen, *l.c.*).

5 : 7-*Dihydroxy*-1-*methylanthraquinone* may be prepared by heating 3 : 5-dihydroxybenzoic acid (1 part) and *m*-toluic acid (4 parts) with sulphuric acid (25 parts) during ten hours at 110°. By crystallisation of the product from benzene the more soluble 6 : 8-dihydroxy-2-methylanthraquinone, which is formed to some extent, is removed. In a similar way condensation of 3 : 5-dihydroxybenzoic acid and *o*-toluic acid results in the formation of 6 : 8-*dihydroxy*-1-*methylanthraquinone* which crystallises from ether in orange prisms, melting at 246°, and forms a diacetyl derivative, melting at 195° (Schunck and Marchlewski, T., 1896, 69, 70).

4 : 6-(*or* 7) *Dihydroxy*-1-*methylanthraquinone*



4-Hydroxyphthalic acid or its anhydride, when fused with boric acid and *p*-cresol, yields a benzoylbenzoic acid from which, by the further action of sulphuric acid, this quinone is obtained. The substance crystallises as a yellow powder from alcohol, and melts at 244°–246°.

A methyldimethoxyanthraquinone, which is probably, although not necessarily, the dimethyl ether of the above quinone, is obtained by condensing 4-methoxyphthalic anhydride with *p*-tolylmethyl ether by means of aluminium chloride and subsequently treating the benzoylbenzoic acid so produced with sulphuric acid (containing 60 p.c. SO_3) in presence of boric acid below 40°. The substance crystallises from acetic acid and melts at 141°. One methoxyl group is hydrolysed by the action of sulphuric acid at 110°.

4 : 5 : 6 (or 4 : 7 : 8) - *Trihydroxy*-1 - *methyl* - *anthraquinone* was obtained by Liebermann and Kostanecki (Annalen, 1897, 240, 304) by hydrolysis of its dimethyl ether, which is prepared by condensation of hemipinic acid and *p*-cresol in presence of sulphuric acid. The same authors prepared 5 : 6 : 7 - *trihydroxy*-1 - *methylanthraquinone* by condensation of *m*-toluic acid and gallic acid. This substance melts at 235°–240°, and gives a triacetyl-derivative, melting at 217°–218°. An isomeric methylanthragallol, namely, 6 : 7 : 8-*trihydroxy*-1-*methylanthraquinone*, golden yellow needles, melting at 297°–298° (triacetate, m.p. 208°–210°), is obtained by heating together equal parts of gallic acid and *o*-toluic acids at 130°–135° for 12 hours.

β-Methylanthracene

This hydrocarbon is found in varying quantities, together with anthracene and phenanthrene, in the fraction of coal tar which distils above 340°.

It may be synthetically prepared by the following reactions.

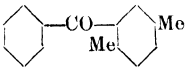
1. By passing the vapours of ditolylmethane (Weiler, Ber. 7, 1185) $CH_2(C_6H_4CH_3)_2$, ditolylethane (Fischer, *ibid.* 7, 1195),

$$CH_3\text{-}CH(C_6H_4CH_3)_2$$

or of oil of turpentine (Schultz, *ibid.* 10, 117) through a red-hot tube.

It is best in this reaction to employ ditolylethane, since the hydrocarbon from ditolylmethane is mixed with anthracene.

2. By boiling *p*-xylylphenylketone for several days on a reflux apparatus (Elbs, J. pr. Chem. 1890, 41, 3).



3. By the distillation of chrysophanic acid $C_{15}H_{10}O_4$, emodin $C_{15}H_{10}O_5$ (Liebermann, Annalen, 183, 163), colophonium, benzoe resin (Ciamician, Ber. 11, 273), chrysarobin $C_{30}H_{26}O_7$ (Liebermann and Seidler, Annalen, 212, 34) and methylquinizarine $C_{15}H_{10}O_4$ (Nietzki, Ber. 10, 2013) with zinc-dust.

According to Scholl (Monatsh. 1918, 39, 237), β-methylanthracene is best prepared synthetically by reduction of 2-methylanthraquinone with hydriodic acid and phosphorus. The melting-point of the substance so obtained is 206°–207°.

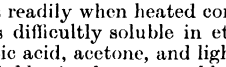
Preparation (Japp and Schultz, Ber. 10, 1049). The high boiling distillate of coal tar, known as crude phenanthrene, is freed from the greater part of the anthracene it contains by oxidation with potassium dichromate and sulphuric acid. The dark brown mass is

extracted with hot alcohol, the well-cooled solution allowed to deposit as much anthracene and phenanthrene as possible, the mother-liquors which contain the methylanthracene evaporated and the residue repeatedly recrystallised from alcohol.

β-Methylanthracene crystallises from alcohol in pale yellow needles and melts at 202°–203°. It sublimes readily when heated continuously at 100°. It is difficultly soluble in ether, alcohol, glacial acetic acid, acetone, and light petroleum, readily soluble in benzene, chloroform, and carbon disulphide.

Oxidation with nitric acid converts it into methylanthraquinone

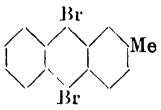
Chromic acid oxidises it for the most part direct to anthraquinone-2-carboxylic acid



Methylanthracene combines with picric acid, forming a compound which crystallises in large red needles; alcohol and water decompose this compound.

When sunlight acts on a benzene solution of the hydrocarbon, a dimeride, bis-β-methylanthracene, is formed (Orndorff and Megraw, Amer. Chem. J. 22, 152). It crystallises in rhombic crystals from toluene and melts at 228°. The substance is sparingly soluble and is converted on melting or solution in xylene into β-methylanthracene.

9 : 10-*Dibromo*-2-*methylanthracene*



is produced by treating methylanthracene in CS_2 with bromine; it crystallises from glacial acetic acid in yellow needles, m.p. 142°–143°.

The position of the halogen atoms is proved by the oxidation of the substance to 2-methylanthraquinone.

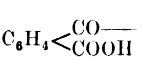
Tetrabromomethylanthracene $C_{15}H_8Br_4$ is formed when dibromomethylanthracene is treated with bromine. It crystallises from toluene in yellow needles. Oxidation with nitric acid converts this compound into dibromomethylanthraquinone $C_{15}H_8Br_2O_2$.

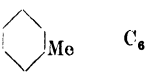
The action of halogens on 2-methylanthracene has been studied by Fischer and Reinkober (J. pr. Chem. 1915, [ii.] 92, 49), who find that the products vary much according to the conditions employed. In benzene chlorination gives a mixture of mono- and dichloro-derivatives, whilst in chloroform the hexachloro-derivative, melting at 193°, is obtained. A mixture of mono- and decachloro-compounds is ultimately produced in a concentrated solution in carbon disulphide.

2-*Methylanthranol* (Limpach, Annalen, 1900, 237, 251). This compound, m.p. 100°, is produced by the action of sulphuric acid on *o*-(*p*-methylbenzyl) benzoic acid. It may also be obtained by reducing 2-methylanthraquinone with aluminium bronze in sulphuric acid solution (Bayer, D. R. P. 201542).

β-Methylanthraquinone 
(O. Fischer, Ber. 8, 675) is obtained by boiling methylanthracene in alcoholic solution with nitric acid, or by carefully oxidising the hydrocarbon with CrO_3, in which latter case, however, considerable quantities of anthraquinone and anthraquinone carboxylic acid are also formed.

It has also been isolated from the by-products which accumulate in the manufacture of anthraquinone (Wachendorff and Zincke, Ber. 10, 1485; Börnstein, *ibid.* 15, 1820). This substance is identical with the methylanthraquinone which is obtained synthetically by heating *p*-methyl benzoylbenzoic acid with concentrated sulphuric acid (Gresly, Annalen, 234, 239).





This latter preparation is carried out in the following manner:—

The powdered acid is slowly added to 7 or 8 times its weight of concentrated sulphuric acid, and the mixture gradually heated until at the end of half an hour the temperature has risen to 120°–125°.

The clear dark brownish-red coloured solution is kept at this temperature for about an hour, allowed to cool and poured into much water. Steam is passed through the liquid for some time, the precipitate collected, washed well first with water, and lastly with dilute ammonia, dried, and the greenish-yellow mass purified by recrystallisation from a mixture of xylene and alcohol. Yield 70–75 p.c. of theory.

β-Methylanthraquinone sublimes in yellow needles, m.p. 176°–177°; moderately soluble in ether, acetone, chloroform, or hot alcohol; difficultly soluble in glacial acetic acid and benzene.

1-*Chloro*-2-*methylanthraquinone*. 2-Methylanthraquinone (15 parts) is heated with nitrobenzene (25 parts), iodine (1 part), and sulphuryl chloride (15–20 parts) at 100° (D. R. P. 269249, 293156; Fr. Pat. 460,432).

3-*Chloro*-2-*methylanthraquinone*. This substance was first obtained by Heller and Schülke (Ber. 1908, 41, 3637) who condensed phthalic anhydride with *o*-chlorotoluene in presence of aluminium chloride and heated the resulting *o*-(*o*-chlorotoluoyl) benzoic acid with 20 p.c. oleum. Subsequently Ullmann and Dasgupta (Ber. 1914, 47, 557) described the same process with slight modifications and obtained a yield of 92–93 p.c. of the theory. This derivative crystallises from alcohol in colourless needles (H.S.) or plates (U.D.), melting at 212°–213° (compare also D. R. P. 205218, 211967).

3-*Bromo*-2-*methylanthraquinone* has been prepared from *o*-bromotoluene in an analagous manner by Grünthal and Ruthenburg (Ber. 1912, 45, 795). The yield was 85 p.c. of that theoretically possible. The compound occurs in long pale yellow needles and melts at 219°–220°. D. R. P. 216715 describes the preparation of an isomeride by direct bromination of 2-methylanthraquinone at 170°. This melts at 200°–202°, and in all probability hydrogen in the methyl group is displaced.

1-*Iodo*-2-*methylanthraquinone*. This derivative was obtained by Scholl (Ber. 1907, 40, 1691) in the course of his work on the synthesis of flavanthrene (*q.v.*). It crystallises in brown leaflets, melting at 169°, and results from the action of potassium iodide on a solution of diazotised 1-amino-2-methylanthraquinone.

Dibromo-2-*methylanthraquinone*, m.p. 140°, may be obtained by brominating *o*-(*p*-toluoyl) benzoic acid and subsequently closing the ring in the usual manner.

Dibromomethylanthraquinone is obtained by the action of bromine at 130°–140° on β-methylanthraquinone. It is colourless and melts at 219°–220° (O. Fischer, J. pr. Chem. 1909, [ii.] 79, 555).

ω-Dichloro-β-methylanthraquinone is obtained by chlorination of methylanthraquinone. The substance melts at 200° and is converted by the action of sulphuric acid (66° Baumé) at 130° into β-anthraquinone aldehyde (Badische Anilin und Soda Fabrik, D. R. P. 174984).

3-*Chloro*-2-*dibromomethylanthraquinone* is obtained in 91 p.c. yield by the bromination of 3-chloro-2-methylanthraquinone in closed vessels at 160°–170° during five hours. The substance crystallises from toluene in hexagonal leaflets, melting at 210°–211° (Ullmann and Dasgupta, *l.c.*).

Methylanthraquinone disulphonic acid (O. Fischer, *l.c.*) $C_{15}H_8(HSO_3)_2O_2$.

Preparation. — Methylanthraquinone is heated with 5–6 parts of fuming sulphuric acid for several hours at 250°–270°. The alkali salts and the barium and calcium salts of this acid are soluble in water. Fusion with potash converts the acid into methylalizarin.

Nitromethylanthraquinone

$$C_{15}H_9NO_4 \text{ or } CH_3{\cdot}C_{14}H_6(NO_2)O_2$$

Preparation.—Methylanthraquinone (2 parts) is dissolved in concentrated H_2SO_4 (12–14 parts), and to the resulting solution KNO_3 (1 part) is slowly added. The product after standing 24 hours is carefully mixed with water, the precipitate collected, and extracted repeatedly with alcohol until the filtrate is only slightly yellowish-coloured. The resulting nitromethylanthraquinone is purified by recrystallisation from acetic acid (Römer and Link, Ber. 16, 695), from which solvent it is obtained in yellow needles melting at 269°–270°. It is difficultly soluble in alcohol, ether, benzene, chloroform, glacial acetic acid, and ethyl acetate, readily soluble in nitrobenzene. It dissolves in sulphuric acid, producing a yellow solution which on warming turns brown. Water precipitates from this solution a purple precipitate, which dissolves in alkalis with a violet-blue colour. Nitromethylanthraquinone sublimes in small almost colourless needles. It is not decomposed by boiling caustic potash solution.

1 : 5-*Dinitro*-2-*methylanthraquinone*. Together with the 1 : 8-isomeride this compound is prepared by the action of a mixture of sulphuric and nitric acids at 60°–70° in 2-methylanthraquinone. The concentration and amount of nitric acid is in this case greater than in the experiment described above. The 1 : 5-derivative is more sparingly soluble than is the 1 : 8-isomeride in boiling glacial acetic acid. It is bright yellow and melts at 251°–252°. 1 : 8-Dinitro-2-methylanthraquinone melts at 189°–190° (Schaarschmidt and Stahlschmidt, Ber. 1912, 45, 3454).

Aminomethylanthraquinone,

$$CH_3{\cdot}C_{14}H_6(NH_2)O_2,$$

is readily produced by the reduction of nitromethylanthraquinone with $SnCl_2$ (Römer and Link, *l.c.*). The freshly precipitated nitro compound is added in small quantities at a time to a dilute solution of $SnCl_2$ in KOH, and the product heated nearly to boiling. The resulting precipitate, which must dissolve completely in excess of cold HCl, is purified by recrystallisation from dilute HCl. The reduction of nitromethylanthraquinone may also be readily effected by means of a hot aqueous solution of sodium sulphide.

Aminomethylanthraquinone crystallises in glittering red needles which melt at 202°, and sublimes on heating in long dark red needles. It is almost insoluble in water, readily soluble in alcohol, ether, chloroform, benzene, and glacial acetic acid. Boiling with hydriodic acid and phosphorus converts it into aminomethylanthranol; at 150°, however, aminomethylanthracenedihydride $CH_3{\cdot}C_{14}H_{10}NH_2$ results.

The *acetyl-derivative*,

$$CH_3{\cdot}C_{14}H_6O_2NH(C_2H_3O),$$

crystallises from glacial acetic acid in yellow needles, m.p. 176°–177.°

An isomeric aminomethylanthraquinone, probably 2-amino-6- (or 7) methylanthraquinone is prepared from amino-*p*-toluoylbenzoic acid by heating with 80 p.c. sulphuric acid at 200°. It crystallises in brick-red needles and melts at 175° (D. R. P. 134917).

1 : 3-*Diamino*-2-*methylanthraquinone*. 1 : 3-Dinitro-2-*p*-toluoylbenzoic acid is reduced to the corresponding diamino-acid by means of iron and dilute acetic acid. The conversion of the latter to an anthraquinone derivative occurs with unusual facility and it suffices to heat the substance with acetic acid. The diaminomethylanthraquinone crystallises in yellowish-red needles which melt at 273°–276° (D. R. P. 205036).

1 : 4-*Diamino*-2-*methylanthraquinone* crystallises from alcohol in dark violet bronzy needles melting at 252°. It is obtained from the lactam of 2 : 5-diamino-*p*-toluoylbenzoic acid by heating with 5 p.c. oleum at 180° (D. R. P. 260899).

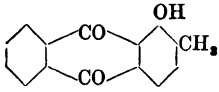
1 : 5-*Diamino*-2-*methylanthraquinone* and 1 : 8-diamino-2-methylanthraquinone are obtained by the reduction of the corresponding nitro-derivatives (*vide supra*) with sodium sulphide. The former crystallises in red needles from acetic acid and melts at 201°–202°, and the latter separates from toluene in brown-red needles, melting at 206°–208°.

A *triaminomethylanthraquinone* of unknown constitution has been described (D. R. P. 205036).

1-*Bromoamino*-2-*methylanthraquinone* is the first product of the action of bromine on 1-amino-2-methylanthraquinone. It crystallises in brownish-red needles, melting at 215°–216° (D. R. P. 131402). Further, a considerable number of nuclear substituted chloro- and bromo-amino- and diamino-methylanthraquinones have been mentioned (D. R. P. 131402 and 205218), but these are of unknown constitution. It is

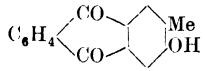
stated that certain substances of this type may be employed for the preparation of sulphurised vat-dyes.

1-Hydroxy-2-methylanthraquinone (Weizmann, Bentley and Gardner, *l.c.*)

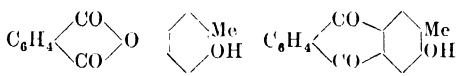


Phthalic anhydride condenses with orthocresol in presence of boric acid at 170° and yields 2′-hydroxy-3′-methyl-2-benzoylbenzoic acid. The yellow solution of this substance in concentrated sulphuric acid goes red on heating and yields on dilution this hydroxyanthraquinone. It forms yellow needles on crystallisation from acetic acid and melts at 184°–185°.

3-Hydroxy-2-methylanthraquinone

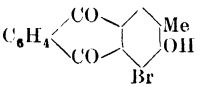


Preparation (Fraude, Annalen, 202, 613).—By heating 2 parts of *o*-cresol, 3 parts phthalic anhydride, and 100 parts of sulphuric acid at 160° for two days. The product is poured into water, extracted repeatedly with ether; the ether distilled off, the residue dissolved in dilute soda, acidified with HCl, and the precipitate purified by sublimation and recrystallisation from alcohol.



Hydroxymethylanthraquinone melts at 260°–262°, is readily soluble in alcohol, ether, and acetic acid; it dissolves in alkalis, also in lime and baryta water, forming a dark reddish-brown solution. When strongly heated it sublimes in golden-yellow leaflets.

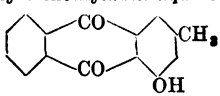
Bromohydroxymethylanthraquinone



is obtained by heating 4 parts of dibromo-*o*-cresol phthaleïne ($C_{22}H_{16}Br_2O_4$) with 1 part of phthalic anhydride and 200 parts of sulphuric acid at 150° for five hours.

Small yellow needles, m.p. 205°. Fusion with potash converts this substance into α-methylalizarin.

4-Hydroxy-2-methylanthraquinone.



Bentley, Gardner and Weizmann (*l.c.*) obtained this quinone in a manner analogous to the preparation of 1-hydroxy-2-methylanthraquinone, by substituting *m*- for *o*-cresol. It melts at 178° and consists of yellow needles which are crystallised from acetic acid. A quinone probably identical was obtained by Römer and Link (Ber. 16, 700) from the aminomethylanthraquinone described above.

Preparation.—Aminomethylanthraquinone is dissolved in sulphuric acid, and solution mixed with small quantities of water until the resulting precipitate becomes reddish-coloured.

The well-cooled product is slowly mixed with a solution of KNO_2 until the precipitate becomes light yellow and free nitrous acid is evolved, then an equal volume of water is added and the whole heated to boiling.

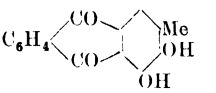
The precipitate is collected, dissolved in boiling dilute caustic potash solution, precipitated with HCl, and recrystallised from alcohol.

Hydroxymethylanthraquinone crystallises from alcohol in orange-yellow needles which melt at 177°–178°, and sublimes in long thin yellow plates when carefully heated. It is almost insoluble in water, difficultly soluble in alcohol, readily soluble in ether, and benzene. Cold caustic potash solution dissolves it sparingly.

Fused with potash a small quantity of a colouring matter is produced which dissolves in alkalis with colorations similar to those produced by alizarin. Hydroxymethylanthraquinone, if freshly precipitated, dissolves in boiling lime or baryta water, but is insoluble in sodium carbonate or a solution of alum. Its alcoholic solution is not precipitated by alcoholic lead acetate.

The *acetate*, $CH_3{\cdot}C_{14}H_6O_2(C_2H_3O_2)$, crystallises from alcohol in orange-yellow plates which melt at 177°.

Dihydroxymethylanthraquinone (α-methylalizarin),



is readily prepared by fusing methylanthraquinonedisulphonic acid (O. Fischer, *l.c.*), hydroxymethylanthraquinone, or bromohydroxymethylanthraquinone (Fraude, Annalen, 202, 166) with potash. The mass is dissolved in water, acidified with HCl, and the precipitate purified by sublimation. Orange-yellow needles, m.p. 250°–252°, moderately soluble in alcohol, ether, and acetone. The calcium and barium salts are insoluble blue precipitates.

The absorption spectrum of a solution of this substance in concentrated sulphuric acid is represented in Fig. 1.

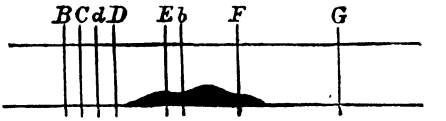


FIG. 1.

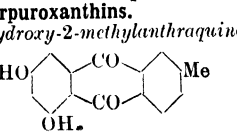
It corresponds very closely with that of alizarin itself (Liebermann and Kostanecki, Ber. 19, 2330). Methylalizarin dyes mordanted cloth similarly to alizarin, but according to some authorities the tinctorial power of methylalizarin is much inferior to that of alizarin, hence the introduction of this substance into artificial alizarin is avoided by the alizarin manufacturer as much as possible.

Methylpurpuroxanthins.

5 : 7-*Dihydroxy-2-methylanthraquinone*



3 : 5-Dihydroxybenzoic acid (4 grams) and *p*-toluic acid (15 grams) are heated to 110° with sulphuric acid (200 grams) during three hours. The compound melts at 267° and forms a *diacetyl* derivative which crystallises in yellow needles, m.p. 165°–167° (Marchlewski, T., 1893, 63, 1142).

1 : 3-*Dihydroxy*-2-*methylanthraquinone*
