gested by the writer, which consists of sentences containing two phrases, two clauses, or a phrase and a clause, proved to be a good developmental index for later linguistic development. Such sentences were rare in the speech of the preschool children, and reached a maximum of about 6 per cent at 4½ years. However, they increased to 10 per cent by 9½ years. The same trend appeared, although much more slowly, among the twins. Incomplete sentences, which were nevertheless sufficiently complete to enable the scorer to detect omissions, decreased in McCarthy's data from 25 per cent at 2 years to about 8 per cent at 4½ years. For some unaccountable reason the percentage of incomplete sentences did not show similar decreases with age in the data of Day and Davis, as they continue to constitute 15 or 16 per cent of the responses even up to the 9½-year level

Shire (1945) found that several measures of linguistic maturity when combined were quite helpful in predicting success in first-grade reading. The measure of linguistic maturity which correlated best with reading achievement was the number of elaborated sentences in a sample of 50 responses. She points out that children who did not make satisfactory progress in two semesters of first-grade reading showed linguistic immaturity, particularly by the absence of elaborated sentences, the shortness of their average sentence, lack of connectives, and lack of variety in their vocabularies as indicated by a comparatively small number of different words in the sample of 50 sentences. Multiple correlations for several combinations of language variables and intelligence test scores in the prediction of first-grade reading ranged from .45 to .63, the number of elaborated sentences and the number of nouns adding most to the intelligence test scores in the prediction. It would seem that kindergarten and first-grade teachers could be taught to record the spontaneous speech of their pupils in the determination of reading readiness.

Williams (1937*a*) has attempted to quantify the complexities of sentence structure by assigning arbitrary scores to certain types of structure for his language achievement scale. He gives a score for completeness of the expression unit in which a response has subject, verb, and object expressed if the verb requires an object. A score of 2 is given for a complete unit, 1 for an incomplete unit, and 0 for unintelligible responses. He also assigns weights for complexity of sentence as follows: unintelligible, 0; simple sentence, 1; compound, 2; complex, 3; and compound-complex, 4. In addition he has devised a score for word usage composed of the number of words given in conventional usage per 50 running words. These appear to be quite objective and easily applicable techniques which are deserving of further experimentation. They have the advantage of permitting correlational treatment of some dimensions of language development which have heretofore been restricted to treatment in terms of percentages of various types of response. They enable the investigator to assign a single quantitative score for several important dimensions of language development instead of depending on inspection of a series of categories.

The two studies by Stormzand and O'Shea (1924) and by Heider and Heider (1940*b*) yield valuable data on sentence structure in written composition, as may be seen in Table 8. In written language, sentences are much more likely to be complete, and hence there is not the necessity of providing a category for fragmentary responses as in the records of oral responses of younger children. Stormzand and O'Shea report their data in terms of school grades, whereas the Heiders' material is in terms of ages. However, the results of the two studies have been aligned in Table 8 so

TABLE 8

COMPARISON OF PERCENTAGES OF DIFFERENT TYPES OF SENTENCE STRUCTURE IN TWO STUDIES OF WRITTEN LANGUAGE

Type of Sentence	Heider and Heider * Stormsand and O'Shea †	Age	8	9	10	11	12	13	14				Freshmen	Upper Classmen	Adults
		Grade		4	5	6	7	8	9	10	11	12			
Simple	Heider and Heider		53	45	40	36	30	27	27						
	Stormsand and O'Shea			48		59	46	48	38	44	39	38	30	22	37
Compound	Heider and Heider		31	36	38	38	41	42	43						
	Stormsand and O'Shea			25		6	13	14	18	18	17	20	18	23	13
Complex	Heider and Heider		8	9	12	13	13	14	12						
	Stormsand and O'Shea			27		37	41	37	44	38	44	42	52	55	46
Compound-complex	Heider and Heider		8	10	10	12	15	17	18						

* N = 817 children who wrote short compositions on a movie they had seen in class.

† Based on 10,000 sentences selected from essays, newspaper articles and editorials, modern light fiction, adult letters, and compositions of university, high school, and fourth- to eighth-grade pupils.

as to compare the 9-year-olds with the fourth graders, etc., assuming that the children were normally placed in school for their ages. It is difficult to evaluate the developmental significance of such data, however, without any adult norm for the expected level at maturity. The nearest approach to such material is provided in a study by Thorndike, Evans, Kennon, and Newcomb (1926–1927), in which 45 samples of writing were analyzed for grammatical construction. There were 18,113 occurrences of the simple sentence in the sampling, and 438 other types of sentence construction were listed with their frequencies per 100,000 sentences. LaBrant's (1933) material is treated using the clause as the unit rather than the sentence, so again comparisons are impossible.

It is indeed unfortunate that more direct comparisons cannot legitimately be made among these various studies. The similarity of the labels of many of the categories is likely to mislead the naïve reader, who has not handled data of this sort, into thinking that many figures are comparable which actually are not because of differences in methodology, and the counterbalancing effect of the treatment in terms of percentages is likely to be confusing.

Various investigators have been concerned with the incidence of the different parts of speech as they occur in the running conversation of children. The most detailed study of this sort is by Young (1941), who presents, in addition to her own data on 74 cases, the results of six other investigations. Young is chiefly concerned with reconciling certain differences which appear in the literature which she interprets to be due to difference of definition of grammatical terms. She adheres strictly to the definitions in Jespersen's *Essentials of English Grammar* (1933). In the opinion of the present writer, such analyses are of significance for child development only in the very early stages of sentence formation before all the various parts of speech have come into active use. As Young herself states: "The proportions of the parts of speech changed most rapidly before the age of 3, and after that age the rate of change tended to be slower" (p. 87). As soon as the child begins to use

full and complete sentences which are grammatically correct, the percentages of the various parts of speech become more or less set by the conventions of the language. The beginnings of the use of modifiers and of prepositions and connectives are probably quite significant and mark important milestones in the development of the child's speech, but as soon as they are employed characteristically their developmental significance becomes submerged in a number of other factors. In addition to being controlled by the demands of conventional usage, they are definitely related to the situation in which the language sample is taken, as Goodenough (1938) has shown in her excellent study of pronouns, in which she states:

> Proportions of the various parts of speech in the language of children are frequently quoted in a fashion that might lead the reader to think that these proportions depend almost wholly upon the child's level of development and vary but little with the conditions of observation. The unsoundness of this point of view will be apparent from an examination of the data here presented. As a matter of fact, while most of the pronouns here listed show a distinct difference in frequency of usage according to the immediate situation under which they are used, age differences are not always apparent, even when no allowances are made for the increasing length of the sentence [p. 338].

More promising leads are afforded by additional indices of improvement in sentence structure as reflected in specific changes in various types of grammatical forms. Such approaches lead the investigator into more detailed treatment and classification. Verb forms, especially the use of past and future tenses, have been studied by Lewis (1951), Adams (1938), M. E. Smith (1939), and Ames (1946). The understanding of prepositions has been described by Grigsby (1932), and their use in written language has been treated by Heider and Heider (1940*b*). Connectives have received special treatment from E. A. Davis (1937*a*) and also from the Heiders. A study of determining and numerating adjectives has been presented by Carroll (1939), and pronouns have received detailed treatment from Goodenough (1938), E. A. Davis (1938*a*), and Young (1942*b*). Infinitives have been studied by E. A. Davis (1937*a*), Young (1941), and Heider and Heider (1940*b*), and the various types of clauses which were brought to the fore by LaBrant (1933) have also been analyzed in greater detail by E. A. Davis (1937*a*, 1941), and by the Heiders.

Lewis (1951) brings out that at first the language of the child is concerned exclusively with the immediate situation in which it is spoken and that gradually it begins to deal with things that are absent. This matter of reference to things absent has also been emphasized by both K. and C. Bühler (both, 1930). Lewis relates the child's use of past and future tenses to the functions of his earlier undifferentiated speech. It is because of the child's use of speech as an instrument to draw others into his social circle that he begins to speak of absent things and events. Lewis points out that the child uses a word manipulatively in an effort to call attention to an object which he wishes brought into the present situation. In such instances he claims that the child's utterance is much more an expression of his needs within the present situation than a reference to an absent object. The adult's conversation with the child then becomes a potent factor in the emergence of the use of past and future tenses.

Ames and Learned (1948) studied children's verbalizations in regard to space and found that the largest number of new words relating to space are added to the child's

vocabulary between 2 and 2½ years. Children were found to respond first to a space word, then to say it spontaneously, and later to use it in answering a question. Looking and pointing definitely preceded verbalization. A further sequence from general to specific and then to somewhat more general responses was noted. For example, a child when asked, "Where do you sleep?" at first answers, "Home"; later he is likely to say, "In my crib"; but at a still later age, "In my room." The child's use of space words seems to parallel the increasing expansion of his spatial experience.

Quantitative expression in the use of such words as "some," "any," "several," and "two" was studied by Martin (1951) in 150 representative children of both sexes from 3 to 7 years of age. The median number of different quantitative words used increased from 4.0 at 3 years to 9.0 at 7 years.

Adams (1938) approached the problem of verb forms by using the records of the speech of twelve 4-year-olds taken during nursery school activities. He tabulated the first 50 verbs in each child's record and compared them with those in 100 consecutive sentences of adult spoken language. He found that 59 per cent of the adult speech and 56 per cent of the children's speech was in the present tense. The adult speech was found to contain a larger percentage of sentences in the compound tense than the children's, and the children's speech to contain a greater percentage of sentences in the present and present-progressive tenses. He found that at 4 years the future tense has come into common use and occurs 10 per cent of the time, and the preterite or simple past is employed about as often as in adult speech. As the verb takes on past and future forms, the times referred to are immediate rather than remote. Only 4 children made reference to any time earlier than the previous day. Children's use of future tense nearly always involved reference to the future of the day of speaking.

Ames (1946) reports that children first speak of the present, then of the future, and that references to the past occur later. They first react to time words by ability to wait, then by the use of time words, and not until later are they able to answer questions dealing with time. Leopold's (1949*a*) third volume on the development of speech in his bilingual daughter presents an interesting section on the development of syntax in the first 2 years from the linguist's viewpoint.

The data available on the use of various types of clauses and on the use of infinitives and auxiliary verbs are almost impossible to summarize Much of this work has been done on written language, LaBrant (1933) using school compositions on different topics from grade 4 to the adult level, and the Heiders (1940*b*) using compositions in response to a standardized situation. In the latter study emphasis is placed on the comparison of groups of deaf and hearing children rather than on the developmental trends in either the experimental or hearing group. E. A. Davis (1937*a*) attempted similar analyses on the oral language of her subjects recorded in a standardized situation on younger children. In most of these analyses she reports data only for the total group, although each age level is heavily weighted with twins and only children, both of which groups showed significant and contrasting differences from the singletons in all other aspects of language development. Her samples are short for each individual, and the more complex and elaborate forms occurred so rarely as to make the means unreliable. In a later study (1941) she reported further analysis of the same data. Only the brightest and linguistically most advanced children were able to place a subordinate

clause early in the sentence. This ability emerges in the brightest children at the kindergarten level. Younger children were reported to use the interrogative in indirect discourse more than older children.

J. E. Anderson (1937) pointed out in his study of indices of linguistic development that it is not possible to get an adequate sample for detailed analysis of written language in a passage of only 150 words. This is probably even more serious for oral language in which fragmentary remarks are likely to be more frequent, and hence samples of a given length are likely to yield fewer of the more complex forms in complete sentences for statistical treatment. Goodenough (1938) also states on the basis of her study of pronouns: "A sample of 50 responses is not sufficient for the study of individual differences in the use of separate pronouns, but the consistency of the group trends . . . is evidence of their validity as group measures." A more detailed index, however, was the percentage of pronouns in the total sample, which showed little consistent change with age or sex after 3 years; nevertheless, certain specific groups of pronouns showed very pronounced changes with age and with the conditions of observations. The chief trends noted in this analysis indicated that there was an increase with age in the use of the first personal pronoun and that it is used more frequently during play with other children than in conversing with an adult.

Shire's (1945) analysis of pronouns confirmed Goodenough's results. In comparison with Goodenough's 5½-year-old group, Shire's 6½-year-olds showed an increase in the number of pronouns used in a sample of 50 remarks. On the average about five more first person singular pronouns were used and there were about twice as many occurrences of *we, us,* and *ours.* The third person singular personal pronouns practically doubled, whereas there was practically no change in the use of third person plural pronouns or the impersonal pronouns. Young (1942*b*) found greater age, sex, and socio-economic differences in the use of possessive than personal pronouns. Marked decreases in the use of possessive self pronouns were accompanied by increases in the use of possessive pronouns referring to others. Valentine (1942) notes that both pronouns and prepositions are used by young children of 2 to 2½ years in certain specific situations in which they have been learned and not in others, and that the use of these parts of speech does not become generalized until a later period.

Gheorgov (1905) pointed out that the child has a fairly well-developed awareness of self long before he begins to express himself in language, but that it is only with the use of words that the higher types of concepts can be differentiated, such as the *I,* the *self,* and the *mine.* He also calls attention to the familiar phenomenon of the child's designation of himself by his own name which he hears others use when speaking or referring to him. This use of the own name often precedes the correct use of the first personal pronouns and is regarded by some as a sign of immaturity in speech. Goodenough (1938) also found that, contrary to popular opinion, the absolute number of pronouns shows no increase with age after the maximum has been reached at 3½ years, and in proportion to the total number of words used the number of pronouns actually declines. Young (1942*b*) also conducted a detailed study of the personal and possessive pronouns occurring in her major investigation. She found that they constituted 28 per cent of all the comprehensible words spoken by the nursery school children. The first person singular pronouns *I, me,* and *mine* constituted 36 to 39 per cent of the total, whereas the impersonal *it* accounted for 19 per cent. In face-to-

face situations, *you* accounted for 15 per cent of the pronouns and the plural forms of *we* or *us* accounted for only 5 per cent.

Symonds and Daringer (1930) report that in written compositions the use of pronouns is high up to the ninth grade but that thereafter it decreases as the writing takes on a more impersonal and more abstract nature. Goodenough (1938) concludes from her study that the use of an unusually large number of pronouns after the age of 3½ years may be interpreted as evidence of linguistic immaturity. As the vocabulary increases the use of the third person neuter pronoun declines, for proper and common nouns come to be substituted for it as the child is able to be more specific in his speech. In conclusion, Goodenough (1938) brings out a very important point for methodology in future research on language development, for she says:

> Many of the formal grammatical classifications of adult usage are inadequate to bring out significant developmental trends in the speech of children. The very marked changes that occur in the use of pronouns, for example, are almost wholly obscured when all pronouns are grouped into a single class. Developmental processes are qualitative as well as quantitative, and in devising systems for classifying behavioral manifestations it is necessary to keep these qualitative changes in mind if the systems are to be useful. It is suggested that in the study of children's language, too much attention has been paid to the type of grammatical analysis used by adults and too little to the developmental changes in conceptual thinking and social drives that lie back of the verbal expression [p. 344].

Carroll (1939) made a special study of determining and enumerating adjectives in children's speech, and he recommends the study of adjectives as an easy approach to the minute details of syntax because they occur frequently and constitute a relatively large part of the total number of words (about 15 per cent). Shire (1945) found that adjectives constituted 12.3 per cent of the total number of words used by her 6½-year-olds.

According to Carroll (1939) numeratives are very infrequent at 2½ years and occur much more frequently at later ages. Both definite and indefinite adjectives excluding articles show increases with age, although there are relatively fewer definite adjectives and more indefinite adjectives as age increases. The growth curve for the use of the indefinite article, *a*, levels off between 3½ and 4½ years, but for *the*, the curve shows a sharp rise throughout the age range studied, namely, from 2½ to 4½ years. This appears to be in accordance with Young's (1941) finding of a steady increase in the use of articles from 30 to 60 months. The use of articles was found by Loomis and Moran (1931) to be a better index of mental ability than the use of any other part of speech ($r = +.52$). It also correlated +.51 with average school grade and +.32 with paternal occupation. This detail has been overlooked in most earlier work because articles have seemed like such insignificant words that most previous investigators have grouped them with adjectives and have not treated them separately. The use of many verbs was slightly negatively correlated with intelligence. All these results challenge research workers to comb the field of language development for other significant indices.

Another interesting measure which thus far has received little attention was suggested by Busemann (1925), who used a ratio of the activity words to the qualitative words. It really amounts to an activity quotient determined by dividing the total number of verbs by the total number of adjectives. Busemann claims that this in-

dex shows a rhythmical cycle of alternating action and qualitative periods throughout the life cycle. His data, however, do not appear adequate to support these claims, as the results he reports could be accounted for on the basis of sampling. He claims that high activity quotients are related to periods of emotional instability in the child's life. This index has been used by Boder (1940) on various types of adult writing, and he finds that it varies with the subject matter, scientific writing yielding the highest quotients, with fiction, legal writing, and plays following in the order named. He claims to find alternating activity quotients in the writings of Emerson.

Feldman and Cameron (1944) used activity quotients obtained from 3 children, 17 normal adults, and 28 seniles. The ratios were highest for the seniles (2.99) and lowest for adults (1.52), with the children intermediate (1.83).

Ellsworth (1951) analyzed parts of speech in written language of children, normal adults, and schizophrenics. The percentages of the parts of speech obtained on the adult schizophrenic groups resembled those of the fifth graders (youngest group) most closely. These groups used relatively high percentages of nouns and pronouns and relatively low percentages of verbs and adjectives. Ellsworth interprets this as a regressive pattern for the schizophrenics. Both children and schizophrenics, he says, know what they are talking about and assume that others will understand them. They therefore see no need to refine their language. He relates the greater use of pronouns to the egocentricity of children and schizophrenics, but found that the schizophrenics revealed their tendency to project on others more in their greater use of third person pronouns.

The educational and English journals are replete with minor articles on the incidence of various types of grammatical errors in the oral and written language of school children. Most of them are poorly controlled with errors often being jotted down at the whim of the teacher at odd moments during the school day. In general they are extremely pessimistic and stress the fact that errors continue in the speech and writings of children throughout the school period in spite of the educational influences aimed to overcome them. One of the better studies on written language is by Symonds and Daringer (1930), in which the authors report that in the fourth grade there are on the average about 2 errors to every sentence, and that this ratio shows a gradual decrease until about the eighth or ninth grade, when there is about 1 error per sentence in children's writings.

Carlton and Carlton (1945) studied the errors made in oral English by mentally defective adolescents and normal children of the same mental ages. They were shown picture sequences and asked to tell stories about them until samples of approximately 60 clauses were secured. The mental defectives made more errors in oral expression than the normal cases of the same mental ages. Only four kinds of errors accounted for approximately half of the total errors in all groups, and among the normals seven errors accounted for over two-thirds of all errors. The most common errors were not the ones that were most common 2 or 3 decades ago, and these authors make a plea for curriculum adjustment in the light of modern research. Such revision of the curriculum is being planned by the National Council of Teachers of English Curriculum Commission, which has a series of four volumes in preparation on this topic.

One of the soundest and the most optimistic articles on the study of errors is by E. A. Davis (1939). She points out that

dex shows a rhythmical cycle of alternating action and qualitative periods throughout the life cycle. His data, however, do not appear adequate to support these claims, as the results he reports could be accounted for on the basis of sampling. He claims that high activity quotients are related to periods of emotional instability in the child's life. This index has been used by Boder (1940) on various types of adult writing, and he finds that it varies with the subject matter, scientific writing yielding the highest quotients, with fiction, legal writing, and plays following in the order named. He claims to find alternating activity quotients in the writings of Emerson.

Feldman and Cameron (1944) used activity quotients obtained from 3 children, 17 normal adults, and 28 seniles. The ratios were highest for the seniles (2.99) and lowest for adults (1.52), with the children intermediate (1.83).

Ellsworth (1951) analyzed parts of speech in written language of children, normal adults, and schizophrenics. The percentages of the parts of speech obtained on the adult schizophrenic groups resembled those of the fifth graders (youngest group) most closely. These groups used relatively high percentages of nouns and pronouns and relatively low percentages of verbs and adjectives. Ellsworth interprets this as a regressive pattern for the schizophrenics. Both children and schizophrenics, he says, know what they are talking about and assume that others will understand them. They therefore see no need to refine their language. He relates the greater use of pronouns to the egocentricity of children and schizophrenics, but found that the schizophrenics revealed their tendency to project on others more in their greater use of third person pronouns.

The educational and English journals are replete with minor articles on the incidence of various types of grammatical errors in the oral and written language of school children. Most of them are poorly controlled with errors often being jotted down at the whim of the teacher at odd moments during the school day. In general they are extremely pessimistic and stress the fact that errors continue in the speech and writings of children throughout the school period in spite of the educational influences aimed to overcome them. One of the better studies on written language is by Symonds and Daringer (1930), in which the authors report that in the fourth grade there are on the average about 2 errors to every sentence, and that this ratio shows a gradual decrease until about the eighth or ninth grade, when there is about 1 error per sentence in children's writings.

Carlton and Carlton (1945) studied the errors made in oral English by mentally defective adolescents and normal children of the same mental ages. They were shown picture sequences and asked to tell stories about them until samples of approximately 60 clauses were secured. The mental defectives made more errors in oral expression than the normal cases of the same mental ages. Only four kinds of errors accounted for approximately half of the total errors in all groups, and among the normals seven errors accounted for over two-thirds of all errors. Such revision of the curriculum is being planned by the National Council of Teachers of English Curriculum Commission, which has a series of four volumes in preparation on this topic.

One of the soundest and the most optimistic articles on the study of errors is by E. A. Davis (1939). She points out that

reports based on frequency of error alone are inaccurate and misleading, and that it is necessary to take into account the frequency of occurrence of a given construction in a given sample of language before it can be properly evaluted. Most teachers, she states, find it easier to note errors than correct usage. In an analysis of the most frequently occurring grammatical errors in her major study (1937*a*), she points out that a pronoun is inflected correctly once for every 16 words and incorrectly once for every 873 words. Adjectives, however, are compared correctly once for every 407 words and incorrectly once for every 16,211 words. The opportunity to inflect a pronoun occurred approximately 17 times for each child, whereas adjectives were compared less than once per child in the data analyzed. She tried a variety of measures of error approached from the positive rather than the negative angle and found that the mean occurrence per child, the number of occurrences per 1000 words, the ratio to the total words used, ratio of times correct to times incorrect, percentage of correct usage, and errors per 1000 chances to use the construction all revealed definite improvement with advancing age. In general, she found that the number of correct usages increased, and the number of incorrect usages decreased, with advancing age, both absolutely and when studied in relation to the total number of words used. For some constructions there was a marked difference in the children coming from the upper and lower socio-economic levels, those from upper levels presumably having the better example and hence fewer errors. It is also interesting to note that the greatest improvement in the elimination of errors occurred in the less privileged group during the early school years.

The Functions of Language in the Child's Life

Of considerably more interest to the child psychologist than the use of various types of word forms are the analyses which attempt to answer the questions of why the child talks, what motivates him to use language in certain situations, what needs he satisfies by the use of language, and what functions language fulfills in the child's life. The early biographical studies approached this problem by classifying responses as declarative, interrogative, exclamatory, and imperative sentences in accordance with the formal classifications of conventional grammar. As has already been pointed out, however, this system does not lend itself well to the psychological analysis of the language of young children. These categories have been designed to fit written discourse but prove unsatisfactory for the conversation of adults and especially unsuitable for the conversations of children.

Snyder (1914) was one of the first to point out this inadequacy and modified the usual grammatical classifications in her study of a 2½-year-old boy. M. E. Smith followed Snyder's classification of sentences in her 1926 study in which several subdivisions and variations of the usual categories were provided. In that analysis she reported:

> There are more declarative sentences, at all ages, than any other type. Also the proportion of imperative sentences, including variations, is probably significantly greater than the proportion of questions at 2, 3, and 4 years.

The appearance of Piaget's (1926) *The Language and Thought of the Child,* which presented an entirely new approach to the study of the functions of the child's language, stimulated much further research

and controversy in the field. Piaget was chiefly interested in the child's language as a means of revealing his thought processes. He recognized two major types of speech in the child's language: first, egocentric speech and, second, socialized speech. Piaget was the first to emphasize the rôle of egocentricity in the child's life. He claimed to have discovered its importance through a functional approach to child language. In egocentric speech, as Piaget defined it, "the child does not bother to know to whom he is speaking nor whether he is being listened to. He talks either for himself or for the pleasure of associating anyone who happens to be there with the activity of the moment. . . . He does not attempt to place himself at the point of view of his hearer." Socialized speech, on the other hand, is speech "in which the child addresses his hearer, considers his point of view, tries to influence him or actually exchanges ideas with him." Piaget recognized three types of egocentric speech, namely, echolalia, monologue, and dual or collective monologue. He subdivided socialized speech into: (1) adapted information, which occurs when "the child really exchanges his thoughts with others," (2) criticism, (3) commands, requests, and threats, (4) questions, and (5) answers. He reported data consisting of about 1500 remarks recorded for each of 2 children 6½ years of age taken down during free play in La Maison des Petites in Geneva. About 38 per cent of the child's remarks fell in the egocentric categories, and only about 45 per cent were spontaneous socialized speech with an additional 17 per cent made up of answers, which were classed as socialized remarks, making a total of 62 per cent socialized speech. Piaget reported a higher percentage of egocentric remarks at ages from 3 to 5 and stated that there occurs a definite socialization in the child's speech at 7 to 8 years of age. He implied that adult conversation is highly socialized and that this egocentrism is a symptom of psychological immaturity, which is outgrown with age.

McCarthy (1930), in seeking a more satisfactory method of treating children's language from the functional point of view, applied Piaget's categories to her data. Although the method at first appears quite subjective, she found that it possessed a fairly satisfactory degree of reliability, for when four scorers attempted to classify identical responses in the various categories of the functional analysis after studying Piaget's definitions, the average intercorrelation was +.78, and this value would have been +.88 if only three scorers were included, as one of the scorers, who was obviously less interested in the task, had consistently lower correlations with all the others. It appears, then, that really conscientious scorers can classify the responses of preschool children into these categories with a satisfactory degree of agreement. In the application of this classification scheme to her data McCarthy adhered to a literal interpretation of Piaget's definitions of the terms for each category. Piaget's examples often do not fit his definitions, but where confusion occurred the definition was used as the criterion rather than an isolated example. It was necessary to modify the classification slightly in order to make it include all the responses in McCarthy's data. She therefore added two classes, namely, social phrases and dramatic imitation. For convenience, and in order to make it cover a few other responses not included in Piaget's group, his category of "commands, requests, and threats" was termed "emotionally toned responses" and made to include wishes and desires as well. The category of adapted information ac-

counted for such a large percentage of the responses that it was broken into four subheads as follows: naming, remarks about the immediate situation, remarks associated with the situation, and irrelevant remarks.[1]

Egocentricity of Children's Speech. As a result of this analysis McCarthy (1930) found a much smaller percentage of egocentric responses than that reported by Piaget, as all egocentric categories together never exceeded 6.5 per cent at any age level; the average for all age levels was only 3.6 per cent. This seeming discrepancy, which is probably much more apparent than real, has aroused considerable interest and controversy. A number of other writers have since attempted to apply some sort of functional analysis suggested by the Piaget classification. None of the American writers has found his classification usable in its exact form, but unfortunately several investigators have made their own versions in modifying the classifications, so that direct comparisons are difficult if not impossible.

In general, the studies employing a functional approach are of two types. Those studies which attempt to classify on the basis of a literal interpretation of Piaget's definitions invariably emerge with a much smaller percentage of egocentric responses, as did McCarthy's. The second group of studies, particularly those by Rugg, Krueger, and Sondergaard (1929), Adams (1932), and Fisher (1934), who definitely set out to look for egocentrism as it is found in the speech of children, and devised their own definitions of egocentrism, usually in terms of the subject of the sentence, invariably find a high percentage of egocentrism which agrees rather closely with that reported by Piaget. The former group of studies have been summarized in Table 9, which represents the percentages found in each of the studies by McCarthy (1930), Day (1932), Smith (1935*a*), and E. A. Davis (1937*a*), for five of the major categories in the functional analysis.

These figures must be interpreted with extreme caution because of the varying circumstances pointed out in the footnotes to Table 9. Day used the identical method employed by McCarthy, but her subjects were twins and showed marked linguistic retardation and immaturity throughout. The data reported in this table from Davis's study are those given for singletons with siblings, since that group is most nearly comparable with McCarthy's and Smith's data. Davis unfortunately placed all criticism in the same class with adapted information, which would tend to raise the percentage in that category by 1 or 2 per cent. She also treated all expressions of liking and desire, which the other authors treat as emotionally toned responses, under adapted information. Smith collected her data, which are shown in Table 9, in two different situations, one in which the child conversed with the experimenter as in the other three studies, and the other in which data were collected during the free play situation in a nursery school where the child was conversing with other children. Smith used a category called "monologue" and then grouped under "collective monologue" remarks about the immediate situation, remarks associated with the situation, and irrelevant remarks. These were all considered to be types of adapted information and were classed as socialized speech in McCarthy's investigation. Without defining her interpretation of egocentrism Smith computed coefficients of egocentrism which decreased from 40 at year 2 to 26 at year 5. Thus, Smith agreed with Piaget's findings but did not specify how she interpreted his categories or exactly

[1] For more detailed description of these categories, see McCarthy (1930, pp. 37–42).

TABLE 9

Percentages of Responses in Main Categories of the Functional Analyses in Four Major Studies

Age	Egocentric Speech				Socialised Speech															
					Emotionally Toned				Adapted Information				Questions				Answers

* Day's subjects were twins markedly retarded in all aspects of language development. Classification was identical with McCarthy's. Figures estimated from graph.

† Davis's data for singletons with siblings. She classed criticism and expressions of liking and desire with adapted information, whereas McCarthy and Day classed them as emotionally toned responses.

‡ M. E. Smith's figures given in this table are based on a grouping of data from two types of situations. The adult-child situation which showed fewer egocentric and emotionally toned responses is comparable to the other studies. Smith did not use discrete age groups as was done in the other three studies.

§ Adapted information not given separately by Davis for different experimental groups. These figures probably include data from twins and only children as well as from singletons.

‖ Figures from Smith under emotionally toned responses in this table were classed by her as "imperative sentences."

how she classified her data.[1] She also compared data on 84 cases whose remarks were recorded during conversation with an adult in a situation similar to McCarthy's study with data from 175 children who were playing in a free play situation in a nursery school and conversing with other children. She found no difference in the amount of egocentrism in the two situations, but the data have been grouped so as to mask any real trends which might appear, since age, sex, and occupational group differences were also operating to unknown degrees in the two sets of data being compared for situation.

In regard to the egocentrism controversy McConnon's (1935) data are of particular interest, for she found an average intercorrelation of only +.17 between the number of egocentric remarks recorded in various situations. She used McCarthy's classification and interpretation of Piaget's categories. The correlation between the home situation and the table-play situation, which probably were most comparable with the McCarthy and Piaget situations, respectively, was only −.135. In her critical ratio analysis the measure of egocentrism yielded the largest number of significant differences when the home situation was compared with the various nursery school situations.

In the study by Williams and Mattson (1942), in which children's language responses in different social groupings were studied, it was found that as the group becomes larger the language becomes more social and less egocentric. Only 1 of their 6 subjects indulged in speech while playing alone, and social speech was found to account for 60 to 78 per cent of the sentences, with the remainder being classified as parallel speech in their social usage analysis. When they used Piaget's analysis, however, the amount of egocentric speech ranged from 42 to 58 per cent in the various situations.

In another study McCarthy (1929*a*) compared two methods and found an appreciably higher percentage of egocentric responses in the free play situation (6.32 per cent) than in the adult situation (3.35 per cent). M. E. Smith's (1935*a*) findings on larger numbers of cases are also in the same direction. Unfortunately, however, for purposes of comparison, she grouped the data obtained by these two methods by age levels separately, which are the figures necessarily reported in Table 9. When she compared the two methods of recording responses in the two different situations she put all age levels together, and this rendered the material incomparable with other available data. The figures given in Table 9 for E. A. Davis's (1937*a*) data on adapted information were not given by her separately for singletons, twins, and only children, and hence the figures reported here probably include her total group, which was heavily weighted with twins and only children, both of which are deviate groups in linguistic development.

It thus appears that the data of Table 9 are very difficult if not impossible to interpret. In spite of similarity of purpose and methods of collecting data, presentations of the results have varied from study to study to such a degree that comparisons of data which should be comparable are rendered impossible.

Another study, which is presented very briefly so that figures could not be added to the above table, is that by Johnson and Josey (1931), who attempted to repeat some of Piaget's work on 55 children. They state that their results "substaniate few of Piaget's claims" and that

[1] In personal communication to the writer, M. E. Smith (June, 1947) stated that she "attempted to follow Piaget's definitions as explained by his *examples*." These examples often do not fit the formal definitions.

> instead of finding them egocentric we found them socially minded, willing and able to assume the position of another and even that of an hypothesis. They were quite able to make themselves understood. . . . Six-year-olds, he [Piaget] tells us, cannot reason because they are too egocentric. We found nothing in our investigation to support this view. On the contrary we found all of our children to be socially minded and in no manner dominated by an egocentric attitude.

Valentine (1942) also takes issue with Piaget, particularly in his definition of collective monologue. He raises a number of questions concerning the social situation in which egocentric speech occurs. However, when elementary school children's contributions to oral discussions were studied by Baker (1942), it was found that as the children grew older they devoted less time to talking about their own activities and more time to discussion of "current happenings." Personal activity percentages decreased from 61 per cent in grade 2 to 18 per cent in grade 6. In the higher grades the children's oral contributions became more frequent, shorter, and more to the point.

The most significant American study which has apparently confirmed Piaget's findings with regard to egocentricity of language is that of Fisher (1934). Although she took the work of Piaget (1926) as her point of departure in the search for the degree of egocentricity in the child's language, she did not follow his classification in arriving at her coefficient of egocentrism. Instead she set up a much simpler and more objective method based on the proportion of the total remarks having the self as subject. Her coefficients of egocentrism obtained by this method were in striking agreement with those reported by Piaget; but, with the marked difference in method, the validity of a direct comparison of these indices bearing identical names is somewhat questionable. One of the chief difficulties is that the classification of the same set of remarks on the basis of Fisher's classification and on the basis of Piaget's would in all probability lead to quite different results, since many remarks can be about the self and yet be directed toward a hearer, require a response from the hearer, and in every other way qualify as a socialized response according to Piaget's definitions. Fisher found that 34 per cent of the remarks were about the self, and she concluded that a high degree of concern with self is characteristic of the preschool child. She did not, however, find any relationship between age and remarks about the self. Adams (1932), who also recorded language in a nursery school setting, defines egocentric remarks as remarks which contain self-references. He used separate categories for monologue and social monologue which were subheads under egocentric remarks in Piaget's original classification. His egocentric remarks show a regular increase with age from 13 per cent at 2 years to 41 per cent at 4 years. It is not surprising that workers using such criteria should find results indicative of a relatively large percentage of egocentrism, for in the M. D. Horn (1926–1927*a*) list of the words most frequently used by kindergarten children the word *I* is by far the most frequent, with *my* occurring as the ninth and *me* as the twenty-fourth word in order of frequency.

Another investigation which apparently supports Piaget's conclusions, but arrives at the result by different methods, is that by Rugg, Krueger, and Sondergaard (1929). They found that 40.8 per cent of the remarks of kindergarten children were self-assertive. However, their definition of this category did not exclude socialized responses as was done in Piaget's classifica-

tion, since self-assertive remarks could at the same time be highly socialized.

Those who have disagreed with Piaget's findings when they employ his classifications are not all American investigators so the differences probably should not be explained on the basis of nationality. Ohwaki (1933), who studied her own 2 Japanese daughters, reports that at about the age of 2 years social expression was as frequent as monologue. She attempted to harmonize her findings with those of Piaget by pointing out that if all sentences not directed toward other people are considered as egocentric, talking with animals and the like would be considered egocentric. She thinks, however, that this kind of talking should be considered as very social, since animals are often real companions to children. Huang and Chu (1936) recorded a total of 1500 sentences from 21 nursery school children from 2½ to 5 years of age in the everyday environment and found 80 per cent of their speech socialized and 20 per cent egocentric. Language about other persons was 12.5 per cent of the total, language about the self classified as socialized was 11.6 per cent, and language about the group constituted only 3.3 per cent. Kuo (1937) recorded spontaneous language of 4 Chinese children from 3 to 5 years of age and found that egocentric speech occupied only from 10 to 20 per cent of children's conversation and that it decreased with age.

In her third edition of *Kindheit und Jugend*, published in 1931, C Bühler discussed this problem in some detail and referred to some unpublished German studies which have not found their way into American literature. She states that Piaget's stimulating investigations were refuted by many different child psychologists, at least in regard to their main thesis (egocentricity). She said that W. Stern always pointed out that the egocentric behavior of the children observed by Piaget was furthered by the special environmental conditions prevailing at La Maison des Petites, which she described as a Montessori preschool in which each child was encouraged to work alone on an individual basis with relatively little social intercourse being developed within the group. She also states that, at the suggestion of Doctor Stern, M. Muchow tested the egocentricity coefficients in a preschool in Hamburg and found completely different ratios from those reported by Piaget.

Another unpublished study by Elsa Köhler resulted in 82 per cent of the speech of preschool children being classified as socialized. This is, of course, much more in line with the American investigations which have employed Piaget's classifications. C. Bühler (1931) herself gives the interesting interpretation that the flow of speech which often accompanies a child's activity is really an expression of a need for social contact. She feels that much of the speech classed as monologue is merely expressing a desire to feel close to others and that it is only secondarily to be considered as playful monologue. She believes that Piaget found reason to emphasize the egocentric aspects of children's language because of the rather peculiar characteristics of the play situation in which the children were observed and because records were taken in only the one type of life situation. Although the drive for social contact may be interpreted as egoistic, the very striving for contact, she says, drives the child away from himself and toward others.

An article by Henle and Hubbell (1938) on egocentricity in adult conversations has occasioned some challenging re-evaluations of the significance of Piaget's work. Heretofore the implication had been that as the child grows older his speech becomes more socialized and that the adult uses relatively little egocentric speech. The high degree

of socialization of adult speech has always been implied but never demonstrated. Henle and Hubbell undertook to determine the amount of egocentric speech in adult conversations. They also set up their own criteria of egocentricity. Criticizing the artificiality of Fisher's (1934) technique they proceeded to classify sentences from the point of view of their meaning as ego-related sentences. In this category they include statements of the activities of the speaker, of his feelings and emotions, his ambitions, desires, and interests, as well as all opinions, attitudes, criticisms, and all evaluative and normative statements. The remarks classified were those of college students and other adults and were recorded by a variety of eavesdropping techniques in order to avoid artificiality and to assure spontaneity. They found 40.7 per cent of all the adult remarks fell in the ego-related category. Perhaps individuals of all ages are egocentric in about 40 per cent of their responses, if one uses a somewhat subjective classification scheme based on meaning rather than on the manner of utterance and attendant circumstances, as in Piaget's definitions. If this is true, it may be that the great concern of child psychologists regarding the developmental significance of the supposed outgrowing of the egocentrism of early childhood has been exaggerated in its importance.

Piaget's concept of egocentric speech has been seriously challenged by Vigotsky (1939). He considers that egocentric speech is midway between socialized speech and inner speech. The disappearance of the externalized or vocalized aspect of speech is only an illusory disappearance, he claims. Vigotsky considers that, basically, egocentric speech is the key to inner speech, for it is still subject to observation because it is uttered aloud. It is a form of speech which aids the child's thought processes in a most intimate way, but, rather than waning during childhood and going through an involution, Vigotsky claims that it goes through an evolution with inner speech and thought as the end products. In support of this contention he points out that it is in conformity with the observed facts that the external expression of egocentric speech decreases with age and that it increases when difficulties arise which require conscious reflection.

According to Vigotsky (1939) the functional and structural qualities of egocentric speech and speech for communication with others are not different from each other in the 3-year-old child, but there is a gradual differentiation of the two speech functions so that by 7 years of age the structure and function of the egocentric speech have taken on more the nature of inner speech and have become differentiated from socialized speech. He designed a series of experiments to test his hypotheses regarding the nature of egocentric speech in which he experimentally weakened and strengthened the social demands of the situation. He first obtained children's coefficients of egocentrism according to the methods of Piaget when they were in free play situations in the presence of other children. He seems to have no difficulty in the quantitative aspect of the problem, as he apparently obtains coefficients of egocentrism of the same order of magnitude of those of Piaget. His quarrel is with the interpretation and significance of egocentric speech. After obtaining coefficients of egocentrism in the usual way, he then diluted the social nature of the situation in an effort to destroy the "illusion of understanding" by others, by putting these children in a situation with deaf-mute children, and also by putting them in a situation with total strangers, or alone at a table in a corner of a room which the experimenter observed from out-

side. In all these experiments which lessened the social nature of the situation, the coefficient of egocentrism decreased markedly. It also decreased when an orchestra drowned out the child's speaking voice, as well as when the children were told to speak only in whispers. Vigotsky claims that all these experiments prove his hypothesis that egocentric speech partakes first of the nature of social speech and represents a transition from speech for others to inner speech for oneself. Goldstein (1948) supports Vigotsky's point of view, for he considers the evidence convincing and in harmony with existing knowledge of child development.

In summary, it appears that the controversy over egocentrism is more apparent than real and that many of the quantitative discrepancies can be accounted for in terms of (1) differences in definition and interpretation of terms by various authors, (2) the situation in which responses are recorded, and (3) individual differences in the personality characteristics of the children observed. The writer is inclined to the belief that these three factors are of considerably more importance than the factor of nationality which has been stressed by some. It is evident that there is a high degree of egocentrism (about 40 per cent of all remarks) in the speech of young children if one sets out to look for its manifestations without artificial restraints imposed by a rigidly defined classification system (Rugg, Krueger, and Sondergaard, 1929; Adams, 1932; Fisher, 1934). It should be pointed out, however, that even the highest estimates of egocentrism rarely exceed 50 per cent, and hence the enthusiastic statements one occasionally finds regarding the *predominance* of egocentrism in the speech of young children are quite unfounded. If, however, one accepts Piaget's definitions and adheres to them strictly, much smaller amounts of speech are classified as egocentric in any situation, although more egocentric responses are found in free play and in child-child situations than in adult-child situations. Whether or not egocentrism such as is found in studies reporting high incidence of it is characteristic of childhood, and whether it is outgrown with added maturity, is still an open question. The work of Henle and Hubbell (1938) points to the interpretation that perhaps the degree of egocentrism first called to attention in the speech of young children may be a characteristic of human nature which is merely somewhat more subtly manifested in adulthood. Vigotsky's (1939) ingenious experiments are certainly worthy of repetition, and his challenging interpretations lend added emphasis to the key position of language in the study of the higher thought processes.

Socialized Speech. All the studies which have been cited in the preceding section have been concerned with socialized speech as opposed to egocentric speech. The absolute percentages of socialized speech are the complements of the percentages of egocentric speech. Hence all the factors which influence the percentages of egocentrism also affect the percentages of socialized speech. As has already been pointed out, each author has made slight modifications of the classifications, and each of these changes upsets the balance of percentages in a closed system so that the actual figures available on the various categories of socialized speech are not readily comparable except in the few studies which have employed identical methods. In general, those who have duplicated McCarthy's techniques have confirmed her findings in regard to the main trends. The percentage of answers varies with the amount of participation of the adult to stimulate conversation and with the degree to which the observer waited for spontaneous remarks in the adult-child situations. As

may be seen from Table 9 roughly one-fourth of the responses are answers in the data of McCarthy (1930), Day (1932), and E. A. Davis (1937*a*), whereas M. E. Smith (1935*a*) has only 9 per cent or less in this category at all ages.

The largest single category of socialized speech in most studies which have used this classification is adapted information which amounts to 40 to 60 per cent at the various age levels. It constitutes by far the bulk of the conversation and as a total category shows no definite trend with age. M. E. Smith's (1935*a*) figures are lower than those of other investigators because she classed remarks about the immediate situation and remarks associated with the situation as collective monologue rather than as adapted information. The most interesting trend in the subgroup of adapted information is that naming is very prominent in the speech of young children, dropping from about 50 per cent of the comprehensible responses of McCarthy's (1930) 18-month-old children to about 10 per cent at the age of 4½. E. A. Davis (1937*a*) reports only 6 to 8 per cent naming in the 5½- to 9½-year-old children studied by her. Corresponding to the decrease in the amount of naming there is an increase with age in the number of remarks associated with the situation. The child is able to recall information, to bring his past experiences to bear on the present situation, to look ahead into the future, and to talk about related items as he grows older and gains in experience and in his ability to integrate his experiences and to verbalize about them.

Another striking trend which has emerged quite consistently from a number of investigations is that very young children usually begin to talk about things which have emotional content for them. The first word is often an interjection, and even words which are usually used as nouns are often uttered with exclamatory or interjectional inflection. Apparently young children are motivated to use language in the beginning to satisfy their needs, wants, and desires and to control their environment in accordance with their needs and wants, for the category of emotionally toned responses including commands, requests, threats, and desires constitutes a fairly large percentage of the responses of the youngest children, and this category dwindles in importance with increase in age (Table 9).

In seeming conflict with these findings are those of Young (1942*a*), who reports children over 48 months using more exclamatory expressions than younger children. This apparently is due to the different situations in which her data were collected, as she also finds more commands given to other children than to adults, and an increasing tendency to use verbal expressions instead of physical contact. This latter is undoubtedly due to nursery school training and to the fact that her data were collected in the nursery school situation.

It has been pointed out by Leopold (1949*b*) that emotions, wishes, questions, and statements cannot be completely separated during the 1-word sentence stage. He stresses the highly emotional character of the earliest words and states that this affectivity decreases slowly and never completely disappears, for he states that no objective statement is ever made entirely dispassionately. Rostand (1950) gives an interesting psychoanalytic discussion of the relation between affectivity and the child's progress in the use of various grammatical forms. Sanford's (1942) study on adults is also of interest in this connection.

The figures given by E. A. Davis (1937*a*) on emotionally toned responses are much lower than those of McCarthy (1930) and Day (1932) and really are not comparable with theirs because she classed expres-

sions of liking and desire under adapted information while retaining the category of emotionally toned responses only for exclamations and definite commands. The figures reported for Smith under the heading "Emotionally Toned" in Table 9 are actually classed by her as imperative sentences, but in all probability these are emotionally toned in the sense that the other investigators employed this term. It is interesting to note the decline in the percentage of such responses as the child gains in socialization and in facility of expression. There is also the possibility that the large amount of emotionality in early speech is an accompaniment of the early stage of learning to talk, for the child who understands the speech of others much better than he can express himself may go through a period of emotional stress comparable to the emotional accompaniment which has often been noted in the early stages of learning many motor and other skills.

The category of children's questions has received considerable attention from investigators in recent years, for it has been treated as a separate category in the major studies of language development and it has also received more detailed analysis in studies by Piaget (1926), E. A. Davis (1932), M. E. Smith (1933*b*), and Lewis (1951). This area has been reviewed by Fahey (1942). In most studies of preschool children, questions seem to make up 10 to 15 per cent of the conversation. There seems to be a slight, although irregular, tendency for the number of questions to increase with age, but by 9½ years Davis (1937*a*) reports a marked falling off. Smith (1933*b*) found a slightly larger percentage (16 per cent) of questions asked in the adult-child situation than in the child-child situation (12 per cent), although it must be remembered that the two records were not taken from the same group of children and hence may be affected by sampling errors. McCarthy (1930) and Davis (1937*a*) found that children of the upper socio-economic classes ask a much larger number of questions than children of the lower socio-economic levels. This is undoubtedly due in part to the intellectual factor, but is probably also related to the satisfaction that the children are likely to get when they ask questions. A child from a superior home is somewhat more likely to get a satisfactory answer to his questions and hence will be encouraged to ask more. Davis (1937*a*) found that only children tend to ask more questions than singletons or twins. This can probably be explained on the same grounds as the occupational group differences.

Piaget (1926) was interested in children's questions chiefly for the light they might shed on the development of child logic. He devotes an entire chapter in *The Language and Thought of the Child* to a treatment of 1125 questions asked by one child of one adult over a 10-month period between 6 and 7 years of age. He points out that early *why* questions appear at about 3 years, but, classifying the questions according to the type of answer he thinks is expected by the child, he claims that these are not actually questions demanding causal explanations. He states that the earliest *whys* are affective rather than intellectual, and he postulates the hypothesis of precausality. He claims that children do not ask questions of causal relationship until 7 or 8 years of age.

Lewis (1951) is in essential agreement with this point of view, although he tends to emphasize the social function of the child's questions. He attempts to show

> that the growth of a child's questions is determined by social cooperation working upon two powerful tendencies in the child —namely, to use language as play and as

> a means of satisfying his vital needs. . . . Throughout, the growth of the various categories of questions depends very largely upon the replies that the child receives; that is, upon social cooperation.

This is in line with the hypothesis suggested above that the occupational group differences in the frequency of questions may depend upon the degree to which they are answered. Lewis stresses the fact that the child at first tends to use language as a form of play and in an attempt to satisfy his needs. The play is the game of question and answer in which the child calls upon another person to help satisfy his needs. Lewis points out that it gives the child pleasure to speak merely in order to be spoken to. Apparently children learn very early that they can gain the attention of adults and control others by the technique of asking questions. Lewis also points out that children often ask questions to which they already know the answers, often because they are learning to make formulations of events in words and seek social sanctions for these formulations. In building up his system of knowledge the child is said to begin by making tentative statements which, having an interrogative form, invite corroboration or rejection by others. He thinks that whereas there may be some rudimentary notion of causality in the early *why* questions, the child's real notion of causality develops only out of his constant experience with the causal answers that he receives from others.

E. A. Davis (1932) had mothers of 73 children record samples of 50 consecutive questions, totaling 3650 questions. These were classified and analyzed for form, length, and content. The questions were from children in the upper socio-economic brackets, were subject to the unreliability of maternal report, and were not consecutive samples. Adequate tables on the frequency of the various types of question forms were not provided, although the author discussed this point at some length and presented a few critical ratios. When in her later study (1937*a*) she analyzed over 2000 questions, many of the categories showed discrepancies with the earlier results.

M. E. Smith published (1933*b*) a separate article based on the 3095 questions recorded in running conversations of preschool children. Most of the analyses involve comparisons of responses recorded in the adult-child and child-child situations, but, as mentioned above, the two situations are not comparable, owing to the differences in selection of cases. She found, however, that *what* questions constituted 12 per cent of all questions and *where* questions 11 per cent, both of these categories showing increase with age. *Who, whose,* and *which* questions accounted for only 2 per cent and showed no relation to age. *How* questions were 6 per cent, *when* 1 per cent, and *why* questions amounted to 4 per cent. None of these groups showed significant change with age. Causal questions she found amounted to 8 per cent of all questions, questions of place 13 per cent, being most frequent at 2 years of age and showing a decrease with age. Questions of fact, time, and invention, showed an increase with age. The category accounting for the largest percentage of the questions was that involving questions concerning human actions and intentions, which included 46 per cent of all. Of interest in connection with the recognition of the naming stage and the increase in nouns in the early vocabulary is the finding that questions asking for the name of an object or person constituted one-fifth of all the questions asked by 2-year-olds and were third in frequency. She also reports that 94 per cent of all questions were concerned with some object,

action, or person either in the immediate situation or desired to be there.

Interrelationships of Various Measures of Language Development

As is evident from the foregoing discussions, there is a wide variety of measures and indices of language development which have been employed and traced throughout childhood. Probably the two most widely used measures are those of vocabulary and of length of sentence, the latter having proved to be the most objective and reliable single index. However, comparatively little has been done in an attempt to determine the relative importance of the various aspects of linguistic development or to arrive at any single index of development in this tremendously complex function. One may still ask what is the relative importance of vocabulary, clearness of articulation, length of sentence, completeness and complexity of sentences, and the coefficient of egocentrism. So many of the analyses to which language development has been subjected, particularly the structural, functional, and parts-of-speech analyses, involve classification into percentages within closed systems that relationships can only be inferred from some of the shifts which occur in the percentages. One change or trend in such a system inevitably affects the other proportions, since all figures are relative. The result is that, upon completion of any one type of analysis, a set of values is obtained rather than a single index of the child's level of sentence structure or some other measure which can be correlated with other indices.

Williams (1937*a*) attempted to shed light on this vital question in "An Analytical Study of Language Achievement in Preschool Children." Measures were obtained of ability to make speech sounds by the use of a modification and shortened form of the articulation test of Wellman, Case, Mengert, and Bradbury (1931), of the correctness of word usage, of the development of the sentence or expression unit, and of vocabulary. Word usage was measured by the number of words spoken correctly per 50 running words of conversation. Development of the expression unit was studied for length, completeness in terms of subject-predicate-object relationship, and in terms of complexity of grammatical construction. The scoring was entirely arbitrary and somewhat crude, yet it served to reveal individual differences in each of these measures in quantitative form with considerable reliability. Odd-even reliabilities for the several measures ranged from +.84 to +.91. Vocabulary was measured with the Van Alstyne Vocabulary Test (1929) and a modification of the M. E. Smith Vocabulary Test (1926), described above in the section on vocabulary tests (see pp. 532–534).

Seventy children, ranging in chronological age from 30 to 78 months and considerably advanced in mental age, were used. Unfortunately not all children had all the tests, so the complete tables of intercorrelations are based on only the 38 three- and four-year-olds for whom all measures were available. A condensed tabulation of intercorrelations and the second-order partial correlations reported by Williams (1937*a*) is given in Table 10. The reliabilities obtained by the odd-even method are shown in the diagonal cells. All the original intercorrelations are shown above and to the right of the diagonal, and the partial correlations holding chronological and mental age constant are shown below and to the left of the diagonal. As may be seen, there is a rather strong positive relationship among the various language measures with the exception of vocabulary measures, which appear to be relatively independent of the

TABLE 10

CORRELATIONS OF SEVERAL LANGUAGE INDICES WITH CA AND MA, AND INTERCORRELATIONS AMONG THE LANGUAGE VARIABLES

(After Williams 1937*a*)

$N = 38$	MA	Speech sounds	Word usage	Length of unit	Completeness	Complexity	Van Alstyne vocabulary	Smith-Williams vocabulary
CA	.56	.31	.43	.54	.41	.45	.36	.16
MA		.12	.49	.78	.55	.59	.52	.47
Speech sounds		.91	.64	.60	.61	.62	.16	.01
Word usage		.60	.94	.62	.80	.57	.36	.27
Length of unit		.69	.42	.86	.65	.80	.56	.37
Completeness		.58	.66	.41	.89	.74	.41	.21
Complexity		.60	.38	.67	.61	.87	.56	.41
Van Alstyne vocabulary		.57	.13	.28	.16	.36	.84	.59
Smith-Williams vocabulary		.08	.09	.04	−.02	.22	.76	.87

Reliabilities are shown on the diagonal. Zero order *r*'s above and to the right. Partial correlations holding CA and MA constant below and to the left

others. These relationships are maintained at fairly high levels even when the influences of chronological and mental age are eliminated. Of particular interest is the strong degree of relationship which appears between the accuracy of speech sounds and the various measures of length, completeness, and complexity of the expression unit.

Such results are quite in accord with E. A. Davis's (1937*a*) conclusion that "a child's mastery of articulation is closely related to other phases of language development." She found that faulty articulation, if unduly prolonged, may become a major handicap preventing both adequate command of language and wholesome development of the personality. This is based on a comparison of a group of 160 cases rated as having "perfect articulation" with a group of 88 cases rated as having "faulty articulation." Those with perfect articulation had a mean length of sentence of 4.85 as compared with 4.00 for those with faulty articulation, and the former used 102.2 different words as compared with only 82.5 different words used by the group having faulty articulation. In Part IV of a monograph by Little and Williams (1937) there appears a description of "An Analytical Scale of Language Achievement," with instructions in the appendix for the administration of the scale.

Yedinack (1949) reports interrelationships among several measures of linguistic maturity in four different groups of second-grade children. Length of response correlated with complexity of sentence from +.88 to +.93, being higher in the group having defective articulation than in normal speakers. Correlations of length of response with completeness of response were lower, but also positive, ranging from +.54 to +.68. Complexity and completeness of response correlated +.63 to +.74 in the various groups. Vocabulary yielded very low correlations with these measures in all groups studied. Schulman and Havighurst (1947) gave correlations of vocabulary as measured with the Seashore-Eckerson vocabulary test with Thurstone's *V* factor of

+.79 and of +.46 with the Iowa Silent Reading Test for a group of 16-year-olds.

The eight measures of word fluency devised by Gerwitz (1948*a*, cf. p. 536) were compared with scores earned by the same 38 children 5 to 6 years of age on the Smith-Williams vocabulary test. Different correlational patterns were formed between the various tests of "word fluency" and the recognition and recall types of vocabulary. Gerwitz suggests that two types of abilities may be involved in word fluency and that they probably are related to the restrictiveness of the stimulating situation

Factor analysis techniques were employed by Harris (1948) in a study of the language skill patterns of 200 fifth-grade Indian children. Scores were based on the Gates Basic Reading Test, the Pressey English Test, and five variables involving ratings of written composition. Findings regarding bilingualism and sex differences will be discussed in the appropriate sections (see pp. 591–594 and 577–581).

When completed Templin's investigations will afford ideal data for a study of the interrelationships of vocabulary, articulation, and length and complexity of sentence in the largest cross-sectional study of representative children over the widest age range (3 to 8) yet studied. She will also present longitudinal data on a smaller group of children who were followed from 2 to 5 years of age.

Investigations dealing with the interrelationships of speech and reading have been contributed by Gaines (1941), Shire (1945), Yedinack (1949), Rossignol (1948), and Artley (1948). Gaines (1941) reviews thirteen other studies most of which used poor techniques. Eight of them showed that there was a relationship between speech defects and reading disability, three showed little or no such relationship, and two were inconclusive. Artley also reviews a number of studies in this area. The conclusion is that speech and reading defects are to a substantial degree associated, especially in oral reading, but that there is no agreement as to the causation or the extent of the relationship. Huyck (1940) cites a summary by Rutherford which states that 25 per cent of dysphemia cases have reading and writing defects or other speech difficulties and that 18 per cent of dysarthria cases also have such defects, whereas 16 per cent of children classified as having good speech also had reading, writing, or other language defect Yedinack (1949) found that 40 per cent of a group of 67 second-grade children identified as poor readers also had articulatory defects and that of 71 cases identified as having articulatory defects 38 per cent also had reading disabilities. She concludes that children with functional articulation defects are significantly inferior in both oral and silent reading to children with normal speaking ability and that there is a tendency for children with articulation and/or reading defects to be inferior to normal speakers in vocabulary. It thus appears that, as investigations are directed more and more to the study of the whole child, more reports are appearing in which language disability syndromes are being identified, and children are not so frequently labeled on the basis of one outstanding symptom as they were formerly.

Individual Differences

Racial and Nationality Differences. Data comparing children of different races in language development are meager. Gatewood and Weiss (1930) reported greater frequency of vocalization among white than among Negro neonates, although Irwin (1949) reports no appreciable difference. Anastasi and D'Angelo (1952) studied 50 Negro and 50 white children among whom there was equal representation of each sex.

Socio-economic factors, and parental education were fairly well equated. They studied mean sentence length and complexity of sentence structure. There were slight but statistically insignificant differences in favor of the white groups. Harris's (1948) study dealing with two groups of American Indians is concerned only with intra- rather than inter-racial comparisons, and the various studies of M. E. Smith (1935*b*, 1939, 1940, 1949) dealing with Chinese have involved the problem of bilingualism which obscures comparability of data.

It should be pointed out, however, that strikingly similar developmental trends are to be found in biographical studies from various countries regardless of the language being learned. There is certainly observable a common developmental core in reports from the United States, England, France, Germany, Switzerland, Belgium, Japan, Hawaii, and Australia which would seem to indicate that the process of language learning is essentially the same the world over. The rates of its acquisition of course vary with the native endowment of the children, the sampling observed, and the environmental stimulation they receive. Goldstein (1948) states in speaking of sound acquisition in infancy: "Whatever language we consider, we observe, in the acquisition of sounds, the same sequence in time" (p. 36). He cites Jakobson as having confirmed this in Swedish, Norwegian, Danish, Slavic, Russian, Polish, Czech, Serbocroatic, Bulgarian, Indian, German, Dutch, Estonian, and Japanese. Such observations from the field of comparative linguistics tend to support an organismic theory of language development. (See McCarthy, 1952*c*.)

Sex Differences. One of the most consistent findings to emerge from the mass of data accumulated on language development in American white children seems to be a slight difference in favor of girls in nearly all aspects of language that have been studied. Although Irwin and Chen (1946*a*) found no sex differences in mean number of phoneme types in infancy, the girls began to surpass the boys by about the tenth month of age. Gatewood and Weiss (1930) report greater frequency of vocalization among girls even in the neonatal period, and Hess, Mohr, and Bartelme (1934), in their intensive study of premature infants, report the mean age of onset of speech (use of words) among 86 prematurely born girls was 17.5 months, whereas 65 prematurely born boys did not use words until a mean age of 18.3 months. Of those who used sentences before 2 years, 7 were girls and only 3 were boys, and approximately twice as many girls as boys began to use sentences in the third year of life. Karlin (1947) attributes the observed sex differences in speech development to later myelination of the neural pathways in boys.

Whenever groups of boys and girls are well matched in intelligence and socio-economic background, and when the situation in which responses are recorded does not tend to favor the interests of one sex or the other, there appear slight differences in favor of girls. Whenever such sex differences fail to appear, or in rare instances are reversed, the result can nearly always be accounted for, when the data are available, in terms of selection on the basis of one of the aforementioned factors. The most clear-cut example appears in Table 5, where the mean length of response, which is the most objective single measure so far available, is shown for the sexes separately as obtained in 14 major studies. In this table there appear 64 comparisons of the two sexes for children of the same age groups. Of these, 43 favor the girls, 3 are identical for the two sexes, and only 18 favor the boys. Two of the figures where

the sexes are equal come from Day's (1932) study of twins and 1 from E. A. Davis's (1937*a*) study, whereas 4 of the differences favoring boys come from the Davis study, which presented a situation that definitely favored boys' interests and 3 involved her twin groups.

The toys used by Davis are described by the author as "a motley collection of little covered wagons with detachable oxen, lassoing cowboys, buffalo hunters, scouts, Indians in attitudes of hostility, flight, or pursuit, and various animals and trees" (p. 20). It is difficult to understand the following justification for this choice of toys by a scientific investigator who is seriously interested in making valid comparisons with other available data on the matter of sex differences in language development. She states:

> Since no play object or situation was discovered which was of equal appeal to boys and girls of the ages studied, it was decided to choose objects known to be of especial interest to boys. This was done because (1) boys of 5 years are already "conditioned" against girls' toys, but girls if given the opportunity ordinarily enjoy boys' toys; (2) even if they are not interested in the toys, girls can easily be induced to cooperate in the experiment; and (3) since the language development of girls is slightly in advance of that of the boys, it is only fair that the advantage, if any, of a high degree of interest in the situation should be given to the boys. If the findings still show superiority on the part of girls, the significance becomes all the greater [p. 20].

It should also be noted that in Davis's procedure picture books were shown "only when the toys had failed of their purpose," namely, to stimulate spontaneous language. Toys were considered to have "failed of their purpose" if the child volunteered no remarks after 10 minutes and could not be induced to enter into conversation. Davis herself admits, however, that "roughly about twice as many girls as boys were shown the books," and this following 10 minutes of silence; and that "at all ages boys show slightly more interest in the toys than do girls" (p. 21). "Boys are less likely to be shy than girls. . . . Boys were slightly less negativistic than girls . . . [and] girls were somewhat more distractible than boys, perhaps because they were less interested in the situation," and ratings on talkativeness revealed "a consistent tendency toward greater talkativeness in boys than in girls. . . . The mean time is slightly greater for girls than for boys" (pp. 25–26) (that is, to secure the same number of responses), and "greater spontaneity of speech is unquestionably characteristic of boys" (p. 67).

In view of these circumstances it does not appear that anyone should take seriously, as valid comparisons, the data on sex differences from Davis's investigation. The wonder is that, in spite of the very unequal conditions, the girls maintained their superiority in length of response in 4 of the 9 comparisons and were equal to the boys in a fifth instance on length of response, and showed decided superiority on a number of other measures. The reversal of the usual trend seen in McCarthy's 2½-year-old subjects can be attributed to sampling errors, as the girls of that age group came in undue proportion from the lower socio-economic levels. The reversals occurring in M. E. Smith's (1926) data can be accounted for on the basis of age differences as the boys are about 1½ months older than the girls at the ages at which they excel. In Young's (1941) study in which groups relatively homogeneous with respect to socio-economic level were used, there was not a single exception to the general trend toward a slight superiority of girls in length of sentence.

Of particular interest, however, is the report of sex differences favoring the boys in the two Negro groups studied by Anastasi and D'Angelo (1952). This may be due to racial differences or it may be associated with differential attitudes towards the two sexes reflected in different child-caring practices in the two cultural groups. Among the 18 of the 64 differences which favored boys in length of response, 10 can be accounted for on the basis of age, socio-economic level, twinship, or racial factors. (See McCarthy, 1953.)

Although length of sentence is the most objective and the most reliable single quantitative measure to use for comparison of the sexes, almost all other measures which show developmental trends with age also reveal a slightly more rapid linguistic maturity for girls. Mead (1913) found that feeble-minded girls talked earlier than feeble-minded boys, and Sirkin and Lyons (1941) report speech defects to be twice as frequent among mentally defective males as among defective females. I. P. Davis (1938) reports that girls reach maturity in articulation about a year earlier than boys, first-grade girls having about the same articulatory patterns as second-grade boys. Terman *et al.* (1925) found that gifted girls used short sentences at a slightly earlier age than the gifted boys. Doran (1907), after an extensive survey of the literature on vocabulary, reported that girls have larger vocabularies than boys of the same ages but that the differences were smaller among older children, and M. E. Smith (1926) confirmed this in her vocabulary study.

Sex differences in favor of the girls appear in the comprehensibility of the speech at early levels. In McCarthy's (1930) study boys had only 14 and 49 per cent comprehensible responses at 18 and 24 months as compared with 38 and 78 per cent for girls of the same ages. Similar differences were found throughout the age range studied. Fisher (1934) also found a higher percentage of incomprehensible speech among the boys. They tended to repeat identical speech patterns more often. In the McCarthy (1930), Day (1932), M. E. Smith (1935*a*), E. A. Davis (1937*a*), Young (1941), and Shire (1945) investigations, all other analyses, particularly functional and construction analyses, revealed that, when categories are studied for sex differences which reveal increasing or decreasing trends with age, the trend is evident at an earlier age among the girls. The one significant exception seems to be the report of Anastasi and D'Angelo (1952) in which the Negro boys surpassed the Negro girls not only in length of response but in complexity of sentence structure as well.

Davis summarizes the findings of her own study, which revealed sex differences in favor of girls in spite of a situation which was unfavorable to them, as well as that of other investigators as follows:

> In nearly every phase of language studied, girls were found to retain up to the 9½-year level the superiority which has been previously demonstrated for the preschool period. This is true of articulation, word usage, and length, complexity, and grammatical correctness of sentences. Girls use more personal pronouns and conjunctions than boys, and less slang

It is interesting to note that both Davis (1937*a*) and Young (1941) agree in finding the sex differences more marked among children of the lower socio-economic levels than among those from superior homes. Fisher (1934), whose group was the most highly selected, found the smallest sex differences. This might seem to point to an early differential effect of the environment on the two sexes as revealed in linguistic development. In this connection it is of

interest that in Davis's study twin boys who had twin sisters, rather than twin brothers, were less seriously retarded in language. One hypothesis which she suggests is that:

> The twin sister, developing a little faster than the boy, may act as a pacemaker for him; but it is equally possible that unlike-sex twins because of parental attitude or differing interests are less dependent on each other than twins of the same sex and more likely to seek out the wider contacts which stimulate and facilitate attempts at articulate speech [p. 126].

Wellman *et al.* (1931) also found that girls articulate consonant elements better than boys.

The proverbial claim that the female is the more talkative is in general borne out by the results of scientific investigations and apparently is evident at a very early age. Jersild and Ritzman (1938) found that girls excel boys in the number of words spoken and in the number of different words used, but some might be surprised at the report by Olson and Koetzle (1936) that, although boys tend to speak less than girls during given periods of time, when they do talk, it is at a slightly more rapid rate. Jersild and Ritzman state: "In summary, then, the present findings with regard to sex differences in verbosity and vocabulary indicate that girls tend quite consistently to surpass the boys, but not to a degree that is statistically significant."

The writer has previously pointed out that the magnitude of the sex differences usually found in young children's language is not large enough to yield statistically significant differences when the usual criterion is employed. It is probable that these differences have not proved significant because of the small numbers of cases usually employed at a given age level, and also because so many analyses have been done in terms of percentages, which are rather unreliable indicators. It should further be pointed out that two methods seem to be employed by writers in the field for determining the significance of a difference although all claim to be using the critical ratio. Some use the number of children observed as the N in the formula, and others use the total number of sentences representative of the age level. Obviously, a large number of sentences from a small number of children would yield more significant differences if the latter method is employed than if N is taken merely as the number of children observed. There is need for clarification of methodology on this point and for uniformity of procedure. Young (1941) obtains many large critical ratios in various comparisons of subgroups by virtue of the fact that she employs the total number of cases in the study (74) when comparing data based on smaller subgroups. It seems to the writer that the correct procedure is to use the number of children being studied in the particular subgroups as the N. When such a method is employed the sex differences seldom prove statistically significant.

The vast accumulation of evidence in the same direction from a variety of investigators working in different parts of the country, employing different situations and methods of observation, and employing different analyses and linguistic indices, certainly is convincing proof that a real sex difference in language development exists in favor of the girls. Critical ratios and t values are employed and are interpreted to mean that if the ratio is sufficiently large it is practically certain that if the experiment were repeated the difference would occur in the same direction again. In the array of data cited above there is presented experimental, rather than statistical, evidence of the reality of the differences, small though they may be; and when ex-

perimental trends check in study after study there appears to be little need for the reassurances of statistical significance.

Apparently these small differences in the two sexes in linguistic development are related to later academic success in verbal skills. LaBrant (1933) found, for example, that girls used 148.3 words per theme, whereas the boys used only 124.7 words per theme. The boys in general wrote between 83 and 86 per cent as much as the girls.

Shire (1945) also found sex differences in favor of girls in success in beginning reading, and there were more boys than girls in her lowest decile in first-grade reading. Bennett (1938) in reviewing the literature on reading disability presented a summary table showing 17 groups of cases requiring remedial reading work. The proportion of boys in all these reports is striking, ranging from 60 to 100 per cent of the total groups in the various studies. Is it not possible that exposure to the reading experience at the same chronological age, but at an earlier stage of linguistic maturity, may be partly responsible for the greater toll of reading disability cases among boys? Ley (1930) stated that all forms of difficulty in the development of language occur much more frequently in males than in females, and the higher incidence of stuttering and other speech defects among them is well known. Azoy (1935) found 202 boys to 119 girls in a group of speech defectives and 43 boys and only 22 girls in a group of 65 stammerers. He reported that the sex distribution is the same as that found in Germany. It is probable that this slight though apparently basic difference between the sexes is also partly responsible for the consistent reports of better scholarship among girls in high school and college.

With these data in mind it would be well to re-examine the data on sex differences in intelligence as reported in Terman (1916, 1925), Goodenough (1927, 1928), Monroe (1932), and others which show slight superiority of girls in intelligence as measured with the usual tests having a preponderance of verbal items likely to favor the girls. An unpublished study by Seidl (1937) showed that the Stanford-Binet scores of bilingual girls are apparently more depressed in comparison with their scores on the Arthur Point Scale of Performance Tests owing to their bilingualism than are the scores of a similarly selected group of bilingual boys. It would seem then that bilingualism was a greater handicap to girls than to boys in the intelligence test as they characteristically tend to earn a greater proportion of their scores on verbal items.

Language Development in Handicapped Children. In certain groups of handicapped children, such as the deaf and the blind, sensory handicaps result in a definite restriction of the child's experiences which is often reflected in their language. Maxfield (1936) studied the language development of a group of 8 totally blind preschool children, employing methods similar to those of McCarthy (1930), Fisher (1934), and M. E. Smith (1935*a*), in an exploratory investigation. Although conclusions were necessarily tentative on such a small number, Maxfield demonstrated that the method employed in these other studies of normal children is directly applicable to young blind children. There was an abundance of language among these children with about twice as high a percentage of their remarks being about things as occurred in Fisher's data. The blind children, as a group, asked many more questions, gave fewer commands, and had unusually high percentages of emotionally toned responses. They used fewer nonverbal responses, but more incomplete responses, and had an unusually high incidence of proper names. As Maxfield stated:

> It may be that the trends which have appeared in connection with some of the questions [raised in her study] will be found to group themselves around some fundamental need of the growing blind child. For instance, it seems reasonable to assume that the totally blind preschool child is satisfying his need for a feeling of security through talking a great deal, asking many questions, and using proper names frequently. . . . The trends disclosed . . . probably stand for the blind child's attempt to gain that assurance regarding his environment which seeing children obtain through visual observation [p. 85].

It is also probable that the blind child's greater need for constant supervision provides an environment which is linguistically more stimulating.

Hawk (1937), on the other hand, reports that visually handicapped and blind children show a history of delay in walking and talking and concludes, without controlling intelligence, that visual as well as auditory stimuli play a part in the development of speech. Goldstein (1948) also brings out that there is earlier fixation of sounds which can be observed visually, i.e., by noticing lip formations. This same factor probably accounts for Valentine's (1942) observation that his son B was able to get consonants by imitation, but not vowels. Further investigation of speech and personality factors among blind children has been reported by Brieland (1949).

Thus, although the handicap of blindness does not appear to have a seriously retarding effect upon the child's linguistic development, and may on further investigation actually prove to have a stimulating effect, since the handicap itself forces dependence upon others and requires an abnormal amount of adult attention, the patterns of the functional analysis may be very different in a group of children having atypical needs.

The handicap of deafness, of course, has a much more direct and more serious retarding effect upon language development, for the child who is totally deaf from birth does not acquire language in the normal way and has to be taught to speak by artificial techniques. Children with adventitious deafness, or hard-of-hearing children having various amounts of residual hearing, are much less seriously handicapped, the degree of linguistic retardation being a function of the age at onset of the acoustic handicap, and of the amount of residual hearing, as well as of the type of education and the age at which it was begun. Most of the literature in this field consists of reports of isolated cases, surveys of incidence and causes of hearing loss. There are reports of results obtained with specific educational techniques of interest to teachers of the deaf, and most of the studies of a psychological or educational nature are concerned with problems of the measurement of intelligence in the deaf and with the measurement of their academic achievement. Work being carried on with deaf and hard-of-hearing subjects by Doctor and Mrs. Heider and their associates in the Psychological Division of the Clarence W. Barron Research Department at the Clarke School for the Deaf led to the conclusion by Eberhardt (1940) which states:

> The experiments show that the world of the young deaf child is already organized beyond the perceptual level and that this organization closely follows that of speaking people. They show clearly that language is not essential for organized conceptual thought, at least during its first stages. They are interesting, from an educational point of view, in showing that much of the first language development of the young deaf child in school consists in the learning of words for ideas that he already knows and uses in his everyday life. . . . Of course there are many in-

stances in which a new word introduces a new conceptual relationship, but this is also true for hearing persons [pp. 4–5].

Heider and Heider (1940*b*) point out:

> The deaf child usually does not begin to learn language until he has reached an age at which the hearing child has already mastered most of the forms used in adult expression. The whole process by which he learns language is necessarily different from that of a hearing child. From the beginning it is based to a certain extent on the presentation of carefully selected examples from which rules can be derived, while the hearing child learns by free selection from a wealth of language forms.

They analyzed 1118 compositions consisting of accounts of a short motion picture written by 301 deaf and 817 hearing children of seven different age groups. The hearing children were from 8 to 14 years and the deaf from 11 to 17 years, the youngest children in each age group being the youngest children who were able to write the whole story. A very detailed analysis on complexity of sentence structure was conducted. Among the more significant findings were the facts that the sentences of the deaf were shorter both in number of words and number of clauses than those of the hearing, the deaf used relatively simpler and fewer compound and complex sentences, fewer verbs in coordinate and subordinate clauses, relatively more infinitives, and relatively more prepositional phrases. The authors report, that, in all these, except those of the infinitive and prepositional phrase, the performance of the deaf resembled that of the less mature hearing children. It appeared that the deaf used relatively simple language units, shorter sentences, and relatively few forms requiring precision of use. These differences were found even though the deaf children were approximately 3 years older than the hearing children with whose compositions their work was being compared.

This is in disagreement with results reported by Templin (1950), who found large groups of defective hearing children using longer sentences than normal children in written explanations of scientific phenomena. She interprets this as probably due to their need to use long circumlocutions in sentence structure, as is done in Basic English, because of their meager vocabularies. She also found (1948) fewer spelling errors made by deaf children probably associated with the different learning techniques they must employ and the lack of guesswork based on auditory cues which often lead normal children into spelling errors.

Hudgins and Numbers (1942) analyzed phonographic records of the speech of 192 deaf pupils between the ages of 8 and 20 years who had been taught by the oral method. Teachers of deaf children served as auditors, and a reliability of +.90 was obtained for the method of analysis. Results were chiefly in terms of vowel and consonant errors and errors in rhythm. Approximately 21 per cent of all consonants and 12 per cent of all vowels were malarticulated by the deaf children. Correct rhythm was revealed to be an extremely important element contributing to the intelligibility of the speech of the deaf. The authors concluded:

> Speech is a dynamic process; it cannot be broken down into static positions and isolated movements. An *analytic* method of speech teaching of itself, therefore, violates basic physiological and phonetic principles. A synthetic method in which the basic phonetic unit is the syllable is in keeping with these physiological and phonetic principles; it is the natural method by which hearing children acquire speech.

They therefore advocate a basic revision of the methods which have heretofore been

employed in the teaching of speech to the deaf.

The study by Hughson and others (1942) involved a detailed analysis of the voice and speech characteristics of 367 children resident in the Pennsylvania School for the Deaf, of whom 249 had never received auricular training and 118 were enrolled in auricular classes, that is, classes using group hearing aids for children with residual hearing. Electrical transcriptions were employed. Children receiving auricular training in speech were found distinctly superior to those taught by the traditional oral method. Their superiority was independent of the amount of residual hearing and age of onset of deafness. They estimate a 2-year shortening in the education of the deaf child by the use of this method. The previously cited study by Hudgins and Numbers (1942) agrees that children having auricular training have more intelligible speech than those taught by the oral method.

Effects of Environmental Factors

Institutionalization. Some of the most challenging results have appeared in the recent studies dealing with the effects of environmental deprivation in institutional, orphanage, or hospital environments. It is indeed amazing to note how early this is manifested and to see how lasting are the effects.

Aldrich, Sung, and Knop (1945*a*, *b*, *c*) and Aldrich, Norval, and Knop (1946) present a series of studies on infant crying. Babies were observed 24 hours a day for the first 30 days in a hospital nursery. Comparisons were made with the amount of crying under conditions of home care and after increased nursing care in the nursery. In the hospital the average baby cried 117 minutes per day and had 11.9 prolonged crying spells (i.e., over 3 minutes). In the home situation there were only 4 such crying spells per day. When nursing care was increased in the hospital nursery from 0.7 hour per child per day to 1.9 hours per child per day, there was a 51.4 per cent decrease in the amount of crying. Such findings must have important implications for speech and for emotional development.

Brodbeck and Irwin (1946) compared the frequency and variety of phonemes uttered by a group of orphanage children with those heard among a group living with their own families. Statistically significant differences were obtained in favor of the children who enjoyed the stimulation and the affectional relationships of normal family environments. The differences indicating the handicap of the orphanage group were evident as early as the first 2 months, and the discrepancies between the two groups became more marked by the fourth and sixth months of life. The orphanage groups, however, were already markedly below the children from the homes of unskilled laboring groups, even in the first 6 months, and in spite of the fact that feeble-minded children were not included in the orphanage group. (Cf. Irwin 1948*b* and *c*.) Fisichelli (1950) also found that institutionalized infants were much more retarded than Irwin's subjects, who lived with their own families, in all measures of their prelinguistic utterances that showed developmental trends with age.

Goldfarb (1943*a*, *b*, 1945, 1946) in an interesting series of studies evaluated the language of children who spent their first 3 years in an institution. He compared them with foster children who lived in foster homes from early infancy (approximately 4 months). Comparisons were made on speech sounds, intelligibility of speech, and level of language organization, using the Williams, McFarland, and Little Language Achievement Scale, and picture

vocabulary as measured with the Stanford-Binet Form L. Retests were made after 7 months in foster homes, at 6 to 8 years of age, and again in adolescence. The children reared in an institutional environment showed marked language deficiency in all areas measured. The author characterizes their behavior as passive and apathetic and their personalities as impervious to environmental stimulation. The implication is that the institutional deprivation in the first 3 years produced permanent harm to the intellectual, linguistic, and personal-social development of these children. Further studies on this topic are needed, as only 15 to 20 cases entered into the above comparisons, and the marked difference between foster children and institution children in IQ (28 points) before placement is difficult to interpret. It is impossible to say whether the institutional environment produced the intellectual deficit measured with a verbal test or whether the brighter children were placed earlier, and only the duller and generally more retarded children remained in the institution as long as 3 years. The early age of placement of foster children, however, would seem to preclude the possibility of selective placement.

Freud and Burlingham (1944) in England also found retardation in their studies of *Infants without Families* during World War II. This retardation did not appear until the second year of life. This may have been due to insensitive techniques or to the circumstance that for many of the children in their group the deprivation was deferred until later in infancy.

Similar reports also come from France, where Roudinesco and Appell (1950) note the severe developmental retardation of infants raised in institutional environments. Among those who had been institutionalized for a long period of time only 13 per cent had Gesell developmental quotients of 85 or above, whereas 55 per cent were seriously retarded with developmental quotients below 70, the retardation being most marked in the language areas of the test. After 18 months of an improved regime designed to have nurses and other attendants give more individualized attention to the children, marked improvement in motor, social, and adaptive behavior occurred, but the least improvement was brought about in language development.

Gesell and Amatruda (1941) give a good description of the dynamics of this environmental deprivation and stress that it operates by "attrition" as well as by "impoverishment" and that the results tend to be cumulative. Gatewood and Weiss (1930) report that vocalizations were less in a situation in which newborn infants were "allowed to lie naturally without any external stimulation" than in an experimental situation in which they were stimulated by various forms of controlled stimuli such as light, sound, temperature, odor, and holding the nose. Apparently the sheer monotony, and impersonal character, of the institutional environment lessens vocalization in comparison with the variety and warmth of a normal home environment. Such factors are apparently operative even in the neonatal period.

Williams and McFarland (1937) applied the Smith-Williams vocabulary test to 64 orphanage children who were compared with a large group of children living in their own homes. The orphanage children were markedly inferior in vocabulary scores, much more so than could be accounted for on the basis of socio-economic level or IQ. Moore (1947) used the same vocabulary test and analyzed 2-minute samples of oral language on orphanage and nonorphanage children. In all measures of language she found the orphanage group markedly retarded. She held CA and MA constant and conducted an analysis of variance which

showed a statistically significant difference attributable to environmental influences.

All this evidence should lead to a serious re-evaluation of traditional child-caring practices in institutions and agencies. In fact, such studies have already led many forward-looking social agencies to increase their use of foster homes whenever possible and to place children at earlier ages than formerly. The need for making due allowances for early environmental deprivation when interpreting infant intelligence tests also becomes imperative in the light of such findings.

Occupational Group Differences. There is considerable evidence in the literature to indicate that there exists a marked relationship between socio-economic status of the family and the child's linguistic development. Chamberlain (1900) states that as early as 1847 Degerando reported that "the child of the rich understands more words and less actions, and the child of the poor less words and more actions." This early observation regarding the linguistic superiority of the privileged child has since been confirmed by a number of recent experimental studies. Chamberlain (1900) also reports a study by Lombroso in which 50 children of well-to-do and educated families were found to have much larger vocabularies than 100 children from poor families. In reviewing this study Markey (1928) states: "Both in the precocity with which they interpret the words and in the exactness reached, the children of the former families exceeded those of the poor in the proportion of two to one."

Descoeudres (1921) studied 300 children of the upper and lower classes as they were distinguished by attendance at private or public schools and found that on practically every item of her extensive battery of tests, nearly all of which involved language, the children of the upper social classes were decidedly superior to those of the lower social classes. Stern (1930), who reworked these data, calculated that the difference between the educated class and the working class would be equivalent to about 8 months in linguistic development.

C. Bühler (1931) reported that children from a neglected milieu show retardation in all aspects of their development, but that the retardation is more evident in language than in other aspects of development. She reported data of Hetzer and Reindorf, who compared a group of children from a "good" environment with a group from an "underprivileged" environment. The children from the more favored environment used more words meaningfully at earlier ages, a larger percentage of them were using 2- to 3-word sentences at earlier ages, and the same differences were revealed when syntax, inflection, and sentence structure were analyzed.

The extremely early age at which these differences manifest themselves is evident from the work of Irwin (1948*b*, *c*), who studied phoneme frequency and types of phonemes in relation to the occupational status of the family in the first 2½ years of life. Although the types of phonemes show no relation to occupational status, and frequencies of phonemes are not related to paternal occupation in the first 1½ years, such a relationship does appear to emerge after 18 months of age, or at approximately the average age of onset of true speech.

In the McCarthy (1930), Day (1932), and E. A. Davis (1937*a*) studies paternal occupation was used as a criterion of selection in efforts to secure representative samplings. In all these studies occupational group differences are consistent and strikingly in favor of the upper socio-economic levels in all types of analysis. The children from the upper social levels not only use longer sentences but also use more mature sentence forms at earlier ages. Functional categories, especially questions,

which show trends with age, also reveal more rapid development of children from the more favored homes. In McCarthy's word analysis, children of the lower classes continued to use larger percentages of nouns up to higher age levels, which is probably indicative of linguistic immaturity. In Davis's study 73 per cent of the children from upper socio-economic levels were rated as having "perfect articulation" at 5½ years, but only 58 per cent of the children of the lower levels received similar ratings on articulation at that age. It will be recalled that Fisher's (1934) cases which showed the greatest superiority in linguistic development came, nearly always, from the families of professional men. McCarthy (1930) and Day (1932) found a tendency for the differences between the occupational groups to increase with increase in chronological age, but this was not borne out by Davis's data on school age subjects.

In the study by Young (1941) 6-hour language records were made on 74 cases, half of whom attended the nursery school at the University of Georgia during a period when tuition was charged and half of whom attended when the nursery school was run as a Federal Emergency Relief Project and served only families on relief. Comparisons are made between the "regular" and "relief" cases attending the same school in different years. It was found that the regular group surpassed the relief group in all aspects of language that were analyzed. Relief boys were by far the poorest in language development and regular girls the most advanced.

Worbois (1942) compared the language of children from a one-room rural school and from a consolidated rural school. The groups were matched on IQ, age, home cultural index, and midparent education. Significant differences on the Stanford-Binet vocabulary test and on a verbal effectiveness test were found in favor of the group in the consolidated school. They also used almost twice as many words and half again as many different words in describing the pictures in the Stanford-Binet scale as the children from the one-room school. The principal environmental difference which seemed to be associated with these factors was the education of the teachers, for in the one-room school they had had on the average only 0.6 of a year beyond high school, whereas those in the consolidated school had had an average of 3.0 years of education beyond high school. In their vocabulary study of 16-year-olds Schulman and Havighurst (1947) found statistically significant differences from one socio-economic group to another on the Seashore-Eckerson English Recognition Vocabulary Test, Part I.

Kinds of Experience. Several investigators have reported that travel and events which broaden the child's experiences are accompanied or followed by increases in vocabulary. Drever (1915–1916), after comparing the vocabularies of his own 3 children, who had had a broad environment with considerable travel, and those of slum children, concluded: "Expansion of a child's environment always tends to increase nouns relatively to other parts of speech. Conversely, with a constant or relatively constant environment, the other parts of speech will increase relatively to the nouns."

This is in agreement with Bean's (1932) observation that periods of rapid increase in vocabulary coincided with the widening of the child's experiences through travel and that periods of sentence building paralleled uneventful interim periods. Most of these reports are on isolated cases, yet it is conceivable that the occupational group differences which have been found so consistently in the larger scale studies may be due in some measure to the more restricted environment usually experienced by chil-

dren of the lower socio-economic classes. Parents of children in the lower classes are presumably less gifted linguistically than parents of children in the upper classes, and hence not only afford a poorer example of language for a model but also probably provide less verbal stimulation.

An extremely challenging study by Milner (1951) selected contrasting groups of first-grade Negro children on the basis of "language IQ" obtained with the California Test of Mental Maturity. Patterns of parent-child interaction were studied for the children who were "high" and "low scorers" on a language criterion similar to reading readiness tests. These children were drawn from widely divergent socio-economic levels. Striking differences were found in the patterns of family life between the "high scorers" and the "low scorers." The families of "high scorers" usually have breakfast together and engage in general two-way conversation at breakfast and before school as well as at supper, the children actively participating in such conversation. Children scoring high on the language tests were also the recipients of more overt expressions of affection from significant adults in the home than the children who earned low scores on the language tests as first graders. On the other hand mothers of "low scorers" do not eat breakfast with their children, do not talk to them during breakfast or before they start for school (except for occasional orders and cautions). These children do not talk to anyone at breakfast or before school. Neither do they have any two-way conversation while eating their supper. These factors tend to be concomitant with variations in socio-economic status which has so often been shown to be related to language development. However, since these circumstances are so much more dynamic from the standpoint of language learning and familial attitudes towards children and their patterns of living, it appears that parental attitudes towards children and habits of family life are the really significant factors for language development and that they happen to vary with socio-economic class as well.

There have been a number of interesting facts revealed on the relationship between the age of the child's associates and his linguistic development. The Gales (1906), whose second and third children used twice as many words as the first child at the same age, claimed that "the later children have an advantage in learning much from contact with the older child." Others hold, however, that children understand each other much better than they do adults who are too far above their level. G. S. Hall (1891*a*), in speaking of children of approximately the same age, said: "Their noises are too well understood by each other, the younger holding the older back."

McCarthy (1930) found that the median percentile rank on length of response of the children in her experimental group who associated chiefly with adults was 70. For those who associated with older children it was 42.5. This latter group was drawn chiefly from large families who usually came from lower socio-economic levels. The children who associated chiefly with younger children had a mean length of response very close to the median for their ages, namely, 52.5. It appears, then, that association with adults is likely to be accompanied by linguistic acceleration. Further evidence comes from M. E. Smith's (1935*a*) study in which children were shown to use longer sentences and to use more advanced patterns of language development during the situation in which they conversed with an adult than in the situation involving conversation with other children. If association with adults is frequent in the child's experience, and he follows the pattern found by M. E. Smith, he will get

more practice in using more mature language in situations which are conducive to better language usage. However, Hahn (1948) found that a group of children serving as an audience stimulated even more mature language expression on the part of her 6½-year-olds than one adult did.

Another striking fact which fits into the picture on age of associates is the marked superiority of only children. Of all the groups studied, only children, especially only girls, seem to be the most precocious in all aspects of language development It is true that only children most frequently come from homes of the upper socio-economic levels and are somewhat higher in intelligence, but their linguistic superiority appears to be out of all proportion to what would be expected on the basis of their age, sex, mentality, and socio-economic status. Because of the nature of the family pattern, only children usually have more adult contacts than other children Although these children are undoubtedly of superior native endowment, it must be remembered that their environments differ from those of other children chiefly in affording greater association with adults, broader experience, and greater opportunities for practice in the use of language under optimum conditions.

At the opposite extreme, children in orphanage and institution environments, as shown above, are the most seriously retarded group in language development. Little and Williams (1937), Skeels, Updegraff, Wellman, and Williams (1938), and Flemming (1942) have found marked retardation in vocabulary development among institution children. Although the children of this group undoubtedly come from lower socio-economic levels, are somewhat below the average in native ability, and probably have had restricted environmental experiences, their retardation appears so marked that it is necessary to look for other factors to account for the magnitude of the differences found. Even when Little and Williams (1937) matched cases on mental age, the institution children were much more retarded in vocabulary than non-institution children of the same mental age. If these data are fitted into the picture on age of associates it appears that children living in an orphanage have the maximum amount of association with other children and a minimum of association with, and attention from, adults. If, therefore, association with adults is a facilitating factor in language development, it is understandable why this group of orphanage children should show such marked retardation in linguistic development.

Dawe (1942) reported an educational program emphasizing the understanding and use of language symbols by a group of children in an orphanage. It involved about 50 hours of individual and small-group training in understanding words, looking at and discussing pictures, listening to poems and stories, and going on short excursions. These are the kinds of enriching experiences that the good home in the upper socio-economic brackets usually affords and the kinds of experiences that schools find it necessary to provide in reading readiness programs for underprivileged or immature children. In Dawe's experiment 11 pairs of children were matched on age, sex, school group, MA, IQ, and score on the Smith-Williams vocabulary test. One member of each pair received the training, and the other served as a control. Gains which were significantly greater for the experimental group at the 1 per cent level of confidence were found in all language measures except intelligibility of speech and complexity of organization. Sentence length increased from 5.34 to 6.14, and vocabulary scores increased 17.5 points in contrast to 10.0 points for the control group. Although there was no direct coach-

ing on test items, these language training gains were reflected in an increase in average IQ from 80.6 to 94.8 as a result of the 50 hours of training over a 92-day period. The control group decreased from 81.5 to 79.5 in the same interval in the unenriched orphanage setting. The implications of such findings, if substantiated on larger groups, are indeed far reaching for both education and psychometrics.

In the study by Anastasi and D'Angelo (1952) half of the Negroes lived in a housing development tenanted by both Negroes and whites, whereas the other half were in a segregated housing development. The differences in favor of the whites were more marked in the segregated groups. Where there was opportunity for Negro and white children to mingle freely in social activity their language development was more similar. However, there may have been selective factors operating so that brighter Negroes and duller whites representing the same broad socio-economic brackets may have been living in the mixed situation. Negro boys were superior to Negro girls in the unmixed neighborhood, but girls were superior in both mixed and unmixed white groups. (See Table 5.) This reversal of the sex differences usually found in white groups suggests the possibility of a cultural difference in attitude toward the two sexes or differences in child-caring practices which may be operative.

Effect of Multiple Births. Another line of evidence on the effect of environment comes from studies of children whose environment differs from the normal by reason of multiple birth. Day (1932), who duplicated McCarthy's (1930) techniques with 80 pairs of twins, using the same criteria of selection, found that the twins were markedly retarded in all aspects of language development when compared with McCarthy's singletons. She reported that "the mean length of response for 5-year-old twins is slightly below that of 3-year-old singletons," and a comparison of the yearly gains indicated that the rate of increase in length of response among singletons was about double that found among twins. She attributes the differences to the peculiar social situation of the twin, stating, "One surely could not learn as much or as rapidly, from companionship with an individual so nearly on his own plane, as from one in advance. Satisfactions from this companionship may be adequate to the twin . . . whereas the single child . . . may be motivated to gain his satisfactions from a wider field."

Following up these results, E. A. Davis (1937*a*) compared twins, singletons, and only children at higher age levels. She found the twins retarded in language as compared with the other groups, but the discrepancy between their linguistic status and that of singletons was not nearly so great after the age of school entrance as Day found at the preschool period. It seems that the home situation of the twins during the preschool period is not likely to promote normal linguistic growth, but that after school experience begins, with its opportunities for wider social contacts, much of the initial handicap is overcome. The twins of the upper socio-economic groups made most of the linguistic gains after school entrance, whereas those in the lower economic brackets made comparatively little progress. A study by Howard (1946) on a large number of triplets revealed even more serious linguistic retardation than Day found among twins, for the 5-year-old triplets had a mean length of sentence of only 2.98 words, which is about equal to Day's 4-year-old twins and to McCarthy's 2½- to 3-year-old groups.

Interestingly enough, the Dionne quintuplets showed even more marked linguistic retardation. Blatz, Fletcher, and Mason (1937) reported that Annette, who was

the most advanced of the five in language, began to use words by the nineteenth month and that all the children were using a few words by the twenty-second month. They compare the *total vocabularies spoken* by the quintuplets with McCarthy's (1930) and Day's (1932) data showing the *mean number of words used in a sample of 50 consecutive responses* by singletons and twins, and state that the quintuplets are about 16 to 18 months retarded as compared with the normal children. The *real* comparison which should be made indicates even more serious retardation, since the figures for the quintuplets represent the total cumulative vocabulary ever heard before that age. Obviously, if a short sample of 50 responses recorded in 15 or 20 minutes yielded 66 words for McCarthy's singletons and 55 for Day's twins and the quintuplets did not have as many words in their entire known vocabularies until 32 or 33 months, their retardation in language was indeed serious at that age. It must be remembered also that they were living in a bilingual environment, but up to the time of the report cited above they had used only French and were just about to begin to learn English. It is difficult to explain this retardation entirely in terms of the social situation, since the quintuplets had so much individual attention from adults during their preschool years that it should compare favorably with the amount of adult time and attention which children in smaller families normally receive, unless, perhaps, their environment was psychologically more nearly comparable to that of institution children.

Bilingualism. Another environmental factor which is of prime importance in the acquisition of language by the preschool child is bilingualism. In adulthood the ability to use a second language is a decided cultural advantage, and considerable time and effort are spent in secondary school and college to acquire even a rudimentary knowledge of another language; yet a young child can acquire two languages during the preschool years with apparently little difficulty. However, there are many examples of confusion which children who hear two languages are likely to experience. The usual situation for bilingual children in this country is to hear a foreign language in the home and English at school, and in such instances educational experience reveals that the bilingualism is a handicap to the child's school adjustment and academic achievement. Parents who can speak two languages often ask whether it is advantageous or detrimental to permit the child to hear and speak two languages during the preschool years, when language development normally is progressing so rapidly, and whether a certain mastery of one language should be attained before the second one is introduced. Scientific evidence on these very practical and important problems has been seriously lacking. Most of the studies on bilingualism have been concerned with the effect of this factor on intelligence as measured with verbal tests. Seidl (1937) found that bilingual Italian children usually test on the average 5 or 6 points below average in verbal intelligence and that their scores on performance tests generally run 10 or 12 points higher than on verbal tests. Few studies have been concerned with the effect of bilingualism on the development of the child's language.

Travis and Johnson (1937) studied the relationship of bilingualism to stuttering in 4827 children from 4 to 17 years of age of whom approximately half were monolingual and the other half bilingual. They found that 2.8 per cent of the bilinguals stutter and only 1.8 per cent of the monolinguals stutter. Although, of course, 97.2 per cent of the bilinguals did not stutter, there are 98 chances in 100 that the dif-

ference obtained between the two groups is a real one.

Leopold (1939, 1947, 1949*a*, *b*, *c*), a linguist, has conducted one of the most careful and detailed studies based on diary records, phonetic transcriptions, and vocabulary accounts of his daughters, who were brought up hearing both English and German. He reported (1949*c*) that at first his daughter tried to forge a single-language instrument from the twofold presentation and only considerably later did she separate them into two language systems. He reviewed the literature on bilingual children in 1948 with emphasis on case study reports.

M. E. Smith (1935*b*) studied the language development of 8 children in the same family who had varied experiences with English and Chinese. On the basis of this study she concluded that it is probably better for young bilingual children to receive their two languages from quite separate sources, each adult in the home using one language consistently, and that change from a monolingual to a bilingual environment has a more serious effect on the child's language than change from a bilingual to a monolingual environment. Such changes she thinks are more difficult for infants from 12 to 18 months of age than for children who have acquired greater facility in the use of speech. It does not appear to delay the first use of words but does seem to have a handicapping effect at later ages.

In 1939 Smith published a most comprehensive investigation on the effect of bilingualism on language development. She studied 1000 children of varying racial backgrounds and varying amounts of bilingualism in Hawaii. The major findings were that in general these children preferred to use English. The Japanese children who heard the least English used 50 per cent English words, but the total group used about 88 per cent English words. In comparison with *haole* [1] children and those who were studied on the mainland, Island children were seriously retarded in the use of the English language, a retardation which is not compensated for by greater advancement in other languages used. The more bilingual groups use more nonverbal sentences and shorter sentences than childrn in a less polylingual environment. They are found to use more exclamatory and fewer interrogative sentences, and to use compound and complex sentences much less frequently. The bilingual groups were also retarded in the use of connectives and pronouns and in the use of the copula and inflected forms, and showed the expected decrease in the use of interjections. When a language is disappearing in competition with a new language, nouns and interjections (which, it will be recalled, are the first to be acquired) persist for the longest time. Those words that pertain to intimate aspects of family life and to eating are the last to be abandoned In general, it was found that the children of Hawaii from *nonhaole* homes are retarded in language development at the time of school entrance to a degree so marked that, on most criteria, they are at about the level of 3-year-old children from a less polyglot environment. Smith considers that this retardation is due to the bilingualism of many homes and the prevalent use of pidgin English in the Hawaiian Islands.

There is need for further study of bilingualism in the United States, with other languages as the foreign language, and uncomplicated by the presence of a mutilated form of English. Most of the studies are seriously obscured by the factor of socio-economic status, for most bilingual children either come from highly cultured homes of

[1] *Haole* is an Hawaiian word for almost all Caucasians except the Portuguese.

the upper social levels where the language is being deliberately preserved for cultural reasons, or they come from the lower socio-economic levels where the parents have not been sufficiently intellectual to acquire the second language. On the other hand, there are a number of children whose parents remain in lower socio-economic brackets than those in which they would be found in their native countries because the very fact of a language handicap has necessitated their remaining at manual occupations rather than undertaking more verbal or more intellectual tasks. In McCarthy's (1930) study 10 per cent of the cases were bilingual. These children were more advanced than would be expected on the basis of their age, sex, and paternal occupation as measured by mean length of response. It may be that the handicap is more readily detectable in articulation and in quality of speech than in quantitative measures like length of response. Numerous reports seem to indicate that as far as pronunciation is concerned there is a definite advantage to learning the second language at an early age. Yoshioka (1929), however, states on the basis of meager data that older children can handle two languages better than younger ones and that bilingualism seems to require a certain degree of mental maturation for its successful mastery.

Smith (1949) studied the vocabularies of 30 bilingual children of Chinese ancestry in Hawaii who ranged in age from 37 to 77 months. They were as a group somewhat above average in paternal occupation. Her test was given in English on one day and in Chinese on another day by a Chinese examiner conversant with both languages. In either language taken alone the group had below-average-sized vocabularies for children of their ages. Even when the vocabularies of the two languages were totaled only two-fifths of the children exceeded the norm. When words of duplicate meaning were subtracted only one-sixth of them exceeded the norm. Smith concludes that only the superior bilingual child is capable of attaining the vocabulary norms of monoglots, that it is better to have one name for each of many concepts than two names for a smaller number, and that it is therefore "unwise to start any but children of superior linguistic ability on a second language unnecessarily during the preschool years." She also cites an unpublished study by Motoyma in which 50 bilingual Chinese children had English vocabularies only 40 per cent as large as the average monolingual child at entrance into kindergarten. After a year of kindergarten they had vocabularies 62 per cent of the norm. Two of the most careful studies showing the effect of bilingualism on the measurement of intelligence with both verbal and nonverbal tests are those by Seidl (1937) and by Darcy (1946), both of which show that the bilingual child is penalized in the usual measures of intelligence that best predict his functional intellectual level. Studies on bilingualism have been reviewed by Arsenian (1945). Thompson (1952) in concluding his discussion of this topic states:

> The "functional" intelligence of bilingual children is severely impaired in a cultural sense. . . . There can be no doubt that the child reared in a bilingual environment is handicapped in his language growth. One can debate the issue as to whether speech facility in two languages is worth the consequent retardation in the common language of the realm. There is no research evidence that might help answer this important question [p. 367].

In Harris's (1948) study of fifth-grade Indian children's compositions the Montana children, two-thirds of whom heard only English before school entrance, wrote

shorter compositions than the Pueblo children, three-fourths of whom heard only Indian before school. Error scores were higher for the Pueblo children, but this may have been a function of the greater opportunity for errors in the longer specimens of their writing. It cannot be determined from the data presented whether the differences are racial or due to bilingualism.

It is becoming increasingly urgent that we have adequate information on this problem of the effect of bilingual experience at various ages, for more and more families are having to spend periods of time in foreign countries in government service and are puzzled as to how best to handle the second language to the children's advantage rather than to their detriment. Furthermore, with the increase in air travel in this shrinking world there is great need for more individuals who can communicate in more than one language, and of course there is the ever-recurrent interest in the various forms of a universal language such as Basic English or Esperanto. It is evident that a thorough re-evaluation of the methods of foreign language teaching in secondary schools and colleges is needed.

Effect of the Situation. Considerable interest has been shown concerning the effect of the immediate situation in which language responses are recorded on the general pattern of results. Attention was called to this factor by McCarthy (1929*a*), who in an effort to reconcile the results of her major study with those of Piaget (1926) recorded the language of the same children in a situation in which the child was conversing with an adult and also in a nursery school free play situation. Although the odd-even reliability of length of response samples of 50 responses taken in the adult-child situation was +.91, the correlation found between mean length of response for samples taken in the two different situations was only +.54. Some children who were somewhat shy and restrained in the adult situation talked more freely on the playground, and others who were talkative with adults talked relatively little in this group, thus tending to lower the correlation.

McConnon (1935) conducted a study of 28 nursery school children in which two samples of conversation were recorded in each of six different situations; lunch, morning outdoor play period, indoor free play situation, table-play, afternoon outdoor play, and an outdoor play situation at home. Twenty-five responses were recorded in each situation for the same group of children McCarthy's (1930) methods of recording and analysis were followed quite closely although no construction analysis was conducted. Surprisingly low coefficients of agreement between the two observations in each situation were found, the quantitative analyses yielding the highest mean coefficient of only +.431, the functional analysis yielding a mean correlation coefficient of only +.289 between various situations, and the parts of speech analysis one of only +.072. The two reasons which obviously account for the differences found here are, first, that the quantitative measures, such as length of response and total number of words, are more objective and do not involve judgment and classification by the experimenter, and, second, that they are based on the total sample while the functional and parts-of-speech analyses are based on only parts of the sample, in some instances certain categories being represented by a relatively small number of responses. On the whole, McConnon reports, the home situation yielded the greatest consistency from one occasion to the next. The category of emotionally toned responses yielded the highest consistency coefficient from one

situation to another. Of the various nursery school situations, the lunch period apparently offered more controlled conditions than the other school situations. The two outdoor situations both showed low consistency, as did also the indoor play situations.

An inquiry by Janus (1943) on the relationship between children's language and their play is so inadequately controlled that the conclusions should be disregarded. Space does not permit detailed criticism here, but the article has been severely criticized in print by Dennis (1943).

Williams and Mattson (1942) studied the effect of different social groupings on the language of 6 nursery school children. A Fonda recorder enabled them to secure responses for several children at one time. Records were taken when the child was alone, with the experimenter, and with the experimenter and 1, 2, and 3 other children. Most talking and the most social speech occurred with the largest social group, but the mean length of sentence remained fairly constant for the various social situations. The data were also analyzed for parts of speech and according to Piaget's analysis. All the intercorrelations among the various situations were low. For the quantitative indices they averaged +.31 to +.40, for the functional indices −.05 to +.20, and for the parts of speech only −.07 to +.23. The same children used longer responses and more words in samples of conversation taken in an outdoor home situation than in any of the nursery school situations studied.

Further light on the effect of the situation on language records is afforded by Hahn's (1948) study on 116 first-grade children from upper and middle class homes. Recordings were made of voluntary speeches given by these children in the daily "show-and-tell" situation in the classroom where teacher and classmates were the audience; and 8 days later records were taken in an adult-child situation such as has been employed in most of the major studies. The classroom speeches averaged about 5 or 6 sentences (median 48 words), with a mean sentence length of 10.37 words, as shown in Table 5. In the adult-child situation, although the sample was longer (median 70 words), the mean length of sentence was only 6.85. She found that 6½ times as many "nonsentences" occurred in the situation with the adult as in the group audience situation. She makes the interesting observation that, when an object and an event are not shared visually, longer sentences are required, as when a child told in class of family trips or events at home. Highly personal and family activity stories produced the longest total responses.

In a study by Van Alstyne (1932) it was found that over half the time preschool children tended not to talk to other children while working with play materials. Certain materials appeared to have considerably more "conversation value" than others. Doll play, blocks, crayons, and clay ranked high for percentage of time that their use was accompanied by conversation, whereas painting, scissors, and books were low in conversation value. It is interesting, in view of the sex differences previously shown, that the doll-corner activities and dishes, which are typical girl activities, were among the highest in conversation value. It might be concluded that certain differences in language are due to the effect of the situation, but it must also be remembered that certain situations may attract children of different levels of language development.

It appears from McConnon's investigation that the results of language analyses are dependent upon the situation in which the data are gathered and on the type of index of language development employed.

It is extremely important, therefore, in comparing language studies and in setting up experimental situations for future investigations, to control the situation with great care, to make comparisons only of situations which have been shown to be comparable, and to generalize regarding language development only for the specific situation in which the data have been collected. Apparently there are sufficient differences in the same children's use of language from one situation to another to make it extremely hazardous to infer that a given sample is representative of a child's language development in general.

M. E. Smith (1935*a*) also attacked this problem by comparing children's language recorded in a nursery school free play situation and in the adult-child situation, but since the personnel of her groups differed it is difficult to interpret her findings. She claims superior language usage by children in the adult-child situation. However, as McConnon concludes: "If a typical picture of the child's behavior is to be obtained, a number of situations must be sampled. Observational studies cannot continue to ignore the situational factor in response if the results are to have significance for child development." She further points out: "In order to obtain a stable index of the child's language responses it is necessary to take a number of samples in a number of situations."

In the study by Young (1941) samples of language in four different nursery school situations were obtained. Each child was observed for 10-minute periods totaling 6 hours of observation during about 15 days. The situations studied were outdoor play, indoor play, dinner, and a period in which the children were looking at picture books. It was found that the setting in which the responses were collected had a marked relation to the amount of language obtained in a given time.

In length of response, however, twelve correlations between compared situations ranged from +.90 to +.94. These and all other intersituation correlations reported by Young are unbelievably high considering the degree of reliability which is usually found for data of this type. They are all the more surprising when one considers the small homogeneous groups upon which they are based. Barring computational errors, the only possible explanation of them seems to be in the relatively longer samples employed, which may have yielded more reliable data. These correlations seem to indicate that sentence length in any one setting tends to be markedly similar to that used by the subjects in the other situations studied However, Young states:

> Apparently the four groups were not identically affected by the four different settings in which they were placed . . . a situation somewhat similar to that used by McCarthy, may be expected to yield findings representative of those which would be secured in any of the other three settings, if the subjects are of both sexes and come from widely differing socio-economic levels, as in the present investigation. If, however, a relatively homogeneous group is being studied it seems advisable to secure responses in several different types of situation This appears to be especially important if the subjects are of low socio-economic status [pp. 43–44].

The analysis for parts of speech showed rather marked differences from setting to setting corresponding to the changes found in amount of comprehensible verbal behavior. It seems as if this contribution to methodology should be helpful to future investigators in this rapidly expanding field.

An interesting study by Chapin and Corcoran (1947) reported remarkable success in bringing out speech in a group of 16 "speech-inhibited" children of about 5 years of age through play-group tech-

niques, and several writers, particularly Blanchard (1933), Russell (1944), Werner (1945), Harle (1946), and Allen (1947), report case studies in which children with delayed speech were helped by play therapy or group play contacts of a nursery school. (See section on delayed speech, pp. 606–8.)

However, for most children of the upper socio-economic levels, nursery school experience results in more child contacts and fewer adult contacts, and in the light of the evidence presented earlier it would not be surprising if in some cases there were revealed a retarding effect of nursery school experience, especially for only children of upper socio-economic levels. This possibility, even if later demonstrated, however, should not be interpreted as an indictment of nursery school experience, because such factors need to be evaluated in the light of the child's total development.

Language and Motor Development

As none of the studies conducted so far has devised any single index of language development or measure of linguistic maturity, there are not many satisfactory indications of the relationship of language development to other aspects of the child's development. Language is usually considered to be a substitute or short-cut type of behavior for overt bodily responses, as it is well known that gestures accompany language in the early stages. As was pointed out earlier (see section on gesture language, pp. 521–3), gestures precede the appearance of language and constitute a more primitive form of communication. As language develops and becomes more precise, fewer gestures are needed, and it has often been noted that if a child develops an unusually effective gesture language his development of true language may be delayed for some time. Cases of language retardation are often attributed to the fact that the child develops an elaborate system of gesture language which is so well understood by adults in the child's environment that his wants and needs are satisfied without his having to make the effort to learn to talk. If, in a particular case, it can be shown that such is the cause of linguistic retardation, a refusal on the part of the adults in the environment to understand and respond to the child's gesture-language is usually effective in bringing about the emergence of true language.

Shirley (1933*a*, *b*), who made a careful analysis of the motor development of the same 25 children on whom language records were kept, reported a cyclical relationship between linguistic development and the appearance of certain gross motor skills. Children's vocalizations decreased in frequency during periods when reaching for objects, sitting alone, and walking were being mastered. She found correlations between developmental scores on locomotion and vocalization which were all low or negative tending to "confirm the theory that speech development is held in abeyance at the time when motor progress is most rapid." She states further that, although the evidence is meager, "it points in the direction that early vocalization is held in check by rapid motor progress and that babbling is a type of behavior which a baby resorts to when there is nothing better to do, or when the novelty of a new type of motor activity has worn off." This phenomenon was pointed out as early as 1880 by the German observer Schultze, who said that children appear to learn only one thing thoroughly at a time and that while the child learns to walk he pushes aside the development of speech almost entirely and resumes his linguistic task only after the locomotor one has been finished. It is possible that the slowing-up in rate of gain in vocabulary as shown in M. E. Smith's (1926) data (Table 4) at

the age of 15 months, which was the age of learning to walk in Shirley's group, is another instance of this same phenomenon. Brigance (1934) also noted it in one child who showed a plateau in vocabulary development during the period of learning to walk. After walking became well established this child showed a rapid spurt in vocabulary development. It is relationships of this sort that are all too meager in the literature of child psychology. In all probability many interesting interrelationships such as these are being overlooked because of the methodology which characterizes so many current studies in child psychology.

Wellman, Case, Mengert, and Bradbury (1931), who give detailed tabulations on the ability of preschool children to articulate various sounds, report correlations of +.67 and +.65, respectively, between scores on a tracing path test and the total number of sounds and the number of consonant blends articulated. Bilto (1941) studied 90 speech-defective cases ranging in age from 9 to 18 years and found them to be definitely inferior as a group on three sets of motor ability tasks. Since articulation is so largely a motor function, this may be indicative of a general motor ability. Both articulation and motor ability are undoubtedly related to CA and probably to a third factor such as emotional security. Shirley (1933*b*) found a moderate positive relationship between fine motor coordinations and language development after the age of 45 weeks. H. M. Johnson (1928) reports that nursery school children under 3 years of age frequently use rhythmic vocal accompaniments to their physical activity; Fisher (1934) reports a correlation of +.86 between the use of things by nursery school children and talking about things; and Goodenough (1930) reports a low positive correlation of +.17, with age constant, between talkativeness and physical activity in nursery school children. These observations are interesting in relation to Vandel's (1947) report that higher apes often utter vocalizations in accompaniment to their actions.

Language and Intellectual Development

Language is an area of the child's development in which more marked and more striking degrees of individual variation can be observed than in almost any other. From the idiot who grows to physical maturity without learning to talk, to the gifted child who begins to use words at 8 months and sentences by the end of the first year of life, there certainly is a wide span which is of considerable developmental significance. Individual differences in linguistic development closely parallel the differences which have been shown to exist in intellectual development, and certainly equal and perhaps even exceed them in magnitude. It is also quite certain that language development has contributed heavily to the variations in intellectual differences as they have thus far been measured. Whether or not this is an artifact due to the highly verbal nature of most of the more satisfactory intelligence tests, or whether there is a more basic fabric of intellectual development consisting largely of linguistic maturation, is something which has not as yet been determined. The facts that thus far no satisfactory intelligence test has been developed for age levels before the emergence of language, and that all the intelligence tests which have proved to have a satisfactory degree of validity are heavily weighted with verbal factors, bear witness to the importance of language in mental development.

The age of onset of talking has often been regarded as symptomatic of the child's later intellectual development. One often

hears favorable prognoses regarding the intellectual development of children who talk early, and mothers often become concerned over failure of their children to talk at least by the second birthday. From the scientific evidence available there appears to be some justification for these popular beliefs although the relationship is far from perfect, and the layman accepting such a generalization is quite likely to make serious errors in predicting a child's future mental development merely from a knowledge of the age at which he begins to talk. An idiot never learns to talk, and Terman *et al.* (1925) found that gifted children with IQ's above 140 talked on the average at about 11 months or approximately 4 months earlier than the average child. However, there were in this group of gifted children some who did not talk at all until 2, 2½, and even 3 years of age. So it is by no means certain that a child who is late in talking will be mentally retarded. However, in general, feeble-minded children usually talk much later than normal or superior children. The average age of talking of a group of feeble-minded subjects is reported by Mead (1913) as 38.5 months as compared with the normal age of 15.3 months. (See also Town, 1912–1913.) It thus appears that feeble-minded children are always late in beginning to talk, and a child who talks early is quite likely to be above average in intelligence. However, although delayed onset of speech is often due to general mental retardation, there are many other causes of delayed speech (see pp. 606–8), and a diagnosis of mental retardation should never be made on the basis of delayed speech alone.

After sketching in a descriptive account of ten stages in a linguistic sequence which he says appeared in all 3 of his children, Valentine (1942) notes that the child Y who showed spontaneous cooing at 4 weeks was the most accelerated in each of the stages, B who cooed at 5 weeks was next, and A who did not coo until 7 weeks was the most retarded in all other linguistic manifestations up to 2 years of age. This corresponded well with their later IQ's as Y and B tested about 145 IQ and A only about 110.

Abt, Adler, and Bartelme (1929) report data on age of onset of speech in a group of 1000 cases with an average IQ of 81. The correlations for age of onset of speech and intelligence were −.41 and −.39 for the two sexes separately.

Irwin (1942) has thrown further light on this problem by showing that the speech sounds made by 10 low-grade feeble-minded children, none of whom was using real language (average age 4 years and average IQ 29), approximate those of normal children 1 year of age in such characteristics as vowel ratio, vowel-consonant ratio, and distribution of consonants. Sirkin and Lyons (1941), who examined 2500 institution mental defectives, report that only one-third speak normally and that the lower the intelligence rating the lower is the incidence of normal speech. Speech correction with these cases was found to be unsuccessful below the moron level, and they consider that a minimum mental age of 5 years 6 months combined with a cooperative attitude is essential to successful speech therapy.

In an analysis of the articulatory defects of a group of 53 feeble-minded cases (physical defectives eliminated), Bangs (1942) concluded that MA is 4.9 times as significant as CA in influencing speech proficiency. The sounds avoided by the feeble-minded were no different from those avoided by the normals. However, omissions of sounds which constituted 35 per cent of all errors in the feeble-minded seemed to be one of the most significant characteristics of their speech. They more frequently omit final sounds. Otherwise

their speech corresponds closely to that of normals of the same MA.

In 1945 Irwin and Chen compared a number of their speech sound indices with the results of the Kuhlmann Test of Mental Development and concluded that speech "sound development for the first 2 years of life is independent of intelligence test scores." However, most intelligence tests which are satisfactory at upper ages are highly verbal in nature. Those so far available at the infant level have neglected linguistic development because of methodological problems and have yielded disappointing results. The phonetic approach to infants' vocalization, introduced by Irwin and his co-workers, yields regular trends with chronological age (see Table 2), shows occupational group differences (Irwin, 1948*b*, *c*), and differences between institutional and noninstitutional cases (Brodbeck and Irwin, 1946; and Fisichelli, 1950) in the same direction as intelligence tests do at higher age levels.

Investigators have not been very successful in their attempts to measure intelligence until the child is able to talk or at least to respond to verbal commands, in other words, to participate in verbal tests. It is strange that we have gone on blindly expecting sensori-motor items to reveal intellectual development in infants, simply because they are easy to observe, when they are not related to intelligence at other age levels. A pilot study undertaken by Catalano (1952) under the writer's direction involved follow-up intelligence testing with the Stanford-Binet scale of 23 of the cases 4 years of age previously used in Fisichelli's (1950) investigation of infants. A correlation of +.38 was obtained between consonant/vowel frequency ratio in infancy and later IQ. When corrected for age at time of original testing this value was raised to +.41. Consonant types in infancy correlated +.45 with IQ at 4 years of age. It may very well be that phonetic analysis of infants' vocalizations will yield some of the most valid intelligence test items for the infant scales of the future.

In the studies of McCarthy (1930), Day (1932), and E. A. Davis (1937*a*) the same relationships which were traced with relation to CA also appeared when the data were analyzed according to MA. The marked linguistic superiority of Fisher's (1934) subjects whose average IQ was 132 is significant in considering the relationship between intellectual development and language development. It is also interesting to note that there are differences in intellectual status paralleling the differences in linguistic development, there being slight superiority of girls over boys, of singletons as compared with twins, and of children from the upper as compared with the lower socio-economic levels. This brings up a very interesting problem on which there are not sufficient data for a final answer, namely, whether the more precocious development of language among these groups is due to their greater intellectual endowment or whether their higher scores on the intelligence tests, which are chiefly verbal in nature, are due to the more precocious linguistic development. Shirley (1933*b*) reports quite high correlations (5 out of 6 between +.63 and +.76) between Minnesota Preschool Test scores and cumulative vocabulary, number of different words used per examination, and vocalization scores, all of them being higher at 2 years than at 18 months.

Two studies have attempted to separate the factors involved in this relationship. Day (1932), in an effort to account for the differences which she found between twins and singletons in language development, matched her 4-year-old group of twins with singletons in regard to total test score, CA at time of testing, sex, and occupational

class. The percentages of the total score which each group earned on verbal and nonverbal items of the test were then calculated and were found to match almost exactly. Day (1932) concludes therefore that "the language retardation of these 4-year-old twins does not seem to have been a factor in reducing the total test score and thus lowering the IQ." She also determined "language quotients" for her twins by obtaining ratios between the mean length of response of singletons and of twins of the same ages. The results indicate that "the language retardation is so significantly greater that factors other than 'below average general intelligence' must be responsible for it. The language quotient decreases rapidly as age increases in spite of the fact that the intelligence quotient does not." It thus appears that differences in intelligence do not account entirely for the language retardation of twins, nor does the verbal element in intelligence tests appear to penalize the twin sufficiently to account for the differences in intelligence as measured.

A second study in which an attempt has been made to separate these two influences is that by Williams and McFarland (1937), referred to previously, in which a vocabulary test was given to 242 Iowa City children and to 64 orphanage children. The two groups showed marked contrast in both vocabulary and IQ. When orphanage and noninstitutional children were matched on MA and IQ, there still remained a marked discrepancy between the vocabularies of the two groups, the vocabulary ratios of the orphanage children being only .48 to .68. The authors therefore state: "Thus the orphanage children have vocabularies which are inferior not only to those of children of the same chronological or mental age, but higher IQ, but also to those of children matched for IQ level as well." For the group living in the community the correlation between vocabulary and MA, with CA held constant, was +.43, whereas for the orphanage group it was +.65.

Another approach to this problem comes from learning studies in which subjects learn more readily when they have names for the learning materials. It is well known that meaningful paired associates are learned more readily in the laboratory than nonsense syllables in the same type of learning situation. Pyles (1932) in an interesting study of the factor of verbalization in learning found that, when young children were given names for nonsense molds which covered rewards, 44 per cent solved the problem in 25 trials or less, whereas only 14 per cent solved it when the molds remained unnamed. This brings up the problem of the relationship between thought and language. Carmichael, Hogan, and Walter (1932) demonstrated that in many cases merely saying a word before the presentation of a visual form definitely influences the manner in which the form is apprehended as well as the readiness with which it is recalled. It was also shown by Goodenough and Brian (1929) that verbal instructions were of considerable help to preschool children in acquiring a simple motor skill.

Language and Social Development

During the early preschool period when the child's language is not yet very useful as a means of social communication, he is still definitely an individualist, and it is probably significant that a marked degree of socialization of his behavior occurs during the later preschool period when language itself is becoming a more efficient means of intercommunication. Every nursery school teacher is familiar with the increased facility in controlling a child's behavior which comes as soon as his understanding of spoken language improves and

with the marked change in social behavior which occurs when a child learns to make verbal instead of physical contacts with his playmates. A child who talks very little is often solitary even in a group situation, and a spurt in his linguistic development sometimes appears to facilitate his social contacts so that a previously solitary child may develop friendships as soon as he begins to talk and make verbal approaches to other children.

As indicated above, language responses have been shown to differ from one play situation to another. Further study should be made in order to determine whether the child's stage of linguistic development determines the types of companions he finds congenial and the sorts of play situations in which he will engage or whether the situations themselves determine his linguistic pattern. Schmidt (1941) has shown that speech therapy given to mental defectives facilitates their social adjustments and stimulates them to more gregarious behavior. A positive correlation between maturity of articulation and acceptable social behavior, as measured with the Haggerty-Olson-Wickman Behavior Rating Schedule B, was found in a study by I. P. Davis (1938). This, she considers, may indicate that the factors which retard a child's speech also retard his social development or that the speech difficulty may, in itself, contribute to the retardation in social adjustment. McCarthy (1929*a*) found no very marked correlations between the Marston extroversion-introversion scale ratings and various linguistic measures for nursery school children observed in free play and in the controlled situation with an adult.

Portenier (1937) found that it took longer to elicit a specified number of responses from a group of children who were rated by their nursery school teachers as poorly adjusted than from a group rated as well adjusted. Hahn (1948) reports that 32 per cent of the first-grade children who volunteered speeches before the class in a "show-and-tell" period were leaders, 51 per cent "sometimes lead," and only 17 per cent of them were classed as "usually followers."

Several writers, particularly Despert (1938) and Bradley (1941), have called attention to the seclusiveness and schizoid tendencies of many children who manifest serious lack of speech in spite of normal hearing and normal mentality. McCarthy (1947, 1949*a*, and 1952*b*) and others have called attention to the fact that social adjustment is usually very poor in older children who manifest serious language disorder syndromes. Such children seem to be either very shy or very aggressive and to have no wholesome friendships with their peers. The favorable response of some of these cases to the socializing influence of a nursery school environment will be shown in the next section.

Language Disorder Syndromes and Personality Development

The identification of certain clinical syndromes among cases manifesting language disorders of various types is one of the most interesting trends to appear, and it does much to throw light on the problem of the rôle of language in the adjustment of the total individual, on the dynamics of personality, as well as on the genesis of speech, and on the etiology of the various disorders of the language function.

Most of the evidence comes from the study of those who have failed to develop normal speech and who suffer from some form of language disorder such as delayed speech, infantile speech, or other articulatory defect, or who stutter, or who later manifest a syndrome of reading, writing, and spelling disabilities. There seems to be a new appreciation of the factors of psycho-

logical adjustment among workers in the field of speech correction who are coming to realize that they have largely been treating symptoms and have not been removing causes. Among educators, who are baffled by persistent reading, writing, and spelling disorders and by the slow learning of some gifted individuals, there is considerable concentration on methodology and diagnostic and remedial programs in the basic tool subjects. The constructive approach to the teaching of reading has made notable progress in concentrating on the development of the whole child, in recognizing the immaturity of the beginner through measures of reading readiness, by the expansion of preprimer experience, and through intensive efforts to integrate the learning of the various language arts with the total life experience of the child. Outstanding contributions in this area are Betts's (1946) *Foundations of Reading Instruction* and Strickland's (1951) *The Language Arts in the Elementary School.* An overview of trends in this field is available in the first of a series of volumes prepared under the auspices of the Curriculum Commission of the National Council of Teachers of English (1952) and entitled *The English Language Arts.*

When the broad concept of language disorder is utilized to include such varied manifestations as delayed speech, stuttering, functional articulatory defects, and reading disabilities, it appears that various forms of language disturbance occur much more often in combination in the same individuals than would be expected by chance on the basis of the incidence of any one of them in the population (Gaines, 1941; and Yedinack, 1949).

It has also been shown in a variety of studies (see Johnson *et al.*, 1948) that language disability syndromes seem to appear more frequently among males, to run in families, and to occur more often in families in which twinning occurs, and that these families also produce many individuals who manifest some sort of confusion in lateral dominance as indicated by ambidexterity, mixed eyedness and handedness, and reversal tendencies in reading and writing.

All these lines of evidence have built up in the minds of most investigators, and especially among speech correctionists, a hereditary explanation or some sort of neurological theory in regard to speech, reading, and lateral dominance disturbances (Travis, 1931; Bryngelson, 1935; Orton, 1937; Berry, 1938; and Cole, 1942). This attitude leads to excusing the deficiencies and contributes to their stubborn resistance to treatment. It tends to relieve the individuals and their families from active participation in the overcoming of the disorder, since they come to believe themselves somehow different by native endowment and that hence normal learning in these areas is precluded for them.

The following section presents a summary of a number of significant contributions in this area which the writer believes point to an emotional and functional explanation of most of the language disorder syndromes and indicate that these emotional disturbances are for the most part environmentally determined, but are passed along in families from generation to generation in the form of attitudes toward children and in cultural child-caring patterns which appear to give superficial support to hereditarian explanations.

Studies of Infants. A wealth of material seems to have emerged since the early 1940's centering on the broad area of the relationship of language development to emotional adjustment and normal personality growth, with emphasis on the importance of proper parent-child relationships for normal growth in language and personality. Evidence has been presented in the section on environmental factors of the devastating

effects of environmental deprivation (Gesell and Amatruda, 1941; Goldfarb, 1943*a*, *b*, 1945; and Brodbeck and Irwin, 1946) in orphanage situations where the child lacks close personal contact with the mother or mother-substitute in early infancy. Ribble (1943) and Spitz (1946) have also described the retarding effects of "hospitalism" on young children, and we are now witnessing a marked emphasis on infant psychiatry leading to changes in the practices of some of the most advanced maternity hospitals which are introducing the "lying-in" arrangement advocated by Gesell and Ilg (1943) for newborn babies in an effort to establish closer mother-child relationships in the first few days of life.

In the discussion of the organismic theory of infant vocalization (McCarthy, 1952*c*) it has been pointed out that the organs of speech are first used for the establishment of breathing and feeding, the two most vital physiological processes. The emotional tone of the mother-child relationship which is established in those early days, the security provided by the mother's arms while nursing the child, the tone of her voice, and her facial expression probably have much to do with determining the child's first social contacts and the adequacy of his interpersonal relations. It appears from the clinical literature, which is too voluminous to cite here, that, if these early experiences are warm and satisfying and tend to give the young infant security, breathing, feeding, vocalization, and other vital processes are established normally. There seems to be evidence to indicate that the mother who is emotionally mature, free from fears, and ready to accept the responsibilities of motherhood has a better chance of having a normal delivery and of starting the infant off adequately in these important areas (McCarthy, 1952*a* and 1953).

In an interesting article on "echo-reactions" in young children Stengel (1947) points out that in echoing words the child identifies with persons in the environment, especially with persons to whom he is emotionally attached. Stengel claims that the game of repeating words is one of the means by which the child identifies himself with his models. This author stresses the essentially social nature of these early echo-reactions and their dependence on personal rapport, and considers that the underlying psychological mechanism is identification on a primitive level. Wyatt (1949) also presents an article which emphasizes the importance of the mother-child relationship in this early period. She points out that it is the mother who first brings the language of her social group before her child and that she thus serves as a temporary interpreter for a permanent medium of the culture which has its own set of rules. She stresses that the learning of the mother's speech is deeply emotional, and is achieved through the process of unconscious identification. Since, however, the language is more or less rigid, it imposes early rules, regulations, and frustrations together with gratifications and rewards, and in this process the mother "mediates" between the language and the child but does not "inflict" language upon him.

Goldfarb (1945) points out that infants form strong emotional attachments within the first year of life, probably within the first 6 months. Brodbeck and Irwin (1946), Freud and Burlingham (1944), Roudinesco and Appell (1950), and Buxbaum (1949) also stress the importance of the process of identification with an affectionate adult in the establishment of babbling and word formation. Buxbaum (1949) states that "severely neglected children and those whose attachments to adults are interrupted and infrequent . . . are slow in learning to speak and may remain retarded in speech throughout their lives." These children she describes as "anxious, insecure,

inhibited children who were punished for self-expression or suffered the pangs of hunger, cold, and loneliness." It may be that mothers' attitudes towards boy babies are often different from their attitudes towards girl babies, for girls are more in demand for adoption in our culture, and boys are more likely to be active and to require more restraint and are generally considered harder to train and raise (Goodenough, 1931). Boys in our society have little opportunity to identify with fathers, and even when they have the opportunity, there is such a marked difference in the voice quality of the young infant and that of the adult male that it certainly would make the echo-reaction stage much less satisfying to the boy than to the girl whose voice more nearly approximates that of the mother. If the affectional bond with the mother is so vital to the establishment of a proper groundwork for normal speech, may we not have here a partial explanation of the retardation of twins and other multiple-birth children who have to share the mother during infancy and who never do experience a period in which they have her undivided attention to the extent that a singleton has? This idea could also be expanded to include the precocity of the only child reported by Davis (1937*a*), for only children have longer periods of being the center of the mother's affection. It would also fit in with the frequent observation of marked sibling rivalry in cases manifesting language disorders (McCarthy, 1947 and 1949*a*) and with the frequently observed onset of stuttering and reading failure after the arrival of a younger sibling (Missildine, 1946).

Fowler (1947) stresses the importance of the rôle of the adult in helping the child build meaning into words. She brings out that the extent to which the child makes a connection between words and actions is dependent on the accuracy and consistency with which parents use words in everyday situations. In teaching the child the word "come" the parent should not only say the word but should also help the child to come, give approval and satisfaction, and be consistent in the application of such techniques. In an observational investigation carried on in the home, Lafore (1945) found that the largest number of the parents' positive contacts were directed toward the child's intellectual development and a comparatively small number toward his emotional development. However, out of a total of 913 practices directed at the child's intellectual development, the smallest category involved encouraging the child in the acquisition of language. Yet, in the light of what is known about the importance of language development for intellectual growth and as preparation for the highly verbal situation of the school, what better practices could the parents of preschool children use, who are ambitious for the child's intellectual growth and academic success, than to encourage and assist them in the acquisition of language?

Allen (1947) has a splendid article summarizing a pediatrician's 20 years of experience in dealing with speech-defective children, which stresses that speech must be regarded as a function of the whole child. He says that any speech defect must be regarded as only a presenting symptom and as one feature of some more widespread condition in the child. After eliminating various physical defects, such as defects of the organs of speech, hearing defects, and mental deficiency, he describes a group in which the speech defect is due to mismanaged emotional factors in otherwise physically and mentally normal children. In this main category he recognizes four types: (1) the delay in learning to speak of the "protest child," who has rejected food in his infancy and who has always been difficult to manage; (2) the continuation of

babylike speech in the overprotected child; (3) variations in speech function due to being deprived of a position of emotional dependence; and (4) stammering, in which an emotion is mismanaged by being "throttled down." There results an interference with motor impulses involved in breathing. According to Allen, in various emotional situations such as displacement in the family group, illness, or accidents, the motor impulse in the act of breathing "is prevented from reaching those muscles which should contract first and is transmitted to those muscles which should relax first." With the resulting lack of control over expiration, there is "failure to produce vowel sounds with a repetition of the consonant sounds which precede them." Thus, it is evident that speech disturbances are often associated with disorders in breathing and feeding and probably have their roots in very early infancy when control of these processes is being established.

As will be shown in subsequent paragraphs there are a number of studies which indicate that, in children of preschool age who present speech disorders, other behavior difficulties are common accompaniments.

Delayed Speech. An investigation by Beckey (1942) involved detailed clinical study of 50 children who were delayed in the onset of speech with 50 who talked at the normal age. Factors in the family stock which were found to be associated with delayed onset of speech were speech defects, left-handedness, and mental deficiency. Among prenatal factors considered, those which seemed to be related to delayed speech were age of the mother below 18 years, and asthenia, nervousness, edema, and kidney and heart disorders during pregnancy. Prolonged labor or other abnormal conditions at birth were also significantly related to late speech, as well as asphyxia in the newborn. Poor motor coordination, ambidexterity, and a tendency to respiratory diseases, especially measles and whooping cough, poor health, and glandular disturbances were also more frequent among the late speakers. Retardation in age of walking and dentition, as well as diseased or early removal of tonsils and adenoids, were more frequent in the group of children who talked late. Children with delayed speech were more likely to be boys than girls and more likely to have parents who were less well educated and came from lower occupational levels than those of children who began to speak at the normal age. Environmental factors which appeared to be significantly related to delayed speech were isolation of the child, severe frights, and habitual anticipation of the child's wants by the parents. Beckey also found that children with delayed speech cried easily, played alone, and did not want attention as much as children with normal speech. Significantly larger percentages of children in the delayed-speech group made excessive use of gestures and used defective articulation. It should be remembered in this connection that many children make excessive use of gestures before the onset of true speech and that most of the early sentences are emotionally toned in content (McCarthy, 1930).

Goldenberg (1950) discusses 14 children tentatively diagnosed as "idiopathic language retardation" cases. These were carefully examined with the Nance (1946) battery of tests for differential diagnosis of aphasia in children. He states that 4 of his cases placed in the "idiopathic language retardation" category are probably mental defectives, 3 others he considers to be probably suffering from minor brain injuries because of evidence of disturbed perceptual-motor functioning, and 2 had severe hearing loss. He considers that this nosological category may be a group of known and disparate disorders which have

merely been classed together because of the common language symptoms, or that it may be a group of similarly based defects belonging to a more general classification of disorders, or that it may be a group whose common lack of speech is the symptom of a general organismic defect.

Salfield (1950) reports a case of a 7-year-old boy suffering from what he terms "elective mutism." He considers that this condition may be "a part reaction to parental coerciveness." He cites Kanner and Schumacher in support of his claim that some sensitive children develop "elective mutism" as a "fixation at an early infantile level on which an apprehended danger situation is met by a refusal to speak." Werner's (1945) case study of an unwanted child who did not talk until after 5 years of age is of interest in this connection.

Delayed onset of speech in young children whose general behavior seems to rule out mental deficiency and who give evidence of ability to hear may occur on a purely neurotic basis for fairly long periods of time. It should always be given serious consideration, for Bradley (1941) cites several authors who consider speech disturbances, especially mutism, as highly significant in the diagnosis of childhood schizophrenia. Despert (1938) considers it a capital symptom, especially in younger schizophrenic children. These findings, coupled with the frequent clinical observations on speech disturbances in adult schizophrenics (Kasanin, 1944; White, 1949; and Feifel, 1949), certainly would seem to warrant further investigation. They are interesting when considered in conjunction with Beckey's findings that the children with delayed speech played alone and did not seek or want attention. An unpublished study by Sutter is cited by Beckey (1942) in which 13 children with delayed speech were compared with a control group on 96 different traits. The delayed-speech group approximated the normal in only 10 of these traits. Sutter also noted the tendency of such children to play alone, to make few vocalizations, and to be unusually active physically.

Chapin and Corcoran (1947) describe a highly successful program conducted with 16 "speech-inhibited" children averaging 5.6 years in age who were virtually without speech. After an average of 34 play sessions in a regular nursery group in which they were expected to talk and were treated just like speaking children, and during which intensive observations and individual and group therapy were carried on with the mothers, all the children began to talk, and 12 of the 16 were discharged as speaking normally for their ages or as able to go on to regular school. These results were accomplished over a 5-month period.

In discussing a paper presented by Kanner (1946) on autistic children, Despert points out one characteristic which seems to be common to all young schizophrenic children, regardless of the presenting peculiarities of their speech, and that is the unnatural peculiar voice quality and lack of expressiveness, which makes it hardly seem to belong to the personality. She claims that what Pichon called "la fonction appetitive" or the desire to communicate with others, which manifests itself in infants long before true language emerges and which seems to be associated with emotional tone, is apparently lacking in schizophrenic children.

Several writers, Blanchard (1933), Bender (1940), Russell (1944), Werner (1945), Harle (1946), and Allen (1947), to mention only a few, have reported case studies in which play therapy, nursery school, and kindergarten experiences helped to overcome problems of delayed speech; and many have commented on the tendency to seclusiveness and withdrawal which apparently, in its most extreme form, is the

mutism of the child schizophrenic mentioned by Bradley (1941) and by Despert (1938).

Articulatory Defects. In a study by Stinchfield, cited by Beckey (1942), the speech-defective group also presented problems of food finickiness, constipation, sleeplessness, and enuresis. Lack of a speech symbol to express need could account for the enuresis, but both could also be caused by an emotional problem.

Wood (1946) studied 50 children having articulatory defects which were not associated with mental deficiency or organic or hearing involvement, together with their parents, who also were of normal intelligence and hearing. The parents of these children having articulatory defects were found to be much more neurotic than the normative groups on the Bernreuter personality inventory and on the California Test of Personality. The children were not significantly different in personality when measured with the California Test of Personality or with the Pintner Aspects of Personality, but those given Thematic Apperception Tests revealed considerable evidence of frustration, withdrawal, lack of affection, elements of anxiety and insecurity, lack of achievement, aggressiveness, hostility, and escape. In nearly all, these evidences were well substantiated by factual material obtained in case histories. All 50 children received speech therapy, and all improved in their scores on an articulation test. However, the mothers of 25 of the cases received psychotherapy and were assisted to overcome their neuroticism and to develop more social outlets and insight into the children's problems. The children whose mothers received psychotherapy made statistically significantly greater gains in their articulation test scores than the children who merely had speech therapy but whose mothers were not treated.

Stuttering. The repetitions in the speech of 62 young children from 2 to 5 years of age were the subject of detailed study in a series of articles by D. M. Davis (1939, 1940*a*, *b*). The repetitions in 1-hour verbatim records in a free play situation were employed. The data indicated that all children of this age range do repeat some words. The distribution of percentages of repetition ranged from 6.2 to 43.9. The author states that, "a child whose speech is such that approximately 1 word in 4 is repeated either in part or in whole in a word or phrase repetition is not presenting any abnormality in speech but is talking 'normally.'" In this connection it should be recalled that first words and many baby words are reduplicated monosyllables and are well accepted by most parents. The data for syllable repetition, however, in D. M. Davis's study revealed a very skewed distribution with 16 of the 62 children showing no syllable repetition. Apparently this type of repetition is more significant for the genesis of stuttering than word or phrase repetition. The types of repetition showed very low intercorrelations ranging from +.03 to +.35. Syllable repetitions were found to decrease with age, and boys repeated more than girls. A composite measure of all repetitions was negatively correlated with CA (−.48) and with MA (−.44). Correlations of repetitions with mean length of response were −.48, and with vocabulary −.47. All these relationships approached zero when the measure of repetitions was restricted to syllable repetition, which was the one which seemed to be most related to the genesis of stuttering.

Kastein (1947) also mentions this tendency towards repetition in the speech of normal children. She states that for a period of several weeks or months between 2 and 3 years of age every child is inclined to repeat syllables or words. This tend-

ency she interprets as due to a discrepancy between the thought tempo and the speech tempo. When the child is helped to increase his vocabulary normally, this discrepancy gradually narrows and the repetition disappears. It is apparently at this period that overanxious parents with high standards for their children, and perhaps undue concern over speech because of speech problems in other members of the family, become alarmed at the child's normal repetitiveness and call attention to it. The child thus discovers that this manner of speech is a means of getting attention or of punishing the parents, and a fixation on this level may be created and labeled or diagnosed as stuttering by the parents.

Johnson (1942) studied 46 stuttering children who were compared with a group of 46 nonstutterers between 2 and 9 years of age. He found that in three-fourths of the cases the original diagnosis of stuttering was made by the parents and that with 92 per cent of the stutterers the first phenomena so diagnosed were "beyond doubt essentially effortless repetitions of words, phrases, or the first sounds or syllables." Such repetitions also occurred in the speech of the nonstutterers but were not so labeled by parents who were more relaxed about the onset of speech. In Johnson's study the typical hypertonicity, facial grimaces, etc., of the stutterer were not present at the onset, in his stuttering group, but appeared only later.

In McCarthy's (1947) study several stutterers had to accept the arrival of a younger sibling, of whom they were very jealous, at about 2 years of age, or at just about the time they were probably beginning to combine words into sentences and to attract parental attention with their language. Another frequent age of onset of stuttering is the age of school entrance, which is one of the most serious steps in the emotional weaning of the child. This is the time when he has to accept a parent substitute and at which he makes the tremendously important psychological transition from adjustment to the immediate family circle to the larger world of the school.

Glasner (1949) studied 70 young stutterers between 2 and 5 years of age. Fifty-four per cent of them had feeding problems, 27 per cent were enuretic, and 20 per cent suffered from exaggerated fears or nightmares. He identifies three kinds of stutterers: (1) the relatively healthy child whose environment is confused, (2) the severely disturbed child with stuttering as only one symptom, and (3) the dependent, confused, fearful, shy, anxious, and restless child. The third type he finds by far the most numerous and points out that these children have a background of overprotection and pampering and obsessively perfectionist parents.

Similar conclusions emerge from Moncur's (1951) study, in which 48 stutterers between 5 and 8 years of age were compared with a matched group of nonstutterers. In this study "every stuttering child exhibited several symptoms of maladjustment." A questionnaire given to the mothers of both groups yielded many significant differences between the groups. More mothers of stutterers employed harsh disciplinary measures, threats, shame, humiliation, or corporal punishment. They admitted more inconsistency in discipline from time to time and greater disagreement with the fathers on disciplinary matters. They were more indulgent and pampering especially in regard to eating habits, and there were more illnesses, accidents, and unfortunate health conditions affecting the households of stutterers.

Stein (1949) reports that many of the symptoms observable in stutterers succeed each other in the reverse order in which

they appear in infantile speech development. Duncan (1949) found five questions on the Bell Adjustment Inventory which differentiated stutterers from articulatory cases. All the items were indicative of disturbed parent-child relationships.

Reading Disability. By school age the language disorder syndromes have a more widespread manifestation because by this time the child is expected to acquire the secondary forms of language, namely reading and writing, and, as pointed out, because the adjustment to school life is the next big step in the psychological or emotional weaning of the child from the mother. Unfortunately there seem to be ever-increasing numbers of children who fail to learn to read by any of the usual methods of instruction. Schools are continually confronted with the problems of the reading disability case, the poor learner of normal mentality, the mirror reader, and the mirror writer; and remedial programs are having to be provided throughout educational systems to try to meet the problems presented. The approach through remedial methods and techniques is often discouraging until the emotional difficulty is overcome (McCarthy, 1949*a*).

The argument is often presented that the children who suffer from reading disability problems and other language disorder syndromes are disciplinary problems because of school failure and discouragement (Preston, 1940). This is undoubtedly true, but it is often only a secondary factor. The question is seldom asked why these children failed to learn to read in the first place. Studies of their preschool histories usually reveal that they presented personality problems before the attempt to teach them to read. Delinquents as a group are usually very much retarded in reading and related skills, and, as Gates (1936), Witty and Skinner (1939), and Rogers (1942) have pointed out, children who cannot read rarely make a constructive adjustment.

McCarthy (1947, 1952*b* and *c*) as a result of clinical treatment of approximately 50 cases of language disorder, identified two behavior syndromes usually found among poor readers. One group manifested an aggressive personality syndrome which probably represents the older "protest child" mentioned by Allen (1947) at the preschool level and the delinquent nonreaders at higher age levels. The other group manifested a submissive syndrome of infantile behavior. In tracing the aggressive syndrome McCarthy found that it was usually associated with marked parental rejection of the child, harsh disciplinary methods, and unfavorable comparisons with siblings. The submissive group, on the other hand, seemed to be composed of those who were at least superficially, severely overprotected by their parents. This syndrome seems to be associated also with bad health histories, undue concern about health, and a variety of psychosomatic complaints (Despert, 1946*b*; Krugman, 1946). These children seem to get little expression of real love and affection from their parents except when they are sick, and the parents then manifest undue concern. The basic dynamism seems traceable to emotional insecurity stemming from unwholesome parental attitudes of rejection and overprotection (often inverted rejection due to guilt feelings). The submissive child with overprotective parents seems to be more amenable to psychotherapy and remedial work than the aggressive one and is more likely to be found in a remedial program. The really overprotective mother can be helped to show her love more wisely and to release the child for normal growth without arousing guilt feelings, and the immature child can be helped to grow, whereas it is difficult to make the aggressive child suffi-

ciently secure for learning to progress if there is no basic parental love on which to build.

Sobel (1948) reports that work with children having school difficulties invariably reveals "related if not causative emotional factors" which are often secondary to early warping experiences with significant adults. This ties in well with the study by Milner (1951) cited in the section on the effects of the environment (p. 588).

Stewart (1950) studied 30 bright children from 8 to 12 years. They were divided into contrasting groups on the basis of reading achievement, but the groups were similar in age, intelligence, grade level, and socio-economic background. He found no *single* trait characteristic of all inferior readers or all superior readers. He admits, however, that the parents of many of the inferior readers are "more indulgent, overprotective, and capricious than they are rejecting." This study is obscured by the fact that the control group of good readers was also drawn from the clinic files of maladjusted children who did not happen to show the nonreading symptom as part of their clinical syndromes. It was also handicapped by the search for a single trait rather than for one or more syndromes such as McCarthy (1947) noted.

Carefully matched groups of over 200 "problem readers" and "nonproblem readers" in the parochial schools of Cleveland were studied by Sister Mary Vera (1942). Using the California Test of Personality she found that the "problem readers" had poorer personality adjustment manifesting significantly greater feelings of inferiority, poorer school relations, and greater withdrawal tendencies. This particular group was not characterized by greater neuroticism or by antisocial trends as measured with the group pencil-and-paper test employed. One cannot help wondering, however, how valid are the personality measures obtained when such an instrument is given to the more seriously retarded of the "problem reader" group.

Missildine (1946) studied 30 children with reading disabilities and found that 20 came from homes where the mothers were overtly hostile or of a coercive, perfectionist nature. Only 2 in his group were overprotected. Nearly all his cases harbored severe affective disturbances involving some member or members of their families. He also found the contrasting syndromes, however, for some were described as "restless, indifferent, happy-go-lucky" whereas others were "crushed, unhappy, and inadequate." This author concludes that children who do not respond readily to specific remedial techniques should have a psychiatric examination and that real harm may result if the reading disability is regarded as the primary issue and the basic affective disturbances go untreated. Unfortunately, however, many psychiatrists seize upon the reading failure and are concerned only with the secondary symptoms following prolonged reading failure (Robinson, 1946).

Nondirective therapy was employed by Axline (1947) with 37 second graders who were selected as seriously maladjusted in reading at the end of the first semester. Every child was found to have a serious problem of one kind or another which created anxiety. No remedial instruction was given in reading, but the children were made to feel secure in the classroom situation and were encouraged to talk out their problems while painting or engaging in other creative work. Marked gains in all measures of reading achievement occurred for nearly every child after 3½ months of such therapy. Similar results were obtained by Bills (1950) with 8 retarded readers who received play therapy. The implications of such studies for teaching are indeed challenging.

A very significant evaluation of a therapeutic program was published by Redmont (1948) in which he studied the intensive 6-week summer remedial reading program at Pennsylvania State College. Twenty-four severe reading disability cases were in residence, and each was assigned to a student tutor. Blind Rorschach tests were given to the children and to their tutors before and after the therapy. The nonreading children were insecure, withdrawing, anxious, and rigid, similar to McCarthy's (1947) submissive syndrome. The most striking and probably the most significant finding in Redmount's study was that there was a positive relationship between the quality of the personality organization of the tutor and the amount of improvement in the child in 70 per cent of the cases. The better the teacher adjustment as revealed by the Rorschach, the greater the likelihood of improvement in the child. Although good personality adjustment of the teacher was no guarantee of improvement in the child, teacher maladjustment was definitely associated with adverse or indifferent results for the children in both reading and personality adjustment.

If this emotional insecurity explanation of language disorder syndromes is correct, it is not surprising that there are currently such large numbers of children manifesting basic learning difficulties, for the schools of today are populated entirely with children who have known only depression, war, and post-war years with their accompanying tensions, deprivations, and frustrations exaggerating the insecurity of both adults and children and making it more and more difficult for adults to want, welcome, love, and nurture children in wholesome patterns of family life.

The study of speech in relation to personality has also yielded some interesting trends in the clinical literature on older subjects and adults. There is an increasing recognition among psychologists not only of the importance of language and speech in themselves, as communication, and for intellectual growth and experience but also of the fact that *how* a person speaks and expresses himself in writing is often as important or perhaps more significant for indicating personality adjustment than *what* is said (Lloyd, 1941; Feldman, 1948; Freestone, 1948; and Buxbaum, 1949). Analysis of verbal responses to projective techniques and of sentence completion and association tests have contributed to this trend, for, as Breckenridge and Vincent (1949) state, speech is "a thermometer of the emotions." Gunderson (1942) did an experiment with young school children asking them to name "pretty" words or "kitchen" words, etc., and concluded that for young children words have associations rather than generalized meanings. Skinner (1936) has described the verbal summator which has possibilities as a verbal projective technique, and Sanford (1942) conducted an intensive analysis of the samples of the speech of 2 adults by means of 234 "mechanical," grammatical, "psychogrammatical," and lexical categories. Rostand (1950) has written on grammar and affectivity, and Templin (1938) reported a study of the relationship between aggressiveness and various types of speech defective adults.

There has been a vast expansion since 1944 in the field of semantics which it is impossible to evaluate here. Readers who are interested in this aspect of the problem of language are referred particularly to Walpole (1941) *Semantics*, Johnson (1946) *People in Quandaries*, Seegers (1943), Murray (1941), and Rapaport (1952). Seegers (1943) brings out that as civilization has grown we have complicated communication and increased our dependence

on symbols without being sure we know what those symbols mean and that we often forget that two people may use the same word with entirely different meanings. Heinemann (1949) described a homonym test which differentiated between equated delinquent and nondelinquent boys. One outstandingly good item involved association to the homonym "no" "know," the delinquent boys giving associations to the former meaning much more frequently than the normal boys, who tended to associate with the "know" meanings.

Newman (1939) presented case material which shows the affective implications of many of the phenomena of speech, yet he pointed out that, in spite of the clear demonstration of the importance of the affective aspects, "the dogma that the function of language is intellectual and collective still persists." Murray's (1941) brief article harmonized these aspects of language rather well at the same time stressing the importance of language for the betterment of human relations. Although he considered that the function of speech is to facilitate the meeting of ideas and purposes as related to facts and reality, he emphasized that "a corporate part of this process is an increased warmth in the human relations. Security and confidence take the place of fear and anxiety; good fellowship and affection take the place of anger and hostility; respect, mutual support, and cooperation take the place of envy, jealousy, withdrawal, and disruption." Murray also said that any remaining infantilism or residue of childhood egocentrism may come out in speech to mar human relations. He even went so far as to state that "contributing to every breakdown in human relations has been unmeasured poor speech—speech reflecting the symptoms of immaturity." He considers that, as the semanticists constantly emphasize, there is a large proportion of the population who respond to words as if they were the realities instead of mere symbols of them, and these semantic difficulties permit the feelings rather than the intellect to dominate much of human behavior.

THE ENVIRONMENT AND MENTAL DEVELOPMENT

Harold E. Jones

The Nature of Mental Ability

The studies reported in this chapter are based primarily upon results from the use of standard intelligence tests. Although the deficiencies of our current tests as scientific instruments have been frequently noted (see, for example, Thomas, 1942; Loevinger, 1947), up to the present time we have devised no better way to observe the influence of environment on mental ability.

A mental test has not one but many levels of validity, according to the characteristics of the group to which it is applied; the validity may become very low when it is used with subjects who fall outside a specific cultural or educational range. In such cases it is especially clear, as Stoddard (1951) has pointed out, that intelligence test scores represent not a maximum but a minimum estimate of a child's intelligence. This is also implied in Hebb's (1949) concept of two kinds of intelligence: the innate potential determined by brain structure and neural metabolism, and the average level of performance which has been built up through previous learning. The two kinds of intelligence show varying degrees of correspondence; it is chiefly the second kind which, from an empirical and functional point of view, is represented in mental tests.

On the basis of perceptual theory it has been argued (Combs, 1952) that we tend to underestimate the margin of difference between performance and capacity. Self concepts of capacity, and teachers' and parents' estimates, often tend to achieve a static and mutually verifying expression in behavior. This may be associated with a high *predictive* validity of mental tests, but it leaves us uncertain of what a person's attainments might be under different demands, with different goals, and with enriched perceptual fields.

If there is a wide margin of error in inferring capacity from mental test performance on the basis of any single score, there must be similar error in defining the extent to which environmental variations have affected this score. Nevertheless, for massed data as well as for cumulative records of the same individuals an ingenious variety of methods can be used to illuminate the complex problems of environmental influence.

Individual differences in mental ability have been discussed by E. L. Thorndike *et al.* (1927) as involving three principal aspects: *level, range,* and *speed.* The level of ability that a person reaches is defined by the difficulty of mental tasks which he can perform; the range, or breadth, of ability is defined by the number of different tasks which he can perform at various levels. Speed, or rate of work, is also a factor in mental efficiency, although probably of less direct importance than the other aspects of ability. A useful line of inquiry would be the study of the effects of environment upon specific aspects of intelligence, as represented, for example, in level, range, or speed scores, or in scores from

multiple-aptitude tests, or in component scores derived from factor analysis. In this field, however, few attempts have been made to deal analytically with constituent factors; the principal studies are limited chiefly to general measures of mental function. These general measures, concerned with the capacity to utilize symbols and to acquire *intellective* adaptations, are ordinarily expressed in terms of a composite score, such as the IQ.

The Nature of Environmental Influences

The individual organism comes into being and develops in a maternal environment which supplies nourishment and other biological needs and also provides both protective shielding and some opportunity for functional stimulation. These environmental supports are essential if the organism is to grow, or even to survive. In this connection, no one asks the question, "Which is more important, nature or nurture?" for both are obviously indispensable. Structural and, ultimately, functional development is an outcome of (1) the interaction of genes with their intracellular environment, (2) the interaction of cells, and (3) the interaction of the organism with its surroundings. The hereditary "determiners" or genes cannot function unless the various aspects of the environment play their necessary rôles. On the other hand, the influence of environmental factors is subject to very definite limitations, for, to cite an extreme example, no normal environmental force can change an individual with chromosomes of one species into an individual with the characteristics of a different species. Developmental differences large enough to distinguish species are thus hereditary effects which extrinsic factors cannot (in any given individual) wholly simulate or counteract.

The problem of environmental influences becomes less a matter of general principles, and more a matter for specific analysis, when we turn our attention from the growth of the single individual to the factors which affect individual differences. In this area we may with reason ask, "Which is more important, nature or nurture?" If, however, we attempt to reply to the question (as applied to mental abilities) with an over-all generalization we shall immediately find ourselves in logical difficulties. Suppose that we address ourselves to the task of determining the causes of illiteracy. Haldane (1938) has pointed out that, among adults in England under 40 years of age, illiteracy is probably most often due either to mental deficiency or to blindness. But among adults in Elizabethan England, or in India today, illiteracy may be attributed primarily to the lack of educational opportunity

Thus we are led to say that hereditary and environmental influences on intelligence do not constitute a single problem for which a single quantitative answer can be found, but a family of problems, each with its own relatively complicated answer.

Quantitative Approaches

Hogben (1933), in a book rich with illuminating examples of the interaction of heredity and environment, points out that statistical methods are useful in detecting the *presence* of either sort of influence, but he questions the meaningfulness of attempts to *quantify* the relative influence of genetic and nongenetic causes of variations. "No statement about a genetic difference has any scientific meaning unless it includes or implies a specification of the environment in which it manifests itself in a particular manner" (p. 14).

Several well-known investigations, however, have had a more ambitious aim.

Methods designed to specify quite exactly the proportional influence of causal factors have been applied to studies of foster children by Burks (1928*b*), Leahy (1935), and Wallis (1936), and to studies of twins by Newman, Freeman, and Holzinger (1937). Leahy's computation gave the home environment the very meager credit of determining not more than 4 per cent of the variance in mental ability. A more liberal estimate by Burks was 17 per cent. Wright (1931) and Shuttleworth (1935) have reworked the data of these investigators, applying statistical corrections which give results differing somewhat from each other and from the original studies.

In an early study Fisher (1918) developed statistical techniques by means of which, granted the applicability of certain assumptions, "it is possible to calculate the numerical influence not only of dominance but of the total genetic and nongenetic causes of variability" (p. 433). These methods were used by Conrad and Jones (1940) to test hypotheses concerning the nature of hereditary transmission of intelligence but not for the purpose of calculating the numerical influence of nature and nurture.

One of the earliest and most widely criticized quantitative statements was Burt's (1921) regression equation for predicting Binet mental age from schooling, "reasoning ability," and chronological age. Both Holzinger and Freeman (1925) and Burks (1928*a*) have demonstrated the error in direct inference from regression coefficients to proportional contributions, and Loevinger (1943), in an able critique, has gone considerably further in questioning the nature-nurture statistics based on the assumption of additive factors.

For our present purpose, it is chiefly important that we understand the following limiting conditions of work in this area: (1) The proportional contribution of heredity and environment does not refer to the make-up of individual IQ's or to the general level of intelligence, but either to average effects upon individual differences or to differences between groups. (2) Existing studies are based on fallible and incomplete measures both of intelligence and of the environment; this fact should be remembered when the data are being manipulated to yield an apparently highly exact result. (3) Even if it is ever logically feasible to seek a single value for the effect of environment, the particular value reported in a given study may not apply in samples involving (*a*) a different environmental level, (*b*) a different hereditary selection, (*c*) a change in variability of either of the above factors, or (*d*) a change in any special conditions which may affect the interaction of these factors.

The remainder of this discussion will be concerned with results from several different types of approach. Each of these contributes in its own way to our understanding of what environment can and cannot do; each provides some clue as to the relative importance of environmental factors under specified circumstances. For the time being, however, we must think of these results as rough approximations rather than as precise and final statements.

Mental Growth Curves

One approach to the analysis of environmental influences is based on the study of mental growth curves. If the intelligence of children (relative to age) were generally found to be constant throughout childhood, few questions would be raised about the rôle of differential environmental factors, except perhaps as these may be assumed to operate in the prenatal period or in early infancy.

If, on the other hand, mental development of individuals is marked by variable or systematic changes (that is, by fluctuations or age trends, relative to the group), the extent of possible environmental influence becomes an issue of some interest. Such changes, if registered, are not necessarily due to the environment or subject to educational controls. They may be attributable to errors of measurement, to normative defects of the test, or to changes in the composition of the test, or of intelligence, at different levels. They may be due to variations in the temporary state of the subject, dependent upon physical condition, rapport, motivation, or disturbing emotional factors. They may express a neurophysiological growth pattern differing in rate of evolution for different children; such maturational changes are well established in the patterns of physical growth for various organs and for the body as a whole. Any of these factors, in any combination, may conceivably operate to alter the apparent or actual course of mental development. One of our first problems, therefore, is to ascertain the facts as to the regularity of growth, and then to attempt an assessment of the various agencies which may be responsible for irregular or unpredicted variations.

Growth in Terms of Averages. An implicit belief in the lawfulness and uniformity of mental development has at times accompanied the acceptance of IQ and mental age as indices of intelligence most convenient for general use. For any group of children with an average IQ of 100 at age 10, the average will remain substantially the same at 11 and at 12 years if we allow for slight practice effects which tend to increase the IQ, and slight standardization errors which in our present instruments sometimes tend to decrease it. This constancy, however, is the necessary outcome of a scale conceived in terms of mental age.[1] In such a scale, a gain of 1 year in mental age is that increment which occurs (on the average) in 1 chronological year, and the average rate of development during childhood must appear to be constant since it is expressed in terms of constant and equal increments of mental age. It is, of course, now generally understood that such a picture of growth is merely a convenient artifact—convenient largely because of its adaptability for use in connection with an educational grade system based on chronological age.

One approach to the problem of mental growth pattern is through determining the overlapping of distributions of scores at successive ages. In a somewhat selected group, Bayley (1933) has shown that in early childhood overlapping is very small even when retests are given at short intervals. Thus, at 5 months no cases in her sample equal or exceed the average mental score attained at 6 months. At 5 years, on the other hand, evidence of age changes can hardly be seen within a period so short as a month; the distributions for tests given at monthly intervals overlap to such an extent that they are almost identical.

When raw scores are transformed into "absolute" measures, it is possible to compare the data from different scales by computing mean scores at each age as a percentage of the adult mean. This is illustrated in Figure 1, from Jones and Conrad (1944). The three studies represented involve, respectively, a clinic sample from Illinois, tested by the 1916 Stanford-Binet (average IQ approximately 80); the chil-

1 Heinis (1926) derived a logarithmic formula for mental growth and proposed the use of a "personal constant," based on the logarithmic equation, to avoid alleged arbitrary features on the mental age scale. This proposal has been analyzed in a definitive discussion by Bradway and Hoffeditz (1937). Gesell (1928), in plotting developmental age, has also used a logarithmic method to express the relative rate of what is "arithmetically implicit" in an age scale.

dren of the Harvard Growth Study, tested longitudinally with a variety of group tests, and a cross-sectional public school sample used in standardizing a group mental scale. The almost identical parameters of mental growth exhibited in different samples and through different tests suggests a lawful pattern of development in which the individual's response to his environment is influenced by innate or organic limitations.

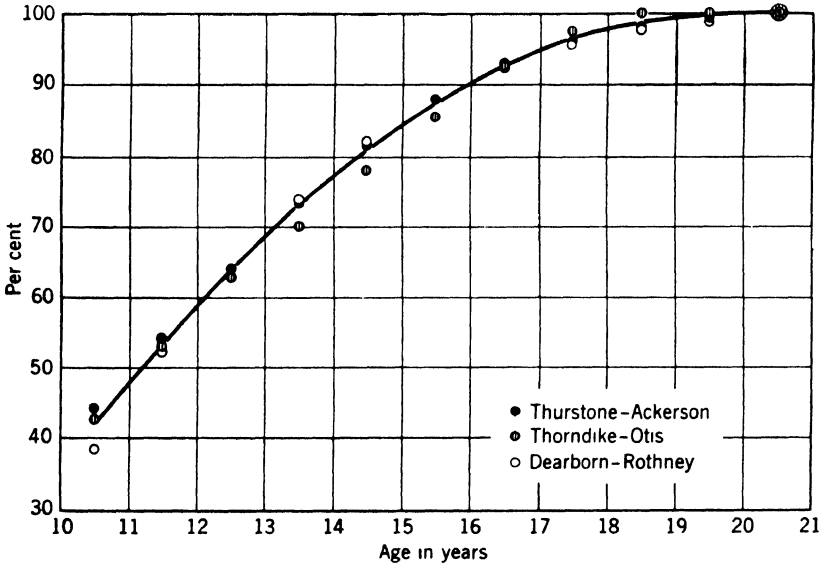

FIGURE 1. Mental growth curves in terms of percentage of mature status. (After Jones and Conrad, 1944, p. 153.) Reproduced by permission of the National Society for the Study of Education.

A theory of environmental influence must be able to deal with the fact that in terms of units other than mental age the growth of intelligence is not linear but with increasing age exhibits a decreasing rate of change. If environment were the predominant factor in mental growth, we might reasonably expect a positive rather than a negative acceleration in later childhood and adolescence, since individual development involves a multiplication of environmental contacts and also an increasing scope of response to the environment.

The phenomena of differential mental growth (Conrad, Freeman, and Jones, 1944) are also of interest in this connection. Different mental functions exhibit differences in the rate, peak, and total magnitude of growth and in the pattern of decline (Jones and Kaplan, 1945) after the peak is reached. Cumulative environmental effects are partly responsible for these differences, as expressed for example in the long-continued growth of functions based on information and on size of vocabulary. But in general the varying patterns admit of no easy explanation in terms of extrinsic factors.

The foregoing may suggest some of the limitations in the portrayal of mental growth in Figure 1. The analysis of overlapping distributions in successive ages, and the techniques for transforming raw scores into absolute scores, appear to justify confidence in the general form of the curve as shown. But it is well known that the same or similar scores may be obtained through

different patterns of item performance. Jones (1931) showed that children and adults matched for mental age perform very differently on various items of the Stanford-Binet.[1] The differential difficulty values of items, in relation to age, signifies that the growth of total scores in an intelligence test involves not merely quantitative changes but also changes in composition, i.e., in the relative weighting of subscores.

IQ Constancy. Another source of evidence concerning variability in growth is based on the study of changes in individual scores. Although average IQ's maintain approximate constancy by force of standardization, individual IQ's are under no such requirement. The common finding that the probable error of an IQ (Stanford-Binet) is approximately 5 points appears reassuring from the point of view of those who wish to classify children on the basis of a single test, but when we consider this statement we should also bear in mind the fact that with a probable error of 5 points (if differences are normally distributed) one child in five may deviate as much as 10 points in a retest.[2] Such a difference is of sufficient practical importance to justify an inquiry into its possible causes.

As would be expected, greater average shifts in IQ are found over longer periods. Bradway (1944), for example, reported results with 138 children who were tested in the preschool period with both forms of the 1937 Stanford-Binet and retested 10 years later with Form L; the mean IQ changes were from 10 to 13 points in different subgroups.

Predictive Correlations. IQ differences on retests may be influenced not merely by changes within the group but also by upward or downward trends of the group as a whole; such trends could be due to practice effects, to errors in standardization, or to other factors which will be discussed in a later section. If our interest is primarily in the constancy with which individuals maintain their relative rate of mental growth, the most straightforward index is the coefficient of correlation between mental status on two different occasions.

Various reviews[3] have shown that retest correlations are rarely as high as .95, and most commonly fall between .80 and .90. Reports on this subject, however, are often difficult to interpret, since they have usually included cases at many different age levels and with different test intervals. R. L. Thorndike (1933) has shown that on an immediate retest the most probable correlation is .89. This value falls to .87 at 10 months, .81 at 30 months, .70 at 60 months. It is recognized, however, that age as well as test interval may influence the results. If the first test is given as late as the tenth year of age, prediction may be better than Thorndike's estimate; thus, in a study by Byrns and Henmon (1935), 250 college students were located who had been tested 8 to 10 years previously. For this selected group the initial IQ (National Intelligence Test) correlated .81 with a group test score obtained in college. On the other hand, if the initial test is given before 2 years of age, correlations with later status may approach zero.

1 See also Laycock and Clark (1942). Kounin (1943) has proposed that the difference in performance between younger and older persons of the same mental age is due to an increase in "intrapersonal rigidity." This is not supported by Thompson and Magaret (1947), who find that the chief source of handicap for the older subjects is in the degree to which items are saturated with the general intelligence factor.

2 The probable error of the IQ is not a fixed value but may vary according to the age, intelligence level, and test experience of the subject. In the Terman and Merrill (1937) standardization, the average difference between IQ's on Forms M and L was 5.9 for cases with IQ of 130 or above, decreasing to 2.5 for cases with IQ below 70.

3 The best of these are by R. L. Thorndike (1933, 1940). For longer intervals Bradway (1944) summarized results from eight studies involving constancy correlations between IQ's in the preschool ages and in later childhood.

Retest correlations at 3-year intervals are given in Table 1 from two longitudinal studies. The first of these was based on

TABLE 1

RETEST CORRELATIONS AT 3-YEAR INTERVALS

	Ebert and Simmons (1945)	*Honzik et al. (1948)*
	r	*r*
Age 2 by 5		.32 ± .06 PE
Age 3 by 6	.56 ± .04 PE	.57 ± .03
Age 4 by 7	.55 ± .04	.59 ± .03
Age 5 by 8	.70 ± .03	.70 ± .02
Age 7 by 10	.76 ± .02	.78 ± .02
Age 9 by 12 or 13		.85 ± .01

181 children in Cleveland, Ohio; the second, on 113 children at age 2 and on approximately 200 at subsequent ages, in Berkeley, California. Lower predictive coefficients are shown in the earlier years. Going back to still younger ages, the evidence from tests at around 1 year indicates that, when pathological retardates are excluded, later mental status cannot be predicted from existing mental scales. Moreover, we seem to have little prospect of significantly improving predictions from this age level through new items or item weightings. This is not due to lack of reliability in the early tests. With items involving problem solving, imitation, memory, and other forms of adaptive reaction, Bayley (1940*a*) obtained a reliability coefficient of .94 by combining scores obtained at 7, 8, and 9 months; these measures correlated .81 with mental scores 3 months later, but only .39 with scores at around 21 months, .22 with scores at around 30 months, and practically zero with all later measurements to 6 years and beyond. Although other studies have not covered this age range, similar results have in general been reported between mental tests given at 1 year and 3 to 4 years later.[1]

From such results, it might be expected that, in the case of mental scores obtained still earlier in infancy, the correlations with later status would also vary around zero. It is interesting to note, however, that Furfey and Muehlenbein (1932), L. D. Anderson (1939), and Bayley (1940*a*) all report negative correlations between test scores obtained at 6 months or earlier and test scores obtained at 4 years or later. Although the prediction indices found in these studies are not statistically significant, they are sufficiently consistent to suggest that in a normal sample early status and later growth rates may be negatively related. Speculation on this point may well be reserved until the findings are confirmed by other studies. Of possible relevance is the investigation by Dubnoff (1938), who tested 489 infants in Kazan, U.S.S.R., by the California First Year Mental Scale. Approximately one-third of the group was of Tatar extraction; one-half was tested in homes, and one-half (factory workers' children) in crèches or factory nurseries. Scale scores during the first year favor the Kazan group; in terms of the variability of the Kazan group, the difference is about 2 SD at 1 month. From the fourth to the eighth month the difference drops to about 1 SD, and by the tenth month the averages become approximately equal in the two groups. It could be contended that the relative gain of the California group from 1 to 10 months is due in part to a more favorable environment with regard to medical care, diet, sunlight, and to a more intelligent régime of care by the mother. Dubnoff comments:

1 For 91 cases, L. D. Anderson (1939) reported a correlation of .06 between Gesell scores at 1 year and the Stanford-Binet at 5 years. Furfey and Muehlenbein (1932) found a correlation of −.20 between mental scores at 12 months on the Linfert-Hierholzer scale and Stanford-Binet IQ's given at an average of 4.8 years. For 150 cases, Wittenborn (1953) correlated a general maturity quotient (Gesell), obtained in infancy, with the Stanford-Binet and the Arthur Performance Scale given from 4 to 7 years later; the coefficients were .05 and 12 respectively.

> Due to the cold winters, the Kazan child is heavily clothed, and often wrapped in blankets which prevent freedom of movement. Except for about 2 months of the year he is never exposed to sunlight. Rickets is prevalent. . . . The level of education of the parents is very markedly lower than that of the California sample [p. 70].

Environmental factors, however, cannot be adduced to explain the initial superiority of the Kazan infants. Dubnoff's work, together with other related studies, may lead to the speculative suggestion that between natio-racial groups, as within a given group, a slight tendency exists for early precocity to be associated with a slower mental growth at later ages and perhaps with a lower average intelligence level at maturity. A parallel situation may be noted when we compare different animal species; among the primates, for example, the maturity of performance at a given age in infancy can be used inversely to predict the general level of adaptive ability that will be attained at the end of the growth span. Another interpretation, applicable to human infants, is in terms of the greater amount of social stimulation received by infants living in crowded homes; Gilliland (1949) believed that this might account for results in three studies in which he found slightly higher scores for Negro than for white infants, but it is still an open question as to whether, within a normal range, the mental growth patterns are significantly modified by such factors.

To summarize the foregoing, we have noted an apparent slight tendency for mental scores in early infancy to be negatively correlated with mental scores at 4 years or later. At 12 months of age the correlation is close to zero.[1] Beyond that point, however, a positive relationship emerges. Figure 2 shows the smoothed-curve relationship, in terms of the z transformation, between intelligence scores at 18 years and at successive earlier years. The upper curve is based on Bayley's (1949) data from the Berkeley Growth Study (N = 40–50), the lower curve on another longitudinal study in Berkeley (N = 140–153) reported by Honzik, Macfarlane, and Allen (1948). Both investigations used the Wechsler-Bellevue at age 18 and a variety of individual tests at earlier ages (chiefly the Stanford-Binet, and below age 6 the California Preschool Schedules). In each of the groups, it is apparent that at as early as 2 years of age individual differences are beginning to appear which carry forward to some extent into later childhood. The rate of increase in predictive power is more rapid in the preschool period than later (differences in the level of the two curves are due primarily to differences in variability of the two samples).

The Age Ratio. J. E. Anderson (1940) has pointed out that as we go up the age scale the prediction of later from earlier status involves an increasing proportion of similar elements. The 10-year tests are in content more similar to the 9- than to the 8-year tests. Moreover, the cumulative composites of performance which are represented in test scores are more similar between adjacent than between separated age levels. They become increasingly similar for adjacent levels as maturity is approached, and the increment from 1 year to another has a proportionately smaller effect upon total scores.

Figure 2 is, of course, based upon actual scores (point scores or mental ages). An individual's performance changes from year to year as a result of successive increments of growth-and-learning, as well as from er-

[1] Apparently the only instance of a higher correlation is in a small sample of lower middle class children studied by Cattell (1940). An r of .18 between scores at 9 months and Stanford-Binet at 3 years, and of .57 between 12 months and 3 years was reported.

ror factors. What would be found if we were to set up an artificial series in which the increments for each year were cumulated at random? Thus, at 3 years individual A would be given an arbitrary measure consisting of his own score at 2 years plus B's increment from 2 to 3 years. The resulting 3-year score could then be added to C's actual increment from 3 to 4 years, in order to obtain an arbitrary 4-year score for A. Such a series (as Anderson has shown by cumulating random numbers) would neecssarily result in a curve of relationship somewhat similar to that actually obtained in Figure 2. Several factors might operate to produce differences in the two curves. For example, if actual mental growth involves greater annual increments for those who already have higher status, then the correlation curve for actual scores, other things being equal, will be higher than that based on arbitrary cumulations. But in any event we must expect that during the first few years of life the predictive power of our tests will be proportionate to the age of testing. It will also be inversely proportionate to the length of the interval over which prediction is attempted. Honzik

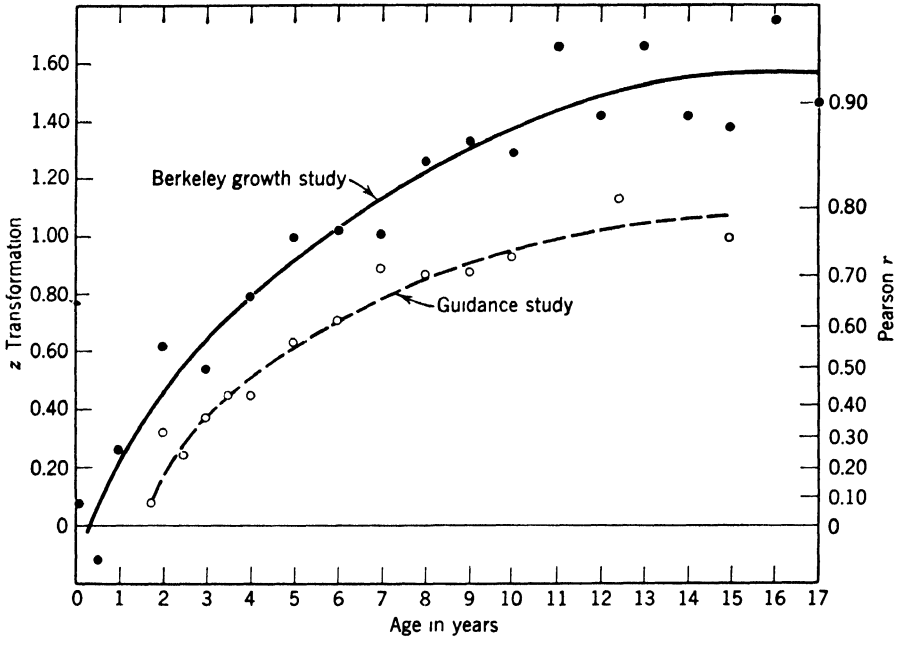

FIGURE 2. Correlations of intelligence scores at 18 years with scores at successive earlier ages

(1938) has proposed the concept of the *Age Ratio*

$$\left(\frac{\text{CA at Test 1}}{\text{CA at Test 2}}\right)$$

to express both these factors. The Age Ratio shows a high positive correlation with retest coefficients during the first 6 or 8 years; in later years retest coefficients tend toward greater uniformity even with wide variations in the age span.

Two implications of the Age Ratio concept may now be pointed out. If hereditary components in mental ability are more fully manifested at maturity than at earlier ages, children whose eventual status is to

be either high or low will tend to fall nearer the mean in earlier tests and in later tests will gradually approximate their final position.[1]

Individual Growth Curves. The foregoing argument should also be considered in relation to statements about the "plasticity" of early childhood (susceptibility to environmental influences). Figure 3 illustrates an individual growth curve of a fairly typical or normal form The curve is based on sigma or standard scores and is smoothed, the actual points also being shown. It may be noted that this is a relative, not an absolute, growth curve. A horizontal line indicates that the child is maintaining his position in the group; an ascending or descending line indicates that he is growing faster or slower than the group average.

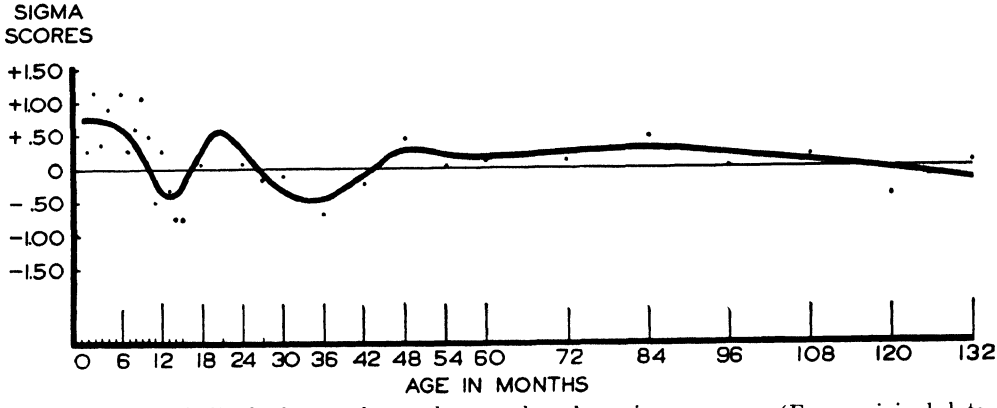

FIGURE 3. An individual mental growth curve based on sigma scores. (From original data, Berkeley Growth Study.)

The mental growth [2] of the individual represented in Figure 3 is marked by some irregularities during the first 4 years. At 4, however, he achieves a fairly even, stable position which is maintained with only very minor changes to 10 years. Such a growth pattern has been variously interpreted as due to the changing nature of early tests, to a fundamental instability in early growth (related to physiological instability), and to a sensitive response to environmental changes Although these factors cannot be wholly excluded, it may be pointed out that, in terms of the previous analysis of the Age Ratio, curves of this general type would be expected to be fairly common even in a constant environment or in a function insensitive to differential environmental factors. We should be cautious in attributing greater retest changes in early childhood to some inherent factor of modifiability if it is possible that they are chiefly

1 This appears to be illustrated in a study by P. Cattell (1937), who made ability classifications of children on the basis of an average of initial tests and retests (thus eliminating changes within extreme groups due to regression). Children of superior average ability tended to increase in IQ on the retest. Among mental defectives, on the other hand, Roberts, Norman, and Griffiths (1938) have reported an average downward shift of about 2 IQ points per year in the age range from 10 to 14 years. It is, of course, possible that this latter finding is associated with an earlier limit of growth in the feeble-minded. See also Sloan and Harmon (1947).

2 Standard score curves indicate changes in status, relative to the group, from one measurement to another. They do not provide a direct measure of growth, and, since they are usually based on unanalyzed composite scores, they do not permit inferences as to the composition or dynamics of growth. From this point of view, it may be more appropriate to speak of them as "status curves" than as growth curves.

due to a statistical factor, namely, to a relatively small proportion of similar elements in successive tests.

The growth stability manifested by the individual in Figure 3 is by no means found in all cases. Goodenough and Maurer (1942), in an able analysis of retest data from Minnesota studies, present a number of individual mental growth curves, some of

Case 553 is a boy whose mental test scores increased from a preschool sigma score of −2 to later sigma scores of +2.4 in spite of a bad physical history. He is small-statured, thin, with very poor musculature, and presents a history of early ear infections and chronic bronchitis from infancy, headaches (early glasses), stomach pains (appendectomy); he has had three operations and three serious accidents.

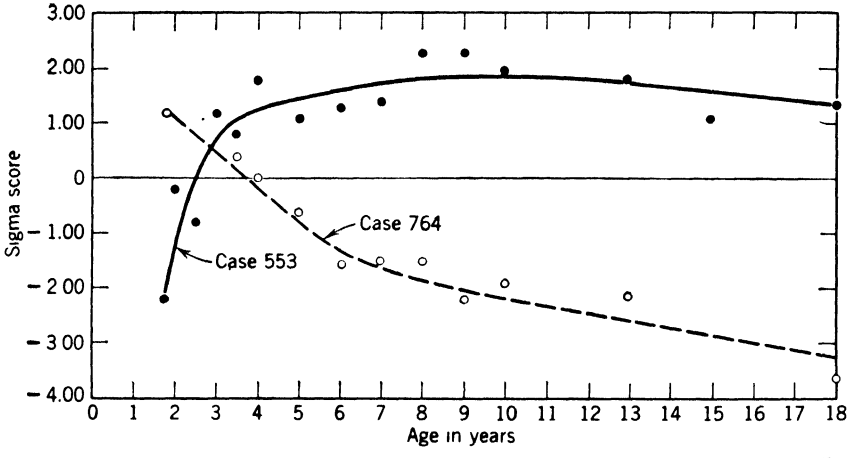

FIGURE 4. Individual mental growth curves: two contrasting cases. (After Honzik *et al.*) *Journal of Experimental Education.*

which exhibit IQ changes of 20 to 50 points in a span of 8 or 9 years. Unable to demonstrate associated environmental changes or cumulative environmental effects which might account for such extensive shifts in IQ, these writers are inclined to emphasize the rôle of inherent factors in determining mental growth patterns. In another longitudinal study covering a 16-year span Honzik, Macfarlane, and Allen (1948) analyzed IQ changes for varying intervals; between 6 and 18 years variations of 30 or more points occurred in 10 per cent of a sample of 222 Berkeley children. Two of these, a case showing large gains and a case showing large losses, are illustrated in Figure 4. A brief description of these cases follows:

Only one 6-month period in his life has been free of illness. In spite of a frail frame, which has suffered many serious indignities, an early strained family situation, and relatively low mental test scores in his early preschool years, his tested ability steadily increased until 9, from which time he has maintained high and fairly stable scores. His mother is a normal-school graduate; his father completed high school. His greatest security lies in his intellectual interests and achievements, but he has made good social adjustments and an amazingly good adjustment to his handicaps.

Case 764 is an example of a gradual lowering of IQ from 133 to 77 and of sigma scores from +1 to −3. She is an only child born when the mother was 44, the father 37. The estimated IQ of the mother

is 65 to 70. The father is a skilled mechanic. The parents went to school until age 14.

Obesity began in late preschool years and increased steadily until therapy was instituted at age 14. Weight was normal at 17. There were, however, no IQ variations in relation to these physical changes. She was always overindulged by the mother, who lived to feed her and keep her young and who was always complaining that her daughter never gave her enough affection.

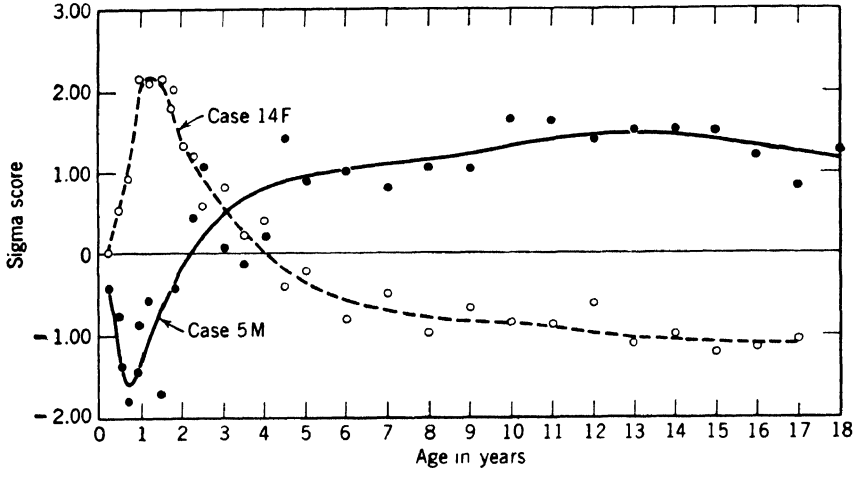

FIGURE 5. Individual mental growth curves: two contrasting cases. (From original data Berkeley Growth Study.)

Even more striking contrasts in growth pattern are illustrated in Figure 5, showing two cases from the Berkeley Growth Study.

Age trends of such magnitude may usually be expected not oftener than in 3 or 4 per cent of the cases in a normal sample. It is obvious that to a great extent they represent a genuine shift in abilities and are not an artifact of the measuring instruments. To interpret systematic changes of this nature as due to environmental factors raises the question, "What environmental factors?" The case histories have usually failed to disclose significant clues. It is equally hypothetical, however, to regard the trends as produced solely by intrinsic growth changes. They are discussed here not as providing conclusive evidence for one view or another but as illustrating the extremes (within normal samples) which must be taken into account in mental growth theory.

Group Constancy over Long Periods. The relative stability of the "average" individual is illustrated by the stability of groups in relative intelligence level. In a long-interval study concerned with IQ's in relation to later attainment, Embree (1948) found that the mean IQ in childhood of those later entering college was 118. The means for other groups were: college graduates, 123; those with advanced degrees, 126; honors graduates, 133; Phi Beta Kappa, 137.

The now rapidly developing field of gerontological research will eventually provide us with mental test data covering the whole span of life, and the current problems of development and environmental influence will then be seen in a much longer perspective. Already, however, we are beginning to get results from quite extended

programs. Terman and Oden (1947) reported a quarter-century follow-up of the Stanford study of gifted children, first tested in 1921. In various aspects of adult attainment the record of this group has not been disappointing. Originally selected as in the ninety-ninth percentile of mental ability, in the latest measurements they were estimated by R. L. Thorndike (1948*b*) as falling close to the ninety-sixth percentile of the general population; this is on the basis of an ingenious series of comparisons using as a reference the norms on a vocabulary test administered to a Gallup poll sample.

A Classification of Factors Influencing Changes in Test Scores

In order to assess the importance of extrinsic factors in mental growth, we should attempt to gain some conception of the range and magnitude of other influences which affect test scores. These were briefly indicated on page 632 and are here discussed in greater detail.

Changes in Test Composition. Changes due to the measurement of different abilities cannot be attributed to "chance" factors and yet are not true variations in the growth rate of any one function. For example, consider two children, one possessing unusual motor aptitudes but poor at verbal tasks, the other showing an opposite pattern. In the preschool years the first child may stand relatively high, but these positions may be reversed at later ages when intelligence tests become more verbal in content.

Variability Changes. Contrary to common belief, the variability of mental scores does not always show a regular increase with age but may exhibit cyclical changes. Bayley (1949) has summarized evidence from a number of studies in which variability tends to be greater between the ages of 10 and 12 years than either before or immediately after. She postulates that scores are relatively homogeneous in the early and also in the late stages of the development of a function and more dispersed during periods of rapid growth when individuals are at varying stages of maturity. Variability changes may, therefore, reflect test composition and the growth characteristics of component functions. The effects of these changes upon IQ will be especially marked for individuals toward the upper end of the IQ distribution.[1]

Changes in the Standardization Sample: Errors in Norms. A child whose IQ is constant in relation to a constant sample may exhibit an *apparent* variation if the standardization sample varies. Bayley (1949) has demonstrated this very clearly in comparing standard scores (in a longitudinal study) with test standardization IQ's. In individual cases the two sets of scores show discrepancies in trends; e.g., standard scores may remain approximately constant over parts of the age span in which the IQ's are increasing or decreasing.

Administrative Factors. "Error" factors in administration are of many sorts, pertaining to the test situation, test scoring, and the "personal equation" of different examiners. This last was apparently a negligible factor in studies by Goodenough (1928*a*) and Kawin (1934) but has been emphasized by P. Cattell (1937) in connection with the interpretation of mental test data from the Harvard Growth Study.

An experiment by Lantz (1945) indicates that the experience of failure tends to reduce scores and that, to a lesser degree, the

[1] The substitution of IQ equivalents (computed from the standard deviation) for the more usual IQ has often been suggested as a means of reducing apparent IQ changes, particularly when the retest involves a different test instrument. This will not, however, control IQ changes due to irregular age trends in variability unless the table of equivalents is adjusted to take account of this phenomenon.

experience of success leads to improved test performance. A possible implication is that test scores may be influenced to some extent by the examiner's attitude, according to his emphasis upon successful or unsuccessful aspects of a subject's responses. This is a complex matter, since learning experiments, such as those of Postman and Brown (1952), have shown that success and failure may affect performance not only directly but also indirectly through raising or lowering the aspiration levels. As might be expected, however, some subjects are much more vulnerable than others to effects of this nature; Mandler and Sarason (1952) demonstrated this when they classified subjects (college students) in high-anxiety and low-anxiety groups. On mental test items, the former were more variable, and more likely to be handicapped by knowledge of failure. Other experiments (see, for example, Beier, 1952) have shown that persons who are faced with a threatening situation may show measurable losses of flexibility and efficiency in mental performance, and that these effects may extend through various levels of functioning, from motor coordination to abstract thinking. Whether a mental test is regarded as a threat, a pleasurable challenge, or as something in between may depend upon many subtle factors in the management of the test situation.

Negativism. Among preschool children, even when testing conditions have secured generally good cooperation, negativistic responses may occur on individual items, with a small to large effect upon test scores.[1] Of several studies on this subject, Mayer's (1935) report on negativism encountered in the normative group of the Revised Stanford-Binet is probably most comparable with the ordinary test situation, since the effort was directed primarily toward getting the best possible response, with the study of negativistic responses only a secondary aim. Under good testing conditions and with highly trained examiners, the average number of negativistic responses per child ranged between 4 and 7, at ages 2½ to 4½ years. About 75 per cent of the cases in that age range gave at least 1 negativistic response in one of the two testing periods. At 2 years of age less than 25 per cent of the total negativism could be overcome by adroit management, but at 5½ years 90 per cent was overcome. This last level could be reached only with skilled examiners, however, and it is possible that at these ages slight differences in examining technique may be of critical importance to test scores.

Practice Effects. Practice and special training on the part of the subject may introduce spurious changes in mental test scores. According to Terman and Merrill (1937), the *average* gain from a first to a second test is, at different age levels, from 2 to 4 IQ points. Successive additional tests produce smaller gains. An experiment by McIntosh (1944), involving weekly retests for 6 weeks, showed no significant differences beyond the second test and no relation between the practice effect and ability level, although Peel (1951) in a single retest reported greater gains among brighter children. Analyzing results from several group tests, Adkins (1937), following Thorndike, has suggested that the improvement of scores on retest with the same examination may be largely a matter of increased speed on tasks previously solved. If this is so, work-limit tests would be of greater value than time-limit tests in longitudinal studies. The reader

1 Whereas error factors are frequently susceptible to environmental changes, and thus operate to reduce constancy coefficients, it may be noted that retest correlations may be spuriously raised if an error factor occurs systematically, for example, if children negativistic on one occasion tend also to be negativistic on succeeding tests, with similar effects upon scores.

interested in the earlier literature on practice effects and other conditions of testing will find a list of such studies in a review by R. L. Thorndike (1940).

Coaching. One special case of practice effect which deserves separate mention is the effect of coaching or specialized training.[1] Although our present studies in this field point to no very clear-cut conclusion, they suggest, as might be expected, that training is most effective when devoted to material similar to that in the test, and that the effects of training are, characteristically, to produce a temporary but not permanent rise in IQ. The application of these findings is greatest at the preschool ages, when test materials are relatively similar to everyday playthings. Earlier reports on the effects of coaching have been reviewed by Burks (1928c).

Intrinsic and Extrinsic Factors. All the factors discussed above may be regarded as involving errors in measurement. In addition to these error factors, mental growth may be conceived as involving actual changes, which have an origin in either intrinsic or extrinsic forces. Intrinsic alterations may arise from specific or general changes in the rate of growth. Relevant factors are the form of the growth curve, with reference to possible cyclical changes, and the age of completion of growth; a neurophysiological basis is implied.

Extrinsic influences on mental growth are roughly of two sorts, social and personal. The social factors include general environmental conditions, such as socio-economic factors in the home and neighborhood and specific educational régimes. What are here called personal factors are those nonability aspects of a person's make-up which actually affect the course of growth in ability rather than merely modify the score at a particular test period. The personal factors, if traumatic, such as physical diseases or extreme emotional episodes, may affect mental growth fairly directly. The more permanent aspects of physical and mental constitution may influence mental development by virtue of the fact that they comprise part of the equipment through which the individual assimilates the environment.

In evaluating extrinsic relationships, one of the first facts with which we are confronted is that in the preschool period the prediction of later intelligence can be improved by taking into account a measure of the home environment. The varying interpretations of this finding will be discussed in the ensuing section.

Relationships to Cultural-Economic Factors

Education of the Parents. Figure 6, from Bayley's (1953) data, shows at successive ages the relationship between mental scores of children and the education of their parents (in terms of the average years of schooling of father and mother). This is an admittedly imperfect index of the cultural status of the parents and an even less perfect index of the extent to which cultural factors actually enter into the child's environment. Nevertheless, if we compare Figures 6 and 2, we can see that the parents' education (obtained before the birth of the child) yields a much better prediction of the child's intelligence at 18 years than does the child's own test score at ages below 2 years. The relation of parents' education to the child's test score is negative in infancy (a fact consonant with the discussion on page 637). It increases sharply during the period from 1 to 2 years and thereafter shows only minor changes. Somewhat similar corre-

1 The studies of Greene (1928) and Casey, Davidson, and Harter (1928), reported in the *Twenty-seventh Yearbook of the National Society for the Study of Education*, are particularly relevant to this problem.

lation curves have been reported by Bayley and Jones (1937) for other measures of social and economic factors.[1]

For such findings the most obvious interpretation is that better-educated parents provide environments more stimulating to mental growth and that in general children tend to acquire the intellectual status characteristic of the environment to which they are exposed. Equally reasonable, however, is an interpretation based primarily on the maturing of hereditary potentialities. As a corollary to the discussion of the Age Ratio, the argument has been advanced that, as children approach their eventual intelligence level, they manifest the degree of relationship to parents' intelligence (or to other factors correlated with parents' intelligence) that would be expected on the basis of the inheritance of abilities.

The hypothesis that mental growth involves growth toward hereditary levels is supported by analogous findings from studies of physical growth. Bayley (1953) has reported, for successive ages in childhood, increasing correlations between the heights of boys and their fathers, and increasing correlations between body-build measures of daughters and their mothers. In the case of boys, a gradual upward trend in the correlation of the child's height with the midparent height, from .22 at 2 months to .50 at 5 years and .77 at 17 years, is probably only in small part explainable in terms of environmental factors.

The relationship curve as given in Figure 6 presents us with hypotheses rather than with definitive evidence of causal relationship. Each of these hypotheses may

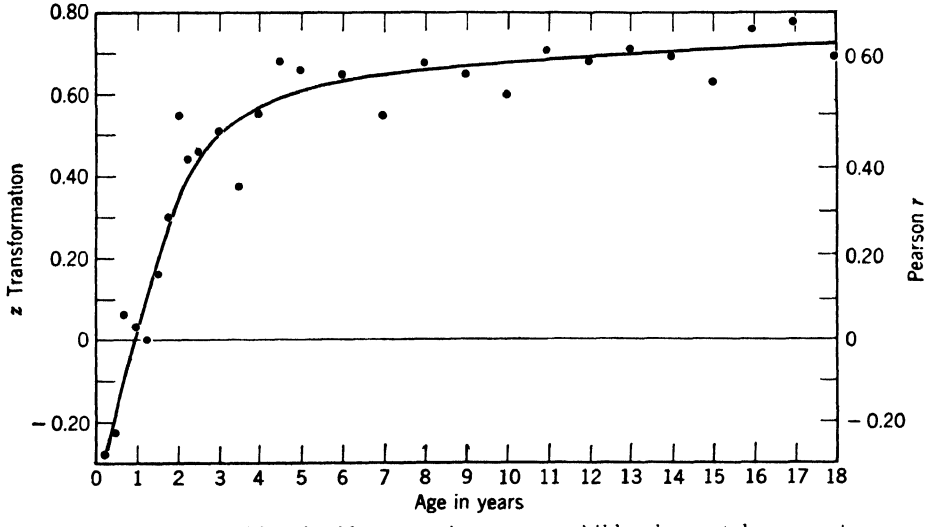

FIGURE 6. The relationship of midparent education to children's mental scores at successive ages. (After Bayley.) *Journal of Educational Psychology.*

1 Correlations with social status are usually lower than with measures of parent education. Stroud (1928) reported an r of .25 between IQ and tax assessments; Chapman and Wiggins (1925), an r of .32 between IQ and the Chapman-Sims Scale of Socio-Economic Status. These studies were based on large samples. When cultural items are included in a home rating or an environmental scale, Burks (1928*b*) found a correlation of .42, and Leahy (1935) one of .53, with intelligence measures. In interpreting correlational data in this field, attention must be given to the characteristics of the socio-economic measures, particularly with regard to skewness of the distributions.

serve as a partial explanation of the facts as obtained, but their relative cogency cannot be estimated unless we turn to evidence involving some form of experimental design. Such evidence will be presented in connection with a discussion of studies of foster children.

Perhaps the most elaborate study employing correlational methods is by Van Alstyne (1929), who examined the relationship between children's intelligence (Kuhlmann-Binet) and various factors in the home environment. The sample, consisting of seventy-five 3-year-old children, was drawn from very diverse environments in New York City, and the correlations may tend to be higher than in a more representative group. Table 2, showing r's and PE's, presents illustrative results from this study.

TABLE 2

THE MENTAL AGE OF CHILDREN AS RELATED TO ENVIRONMENTAL FACTORS

(From Van Alstyne [1929].)

Child's MA by:	r
Mother's education	.60 ± .05
Father's education	.51 ± .06
"Opportunity for use of constructive play materials"	.50 ± .06
"Number of hours adults spend daily with child"	.32 ± .07
"Number of playmates in home"	.16 ± .08
"Number of hours father reads to child"	.06 ± .08
Nutrition index	−.03 ± .08

In general, environmental factors that might reasonably be expected to have some bearing upon mental development yielded no higher correlations than those found for less relevant factors (e.g., a biserial r of .54 ± .08 was found between the child's MA and whether or not he slept alone in his own bed). Both groups of factors illustrate in similar degree the general relation between socio-economic status and intelligence.

The relationship of environmental factors to IQ change has been examined by Bradway (1945) in the case of 50 California children showing especially marked increases or decreases in a retest after 10 years. Initial and retest IQ means for contrasting groups were: 107, increasing to 126; and 113, decreasing to 96. Bradway called attention to the fact that direct measures of the children's environments, such as home status indices, yielded smaller differences for the two groups than measures of parental and grandparental characteristics, such as intelligence scores based on vocabulary or on occupation.

Occupation and "Social Class." The principal earlier sources of material on the relationship of intelligence to socio-economic factors include a volume by Schwesinger (1933) and one by Lorimer and Osborn (1934). Subsequent reviews or critical summaries have been published by Neff (1938), Loevinger (1940), Herrick (1951), and McCandless (1952). Neff pointed out that in various studies of school children a range of about 20 points in IQ has been found between children of the highest and lowest socio-economic groups. This also holds among preschool children, as shown in Table 3. The differences commonly reported are sometimes more marked for verbal tests but are not limited to verbal tests. Thus, Havighurst and Breese (1947) found that children of higher family social status were significantly superior to those of lower status in each of the Thurstone tests of primary mental abilities. In another study, Janke and Havighurst (1945) obtained significant social class differences for each of a series of verbal and nonverbal tests, with the exception of the Minnesota Mechanical Assembly Test.

TABLE 3

MEAN IQ'S OF PRESCHOOL CHILDREN, CLASSIFIED BY FATHER'S OCCUPATION *

Father's Occupation	*Goodenough (1928b)*	*Terman and Merrill (1937)*
I. Professional	116	116
II. Semiprofessional and managerial	112	112
III. Clerical and skilled trades	108	108
IV. Semiskilled and minor clerical	105	104
V. Slightly skilled	104	95
VI. Unskilled	96	94

* Goodenough's sample consisted of 380 Minneapolis children between the ages of 18 and 54 months the Kuhlmann-Binet was given twice to each child, the means reported in Table 3 being based on the initial test only. The Terman and Merrill sample consisted of 831 children, ages 2 and 5½ years, in the standardization groups for Forms L and M of the revised Stanford-Binet. In this latter sample, an additional classification of "rural owner' was included, with a mean IQ of 99.

Similar occupational and social class differences are observed when other criteria are employed. If, for example, we examine the percentage distribution of the parents of gifted children, or the parents of persons listed in *Who's Who in America,* we find a very disproportionate number in the higher occupational brackets. On the other hand, parents of children admitted to feeble-minded institutions tend to cluster in the lower brackets. If we turn to results from item analyses, Herrick (1951) has summarized nine studies with reference to items which show large or small social status differences. Although there are some inconsistent findings, several studies indicate that high-status children are relatively more proficient in linguistic tests (especially those involving thinking or reasoning) and do relatively less well in tests emphasizing rote memory and perceptual functions.

The assertion has been made by Neff (1938) that the occupational hierarchy in IQ can be accounted for entirely in environmental terms. This would seem to be implied in Pieter's (1939) suggestion of a "coefficient of innate intelligence," to be obtained through dividing the IQ by an environmental index. A somewhat similar line of argument is advanced by Davis (1948) and Davis and Havighurst (1948) These writers criticize existing intelligence tests as being too narrowly limited to problems of an academic type, which are not equally relevant, comprehensible, or motivating among children of different social classes. Support can readily be found for the argument that current testing methods emphasize subject matter, problems, and tasks which are more compatible with middle-class than with lower-class goals and experiences; such tests tend to underpredict the educability of lower-class children We cannot, however, jump to the conclusion that these biasing factors account for all or even a major part of the social class differential. Davis's criticisms incur special difficulty with nonverbal tests and with the mental test differences found in the preschool period.

It may be useful to repeat once more the generally acknowledged fact that the validity of mental tests diminishes when we apply them to groups deviating in cultural norms from the original standardization group. Davis (1951), however, goes so far as to deny that genetic factors (although influencing individual mental development) are in any important way related to social level or are segregated by socio-economic conditions.

The hypothesis that the intelligence differential between the social classes is to some extent a hereditary sampling dif-

ference emerges from two assumptions: (1) individual variations in intelligence are, in part, genetic in origin; and (2) differences in the selection of occupations and in occupational success are in part determined by intelligence. These differences, moreover, tend to be confirmed both through assortative mating and segregation and, in a competitive society, through the tendency for the more intelligent to rise and the less intelligent to sink in the social scale. This vertical mobility is, of course, incomplete and resisted by considerable inertia; [1] we cannot doubt that it occurs, although up to the present time most studies of interclass migration have failed to utilize measures of mental abilities.

The monograph by Eells, Davis, *et al.* (1951) is an important contribution to the literature on social status. Approximately 5000 children, ages 9 and 10, and 13 and 14, were given five standard tests. Correlations with social status indices (based on parental occupation and education, housing and dwelling area) ranged as high as .43 with Terman-McNemar IQ and as low as .20 to .28 with the Thurstone Spatial and Reasoning Tests, and the Otis Nonverbal IQ. Status differences on individual items were analyzed in greater detail than in any previous study; an additional item analysis would, however, be desirable, comparing social groups not by age but by mental age or IQ. In general, the results supported previous studies in showing a relation between status differences and verbal symbolic content. The concluding statement refers to "the substantial number of items showing large status differences for which no reasonable explanation can be seen. This may, of course, merely reflect lack of insight on the part of the writer. The presence of such a large proportion of unexplained differences should, however, lead to caution in accepting the idea that all status differences on test items can be readily accounted for in terms of the cultural bias of their content" (p. 357).

Another approach to environmental correlation is found in the study by Thorndike and Woodyard (1942) of the average intelligence of sixth-grade children, in communities of 20,000 to 30,000 population, as related to average income and "general goodness" of community life. Income was estimated from such data as teacher salaries, wages, and median rentals; "general goodness," from expenditures for education, community health, and various economic and social items. For 30 communities, a correlation of .78 was reported between intelligence and income, and .86 between intelligence and "general goodness." [2]

McGehee and Lewis (1942) have stated the intelligence-environment relationship in still another way, by computing, for a large sample of children in 36 states, the ratio of superior and retarded children to "normal expectancy." The results, according to

1 Since the members of lower classes have a reduced educational opportunity, it is here that we must look for the greatest discrepancy (in terms of the number of individuals) between potential and realized attainment. One illustration of this is to be found in a study by Goetsch (1940), who examined the college records of a sample of over 1000 high school graduates all of whom had IQ's of 117 or above. In spite of an intelligence adequate for college work, only about one-quarter of these attended college full-time if the parental income was under $2000 a year. Where the parental income was $5000 or above, more than 90 per cent attended college full-time.

2 These are, of course, correlations between averages The level of such environmental correlations may be expected to vary considerably in relation to the selection of communities; a later study by R. L. Thorndike (1951) obtained markedly lower coefficients. It is of special interest that in this instance environmental correlations with intelligence were higher than with achievement; Thorndike explains this on the assumption that differences between communities are chiefly in nonschool factors, and that schools tend to introduce a standardizing influence.

parents' occupation, are shown in Table 4. Although the proportion of high IQ children is larger in the higher socio-economic

TABLE 4

RATIOS OF EXCEPTIONAL CHILDREN TO NORMAL EXPECTANCY

Social Class	*Superior*	*Retarded*
Professional	2.40	.14
Semiprofessional and business	1.62	.49
Skilled workmen	.88	.98
Semiskilled	.92	1.39
Unskilled	.30	1.53

levels, the great bulk of superior children is to be found in the much larger total membership of groups lower in the social scale. The social and educational implications of this fact have been developed at some length by Warner, Havighurst, and Loeb (1946).

Special interest attaches to the fact that the social differential in intelligence is well established as early as 2 or 3 years of age and is relatively constant in later childhood. From the public school data of the Harvard Growth Study, Shuttleworth (1940) has shown that from 8 to 18 years the mean IQ of children in white collar groups remains fairly constant around 108; the mean IQ was similarly constant around 96 in families where the father was an unskilled or semiskilled laborer. If the social differential is due to family (and neighborhood) environmental effects acting directly, one would expect it to be small in early childhood and to increase gradually with age. The constancy of the difference appears to be more difficult to explain on an environmental than on a primarily hereditary basis.

An additional line of evidence, contrary to the environmental hypothesis, has been supplied by Lawrence (1931), who showed a relationship between children's IQ and the occupational status of their parents, even where environmental differentials were ruled out (in the case of children removed from their homes in infancy and brought up in an institution). D. C. Jones and Carr-Saunders (1927) added a further relevant finding in comparing the intelligence of children of different social origins who lived in an orphanage for varying lengths of time. Continued residence in this less differential environment apparently had little or no effect in reducing or "leveling" the original social differential in intelligence.

A study by Outhit (1933) provides an interesting comparison between the intelligence of children and their parents. Fifty-one families were represented, with 4 or more children in each family. The Army Alpha was used with adults and with children above 12, scores being transformed into IQ's for comparison with the Stanford-Binet IQ's of the younger children. Figure 7 indicates a tendency toward a greater occupational differential among parents than among children or, in other words, a tendency for children of either superior or inferior parents to regress toward the mean of the total group. This result would be predicted on the basis of genetic factors, but, so far as home environments are concerned, it is by no means clear that environmental theory would lead to the same expectation.

Rural-Urban Studies. That rural children in the United States attain lower average IQ's than urban children has been confirmed in numerous reports. The choice of tests is an important factor in this connection. Tests are usually devised by city dwellers and validated on city children; it is reasonable to expect that their content and perhaps also their time limitations will tend to handicap rural children. Attitudes and incentives important for efficient test performance may be stimulated in varying degrees by different school systems; in gen-

eral, rural children probably receive less practice than urban children in working at high pressure under speed and accuracy requirements. Shepard (1942) has shown that rural children, inferior to urbans on verbal tests and on tests involving speed of performance, were definitely superior in mechanical assembly and in error scores in spatial relations tests. Environmental demands and practices must be assumed to have some part in determining such differences.

As long ago as 1929 Shimberg demonstrated that the urban superiority on an information test could be reversed if the test were originally scaled from items supplied by rural teachers and standardized on a rural group. A similar experiment has not been attempted with other types of material; it is probable that a distinctive "urban" and "rural" content is more apparent in an information test than in other tests.

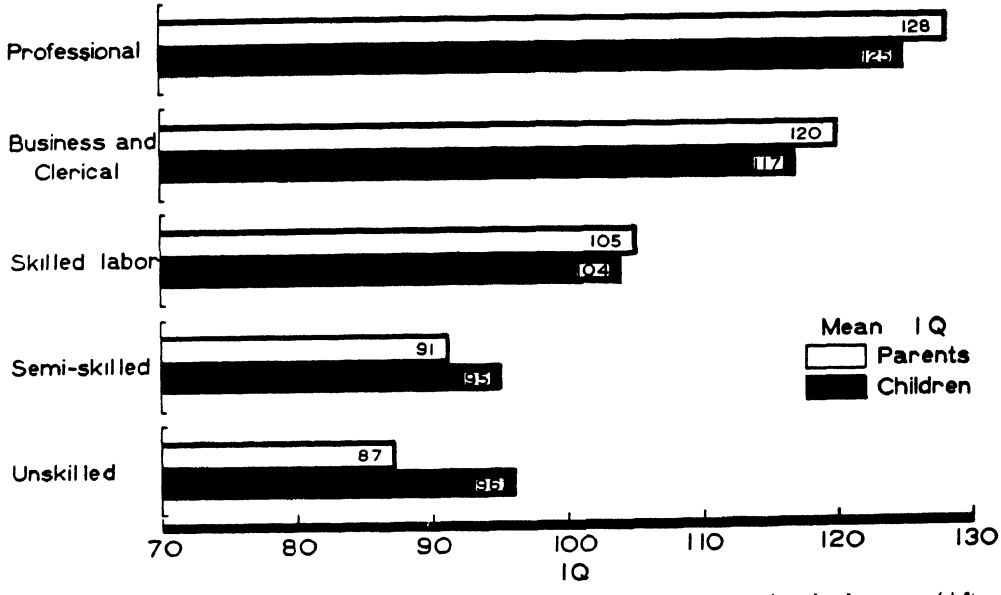

FIGURE 7. Parents' and children's intelligence, in different occupational classes. (After Outhit.) *Archives of Psychology.*

Numerous investigations have reported not merely a low IQ for rural children but also an IQ diminishing with age. Among these are: (1) the often-cited report by Gordon (1923) on English gypsies and canal boat children, showing marked negative correlations between age and IQ; (2) Asher's (1935) study of children in the east Kentucky mountains (in this group the median IQ dropped steadily from 84 at 7 years to 60 at 15 years); (3) a report by Edwards and Jones (1938) on school children in the mountains of north Georgia (IQ's dropped from around 100 at ages 7 to 9 years to 76 at age 14, and 70 for those older); (4) Jordan's (1933) study of the children of mill workers in a North Carolina town (IQ's decreased from 100 at age 6 to 85 at 13 years); (5) studies of Iowa children by Baldwin, Fillmore, and Hadley (1930) and by Skeels and Fillmore (1937). In the last report, children from underprivileged homes (either rural or urban)

were examined at the time of entrance to an orphanage; the mean IQ diminished from 93 at age 4 to 80 at age 14.[1]

Representative results from a group test survey are shown in Figure 8. Chapanis and Williams (1945) administered the Kuhlmann-Anderson test to 4311 children in "a fairly rich agricultural area" located near the center of Tennessee. Approximately 90 per cent of the white children and 73 per cent of the Negro children in the county were tested. It seems probable that, since the survey was based on children in schools, a somewhat superior selection of children in the county was obtained at the upper ages. Nevertheless, the mental ages of all groups exhibit a somewhat regular divergence from the norm, and the mean IQ's for all cases decrease from 94 at age 6 to 76 at age 15.

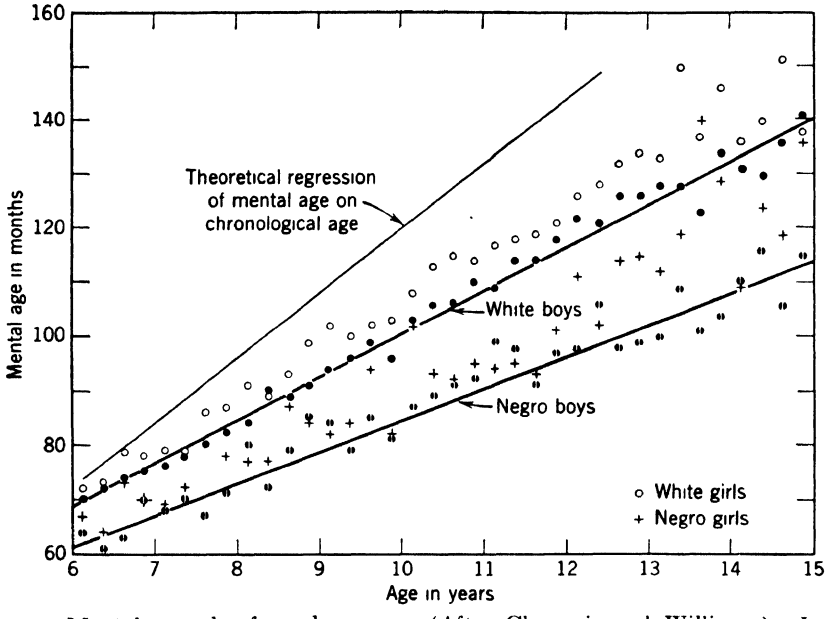

FIGURE 8. Mental growth of rural groups. (After Chapanis and Williams.) *Journal of Genetic Psychology.*

Results of this nature have been variously interpreted as due to (1) the "retarding effect of poor homes on mental development" (Skeels and Fillmore, 1937), (2) the effect on the Stanford-Binet of "continued existence at a critically low level of social and cultural status" (Neff, 1938), or (3) the effect of using tests which at higher age levels become increasingly inappropriate for the groups to which they are applied (Asher, 1935).

The first of these interpretations, in line with other Iowa studies, proposes an actual psychological handicap resulting from

[1] Speer (1940*a*, *b*) and a number of other investigators have utilized similar material from children referred to institutions because of conditions in their own homes. Older children, who have lived longer in homes characterized by poverty and frequently by other undesirable factors, have lower average IQ's than younger children from similar environments. It must be noted, however, that these test scores are not based on cumulative records or on sibling comparisons, but on different samples which may have been subjected to different selective factors. Thus it seems likely that among the older children in very inferior environments some of the brighter ones have already been removed by relatives or by placement agencies.

a poor environment. The second and third interpretations are more purely psychometric, although the second seems to imply some actual cumulative handicap in mental test abilities, whereas the third is concerned primarily with an age differential in the tests which lowers their validity.

It would be permissible to hold all these interpretations simultaneously, but they would still fail to give an adequate picture of the complex situation involved in the comparison of different cultural groups. In studying the possibility of differential environmental handicap on different test items, Jones, Conrad, and Blanchard (1932) made an item analysis of test results for 351 New England rural children, aged 4 to 14, as compared with 905 children in the 1916 Stanford-Binet standardization and also with 212 children from a relatively homogeneous urban sampling which was highly superior in socio-economic status. The three groups had mean IQ's of 92, 101, and 117, respectively.

Several individual items were identified as showing very different levels of difficulty in the three groups, with a tendency for the differences to increase with age These were all verbal items, again illustrating the principle that items which in a common environment may be a good index of intelligence may in widely differing environments become predominantly a good index of the environment.

Under such conditions the resulting IQ's will require reinterpretation, and in this particular study the authors estimated that social and educational factors could on the average account for about half the mean difference of 10 points in IQ between the rural and the normal urban groups. These environmental handicaps, however, appeared to be specific to certain test items, rather than general. As would be expected if the rural-urban difference is in part due to a difference in hereditary capacities, certain types of tests were found with a marked difference which could not readily be explained in terms of differential opportunities for special training, or differential interest or motivation.[1] On the basis of this item-and-age analysis, the conclusion was offered that the rural group (although representative for the communities studies) presented an inherently poorer selection than the urban comparison groups.

The study of selective rural migration (selective drainage into urban centers and urban occupations) may in the future result in a fuller understanding of rural-urban differences. It is interesting that both in the study discussed above and in an English study by Thomson (1921) fewer high IQ's were found in rural communities accessible to city districts than in comparable communities more remotely located. Areas supplied by good transportation and near a growing urban center are probably in some regions more subject to selective drainage. Similar interpretations may apply to results obtained by Bickersteth (1919) in the Yorkshire dales and by Macmeeken (1939) in isolated rural and coastal sections of northern and western Scotland. It is hard to see how the children in these remote localities could have acquired relatively high average IQ's on the basis of superior cultural opportunities. Economic factors are important in determining the nature of selective migration. Lorimer and Osborn (1934) have cited a number of surveys indicating that in relatively prosperous rural areas the cities attract from both the upper and lower extremes of social status. In depressed rural areas, on the other hand, a survey by Gee and Corson (1929) indicated that the less intelligent

1 These included the ball-and-field test, memory for designs, digit memory, picture description, and comprehension

Results which are in general similar to those of this study have been obtained by Bruce (1940) in a Virginia survey of rural white and Negro children.

are more frequently "bound to the land," whereas those of higher social, educational, and intellectual status tend, in greater proportions, to migrate to urban centers. This is supported by Mauldin (1940) and Sanford (1940) on the basis of data from small southern communities.[1]

Rural-urban differences are maintained into high school and beyond; Nelson (1942), testing over 1000 students entering the State College of Washington, found higher average scores for urban students in all parts of the ACE test. Similar differences were found for (*a*) test materials which might be expected to be especially vulnerable to environmental influence and (*b*) subtests (such as figure analogies) regarded as more "culture-free." This would seem to point to the probability of a difference in selection.

In concluding this section, the interpretation of rural handicap as due to lack of cultural privilege is seen to provide only a partial explanation. Commenting on the lack of schooling of southern mountain children,[2] Goodenough (1940*a*) pointed out that our pioneering New England ancestors did not find schools ready made in the wilderness.

> They made schools, and it did not require two centuries of residence for them to do so. Accordingly, I find it hard to accept the idea that the low IQ's of the mountain children are to be explained solely on the basis of educational deprivation. One is forced to ask: Why were they so deprived? [P. 329.]

The principal outcome of the socio-economic and rural-urban studies is to emphasize the fact that, among groups as among individuals, differences cannot be explained in terms of a fixed structure of relationship. With changes in any of the related factors (test composition, hereditary selection, or environment) group or individual differences will represent varying degrees of hereditary or environmental influence.

"Hospitalism." Another form of environmental deprivation is that experienced by institution children, who may receive less adult attention and less language stimulation than children in normal homes. A number of writers, particularly Spitz (1945, 1946) and Fischer (1952), have emphasized the conception that the child in an institution is frustrated in his attempts to form a libidinal object-relation with a mother or mother-substitute. This relationship is held to be essential to normal mental development, particularly in the third to sixth month of infancy.

Alleged effects of hospitalism, leading to severe mental retardation, have been described for individual children and for small groups, but as yet no studies with appropriate control groups have been conducted. At the present time there may be some question as to whether the conclusions rest primarily on empirical findings, or on deductions from psychoanalytic theory.

It would not be surprising if institutional life were found to involve developmental handicaps. So far as mental functions are concerned, we would not expect this handicap to be clearly shown during the first 6 months of life, or to be of great magnitude in later months. It is often difficult, however, to make proper allowance for samp-

1 For other studies of rural groups, see Clark and Gist (1938), who reported the occurrence of selective migration in Kansas, and Klineberg (1938), who reported its occurrence in a study in southern Germany but found no evidence for it in a parallel investigation in New Jersey. Conflicting evidence in this field is an indication not of inadequacy in the studies involved but rather of the varying balance of the complex factors influencing selection. For a critical discussion of earlier research, see Thomas *et al.* (1938, pp. 110 ff.).

ling factors when the effects of institutional life are being studied.

Racio-Cultural Comparisons. Comparative studies of Negroes and whites have frequently reported a difference between average IQ's with a tendency for the amount of difference to increase with age. Several studies have also indicated, among mixed bloods, a relationship between intelligence and the degree of white admixture. In these comparisons, however, educational factors and social status have usually been uncontrolled. Until further, more crucial evidence is supplied, we must remain in some doubt as to the bearing of Negro-white investigations upon the nature-nurture problem.

Another approach which has given suggestive results is represented in the well-known work of Klineberg (1935), who studied the intelligence of Negro migrants from the South in relation to their length of residence in New York City. The average IQ for children newly arrived was 81.4 (Stanford-Binet), as compared with 84.5 for those who had been in New York 2 to 3 years, and 87.4 for those in residence longer than 4 years. It is reasonable to interpret this as an environmental effect (including greater test sophistication), provided that similar selections of migrants arrived in successive years, and provided also that no selective factors have operated with regard to continued residence in New York. Could an educationally improved environment, exerting its effects early enough and long enough, bring the average IQ of these children not merely to 87 but to the norm of 100 or even higher? An affirmative conclusion is an inviting one but is perhaps a premature "extrapolation" from the facts now available.

Numerous studies of American Indians have obtained somewhat lower means for Indians than for whites. This may be a special case of rural-urban and social class difference. As contrasted with verbal tests, performance tests are sometimes reported as yielding little or no difference. A study illustrating this is one by Havighurst and Hilkevitch (1944). With careful attention to representative sampling, they found among 660 Indian children a mean score on the Arthur Performance Scale approximately equal to the norms. It is of special interest, however, that marked intertribal differences were discovered. These could not readily be assigned to cultural influences from contact with whites; the Shiprock Navajo, for example, with considerable contact with white culture, obtained a mean IQ of 95, whereas the Oraibi (Hopi), with only moderate contact with white culture, registered a mean of 113 (about 90 cases in each sample). The evidence from this study suggests that the verbal factor, but not the speed factor, is a handicap in Indian test performance. Here, as in some other racio-cultural as well as in some social class comparisons, bilingualism may be one of the sources of difficulty. A survey of studies on this topic will be found in Chapter 9, Language Development in Children.

F. S. Freeman (in a volume edited by Skinner, 1936) has very properly emphasized the fact that the comparison of North American Indians and Negroes with others is hindered at almost every turn by social, educational, economic, and hygienic disparities.

> It remains for the future to demonstrate whether North American Negroes and Indians are by nature intellectually inferior to the whites; and such may or may not be the case. What present data do show is that, under existing conditions of environment inequality, they have, as groups, failed to reach the levels attained by contemporary whites [pp. 419–420].

No attempt will be made in this chapter to cover the enormous (and highly contro-

versial) literature concerning "race" differences. With ethnic groups other than those mentioned above, we are constantly faced by questions of intragroup selection (selective migration) as well as by questions bearing on environmental handicaps and the appropriateness of tests. On the basis of tests ordinarily accepted for measuring intelligence, the weight of evidence points to the probability of a difference, in terms of averages, between American citizens of north European and south European descent. It is possible, but not certain, that this difference would wholly disappear if a correction were made for social status and educational differences. The effect of such a correction can hardly be predicted, for no one as yet has conducted an experiment in which controlled selections of children varying as to racial background have been reared under similar environmental conditions.

Educational Opportunity. The differences discussed in the preceding sections are undoubtedly influenced at many points by differences in formal schooling. Relevant but not entirely satisfactory evidence on this problem is available from studies of adolescents in and out of school. In a report entitled "Schooling Makes a Difference," Lorge (1945) examined at age 34 the intelligence test scores of 131 men who had been tested 20 years earlier. For individuals roughly comparable in IQ at age 14, retest scores proved to be higher for those who completed more grades in school. It seems reasonable to assume that those remaining in school longer developed a continuing pattern of interests and attainments which tended to give them an advantage in later tests. But, in the absence of more complete experimental data, explanations can rarely be as simple as this. For example, we cannot ignore the possibility of differential mental growth rates and differential growth limits reflected both in educational attainment and in later test scores.

IQ changes over a 10-year period were examined by Husén (1951), who compared tests given at induction into military service with test scores obtained in the third grade, for 613 Swedish boys. Gains (found in all groups except those with the smallest schooling) were related to the number of school grades completed. The amount of schooling correlated .80 with the final test scores, but also correlated .61 with the *initial* test score, suggesting that this is another example of the effects of intrinsic difference in growth pattern, reinforced in varying degrees by differences in educational opportunity. Children with initially high IQ's tended to retain their level even when environmentally underprivileged.

Another European study which may bear on this problem is that of de Groot (1948, 1951) who analyzed IQ changes in successive groups of applicants to an industrial training school in the Netherlands. Applicants showed a decline in IQ during the war period, and a subsequent return to the prewar level. Although de Groot attributed this to schooling deficiencies during the war, it is obvious that many other factors, including sampling variations, may have contributed to the trends which he demonstrated.

Vernon (1948) showed that, after the age of 17, boys not attending school declined in ability measures related to scholastic activities but continued to gain in mechanical and spatial abilities. It is reasonable to suppose that the early cessation of schooling may handicap performance in tests which were originally designed to predict scholastic aptitude. On the other hand, the question may be raised whether some of those who leave school early may not do so because of a different pattern of abilities or an early tapering-off of growth in some functions.

Effective gains in intelligence test scores beyond the age of 19 or 20 are not easy to demonstrate in a representative sample but can usually be found in a college population (Livesay, 1939; R. L. Thorndike, 1948*a*). Here again we are confronted with an unsolved question whether the more intelligent enjoy a longer span of intrinsic growth or whether the better-schooled improve their scores through a piling-up of educational experiences. Perhaps the two alternatives have a common denominator in intellectual stimulation and practice. It would be foolish to deny that longer schooling is a factor of advantage in mental test performance; however, the advantage is not without limits, as can be seen in studies of mental decline among adults. Evidence is contradictory as to whether the rate of decline is related to education, but we cannot doubt that some decline does often occur, probably well before the age of 60, even among those who are continuously engaged in scholarly activities (Jones and Kaplan, 1945).

Another interesting line of evidence concerning presumptive educational effects is to be found in studies of secular trends; what changes can be demonstrated over a period of years in comparable samplings when improvements have occurred in educational factors? The most important body of data bearing on this problem is in the comparison of Scottish 11-year-olds in 1932 and 1947. In the later testing, involving over 70,000 cases, Thomson *et al.* (1949) found slight gains, contrary to the hypothesis of a loss based on differential fertility. Similarly, R. B. Cattell (1950), in a comparison of 10-year-old children in the city of Leicester, found after a 13-year interval a slight but significant increase in a nonverbal test. Since he had previously (Cattell, 1940) predicted a decrease of 1 IQ point in each 10 years, he suggested the possibility that the predicted fall in intelligence actually occurred but was masked by an advance in education and test sophistication. The British investigators have also speculated on the possibility of selective reproduction within social classes, and of genetic mechanisms which may serve to resist gene loss in a population, in spite of differential fertility. It may be noted that predictions, made early in this century, of declining average height have also failed and have in fact been quite wide of the mark, since in many comparative studies average heights have shown well-defined increases.

Several investigations in this country have given rather striking evidence of gains in mental test scores. Tuddenham (1948) compared World War I draftees with a sample of 768 men selected as representative of the World War II draft population. On comparable revisions of the Army Alpha, he found that the World War II median could be estimated as falling at about the 82 percentile of the World War I distribution. In interpreting this very substantial gain, we need to bear in mind the possibility that the earlier distribution, obtained in the infancy of group testing, may have included more cases for whom the tests were inappropriate or improperly administered. It is also possible that the World War II draftees were more carefully screened in the initial selective procedures. With regard to educational differences, the later sample had, on the average, 2 years more of schooling; it was a more urban sample, with greater exposure to modern media of communication.

Tuddenham's conclusion that a large proportion of the gain is "a consequence of more and better education for more people" deserves serious consideration but leaves us with the usual problem when mental tests on different populations are compared; i.e.,

to what extent are the differences psychometric and to what extent do they represent genuine increments in mental power? A genetic theory to account for changes of this nature might be that improved communication and increased urbanization reduce the number of retarded children by dispersing recessive gene pools in isolated communities. It is difficult, however, to see how this could account for more than a very minor average gain in IQ within a single generation.

Another example of an apparent secular trend is to be found in Wheeler's (1942) study of Tennessee mountain children, based on 3252 subjects in 40 schools. As compared with results from the same region obtained a decade earlier, the mean IQ (while still well below 100 at nearly all ages) had increased approximately 10 points. Table 5 presents the results for

TABLE 5

IQ GAINS OVER 10 YEARS IN COMPARABLE GROUPS OF TENNESSEE MOUNTAIN CHILDREN

	Mean IQ	
Age	*1930*	*1940*
6	94.7	102.6
8	83.9	99.2
10	84.3	91.4
12	81.4	90.2
14	74.7	85.1
16	73.5	80.0

the even years tested. It seems very improbable that the consistently higher level in the later testing could be due to a selective factor affecting all age levels in a uniform manner; to a considerable degree the same families were represented in the two surveys, and there was little evidence of population shifts due to in or out migration. Wheeler attributes the gains to better schools, greater school attendance, and improved contact with the outer world through better roads. It is a little surprising, however, that the rate of decline in IQ is not affected by the changes which have produced a generally higher level.

Increases in test scores over a period of years are also shown in a remarkable study by S. Smith (1942), who compared the test performance of Honolulu children in 1924 and 1938. Care was taken to obtain comparable samples of all public school children between the ages of 10.0 and 15.0. The writer has computed results in terms of the averages[1] and SD's for the 1924 10-year-old group. Figure 9 exhibits gains which are highly significant in each test and at each age level. The greatest change is in the nonverbal test, in which the 10-year mean for 1938 exceeds the 12-year mean for 1924. When the various racial groups in Honolulu were compared very significant differences were found in each testing. In general, the "whites," Japanese, Chinese, and Koreans obtained high scores, whereas the Hawaiians, Filipinos, Puerto Ricans, and Portuguese scored much lower. Some curious results emerged, however, in comparing results across a time interval. In the nonverbal tests, for example, a critical ratio of 8.5 was found in 1924 for the difference between whites and native Hawaiians. By 1938 an improvement in the nonverbal scores of the Hawaiians brought them nearly to the white average for 1924. Nevertheless, the differentiation of the groups still remained and in fact increased, since the higher-scoring groups tended to make even greater gains in all tests. It has been suggested that this is what would be expected if the original differences are innate, since the more capable groups would presumably take greater advantage of improved educational opportunities than the

[1] Smith presents the nonverbal means and (because of skewing) the medians for the two verbal tests.

less capable groups. The author of this study, however, is careful to point out that the results may be complicated by selective factors in migration as well as by various cultural factors, so that it is hardly permissible to use these data for any conclusive statements about differences between races.

As a concluding note on secular trends, mention may be made of a study by Klatskin (1952) in which a sample of infants around a year of age was given the Cattell Infant Intelligence Scale. As compared with the norms, superior performance was shown on most items, except vocabulary. Klatskin considered that the score differences provide evidence for a trend in the direction of more precocious development, related to changes since the 1930's in infant care. This trend is described as most apparent in the motor components of infant mental tests, resulting from a régime of greater stimulation and exercise, greater parental attention, and less confining clothes. This can hardly be regarded as more than a hypothesis, however, until additional studies are made, with careful sampling controls.

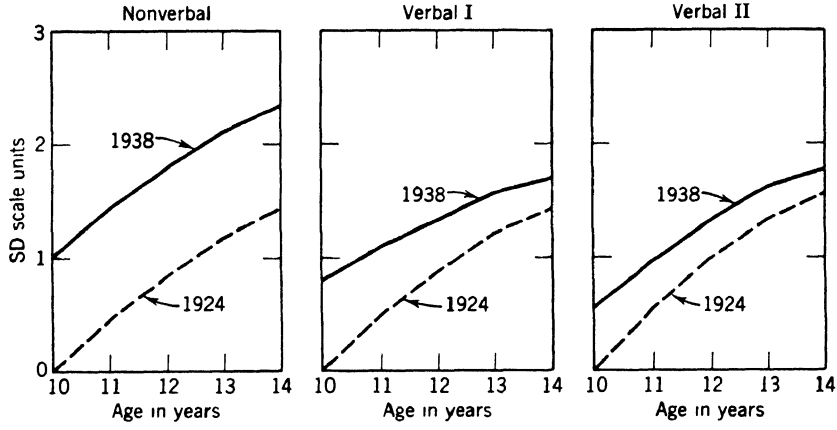

FIGURE 9. Mental growth curves in comparable samples, in 1924 and 1938. (After Smith.) *Journal of Genetic Psychology.*

Mental and Physical Relationships [1]

One of the more competent studies is by Abernethy (1936), who found positive correlations between intelligence and various physical measures at all ages from 8 to 17 years; in the case of height the average r was .26 for boys and .22 for girls in the age range from 2 to 8 years.

The relevance of this topic to the present problem is in part indicated by Sanders' (1934) discussion of differential physical growth:

> Evidence of differential growth, or its end result—differential size—shows that everywhere children with a superior socio-economic environment are on the average heavier and taller than their age-mates exposed to a less favorable environment. . . . The study does not dispute the fact that in all probability there are inherent differences between the various socio-eco-

[1] The best-known earlier treatise on this topic is Paterson's *Physique and Intellect* (1930). Jones (1933*b*, 1936, 1939), in a series of reviews, summarized approximately 300 studies, and later reviews by Shock (1939*a*, 1944, 1947), Carmichael (1940), and Shock and Jones (1941) give a representative account of research on physiological relationships. Perhaps owing to the generally small or zero relationships found, research in this field has diminished in subsequent years.

nomic classes. Its one and only contention is that the rôle of environment cannot be overlooked . . . And, if environmental differences are important enough to affect physical growth, it is most probable that they affect psycho-social adaptations and behavior as well [p. 299].

The hypothesis implied in the foregoing was subjected to a test by Honzik and Jones (1937), who examined the relationship of height to intelligence in a group of approximately 200 children representative of Berkeley, California. Low correlations were found at each age from 21 months to 7 years, but the uniformly positive coefficients for both boys and girls suggested the presence of a genuine, even if meager, relationship; there was, moreover, a slight tendency for growth rates in height or weight to be correlated with increments in mental scores. As in other samples, mental test scores showed an increasing relation to social status[1] (.04 at 21 months, rising to .42 at 7 years).

In the study of this problem, correlational procedures, dealing with average relationships in a total group, may be less effective than the comparative study of individual growth curves. Honzik and Jones have presented such curves for height, weight, and intelligence, with raw measurements transformed into sigma scores to permit direct comparison as to changes in status in the group. Although some cases showed independent or even diverging curves, a number exhibited a striking concomitance in trend. The suggestion has been made that mental-physical relationships are due to a common influence of the social environment, acting upon intelligence through social example and education and upon physical factors through nutrition and hygiene. In this study, however, the relationship between height and intelligence was found to be independent, or nearly so, of the measured factors in the environment, since the correlations changed very little when social status was held constant. For the sample in question it seems probable that genetic factors, and the association of traits in assortative mating, are more important than cultural-economic factors in determining the fact that brighter children tend to be taller and heavier than children of below average intelligence.

Olson and Hughes (1950) also present individual growth curves for a series of physical and mental measures. The curves show a degree of correspondence which they regard as illustrating the "unity of the organism." Partly because physical-mental relationships sometimes involve a time lag, longitudinal studies may be more successful than cross-sectional ones in depicting growth relationships. Time series statistics, however, have not yet been employed in a systematic analysis of the concept of organismic unity.

Future research in this area may lead to greater interest in physical *patterns* than in single variables. On the basis of preliminary evidence (Sheldon and Stevens, 1942), it would appear that a small positive relation may be expected between intelligence and "ectomorphy," or linear build, and a small negative relation between intelligence and "mesomorphy," or athletic build. If these relations are confirmed, however, it is likely that they will be found to rest at least in part on a differential development of interests and activities in individuals of differing physique.

Health and Physical Defects. If physical condition exerts a direct effect upon mental functioning, it may perhaps be expected that intelligence will show a closer relation to measures of health than to measures of physical size or of body form. Our concern here is with studies of general health, nutritional status, or minor physical de-

[1] A socio-economic index based on parent education, occupation, income, and social ratings.

fects, and not with neurological or endocrine disorders, or psychopathologies. In one of the earliest studies in this field, Ayres (1909) determined the incidence of physical defects in three groups of children classified as dull, normal, and bright on the basis of progress in school. The sample consisted of 3304 children. The percentage of each type of defect is given in Table 6.

TABLE 6

PERCENTAGE INCIDENCE OF PHYSICAL DEFECTS IN THREE GROUPS

	Bright	*Normal*	*Dull*
Defective teeth	34	40	42
Adenoids	6	10	15
Enlarged tonsils	12	19	26
Enlarged glands	6	13	20
Defective breathing	9	11	15
Defective vision	29	25	24
Other defects	11	11	21
Average number of defects per child	1.07	1.30	1.65

Similar findings have been reported by later investigators. Where relationships have been analyzed in terms of correlation, coefficients are approximately of the same order as for other physical traits such as height or weight. Among the highest r's reported are those found by Dayton (1928–1929) for approximately 14,000 retarded school children in Massachusetts ($-.29 \pm .01$ for boys, $-.25 \pm .01$ for girls, IQ by physical defects). These correlations, similar to those found for other physical-mental relationships, serve merely to illustrate the fact that physical and mental handicaps are associated in the same samples. We cannot conclude that one type of handicap has caused the other, although to a very small degree such causal relationships may be present.[1]

Studies of developmental disturbances during the prenatal period and of neonatal damage (as in the case of newborn infants suffering from anoxia or from erythroblastosis) have emphasized the extensive nature of the injury that may be produced by these conditions. This injury is sometimes not clearly apparent until a number of months or even years after birth, but the incidence of difficult births among children later classified as mental defectives (Benda, 1943) is sufficiently high to call attention to the hazards involved in the child's first direct contact with the external environment. Difficult birth conditions, however, are not always associated with later measurable impairment. When Usdin and Weil (1952) compared children who had been apneic for 3 or more minutes at birth with a control group who had breathed spontaneously, no IQ differences could be demonstrated between the two groups.

In such defects as infected tonsils, a quasi-experimental approach is possible through studying the mental test performance of children before and after surgical removal of the infection. It has not been possible to show that the focal infections progressively impair mental ability or that their removal has a beneficial effect upon the intelligence (see reports by Rogers, 1922; Lowe, 1923; and Richey, 1934).

[1] In a study of fifth-grade children in New York City schools, Maller (1933) determined the correlation between the mean IQ for each school and the percentage in each school having a given defect. The coefficients were $-.50$ for defective teeth, $-.40$ for visual defect, $-.28$ for malnutrition. These relatively high correlations are due to the use of averages and can be applied to predictions about populations rather than about individuals. It is clear that districts with better health records tend to have higher average IQ's; these districts also have superior socio-economic status, as shown by a correlation of .50 between average IQ and average rentals. Although Maller's results are of unusual interest in describing important aspects of urban social structure, they of course give no indication as to the source of the relationships.

A study of the effects of poliomyelitis deserves some attention with regard to method. Phillips, Berman, and Hanson (1948) located through a Minneapolis clinic 101 children who had had poliomyelitis in the 1946 epidemic and whose earlier Stanford-Binet IQ's were on file in school records. Retests were administered in 1947 to these cases and to a carefully matched control group. Earlier studies on this problem have usually yielded negative results; in the present instance about all that could be shown was that on the average the controls held constant or increased slightly in IQ, whereas the clinic cases held constant or decreased slightly; differences were significant for the younger children and for boys. A further study of 22 clinic cases with an extreme IQ loss (averaging 19 points) indicated that the illness had been relatively severe among these children. However, it is not as yet known whether the retardative effects have a basis in organic brain damage or in some more temporary psychological or educational sequelae of the illness. The mental effects of specific diseases have sometimes been studied through sibling controls. Thus, Gerver and Day (1950) were able to show that children who had recovered from erythroblastosis had significantly lower IQ's than their unaffected siblings. This method of inquiry can be recommended only for those conditions which quite surely involve no differential susceptibility in relation to intelligence.

In a few studies, evidence is available concerning the effect of an improved physical régime upon mental functions. Westenberger (1927) selected the poorest 10 per cent, with regard to physical defects, from a sample of approximately 400 school children in Wisconsin. Medical and surgical treatment was provided over a 9-month period, but without observable effects upon mental development. The investigator concluded: "The influence of defects upon academic performance and intelligence has been somewhat exaggerated in the past." Similar negative results were obtained by Hoefer and Hardy (1928) in a carefully planned 3-year study of the effect of health education.

Effects of changes in physical condition are more likely to be noted in school achievement than in measures of intelligence. Thus, in later reports Hardy (1936) and Hardy and Hoefer (1936) showed that children participating in a health instruction program improved in their school work to a greater degree than members of a control group. Even these gains, however, are not entirely attributable to changes in health régime, since the special attention given to the experimental cases may have had not merely indirect psychological effects, but also more direct effects through changes in motivation. One interpretation of the relationship of physical factors to intelligence is suggested by Halstead (1945), who proposes a physiological energizing factor which may be affected by brain injuries and certain other physical conditions. The *usable* intelligence may thus be impaired without direct impairment of basic mental abilities.

Nutrition. It is to be expected that small positive coefficients will be obtained when measures of nutritional status are correlated with IQ. These correlations arise from the same causes that determine a positive relationship between socio-economic status and IQ (see pp. 645ff.) and tend to disappear if nutritional variations are examined within a single social group. An exception to the last statement may be found in cases close to a subsistence margin. Thus, among 293 children from slum areas, O'Hanlon (1940) found a significant correlation ($.18 \pm .04$) between nutritional condition and IQ.

A more satisfactory approach to this problem is through an experimental procedure, as illustrated in the following two examples. Twenty-five children selected by Smith and Field (1926) as markedly underweight were given school lunches over a 6-month period, together with health lessons and various motivational devices designed to bring about physical improvement. As compared with normal controls, striking gains were shown in weight but mental development appeared to be unaffected. A similar experiment was conducted by Seymour and Whitaker (1938) in a group of 25 underprivileged children (6½ years old) matched with a control from a similar social selection. The experimental group was given daily breakfasts in school, adequate as to variety and amount, whereas the control group received their usual inadequate breakfast of bread and tea at home. Differences between the two groups began to appear on standardized tests (such as cancellation) by the tenth day, but the superiority of the experimental group diminished after the breakfasts were discontinued. Neither of these two experiments points to any actual change in mental growth as a result of nutritional gains.

More positive results have been reported by Poull (1938) and by Kugelmass *et al.* (1944) in a comparison of IQ's of poorly nourished children before and after nutritional therapy. Marked IQ gains were noted for both mental defectives and normals, the amount of gain being greater for the younger children. The writers infer that prolonged malnutrition may involve irreversible effects upon mental development but that in early childhood mental retardation (of nutritional origin) is more readily overcome. If future experiments, coupled with longitudinal studies, confirm these findings, the implications for child development in economically backward areas may be of great importance. We still lack information, however, about the degree of malnutrition which is critical and the specific factors responsible.

A number of studies have dealt with the effects of specific vitamin administration. Although the greater part of the work in this field is still very preliminary, results are available from an impressive study by Harrell (1946), who conducted a controlled experiment with 55 matched pairs of orphanage children over a period of 1 year. The experimental group received 2 mg. of thiamine daily; the control group received a placebo. Neither the children nor their caretakers in the orphanage knew how the groups were divided or the nature of the treatment. The experimental group showed significantly greater gains in a number of mental functions and in educational achievement; these results were confirmed in a second experiment with 20 pairs of children.

In the years following 1945 considerable attention was given to the possibility of stimulating mental development through the use of glutamic acid in one of several forms. Apparent positive effects have been interpreted as due to changes in neural tissues, favoring more efficient oxidation. The clearest indication of favorable results has been obtained with the mentally retarded, and in the first six months of treatment.[1] Experiments of this nature, however, require attention to the use of matched groups, or if possible matched pairs, and to an administrative procedure in which the mental testers do not know which subjects received the experimental treatment and which subjects received the placebo. Studies utilizing careful controls have as a rule yielded

[1] See Zimmerman *et al.* (1946), Zimmerman (1949), Quinn and Durling (1950), Schwobel (1950), and Harney (1950). Gadson (1951) has summarized the work on glutamic acid and mental deficiency.

negative results. The only significant difference found by Ellson *et al.* (1950) was in a motor coordination test, suggesting (as in some animal studies) that if glutamic acid has any behavioral effect it may be upon overt activity patterns. Loeb and Tuddenham (1950) present a detailed comparison of their results and those of previous investigators, showing the probable methodological reasons for the differences in conclusions.

It has frequently been noted that the relationship of mental and physical traits is more readily demonstrated among the feeble-minded than among normals. This may be due in part at least to a larger proportion of the feeble-minded who suffer, in various degrees, from the effects of organic handicaps expressed both in physical structures and in mental function. Stout (1937) has summarized a study of 10-year-old children by the statement: "The fact that a child is normal in intelligence gives little or no clue as to what his health or physical condition may be." On the other hand, among the 2 per cent at the lowest extreme in intelligence it is clear that we have a disproportionate incidence of many different types of physical defects.

Seasonal Factors. An interesting subsidiary problem has been raised by a number of investigations showing a relationship between IQ and month of birth. These studies, principally by Pintner and his associates but supported by other investigators, purport to show that both in the northern and southern hemispheres children born in the late spring, or summer, have slightly higher average IQ's than children born in the winter months. Of 13 studies summarized by Pintner and Forlano (1943) the season of birth with the highest average IQ was either spring or summer in 11 instances; the lowest average IQ was predominantly in children born in the winter. These differences have been, hypothetically, related to the greater amount of sunlight and the lower incidence of illness in the warmer as compared with the colder months.

In the case of children of exceptionally high intelligence the most favorable month of birth appears to be slightly different than for the total population. For children with IQ's above 130, and also for individuals of distinction listed in the *Dictionary of American Biography*, Huntington (1938) has reported a high rate of births in the late winter or early spring months. In conformity with his theories of climatic influence, he has argued that children born from February to April have a maximum developmental advantage due to the fact that the early months of the pregnancy fall in the preceding late spring and summer. It is these months, he believes, that provide the most favorable extrinsic conditions for promoting physical vigor and general development. Huntington has been criticized for failing to account for the complex operation of cultural factors influencing conceptions and abortions. "The various seasonal trends in births cannot be denied, but their explanation in terms of meteorological and resulting physical factors must be subject to doubt until more direct evidence is obtainable" (Jones, 1939, p. 99).

In this connection, Goodenough (1940c) later showed for a sample of over 3000 cases that seasonal differences in the frequency of births occur in the higher but not in the lower occupational groups. Since the children at the higher socioeconomic levels also average higher in IQ, the birth-month factor in intelligence can apparently be fully accounted for on the basis of selective planning or other conditions related to cultural status. This argument is supported by the fact that in samples presenting a restricted socio-

economic range, as in studies of college students (Clark, 1939; Held, 1940; Forlano and Ehrlich, 1941), intelligence differences related to birth month are either reduced or eliminated.

A different aspect of seasonal variation is considered in studies which have dealt with IQ changes in young children in relation to the month of testing. Wellman (1934) has reported that children in the University of Iowa Nursery School tend to show higher IQ's in the spring than in the fall. She attributed this to the effect of nursery school attendance. However, Lodge (1938) and Jones (1941) obtained similar results among children not in nursery school. In the Jones study, data for 1798 tests, given to children between the ages of 2 and 5 years, were examined with reference to the month of testing. The cases were balanced in such a way as to eliminate the influence of age and of test practice. The highest average IQ's were found in November, December, and January; the lowest in May, June, and July. Several alternative interpretations were offered for these results in terms of (1) the influence of climatic factors (such as periodic storms) upon mental performance, (2) the influence of climatic factors upon basic rates of mental growth, and (3) seasonal variations in play activities which have a positive transfer in mental test performance. Further studies are needed in different geographic areas in order to confirm these findings and, if they are confirmed, to provide an adequate explanation of the results.

Physiological Maturing. Chronological age is not always a good index of the *physiological time* through which a child has lived. In a group of the same age, wide individual differences will occur in the level of maturity assessed by physiological methods. These developmental indications include dentition, pubescence, the age of menarche, skeletal age assessed from X-rays, and anatomical age assessed from physical growth patterns. It has been suggested that a child's IQ at any given time should be computed by referring mental age to physiological rather than chronological age $\left(\text{IQ} = \frac{\text{MA}}{\text{PA}} \text{ rather than } \frac{\text{MA}}{\text{CA}}\right)$ This is illustrated in Figure 10. Case 9M presents a mental growth curve, in terms of raw scores, consistently superior to the average of the total group. He is, however, somewhat retarded in physiological maturing, and if allowance is made for this we find that his growth curve (plotted against skeletal age) is even further above the group average. Case 25M has a mental growth curve which agrees very closely with the average, but in skeletal development he is markedly accelerated. In terms of the number of *physiological years* he has lived, we note that his mental development lags considerably behind expectation. When data are treated in this way, it is possible that clues will sometimes be uncovered which will be useful in interpreting deviate mental growth curves or even in improving the prediction about subsequent growth.

Unfortunately, however, the concept of physiological age has as yet been put to little effective use except in a few research centers. The various measures of physiological maturity do not agree perfectly with each other, and a satisfactory composite measure has not been achieved. When we correlate a single index, such as skeletal maturity, with mental age, the coefficients (at a given level of chronological age) are usually too low to command special interest.[1] In one of the most comprehensive

[1] Abernethy (1936) and Bayley (1940b) have reported correlations which at most ages are positive but close to zero. Higher correlations were obtained by Severson (1920–1921) and by West (1936), although West found that coefficients dropped with increasing age.

studies yet reported, Gates (1924) obtained a measure of skeletal age as well as height and some other physical measurements; the multiple r of these with mental age was only .21. In the same sample, mental age predicted educational achievement to the extent of a correlation of .60; when the physical measures were added, this correlation was increased only to .63.

Zuck (1936) and Todd (1938) have sponsored the belief that environmental influences acting through illness or nutritional disturbance have a direct effect upon mental development and that in such cases prior changes are often to be noted in X-rays of the skeleton. Individual cases can no doubt be found to support this view, but the general importance of such relationships remains to be demonstrated.

Several studies have investigated mental test performance in relation to the age at puberty. In general, these have led to the tentative finding that IQ's are on the average lower in late-maturing individuals and higher in the early-maturing.[1] If these indications are confirmed, they can be interpreted as due either to a stimulating effect of sexual maturing upon mental growth or to a tendency of early-maturing individuals to represent a superior selection. The first interpretation would lead us to look for

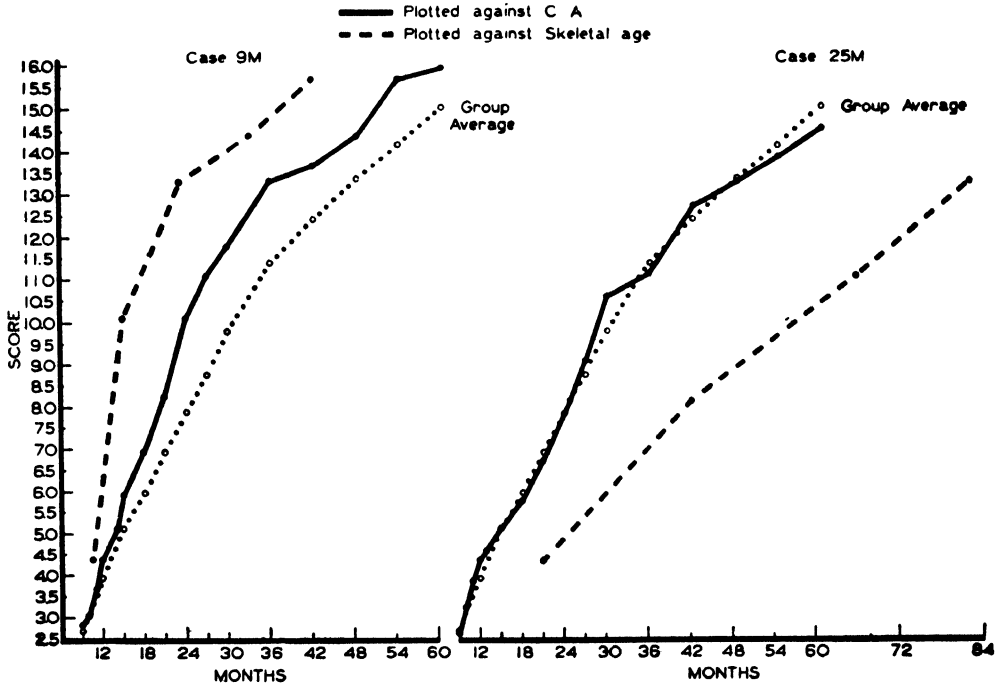

FIGURE 10. Individual mental growth curves, based on chronological age and on skeletal age. (From original data, Berkeley Growth Study.)

[1] A review by Shock (1939a) has summarized a number of investigations in which positive results were obtained. See also Conrad, Freeman, and Jones (1944). Negative results, as by Reymert (1940), have occasionally been reported. It is, of course, well known that at the pathological extreme exceptionally early maturing (pubertas praecox) often occurs without corresponding precocity in mental functions (Keene and Stone, 1937).

a spurt in the rate of mental growth accompanying the increased physical growth in adolescence; this has never been clearly demonstrated.[1] The second and more probable interpretation might rest upon one or several selective factors. It is possible, for example, that (for quite different reasons) the lower socio-economic groups are more heavily weighted with late-maturing individuals as well as with those of lower intelligence (see p. 659).

A readily measured aspect of physical condition is basal metabolism. At the pathological extremes, with which we are not here directly concerned, striking evidence of correlated physical and mental effects can be found in such conditions as cretinism and myxedema, with equally striking evidence of mental improvement after thyroid treatment in certain cases. It is reasonable to inquire whether thyroid function, measured through basal metabolic rate, is related to intelligence in a normal range of cases. This is important for our present topic, since within this normal range thyroid functioning may be disturbed by illness and other extrinsic factors and may also be controlled to some extent by appropriate régime and treatment. Shock and Jones (1940), however, for a school sample of approximately 90 children at an average age of 12 and 14 years, have at each of these ages and for each sex found no demonstrable relationship between highly reliable measures of intelligence and of basal metabolism.[2] This is another instance in which correlations that are quite clear in pathological cases vanish or become obscured when sought in a normal representative group. The authors suggest that "slight variations in functional activity of the thyroid gland are not reflected in changes in mental capacity because in most individuals other adaptive mechanisms are present which may compensate for this thyroid deficiency" (p. 374). To carry over this conception to the general problem of environmental influence, it is a reasonable hypothesis that intelligence itself involves an adaptive mechanism which can to some degree compensate for variations in the environment, at least within an ordinary range of social and physical conditions.

Environmental Factors in the Family Constellation

Birth Order. The hypothesis has been advanced that children who are the first-born in their families suffer, on the average, a handicap in mental development due to both physical and social disadvantages. The fact of physical disadvantage is well established. Many studies have shown that the first-born are on the average smaller and lighter at birth than later-born in the same families. They include more prematures and more cases of abnormal confinement. Jones and Hsiao (1933), in a study of 310 pairs of pregnancies, found among the first-born a greater proportion of instrumental delivery and of cases marked by poor physical condition after birth. A smaller proportion of the first-born receive normal breast-feeding (Schlesinger, 1923). Studies of later health and physical development[3] have not yielded consistent results; there is, however, a tendency to report a higher incidence of tuberculosis among the first-born.

1 The Harvard Growth Study, summarized by Dearborn and Rothney (1941), contains a large body of material pertinent to this hypothesis. No relation was found between the physical growth cycle and performance on intelligence or achievement tests.

2 Similar results have been obtained in other investigations reviewed by these writers, with the exception of two reports by Hinton (1936, 1939) asserting correlations ranging from .80 at age 6 to .53 at age 15 between IQ and basal metabolic rate. The study is difficult to evaluate because complete data are not furnished.

3 Summarized by Hsiao (1931).

The educational and social handicaps of the first-born are a matter of speculation rather than of direct proof. It is argued that first-born have the disadvantage of less experienced nurture by the parents, of less social stimulation (from older sibs), and frequently also of a less well-established economic security. However great or little these environmental differences may be, it is apparent that even in combination with a certain degree of physical handicap the average effects upon mental development are negligible.

It is unfortunate that investigators of this problem have been deceived by a number of errors of interpretation, the most important of which arises from the relation between birth rate and social status. Since families of higher social status tend to have fewer but, on the average, more intelligent children, in a mixed population the first- or second-born, for example, will have higher average IQ's than third or fourth children. This, of course, is not actually a consequence of order of birth but is due merely to the fact that the earlier birth orders are weighted with children from small families, who constitute a superior selection. If we attempt to remedy this difficulty by limiting our comparisons to children of the same family, a new difficulty arises from the fact that many intelligence tests are so standardized that the IQ tends to drop slightly with age. This artifact produces a lower average IQ among children of the earlier birth orders (since they are, on the average, older when tested). Another factor to be considered is the unfavorable weighting of late birth orders due to maternal age. It has been clearly shown that the offspring of mothers near the end of the childbearing period are marked by a slightly greater incidence of certain types of mental defect, including mongolism.

In an earlier critique (Jones, 1933*a*) of research in this field evidence has been given that when these and other methodological difficulties are properly controlled no birth-order differences in intelligence occur in normal samples. So far as this problem is concerned, we must then dismiss the environmental arguments as having little net weight. Atypical results, however, have been encountered in certain highly selected samples. Studies of gifted children by Terman *et al.* (1925) and of eminent men by Ellis (1926), Cattell (1927), and Huntington (1938) have shown a distribution of birth orders differing from chance expectation and strongly favoring the first-born (see Figure 11). No satisfactory explanation of this finding has been given. It is possible that the first-born more often become eminent because of greater incentive, but one would hesitate to apply this interpretation to the Terman material. An explanation in terms of differential educational opportunity would have even greater difficulty in including Terman's results with children. At least for this latter study, which is the only one dealing directly with intelligence test data, it is likely (as suggested by Terman) that the true explanation will involve some selective factor, such as the greater tendency to locate older than younger members of incomplete families in a restricted age range.

Sibling Resemblance. To illustrate the meaning of an r of .50, an example often used is "that degree of resemblance which is ordinarily found among brothers and sisters living in the same family." This order of relationship is now so well established that a study reporting a markedly lower sibling correlation in intelligence would be immediately suspected of an inadequate sampling or of tests deficient

in reliability or validity.[1] E. L. Thorndike (1944), on the basis of sibling coefficients of the usual magnitude, has proposed corrections for range and for attenuation. He concluded that in the general population the true sibling r is probably above .70, "implying a greater hereditary factor than has ordinarily been assumed." This may, however, represent an overcorrection, since sibling r's not far from .50 have been found in quite representative samplings with adequately reliable tests. One illustration is a study in Scotland, in which Roberts (1941) tested in a given community all of the children whose birth dates fell within certain limits. All their siblings of school age were also tested; the sibling correlation, for 650 pairs, was .53.

In one of the earliest studies in this field Pearson (1903) reported that family resemblances in mental traits were of the same degree as those in physical traits such as height, eye color, span, and head measurements. From this he inferred: "We are forced . . . to the conclusion that the physical and psychical characters in man are inherited within broad lines in the same manner and with the same intensity" (p. 204). Two considerations, however, must lead us to a more cautious interpretation of the evidence. First, our present knowledge of genetic mechanisms suggests that if intelligence has a hereditary basis it is genetically more complex than a trait such as eye color; differences in genetic composition might well be expected to produce differences in family resemblance coefficients. Second, a given degree of resemblance may (theoretically) be attained not only through the influence of a common heredity but also through the effects of living in a common environment.

Still another consideration involves the degree of selective mating in the popula-

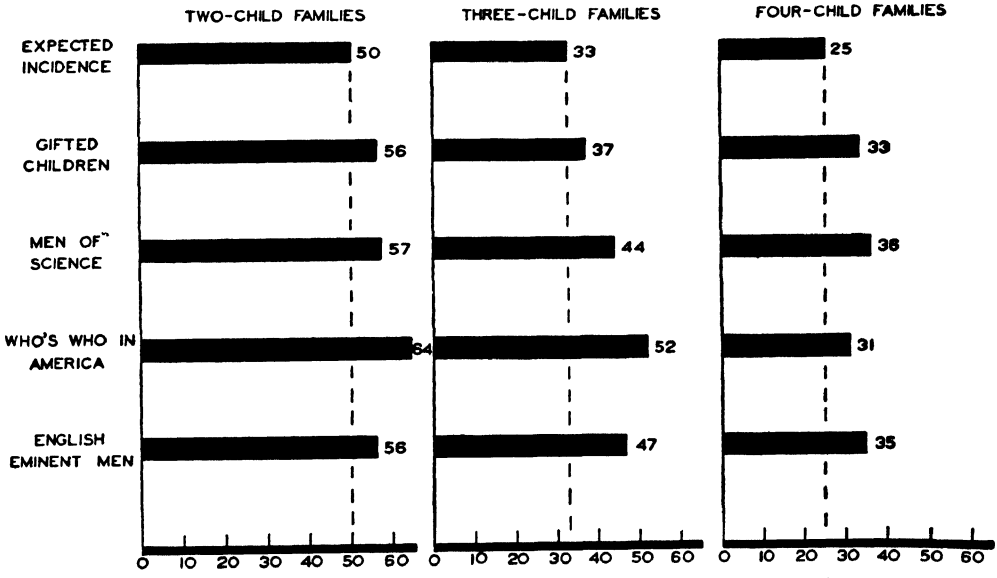

FIGURE 11. Percentage incidence of first-born, according to size of family.

[1] See Schwesinger (1933) for a summary of earlier investigations.

tion. Pearson, in his theoretical calculations, assumed that the correlation between husband and wife in intelligence was close to zero, but more recent studies show that the husband-wife coefficient tends to be as high as, if not higher than, the sibling coefficient.[1] Differences in selective mating with respect to different traits would be expected to have important effects upon family resemblances in these traits. We must conclude, then, that from a given degree of sibling resemblance no *immediate* inferences can be drawn as to causal factors. The pattern of sibling correlations, however, may prove significant when considered in relation to certain hypotheses of environmental influence. These hypotheses are:

I. Siblings of the same sex share, on the average, a more common social environment than siblings of opposite sex. Hence on an environmental basis higher correlations could be predicted for brothers or for sisters than for brothers-and-sisters.

II. Siblings close together in chronological age share a more similar environment than children widely separated as to age. Changes in social and economic status of the family, in home and neighborhood, and in the age and personal characteristics of the parents, as well as differences in schools and teachers, might be expected to have some average effect in lowering correlations for siblings with a wide natal interval, that is, separated by several years in age.

III. Older siblings have lived together longer than younger siblings and hence share a greater accumulation of environmental influences. It may also be assumed that as children grow older they become responsive to a wider range of environmental factors; in these factors families are more diverse than in factors to which younger children are sensitive. The effect of a greater variability in family environments should (on an environmental hypothesis) be to increase sibling correlations.

Each of these hypotheses may, at certain points, be questioned on theoretical grounds, but they have a sufficient common sense basis to justify an empirical test. Table 7 gives data relevant to the first of these hypotheses from a study by Conrad and Jones (1940). A representative sample of 777 pairs of children in New England rural communities was divided into three groups, on the basis of the tests used. Sibling correlations[2] varied around .50, with no tendency for like-sex siblings to show higher r's. As a comment on this finding, it has been suggested that the family constellation involves individual rôle-choices which may have a differentiating effect upon intellectual functions among like-sex siblings. Such factors, if they are conceived as influencing the development of basic mental abilities, may tend to balance out other factors associated with the more common environment of children of the same sex. On the present evidence, however, it is apparent that a defense of Hy-

TABLE 7

SIBLING CORRELATIONS

	Like-Sex Siblings		Opposite-Sex Siblings	
	Pairs	r	Pairs	r
Group A	159	.47	153	.55
Group B	178	.40	144	.55
Group C	158	.44	169	.46

[2] Studies by Willoughby (1927) and S. K. Richardson (1936) also report no significant differences in the coefficients for like-sex and opposite-sex siblings.

pothesis I will require ambitious ventures into speculation.

Data relevant to Hypothesis II have been supplied by Conrad (1931) for a sample of 778 pairs of siblings. Correlations were calculated for three different age groups and for siblings who were (1) less than 3 years apart in age and (2) tested at similar ages (on the average, 6 months apart in age) and at separated ages (on the average, 3½ years apart). For 101 cases in each group, identical coefficients (.49) were obtained. It is evident that the environmental influences associated with age differences of siblings are (on the average) without perceptible effect.

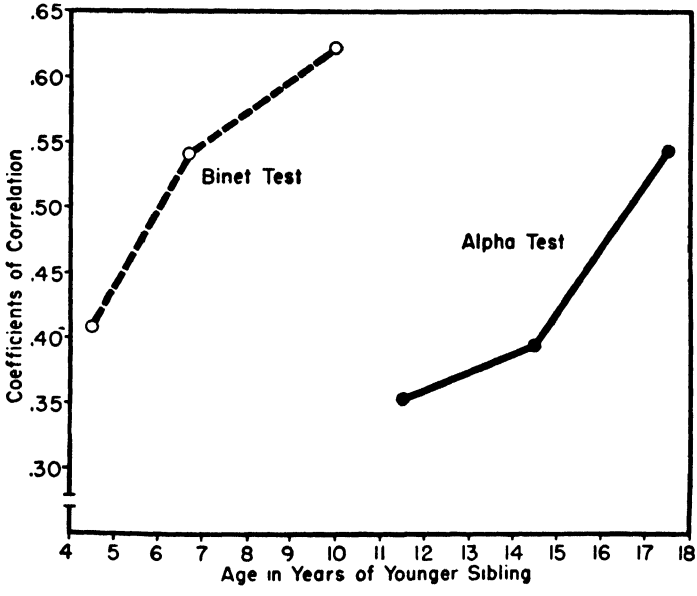

FIGURE 12. Sibling correlations, according to age of the younger sibling.

more than 3 years apart. The coefficients varied around .50, and no comparisons yielded significant differences. The natal interval problem may be approached also by correlating the score difference (IQ, or sigma score) of each sib pair with the age difference (natal interval) of the pair. A positive correlation would be expected if a greater age separation of siblings is accompanied by a greater difference in IQ. For large samples, Conrad in the above-mentioned study and Finch (1933) found all correlations unreliably different from zero. The temporal factor has been examined by S. K. Richardson (1936) in a different way by determining correlations for siblings

With regard to Hypothesis III, Figure 12 presents evidence as to increase of sibling correlation with age. This material, from unpublished data of Jones and Conrad, is based on a sample of 225 pairs of rural children tested with the Stanford-Binet and 210 pairs tested with the Army Alpha. For each subgroup, the maximum age interval between each pair of siblings is 5 years. In each test, the correlations show a definite tendency to increase with age. Although this is consonant with the hypothesis of increasing or cumulative environmental influence, it is unfortunately impossible to eliminate other factors which may also contribute to the age trend.

One might inquire why the correlation drops so sharply when we shift, at around 10 years, from the Stanford-Binet to the Army Alpha. The Stanford-Binet is not more reliable than the Alpha at this age, but it is probably more valid. The difference between these two tests at the same age may be due to much the same validity factors that operate to produce a difference within a given test at different ages. In other words, although the results indicated in Figure 12 can be plausibly attributed to environmental factors, it is equally plausible to account for them in terms of an increasingly valid measurement of basic abilities involving, with increasing age, the more complete expression of hereditary potentialities. It is interesting to note that in the case of the Alpha the highest sibling r (.54) is obtained in an age range extending into maturity, with many of the sibling pairs no longer living in the same homes. Environmental separation has apparently not tended to reduce measures of resemblance. Comparable results have been reported by Hildreth (1925), who found a correlation of .49 for 78 pairs of siblings separated, on the average, from 4 to 5 years.[1]

Before leaving this topic, reference should be made to one other type of sibling study which is of considerable interest for the present problem. This involves the measurement of resemblance among siblings reared in an institutional environment. If the similarity of brothers and sisters is due in part to the fact that they are reared in the same homes, the correlations would be expected to drop not merely when they are separated in different homes but also when they are brought together into the relatively homogeneous physical and social conditions of an orphanage. The best-known evidence on this topic is from a study of 216 pairs of siblings in California orphanages; the reported correlation (.53) shows no evidence of an effect of institutional life.[2] For siblings in a Hebrew orphan asylum in New York, Hildreth (1925) obtained a lower correlation but, on the other hand, found no evidence of a reduced variability such as would be expected if a common environment were influential. Similar results as to variability changes were obtained in an English study by Lawrence (1931), who compared institution children with a control group of children living in their own homes. The evidence suggests that when children move to a more uniform environment their IQ's do not become similarly standardized.

In a smaller number of studies, correlations have been reported between *unrelated* siblings living in the same homes. This is a promising method for examining the effect of the environment provided the original placement has not been made with reference to any social factor related to intelligence. Perhaps the best evidence on this problem is given by Freeman, Holzinger, and Mitchell (1928), who measured the intelligence of 112 pairs of unrelated children living in the same homes. On a

1 In the well-known Chicago study by Freeman, Holzinger, and Mitchell (1928) incidental data were reported for 130 pairs of siblings who had been separated for at least 4 years in different foster homes. The sibling correlation was .25, a diminished resemblance which may have been due to the reduced similarity in their environments. Burks (1928*b*, p. 321), however, has shown that this correlation rises toward the customary value if cases are omitted below 5 and above 14 years of age, eliminating individuals who are less adequately measured by the Stanford-Binet scale. In future studies, it will be desirable to know the sibling correlation before as well as after separation. If adoptive children are for any reason selected members of their families, and if the families themselves are a selected group, initial as well as the final correlations may be low because of reduced variability.

2 Originally reported by K. Gordon (1918–1920, 1919), the data were reanalyzed by Pearson (1918–1919) and Elderton (1923) in order to control age factors and also to render the correlation tables symmetrical. In correlations of siblings and of twins, the recommended procedure is to plot each pair of cases twice, transposing the axes (Fisher, 1930, pp. 178 ff.).

genetic basis alone, the correlation would be expected to be zero, whereas the coefficient actually obtained was .25. Although significantly lower than for true siblings, it suggests that a common environment tends to produce some degree of resemblance among individuals living together. However, a part of this relationship must be assigned to a selective rather than to an environmental factor, since the evidence concerning foster-child studies (see p. 684) indicates that placement agencies tend to locate children with some regard to the social and educational status of their true parents.

Twins. Studies of twins offer unusual advantages in the assessment of environmental influence, but up to the present few "crucial" results can be reported from investigations in this field. The following types of comparisons have been employed:

1. *Fraternal twins versus ordinary siblings.* On a genetic basis, fraternal twin correlations should be of the same order as coefficients for sibling resemblance (approximately .50). In fact, however, they tend to range slightly above this figure, occasionally being reported as high as .70. This difference in correlation, if genuine,[1] may be attributable to the more common environment shared by twins. In line with this interpretation are the results from an ingenious study by S. K. Richardson (1936), who artificially "twinned" siblings by recording their IQ's for tests given at the same ages. Under these conditions (as noted in a previous section), the sibling correlations were the same as when computed with the ordinary age intervals (.49 in each computation). On the other hand, true twin correlations tended to diminish when control measurements were employed for different ages (for example, one twin recorded at 8 years and the other at 10). Richardson concluded that "the environment of twins from birth is so similar that it tends to increase their natural resemblance" (p. 197). The twin correlation in this case was .73 for 92 pairs; the correlation for twins as of different ages was .57 for 45 pairs. This difference is not fully significant and would, moreover, be considerably diminished if Richardson had corrected for variability differences. The procedure is nevertheless a promising one and should be applied in further study with a larger number of cases.

2. *Younger versus older twins.* In the earliest twin study using mental test data, E. L. Thorndike (1905) found that in various traits twins 12 to 14 years of age exhibited correlations no higher than those of twins 9 to 11 years of age. He argued that if twin resemblance is due to environment, correlations ought to increase with age. We have here a possibility of a more sensitive test of hypothesis III, discussed on page 670, but still with difficulties in interpretation. Thorndike's negative results (supported, in general, by later studies) have suggested to some writers that small environmental factors may be acting in opposite directions. The effect of longer residence in the same home may make for greater resemblance; but, on the other hand, with increasing age twins may become more independent in their choice of activities.[2]

3. *Fraternal versus identical twins.* More definitive results have been expected in this than in the preceding types of analysis, since we have a comparison in which

[1] Twin correlations are subject to spurious inflation because of defects in test standardization, producing slightly lower average IQ's at higher ages. Some investigators have not understood the necessity of partialing out CA in order to control this factor.

[2] This can also be expressed by saying that interfamilial variations (differences among families) may tend to produce correlated changes in twins, with an increasing degree of resemblance, whereas intrafamilial variations may lead to uncorrelated or even negatively correlated changes.

environmental factors have been assumed to operate in a similar manner while genetic factors vary. The genetic difference consists in the fact that identical twins share the same gene determinants, whereas fraternal twins share a similar heredity only to the extent of ordinary brothers and sisters. Investigations have agreed that identical twins are on the average much more similar in intelligence than fraternal twins. Table 8 shows the twin correlations obtained in two representative studies.

TABLE 8

RESEMBLANCE OF IDENTICAL AND FRATERNAL TWINS IN INTELLIGENCE

(Stanford-Binet IQ, corrected for age.)

Investigator	Fraternal Twins		Identical Twins	
	N	*r*	*N*	*r*
Stocks and Karn (1933)	119	.65	68	.84
Newman, Freeman, and Holzinger (1937)	52	.63	50	.88

Newman, Freeman, and Holzinger found a mean IQ difference of 9.8 for pairs of siblings, of 9.9 for pairs of fraternal twins, and of 5.9 for pairs of identical twins. This latter difference, it will be noted, is similar to that reported on page 636 in connection with studies of the constancy of the IQ.[1]

1 Assuming that in representative samples identical twins correlate .90 in intelligence, ordinary siblings .50, and random pairs .00, Page (1941) has applied a formula predicting that the average intrapair IQ difference will be approximately 6 points for identical twins, 13 for siblings, and 19 for unrelated pairs, in terms of the 1916 Stanford-Binet.

Such results would be expected if twin similarities were primarily genetic, but we must also take into account the fact of a greater degree of environmental similarity. Several studies have shown that identical twins spend more time together, enjoy more similar reputations, are more likely to be in the same classrooms, have more similar health records, and in many other respects share a more common physical and social environment than that ordinarily experienced by fraternal twins (Stocks, 1930–1931; Jones and Wilson, 1932–1933; Wilson, 1934; Lehtovaara, 1938).

Comparisons of twin populations are sometimes made not in terms of resemblance coefficients but more coarsely in terms of intrapair "concordance" or "discordance" as to specified traits. Thus Rosanoff, Hardy, and Plesset (1937) found that among identical twins in whom one member of the pair had been identified as mentally deficient 91 per cent of the co-twins were also classed as deficients. Among fraternal twins this measure of concordance dropped to 47 per cent.

4. *Twin resemblance in contrasted abilities.* Here we are concerned with the comparison of (*a*) abilities subject to training and (*b*) traits usually thought to be relatively independent of training. In E. L. Thorndike's (1905) study it was found that the degree of twin resemblance in various traits bore little or no relationship to the susceptibility of traits to training. Hence it could be argued that for both kinds of traits twin resemblance is primarily an expression of genetic factors. Lauterbach (1925) and Wingfield (1928) have also used this method in demonstrating, to their own satisfaction, the relatively minor importance of environmental factors. For identical and fraternal twins combined, Wingfield found twin correlations of .75 for IQ, .76 for educational quotient, .78 for arithmetic scores, and .85 for spelling scores.

with no fully reliable differences. The problem is one of great complexity, however, and many factors affecting (*a*) the incidence of training and (*b*) the genetic constitution of the trait in question may operate to produce results which make direct comparisons difficult between different traits.

5. *The method of co-twin control.* Technically superior to the preceding method is a procedure limited to identical twins, in which one member of a twin pair receives specific training while the other is reserved as a control. During the experimental period both twins undergo mental growth owing to intrinsic maturation and to general functioning, and any residual difference between the twins must be attributed to the experimental factor in the environment. First introduced by Gesell in the study of motor traits, the application of this method by Strayer (1930) in studying language development, and by Hilgard (1933) in connection with memory tests, has led to conclusions emphasizing the importance of intrinsic factors. A co-twin study covering a limited age period can, however, yield no general statement as to the comparative rôle of training and maturation. Its results will apply *only* to that particular age level and to the *specific functions* which are experimentally trained.

During the 1920's and 1930's a number of investigators in the U.S.S.R. employed the co-twin method with reference to various traits including intelligence (reviewed by Levit, 1935). This promising line of research, not wholly in harmony with Marxian theory, appears now to have been abandoned.

6. *The comparison of identical twins reared apart.* In the absence of opportunities for the experimental separation of twins, the next best thing is to make use of separations which have occurred as a result of adoption in different homes. Here also reports have usually dealt with a single pair of twins, but in the well-known volume by Newman, Freeman, and Holzinger (1937) results have been assembled for a total of 19 pairs. The sample is, of course, a heterogeneous one, consisting of twins separated at ages ranging from 2 weeks to 6 years; at the time they were studied, their ages ranged from 12 to 60 years.

Ratings of the differences in the educational environments of the twins were made by five judges, three of whom knew only the case histories and two of whom also knew the twins. For all except 6 pairs of twins, the differences in ability were of about the same size as are found among identical twins reared together. Twelve pairs had small or negligible differences both in ability and in educational environment; for 1 pair there was no marked difference in ability even though a large difference in formal schooling had occurred. One pair with similar schooling showed a marked difference in ability corresponding to other differences in cultural opportunity; the remaining 5 pairs had experienced large or fairly large differences in education and showed corresponding differences in ability. Correlations for the 19 pairs were below the usual coefficient for identical twins, but higher than the usual coefficients for siblings reared together (.67 for the Stanford-Binet IQ, .73 for the Otis IQ). Conclusions from this research, emphasizing environmental factors more strongly than in most twin studies, have been challenged in a number of reviews.[1] The method remains, however, a most important one, and,

1 Burks (1938*a*), McNemar (1938), and Woodworth (1941). Woodworth has emphasized the fact that, when twins of identical heredity are subjected to environments differing about as much as those of the children in an ordinary community, the twins nevertheless remain much more similar than random pairs of children in such a community. This would suggest that interfamilial and general educational differences are not of primary importance in determining variations in IQ in the general population.

following the lead of Newman, Freeman, and Holzinger, we may expect significant results from a gradual accumulation of further cases of twins reared apart. An additional 4 cases reported by Burks and Roe (1949) unfortunately add little to our data on mental development, because of abnormalities in 3 of the 4 pairs.

7. *Longitudinal studies of twins.* Psychological case studies of twins have been exemplified not only in the work of Freeman and his associates but also in an interesting report by Koch (1927) on a pair of Siamese twins and in several studies by Carter (1934) on mature identical twins. These have been based on cross-section and retrospective records rather than on cumulative data. Detailed studies are greatly needed in which the year-to-year development of twins is examined with reference to the relationship of developmental and environmental changes, the consistency of small differences, and the interrelationship of differences. With cumulative observations it is possible to examine the rôle of factors which are usually inaccessible to experimental techniques (illness, accidents, and various "crises" of development).

The most careful longitudinal study of a single pair of twins is reported in a monograph by Gesell and Thompson (1941), covering a period from infancy to adolescence. Blatz *et al.* (1937) in a report on the development of the Dionne quintuplets during the first 3 years also present mental growth material of unusual interest which, it is hoped, may eventually be related to data obtained at later ages.

More complete reviews of twin research have been made by several investigators.[1] Although frequently exploited in journalistic treatments, it is clear that twin studies are not merely a scientific "stunt," but deserve continued serious attention as a basic approach to nature-nurture problems. Certain safeguards, however, must be maintained with regard to the following difficulties in twin research:

1. *Number of cases.* Plural births occur only in the proportion of about 11 per 1000.[2] A large population must be covered in order to establish an adequate sample. Thus, in locating approximately 500 pairs of twins, Wilson and Jones (1931) found it necessary to survey a school enrollment of over 75,000 pupils.

2. *Sampling methods.* The best method of locating twins is through birth records or by a questionnaire placed in the hands of all members of the group that is to be sampled. If reliance is placed on a census of twins by teachers, this method may lead to reporting all fraternal twins who are sufficiently similar to be in the same classrooms but may fail to place on record the fraternal twins who, being less similar, are located in different grades or different schools. Such a factor would spuriously increase coefficients of twin resemblance among fraternals, and it may be responsible for unexpectedly high correlations reported by some investigators. A representative sample of twins may ordinarily be expected to include about one-quarter identicals and three-quarters fraternals.

3. *The classification of twins.* In classifying twins as fraternals or identicals, various methods have been used, including reference to obstetric data on fetal membranes; physical measurements; skeletal X-rays; finger prints and palm prints; hair color, form, and distribution; eye color and the pattern of iris pigmentation; mi-

1 Some of the best-known treatments are by Dahlberg (1926), Hirsch (1930), Gesell (1931), Levit (1935), Newman, Freeman, and Holzinger (1937), Carter (1940), and Newman (1940). Especially valuable is an analysis of twin and foster-child studies by Woodworth (1941).

2 Triplet births occur in the proportion of approximately 1 per 8000. Several publications have appeared dealing with small samples of triplets. The best known of these is by Anderson and Scheidemann (1933).

croscopic capillary examination; blood agglutination grouping; and also more subjective methods based on the impression of similarity in general appearance. No one of these methods provides an infallible means of diagnosing identical twins, but with the application of a variety of methods a very high degree of agreement can be obtained in independent assessments by different investigators. In studying a given trait, such as intelligence, it is unsafe to use this trait as a part of the basis for diagnosis. Thus Hirsch (1930) selected identicals in terms of criteria which included mental similarity, a procedure which may have had the effect of exaggerating differences in correlations between the two types of twins. In general, however, errors in diagnosis will spuriously *reduce* the difference between identical and fraternal twin correlations. It is sometimes a wise policy to exclude a small percentage of cases as "undetermined" if these cases show a conflict in the objective criteria employed for classification.

4. *General selective factors.* Twins are subject to a heavier infant mortality than the single-born. The effect of this upon the selection of surviving twins is not fully known. One would expect it to improve the selection slightly; but, if this is so, then the prenatal or circumnatal factors affecting the development of twins must impose a decided handicap, for those surviving into school age are on the average slightly inferior to single-born in terms of a number of physical and mental criteria. This factor may also operate to eliminate divergent members of twin pairs, with the effect of increasing our measures of resemblance for those that survive.

An additional factor to be considered in interpreting research findings is that twins live in a very special social environment. Except in the case of twins reared apart, general conclusions from twin studies may not be immediately applicable to other selections of cases or other types of environment.

Parent-Child Resemblance. Chiefly because of the difficulty of obtaining intelligence test data for adults, relatively few studies of parent-child resemblance have been reported. In an early investigation, Pearson (1910) obtained a correlation of .49 between father and son, using ratings of mental ability. Subsequent studies employing intelligence tests have in general supported his finding that the resemblance of parents and children is of the same order as that of brothers and sisters.[1] This is not unexpected on the basis of hypotheses of genetic causation, but on an environmental hypothesis one would expect the sibling correlation to be higher, since the conditions under which brothers and sisters are reared, in a given family, are more similar than the conditions under which the members of two different generations are reared. It is a matter of unusual interest that these markedly different factors in childhood environments seem unable to exert any distinguishable effect upon the family coefficients.

The suggestion has sometimes been made that, since the mother spends more time with her children during early childhood and has more direct supervision over their activities, a greater resemblance might be expected between mother and child than between father and child. So far as mental abilities are concerned, this does not appear to be the case. With the largest sample reported to date, Conrad and Jones (1940) found no differences in parent correlations. In this study the parents and

[1] Somewhat lower coefficients have been reported by Willoughby (1927) and Freeman, Holzinger, and Mitchell (1928), but Pearson's results agree closely with those of Burks (1928*b*), Jones (1928), Banker (1928), Outhit (1933), Leahy (1935), and Conrad and Jones (1940). A review of earlier studies may be found in Carter (1932).

children over 14 years of age were tested with the Army Alpha; between 10 and 14 either the Alpha or Stanford-Binet was used; and below 10 the Stanford-Binet was used exclusively. Table 9 summarizes the result.

TABLE 9

PARENT-CHILD CORRELATIONS

	Stanford-Tested Offspring		Alpha-Tested Offspring	
	N	*r*	*N*	*r*
Father	232	.49	196	.49
Mother	269	.49	245	.48

The striking uniformity in these results would of course be predicted on a genetic basis, since on the average the two parents play an equal rôle in transmission of hereditary characters. The greater rôle of the mother in the intimate determination of the child's early environment appears to have no differentiating effect with regard to intelligence. An alternative interpretation, however, might be that such an effect, if present, is balanced out by some other environmental factor.

Like sibling coefficients, parent-child correlations tend to increase with age during the preschool period. This is illustrated in Table 10, based on data from a representative sample of children born in Berkeley, California (Honzik, 1950). The correlations are between children's scores on the California Preschool Schedules and ratings of mothers' intelligence made by two psychologists at the beginning of the study. The results, shown in Table 10, are of course not "crucial," since an increase in correlation would be expected on the basis of both environmental and hereditary hypotheses, and also as a result of any increase in the reliability and validity of the tests.

TABLE 10

CORRELATIONS OF CHILDREN'S MENTAL TEST SCORES AND RATINGS OF MOTHERS' INTELLIGENCE

Age	*N*	*r*
1.75	116	.11
2.0	112	.08
2.5	113	.06
3.0	115	.17
3.5	107	.39 ± .06PE
4.0	105	.38 ± .06
5.0	103	.53 ± .05

We have seen that studies of family resemblance have frequently led to ambiguous results as to the relative importance of environmental factors in mental development. In general, however, they have emphasized interfamilial differences in heredity as somewhat more potent than differences in family environments, for a normal range of subjects. These studies not only have their own implications but are also of value in providing a normative background for the interpretation of results from a quasi-experimental type of investigation in which "true" family resemblance is compared with the degree of resemblance achieved in foster relationships (see the section on children in foster homes, page 683).

The Effects of Schooling

The theory of intelligence or capacity measurement implies a curvilinear relationship between education and test scores (for children of a given age). Children of school age with no education will make low scores, regardless of their natural talents or "educability." But it is assumed that, beyond a certain level of educational advance, and within a normal range of school opportuni

ties, increments in training will not be accompanied by corresponding increments in mental test score. To assume otherwise would be to regard intelligence tests merely as tests of schooling. We know, however, that in groups relatively homogeneous as to education wide differences occur in test performance and that these differences persist even after extended exposure to a similar educational environment.

If it is maintained that mental growth can be controlled within narrow limits by educational factors, the burden of proof rests with those making this claim. It would appear to be a simple matter to set up an experiment in which an adequately large group is given experimental training of a type regarded as basically stimulating to mental development, and to compare the subsequent mental test records of this group with records obtained from a carefully matched control. In such an experiment, however, numerous precautions need to be taken. It is unfortunately true that in previous work these precautions have rarely been observed in their entirety:

1. The experimental and the control group should consist of matched pairs from the same population, one member of each pair being assigned at random to the experimental or the control procedure. It usually happens that the experimental group is already "given" to the experimenter in the membership of a specific school sample. He must then make a search for suitable controls. Unless he is fully conversant with the factors which have determined the selection of the experimental sample, it is unlikely that he will succeed in matching this selection completely. Thus, if exceptional intelligence of the parents is a factor determining the placement of children in nursery schools, a matching on the basis of children's IQ will be unsatisfactory, since the children in the experimental group will show differential gains merely as a result of increasing approximation to the level of ability characteristic of their families.

2. In the selection of cases, homogeneous groups are needed. In the nursery school, for example, it is possible that educational experiences provided in the school exert differing effects according to the age and cultural background of the children concerned. The mixture of cases of various ages and various social groups(as usually occurs) may yield results extremely difficult to interpret. An additional factor to consider in selection is the much-discussed phenomenon of statistical *regression to the mean.* If, for example, a group of children of below-average ability is selected for special educational attention, retests will probably show a movement toward the mean not necessarily because of true changes but because of compensation for errors of measurement which influenced the original selection. These difficulties, as well as other ambiguities, can be reduced by increasing the reliability of the measurements, as, for example, by the procedure of basing all scores on the average of two tests on successive days.

3. The criteria for matching the experimental and control pairs should include chronological age, initial IQ, and physical status of the children, intelligence (or, at any rate, education) of the parents, and a socio-economic index for the home. It is insufficient to match merely on the basis of the children's IQ's, since changes in the nature of the tests may lead to later IQ differences arising from unmatched factors in the original selection and not from the experimental procedure.

Attention must also be given to the maintenance of comparable conditions in the initial testing. Thus, if the nursery school children are tested in the stress of their first attendance at school and the control children are tested under familiar conditions

at home, the experimental group may show larger gains on a second test, owing chiefly to gains in rapport. With young children, attention should be given to assessments of effort, cooperation, freedom from inhibition, response to success or failure, and other motivational factors considered with reference to possible effects upon test performance. It would, of course, be desirable to establish controls on the basis not merely of a single period but of a series of tests representing a segment of the growth curve prior to the beginning of the experiment. Children are sometimes given superior educational opportunities because their mental growth appears to be temporarily restricted. This apparent restriction, however, may be due to any of the intrinsic or extrinsic factors discussed on pp. 643ff. Later gains, giving the impression of an improved rate of growth, may represent changes in these factors rather than the effects of the nursery school experience.

4. The experimental situation should be analyzed and described in detail. Investigations which give a vague report of positive effects from undefined "school experience" can neither be interpreted nor repeated unless the specific basis of these effects is made known. Such information is also necessary in order to determine whether the effects are (*a*) merely specific transfers to certain kinds of test items, (*b*) the result of attitude changes or increased incentive, or (*c*) a more generalized change in mental efficiency.

5. Subsequent test comparisons of the experimental control pairs must involve equal amounts of test practice, comparable tests, and comparable conditions in testing. If retests are made by persons who are strangers to the control group but (as teachers or staff members) are well known to the children in the school, differential apparent gains may occur as a result of this factor.[1] These considerations lead to a further requirement namely, that, when a test is given, the examiner should not be familiar with the results of previous tests and should not know whether the child is in the experimental or in the control group. Subjective factors in the administration and scoring of such a test as the Stanford-Binet may lead to a conscious or unconscious biasing of the results by examiners who think they know how the results "ought" to turn out. Krugman (1939) and Goodenough (1940*b*) have discussed the possible rôle of these subjective factors in determining basal and final ages and in reaching decisions as to the scoring of marginal successes or failures.

6. The test program should be continued for several years, in order to determine whether possible effects are temporary (and specific to certain test items at certain ages) or whether they are expressed in more lasting effects upon mental development.

7. Finally, since any obtained effects are likely to be small in magnitude, a substantial number of cases is needed in order to reach a well-founded decision as to the significance of differences.

The reports on the effects of nursery school training should be examined in the

[1] In the report by Barrett and Koch (1930) the nursery school cases making the greatest IQ gains were also those regarded by the teacher as showing the greatest improvement in personality traits. Krugman (1939), in difficult clinical cases, attributed the largest changes in test performance to changes in rapport or cooperation. The following comment by Black (1939) is also illuminating:

"In our experience at the Harriet Johnson Nursery School we have found resistance and shyness to be far less characteristic of the nursery school than of the nonnursery school child, regardless of age. The school situation itself tends to produce rapport between examiner and child before the examination begins. Freedom, a feeling of security in the school situation, and in increasing sense of the friendliness and trustworthiness of adults recognized as belonging to the school make the test situation relatively easy for the child and the examiner" (p. 164).

light of the foregoing experimental criteria. An early study by Woolley (1925), with inadequate controls, reported an apparent effect of preschool education upon mental development. Similar results were obtained a few years later by Barrett and Koch (1930) in an orphan asylum group. Because of the small numbers of cases and the lack of adequately defined experimental conditions, and also because of negative evidence in two other studies (Hildreth, 1928; Goodenough, 1928*a*), the majority of workers in this field turned from the problem as presenting little hope of further reward. It is to the credit of the Iowa group of investigators that they maintained a persistent interest in the possible effects of nursery school education and formulated an extensive and versatile program of research. In general, this research has been interpreted by Wellman and her associates as indicating potency of the preschool environment in generating marked and persistent changes in mental growth. The *Thirty-Ninth Yearbook of the National Society for the Study of Education* (Stoddard *et al.*, 1940) contains a summary of the Iowa studies, together with reports on 9 other preschool investigations, the majority of which were stimulated, in 1938 and 1939, by the strikingly positive findings reported from Iowa. A later summary by Wellman (1945) covers results on 22 preschool groups.

Partly in answer to statistical criticisms, Wellman and Pegram (1944) have reexamined earlier data, with analyses of variance applied to records from an orphanage project in which half of the children of preschool age were enrolled in a nursery school. They concluded, as in a previous report by Skeels *et al.* (1938):

> (*a*) that the control environment (of the orphanage) produced substantial losses in IQ when experienced for long periods, (*b*) that preschool education supplementing the control environment counteracted such losses, (*c*) that whether or not the preschool environment produced gains depended upon the amount and consistency of preschool attendance [p. 263].

McNemar (1945) has also reanalyzed the same data, pointing out the advantage of a covariance method and finding that, whereas gains are demonstrable for the preschool group, losses in the control group are apparently due to selective factors. He therefore rejected conclusions (*a*) and (*b*) above. Conclusion (*c*) is supported by significant positive correlations between IQ gains and amount of school attendance, but McNemar noted that statistical analysis cannot determine whether the changes are due to mental gains from preschool learning or to some factor such as increased rapport. These difficulties in interpreting a given body of data suggest that our chief need in this field is not for statistical methods of greater power and subtlety but for more rigorous experimental procedures with larger numbers of cases.

It may be observed that for the most part the various studies present a negligible relation between IQ change and length of attendance in nursery school. With a few exceptions they agree in showing a slight difference in favor of nursery school groups when these are compared with control groups.[1] Although the difference often fails to be statistically significant, the findings are sufficiently consistent to be of interest. At the present time disagreement exists as to the extent to which errors of measurement, of experimental procedure, and of statistical treat-

[1] The highly controversial literature on this topic includes discussions by McNemar (1940), Goodenough (1940*a*), R. L. Thorndike (1940), Stoddard and Wellman (1940), Wellman, Skeels, and Skodak (1940), and Stoddard (1943).

ment may be responsible for results which have been so enthusiastically advocated as evidence that mental growth responds promptly and permanently to educational influences in the nursery school.

In our discussion of IQ constancy and the mental growth curve it was shown that with many children the preschool period is marked by a considerable degree of irregularity or variation in mental growth. It is tempting to the educator to believe that these variations are readily subject to his management and control, but as yet he cannot regard the evidence in this field as satisfactory. No one doubts, however, that the nursery school presents opportunities for promoting development in traits more directly amenable to environmental influence and perhaps more essential for adjustment at this age level. In commenting on the Iowa studies, Burks (1939) has stressed the importance of such factors:

> The preschool ages constitute the period *par excellence* not only for developing constructive attitudes toward tasks but for integrating these with a sense of personal value and with feelings of security in social relationships. To accomplish this integration, however, would not necessarily mean that maximal mental growth during the preschool years was necessary or even desirable for all children. Rather, it would seem that the growth of adaptive behavior should be stimulated and guided—often in special instead of in all areas—so as to achieve an harmonious balance with the expanding personality needs of each particular child [p. 555].

It seems probable that such gains in IQ as have been reported are not too large to be accounted for in terms of (1) the effect of personality improvement upon mental functioning and (2) the effect of the nursery school experience upon the reliability and validity of measurement. In some studies in which the initial test was given before or shortly after entering school, subsequent gains are often more apparent than real. The initial test "undermeasures," in part owing to the strangeness of the situation and unfamiliarity with the examiner, and in part owing to other psychometric handicaps (inappropriateness of test procedures), which may be controlled after a short period of school experience; this is illustrated for both verbal and nonverbal tests in two studies by McHugh (1943, 1945).

It is quite reasonable to expect some IQ gains among children released from a static and unstimulating environment, whether this release is provided by a nursery school, a foster home, or other environmental change.

Wellman and McCandless (1946) have attempted to examine some of the other aspects of preschool experience which can be hypothesized as related to IQ gain; their results are for the most part inconclusive, although opening an interesting area for further research.

Environmental factors in later schooling have been considered in connection with general studies reviewed on p. 656. The evidence in this area is even less satisfactory than in the nursery school investigations, chiefly because of the lack of data from appropriate comparison groups in definitely contrasting educational situations. Goodenough (1940*a*) has summarized the relevant work in this field through the year 1939, concluding that "the attempts to demonstrate the differential effects of different kinds of school practice upon child achievement have been disappointingly meager when suitable controls have been employed," and that differential effects upon intelligence are even harder to demonstrate by methods used up to this time (p. 330). This should not be taken to imply that the problem has already been

answered in the negative but rather that our present need is for more definitive research.

During the 1940's the study in this field receiving the greatest attention is reported in a monograph by Bernardine Schmidt (1946). Of 195 subnormal children retested at the end of 6 years, more than half were asserted to have made gains in excess of 30 IQ points. A control for a part of this group showed average losses of 3.6 points. Kirk (1948) has analyzed the Schmidt materials in connection with a restudy of some of the original data in the Chicago public schools. So many disturbing points have been raised by Kirk and others that the conclusions of the study now seem in considerable doubt.

Children in Foster Homes

Only a limited view of the possible effects of environmental influence can be given through the experimental control of the school environment. Unfortunately, no studies have been made of a representative sample of children observed under conditions involving an experimental, and parallel, modification of factors both in the home and in the school. Such a study would require the random separation of pairs of siblings (or, preferably, identical twins) and their rearing in homes and schools possessing certain specified differences. We do, however, have a number of investigations of children placed in foster homes. These, though limited in a number of respects, provide us with some of our most penetrating evidence concerning the nature-nurture problem.

Studies of foster children have been discussed in reviews by Goodenough (1940*a*) and Loevinger (1940) and need not be presented here in detail. The two researches that are most comparable as to procedure are by Burks (1928*b*) in California and by Leahy (1935) in Minnesota. Each investigated approximately 200 children placed in foster homes before 12 months of age. Each obtained intelligence tests of the foster parents, a cultural-economic assessment of the home environment, and a record of the foster child's IQ after he had reached school age (between 5 and 14 years). Moreover, in each investigation a "true child" control group was set up which would permit comparisons of parent-child relationship with and without the presence of a systematic hereditary factor.

It is often found that the selection of children available for adoption in official placement agencies is slightly superior in average intelligence; for Burks's 204 cases the mean IQ was 107.4, and for Leahy's 194 cases (all of whom were illegitimate) the mean IQ was 110.5. Figure 13 presents some of the more important results of these studies. In this figure r has been converted to r^2 in order to indicate the percentage of the variance of children's test scores "accounted for" by a given correlation. Thus, in the Leahy study intelligence of the mothers may be said to account for 26 per cent of the variance of own children but for only 4 per cent of the variance of foster children. From the results shown in this figure the inference can be drawn that the correlations with home environment which have been found in the case of true children are due primarily to the common factor of the parents' intelligence rather than to the environment acting as a causative agent. That is to say, the intelligence of the parents finds expression both in the culture of their home and in the IQ's of their children. What, now, will happen when the hereditary factor is eliminated from parent-child correlations (through the use of foster children)? Should we not expect that this elimination will also directly affect the correlation of the child's IQ with measures of

the (foster) home environment? These correlations do actually drop to low values, ranging from .07 to .21. That they remain higher than zero can perhaps be ascribed in part to the tendency for adopted children to shift toward the level of the homes in which they are placed. However, an additional factor is present in that the placement of children is rarely experimentally random. In other words, when placement officers have knowledge of the cultural circumstances of the true parents, this is likely to influence their choice of foster homes. Even with elaborate precautions against selective placement, a positive relation has been shown to exist between the occupations of true and foster parents.

When children are placed at ages later than infancy, the aim of "fitting the child to the home" will result in an increased likelihood of selective placement. This appears to have been a factor in the study of Freeman, Holzinger, and Mitchell (1928) of 401 children in Illinois who were placed at an average age of 4 years, 2 months. When tested at around 11 years, the correlation with a measure of the foster home [1] was .48. This value, as high as would be expected in a "true child" sample, was apparently influenced somewhat by a choice of foster homes appropriate to the intelligence or to the family origins of the children. If this choice were made without including intelligence tests of the true parents, the subsequent correlation of children's IQ with foster parents' intelligence would

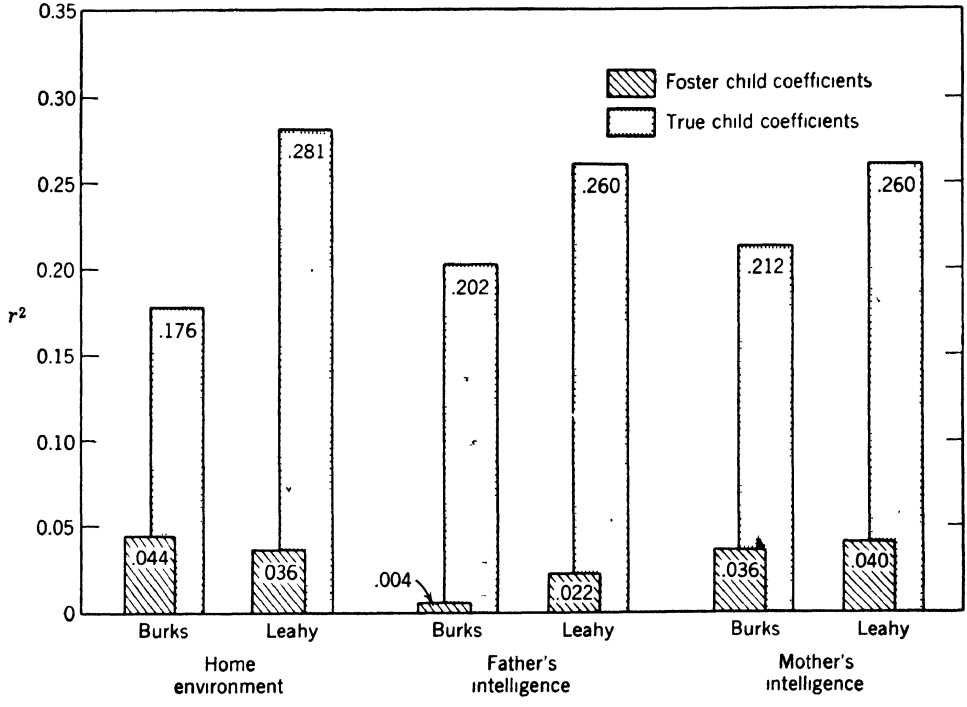

FIGURE 13. A comparison of foster child and true child correlations.

[1] Based on ratings of the material environment, evidences of culture, education of the parents, occupation of the father, and social activity of the parents.

be expected to be lower than for true parent-child relationships. This proved to be the case; for 255 mothers and 180 fathers who were tested when the children were 11 years of age, on the average, the correlation with the foster child's IQ was .28 for the mothers and .37 for the fathers. For a subgroup of 74 children another and more direct type of analysis was possible since tests were available both before and after the children had been in a foster home. The average age of the children at placement was 8 years; at the time of the retest, approximately 12 years. A significant average gain in IQ was shown for children placed in superior homes, and a less significant gain for those placed in poorer homes.

Similar results have been reported in a number of studies in which children were removed from bad home situations and placed in an orphanage or a boarding home (Lithauer and Klineberg, 1933; Wells and Arthur, 1939; Skeels, 1940; Speer, 1940*a*, *b*). In such cases, apparent gains are suspect because of difficulties in obtaining a valid test at a time when a child's home is broken or when emotional factors may be present from previous home conditions. Poverty, drunkenness, sex delinquency, inadequate food and housing, and many other disturbing factors are frequently cited as characteristic of the true homes and as giving rise to the need for placement elsewhere. It is difficult or impossible to appraise IQ gains in foster homes unless the initial tests are given under conditions in which test performance can genuinely register the child's ability. A further, and perhaps the chief, explanation of differences between the results of this study and those of Burks and Leahy can be sought in terms of random sampling differences.

An incidental outcome of the Freeman, Holzinger, and Mitchell study has been pointed out by Lorimer and Osborn (1934). For 156 children classified as members of good, average, and poor foster homes, mean IQ's were obtained of 111, 103, and 91. These differences could be attributed both to environmental influence and to selective placement. However, when the group was subdivided into legitimate and illegitimate children, the former were found to have a mean IQ of 95 and the latter of 106, with similar differences present in each grade of homes. The illegitimate children apparently represent a superior hereditary selection, and this superiority has by no means been obliterated by removal from their true parents.

Similar inferences can be drawn from a report by Stippich (1940) involving a comparison between 48 children whose mothers were feeble-minded, and 29 children of normal mothers; all had been placed in boarding homes before 12 months of age. On the basis of tests given after they were 3 years old, marked differences were noted between the two groups, although they were developing in apparently comparable environments. Twenty-one per cent of the experimental group (children of mentally deficient mothers) and none of the control group fell below 75 IQ. Here, again, the ubiquitous problem of selective placement must be considered. Comparability of the two groups of foster homes appears to be more a matter of assertion than of proof; if there was any tendency to place the children of feeble-minded mothers in less adequate homes this might to some extent account for the results obtained.

Somewhat different results have been reported by Skeels (1941) for a sample of 87 children of mothers who were mentally retarded. After placement in adoptive homes the children attained a mental level "equaling or exceeding that of the population as a whole." For the present purpose, comparisons of small samples of children of feeble-minded and normal mothers are un-

satisfactory unless there is adequate information about (1) the diagnosis of the mothers, (2) the conditions of placement, and (3) the mental status of the fathers. Cases should be ruled out in which the mothers' mental deficiency is of clearly secondary origin, as from injury or disease, and in which there is no other record of mental defect in the family. It is also important to know whether the children who have become available for adoption represent a genuinely unselected sample for the families considered. Results would be extremely difficult to interpret if the more retarded children of a defective mother are kept at home or sent to an institution, whereas the more normal offspring are accepted by foster homes. Finally, the mental status and family origins of the fathers cannot be neglected. In the case of illegitimate children of feeble-minded mothers, the ordinary principles of assortative mating may not be operative. It is obvious that "crucial" findings cannot be expected if a substantial proportion of the true fathers are of normal intelligence or derive from families of normal intelligence.[1]

A more recent foster child study is that reported by Skodak and Skeels (1949) on the basis of a fourth and final testing of 100 children placed in adoptive homes some 15 years earlier.[2] In each case placement was made before the age of 4 months. Table 11 gives the average results for successive tests, based on the Kuhlmann-Binet

TABLE 11

Test	*Mean Age*	*Mean IQ*
I	2.2	116.8
II	4.3	112.4
III	7.0	114.8
IV	13.5	107.1

for foster children under 3 years and on the 1916 Stanford-Binet for older children. Subdivided further by age, the highest mean IQ was obtained at 1 year (120.1) and the lowest, in comparable groups, at 14 years (102.4).

The conclusion was offered that the effect of superior foster home environment is shown in the results and also that in general the children exhibit higher test scores than would be expected on the basis of their familial origin. It is undoubtedly true that the foster parents are on the average superior to the true parents in social and educational status. But the true fathers are representative of Iowa males in educational attainment and perhaps not markedly inferior in occupational status if allowance is made for age factors. The chief stigma of the true parents seems to be in the IQ of the mothers. Intelligence measures available for 63 cases show a mean IQ of 86, or slightly more than 1 SD below that of their adolescent children. Factors to be considered in interpreting this discrepancy are (1) the validity of the mothers' tests, administered at a time of probable emotional stress, (2) regression of the children to the mean, and (3) the probability that the sample of mothers includes some cases of mental retardation of secondary origin. If it is assumed that the difference between true mothers' and chil-

1 Foster-child studies have not as yet utilized intelligence scores for true fathers. The first study making use of test scores for true mothers was carried out by Skeels (1936). Snygg (1938) reported results from Stanford-Binet IQ's of 312 true mothers and adopted children, in a Toronto study. Parent-child correlations in these two investigations were .09 and .13, respectively; mean IQ's of the mothers were, respectively, 84 and 78, and of the children, 115(?) and 95. These results are not in line with those based on our most carefully controlled and most fully reported foster-child studies. Unfortunately, a further interpretation is difficult because sufficiently complete data have not been presented concerning methods of sampling and conditions of testing.

2 Earlier reports in this series are by Skodak (1939), and Skodak and Skeels (1945). The terminal report in 1949 is especially to be commended for the presentation of the original data in complete form.

dren's IQ's can be attributed wholly to the superior educational opportunities of the foster homes, this effect is apparently consummated in early infancy, since the children's IQ's tend to diminish rather than to increase after 1 year of age.

the Burks and Leahy studies. For this sample, Honzik (1952) has examined age trends in the correlation of children's IQ with the education of their own mothers (from whom they had been separated since early infancy). In Figure 14 these age

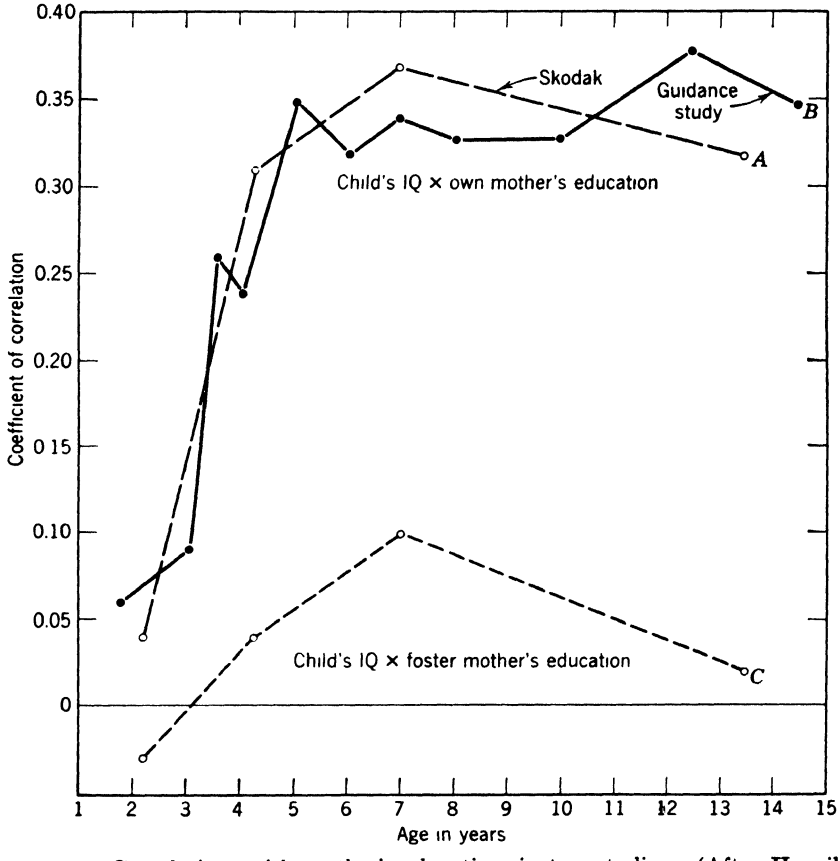

FIGURE 14. Correlations with mother's education, in two studies. (After Honzik.)

The correlational data furnished by Skodak and Skeels are easier to interpret than the data on IQ means. The children's IQ's show approximately zero correlations with measures of the foster parents' education. But the correlation with true mother's intelligence is significant at all ages beyond infancy, and in adolescence is of the order of .4, or only slightly lower than that in

trends (*A*) are compared with similar correlations (*B*) for a sample of approximately 200 Berkeley children living in their own families. The third curve, *C*, presents correlations between the adopted children's IQ and the education of their foster mothers. The framework of environmental theory within which the Skodak and Skeels study was conducted would lead us to expect *A*

to be markedly lower than *B* and perhaps also lower than *C*. The obtained results, however, provide added evidence as to the relatively small weight of environmental factors in producing parent-child resemblances in the variables studied.

One of the most important types of research to be conducted in the future will involve the placement of foster children on the basis of a planned experimental design, rather than the study of children whose location has been previously determined by uncontrolled and incompletely known factors. To appraise the results of such an investigation, it would be necessary to have intelligence tests of all the true and foster parents, a goal that has never yet been reached. The intelligence of the children should be observed cumulatively, and a cumulative inventory should also be maintained of relevant environmental factors in and outside the home. Previous studies, which are necessarily inconclusive at many points, may be regarded as preparing the ground for more thorough and better-controlled investigations which still remain to be conducted. Barker (1951) has pointed out that although we are now ready for such an investigation and that it could lead to solving an important social problem, the cost would be much greater than any amounts now available for research in child development.

So much has been written on the topic of environmental influence that it has not been possible within a single chapter to review all the significant reports and discussions or even to refer to all the principal methods of approach. Little mention has been made, for example, of studies of feeble-minded or gifted children, of the mental growth of institutionalized children, or of mental growth or achievement gauged in other ways than by intelligence tests. Reference has been given, however, to numerous other sources in which further materials can be found. A topic as yet very incompletely studied involves the relationship between intelligence and personality and the effect of variations in emotional adjustment and personal integration upon the nature and the efficiency of mental functioning.[1]

In its social import the nature-nurture problem extends not merely into every branch of education but also (because of the differential birth rate) into the field of population and social planning. It is evident that the approach to this problem has, since 1930, led to striking improvements in research method and to a clearer awareness of the complexity of the issues with which we must deal. When we seek a better understanding of human potentialities in intelligence, we are at the same time appraising the rôles which environmental factors can play in the functional development of our capacities for adaptation. It must be emphasized that this is an extremely varied task. Future research must address itself not to a single ultimate solution of the problem but to an examination of its many aspects, in many specific situations.

CHAPTER 11

THE ADOLESCENT

JOHN E. HORROCKS

Historical Background

There are many possible approaches to the study of human development. The approach may be that of the psychologist, the sociologist, the anthropologist, the biologist, the physician, or the educator. Within each of these disciplines, in turn, are different ways of considering development, depending upon the bias of the investigator and his purposes in engaging in its study. Consideration may be in terms of a large and significant area of growth and development as personality, social behavior, intellectual growth and decline, physical increment, or physical or physiological functioning. Customarily, the modern study of development has tended to become segmented into the study of chronological age groups in terms of growth, behavior, and problems of a given age group as the neonate, the preschool child, the "middle child," the preadolescent, the adolescent, the adult, and the senescent. It has been recognized, however, that such age distinctions are at best arbitrary, that there is much overlapping, and that no one age group may be fully considered without recognizing its antecedents in an earlier age or its implications for a later one. Still, for pragmatic as well as research purposes large age divisions have been found a practical method of approaching the study of development. Children of a given age range, for example, are usually to be found in school together, associating with each other, and confronted by many common physical and culturally engendered problems.

Adolescence has been one of the major age areas widely studied by those interested in development. Historically, in all cultures and in all eras adults have been exceedingly interested in the activities and welfare of their children. This interest has partly stemmed from a concern with the immediate welfare of children. It has also been a product of the longer national and cultural desire for perpetuation and recognition that children must some day assume the responsibility of carrying forward the tasks begun and the institutions erected by their elders.

From earliest historical times one finds discussions and descriptions of the second decade of life. Aristotle described the advent of puberty and its associated physical changes. In his *Rhetoric* he dwelt at length upon the psychological aspects of the period, particularly as they offered a contrast to the characteristics of people of more mature years. In his *Historia Animalium* he discussed puberty specifically in terms of its physical concomitants, including an extended description of the appearance and effect of secondary sex characteristics. Following Aristotle various authors discussed the period of puberty, although their accounts, like his, whereas often observational, were subjective and speculative and led to generalizations that were never subjected to experimental or other objective verification. Also, while in many cases the period of

puberty was not actually written about, it was officially observed and celebrated in cultures ranging from the most primitive to the most advanced. The Roman feast of the *liberalia* during which 16-year-old males assumed the *toga virilis*, and the later Christian custom of confirmation during the period of puberty, are cases in point.

Writers have accorded youth a prominent place in romance and poetry, in biography, and even in philosophy. Plato in his *Dialogues*, although primarily concerned with adults, includes discussions that embody the point of view of youth. Socrates' talk with Lysis in which Lysis complains to him that even his father's servants are allowed to drive the family horses while he is not allowed to do so is reminiscent of the present-day youth who has a similar grievance about the family car. Playwrights and novelists, interested observers of their times, have included descriptions of youth down through the ages, ranging from the lengthy story of Telemachus, the only son of Ulysses, which is told in the first four books of the *Odyssey*, to the more modern writings of Tarkington (1916), Remarque (1928), Marks (1936), and Maxwell (1945). Libby (1901) in a study of the incidence of adolescents in Shakespeare estimates that there are "seventy-four interesting adolescents among the comedies, forty-six among the tragedies, and nineteen among the histories." He notes that there are in particular "thirty characters who, either on account of direct references to their age, or because of their love stories, or because they show the emotional and intellectual plasticity of youth, may be regarded as typical adolescents."

Such considerations of adolescence were, of course, literary or speculative and were neither scientific nor systematic in nature, nor did they approach the problem from the framework of any discipline such as psychology. The nearest approach to a consideration of adolescence from a systematic point of view within an organized area of knowledge occurred in the work of educators or people interested in the education of youth. Francke during the seventeenth century delivered a series of lectures at the University of Leipzig under the title "The education of boys and pubescents" (*De informatione aetatis puerilis et pubescentis*). Rousseau, probably influenced by his own youth, showed considerable interest in the time of pubescence and recognized clear-cut periods of development. He noted that the most crucial event in ontogenesis is the emergence of sex, and he wrote at length in *Emile* upon the period from 12 to 15, which he called "The Age of Reason." Herbart in the early years of the nineteenth century, noting that the ages from 10 to 17 constitute the period of greatest susceptibility to instruction, pointed out that the development of the individual recapitulates not only the phylogenetic stages of development but the cultural ones as well.

The real impetus to the study of development, however, grew out of the work of the nineteenth century evolutionists following Darwin, who, seeking all available evidence to support their theories, felt that in the study of childhood would be found the needed evidence. G. Stanley Hall, after Herbert, was one of the first psychologists to give really serious and prolonged consideration to adolescence as such. His two-volume work *Adolescence* summarized his own thinking and extant research and set the pattern for whatever work was done on adolescence for the quarter-century following its publication in 1904.

The possibility of a two-volume treatise on adolescence in 1904 indicated that a field already existed and that much prior work had been accomplished. Such was the case, for an examination of the literature for the 15 years immediately preceding Hall's book reveals a respectably large

group of publications on adolescence. Of this material a great deal, although by no means all, was due to the work of Hall and various of his students. In 1882 in an article on the moral and religious training of children Hall had indicated the psychological nature of the adolescent and stressed the importance of a careful study of the period. Following a similar line of reasoning Burnham wrote in 1891 that "a study of the psychology of adolescence should form a part of the education of every teacher in the higher institutions. The subject should be studied scientifically from the standpoint of physiology, anthropology, neurology, and psychology, and in its ethical, social, and pedagogical foundations." Burnham in his 1891 study used questionnaires, diaries, and autobiographical accounts in studying subjects' reactions as to the kind and nature of problems which they encountered during adolescence.

In 1893 Daniels described what he believed to be the psychological aspects of adolescence, anticipating a present-day trend with a description of puberty ceremonies in primitive cultures. In 1897 Lancaster approached the study of adolescence through an analysis of published biographies and the administration of questionnaires. Starbuck in 1899 published a book, *The Psychology of Religion,* which, although only incidentally concerned with adolescence, did advance the hypothesis that a close relation exists between the advent of adolescence and religious conversion.

A great many of those writing on adolescence were following Hall's lead. Like his, their early work was often speculative and observational or dependent on a normative survey of a selected sample. There was often a tendency to attempt to fit what was observed into the pattern of evolutionary theory or to interpret data in terms of an a priori point of view. Under such a system errors of judgment and of fact sometimes occurred, some of which were for many years perpetuated in the textbooks, like the "rebirth" theory of adolescence, the *Sturm und Drang* hypothesis, and the preoccupation with proving that "ontogeny recapitulates phylogeny." Describing the inception of adolescence Hall (1904) wrote: "Adolescence is a new birth, for the higher and more completely human traits are now born. The qualities of body and soul that now emerge are far newer. The child comes from and harks back to a remoter past; the adolescent is neo-atavistic and in him the later acquisitions of the race slowly become prepotent." Among the earliest means of investigating adolescence, growing out of the Hall tradition, were the study of the biographies of the great (Yoder, 1894; Swift, 1903), direct conversations with adults about their childhood experiences and impressions (Lancaster, 1898), analyses of the experience of adolescents in literature (Libby, 1901), and, of course, the ubiquitous normative survey.

However, some of the most objective and carefully controlled published work on the adolescent period antedated Hall in its origins, although its interest was a specific aspect of biogical development rather than the wider and interrelated picture that was of interest to Hall and his associates. An example of this specific interest was the attention given to the phenomenon of puberty in women on the part of a group of French medical workers during the first half of the nineteenth century. Various monographs appeared which dealt with feminine puberty from a medical and physiological point of view, although even such sources were not free from a tendency to overgeneralize. The most prolific writer on this topic, however, was Roberton, who published a series of articles on the advent of puberty in women. Although Roberton's identification technique, that of direct questioning, would not be acceptable

as a method today, his results more nearly approximated modern findings than anything published to that time. After establishing, by direct questioning of a large sample of women, the age of advent of puberty as 13.75 with a range from 11 to 20 years of age (1831), he published comparative data on the advent of puberty in various cultures (1842, 1845*a*, 1845*b*, 1846, 1848). In these studies he challenged the then prevalent opinion that the advent of puberty in tropical countries is earlier than it is in nontropical countries. Roberton's findings on climatic relationships with the age of sexual maturity have since been verified by studies such as those of Mueller (1932) and Mills (1937) which indicate that factors of nutrition and a generally favorable environment rather than climate are the decisive factors tending to hasten the onset of puberty.

Correspondingly, many of the conclusions and points of view of Hall and his students at the turn of the century have also been confirmed by later objective studies, although many of them have not. The comparison is not too adverse, however, when it is realized that Roberton was considering one aspect of adolescence and that in very specific terms, whereas Hall and his associates were trying to interpret and explain all of human behavior as it occurred in individuals during the second decade of life. It is characteristic of any science that later investigators are able to profit by new and improved techniques, a greater amount of knowledge, and whatever mistakes their predecessors may have made.

Present-Day Trends

In the years following 1904 Hall's work continued to set the pattern for work on the psychology of adolescence. Later work tended to differ mostly in refinement of research techniques, in a more objective approach, and in the gradual replacement of the old storm and stress theory with the point of view, initially supported largely by anthropologists such as Mead (1928*a*, *b*), that adolescence is not necessarily a time of storm and stress unless the adolescent finds himself in an environment which presents continuing restrictions and frustrations for which the individual is unprepared and for which he has no ready solution. Modern psychology takes the position that adjustment and freedom from storm and stress is a matter of a facilitating environment. If the environment is such that the adolescent can gradually be inducted into experiences for which he is prepared and with which he is able to cope, if he is allowed to assume responsibility and play a mature rôle when he is ready to do so, and if there is a real effort on the part of adults to accept his interests and, where possible, to meet his needs, the adolescent will find his transition into maturity comparatively smooth and uncomplicated. Modern psychology equally recognizes, however, that the adolescent is a human being before he is an adolescent. It is recognized that the adolescent will encounter problems and difficulties as any human does, but in this he has the company of people of all ages. The point of view is that any period of life has its problems and that no one period may be selected as more peculiarly a time of involvement than any other period, unless the culture makes that particular period one that is beset by culturally engendered problems to which it is especially difficult to adjust. This point of view does not deny, however, the fact that an adolescent is undergoing very definite physical changes, that those changes do lead to new feelings and ways of life, and that they do pose problems to which the individual must adjust. One of the earliest full-length statements of this point of view as a psychologist interprets it appeared in a book written

by Leta Hollingworth in 1928, and although her statements were largely undocumented by research the point of view has had ample confirmation in numerous studies, of which Dimock's (1937) represents a good example.

Today studies of adolescence typically tend to be concerned with the relation of age and various behavioral characteristics, the subjects being rather few and selected more or less upon the basis of availability. Adequate sampling is rare. Replication seldom occurs, and investigators tend not to relate their studies to others already made in the aspects of adolescence which they are studying, although this last is more likely to be true of studies concerned with activity and interest than of studies in the area of physical development.

Among psychologists engaged in the study of adolescence there have tended to appear two contrasting interests. One confines itself largely to the study of development with particular reference to linear, areal, and ponderal increments, skeletal growth, physiological change, and capacity for physical endeavor. The other is chiefly interested in problems of personality and social and emotional growth. A third group, borrowing freely from the first two, has been particularly interested in the adolescent's learning and intellectual problems in school and elsewhere. There is, of course, great overlapping in these three areas. Except for a few psychologists the distinctions have never been clearcut, but it may fairly be said that most workers in the area represent one of the three biases of approach no matter how much they may recognize and respect the validity of the other two. As a matter of fact, in many studies such as those by H. E. Jones (1943, 1949) there is a deliberate effort to integrate the three approaches and to show their interrelationships. Such integrations have been made possible particularly by long-term studies such as the California and Harvard Growth Studies and the longitudinal research carried on by the Fels Foundation.

In terms of data collection the two most often-used approaches to the study of the adolescent period are the longitudinal and the cross-sectional. It is recognized that the longitudinal approach is for many purposes the superior technique, but for reasons of expense and time the majority of studies are cross-sectional and are for the most part confined to normative surveys or studies of relationships. The longitudinal approach probably finds its most frequent use in large research centers where funds and facilities are available, although a number of short-duration longitudinal studies, restricted usually to one or two variables, have been made by private investigators and by graduate students doing thesis research. Occasionally a time span longitudinal study of a psychological variable which uses a series of cross-sectional samples of individuals of the same age appears. An example of this approach is Pressey's (1946) study of changes in college and high school students' fears and worries with the passing of historical time. An increasing number of community-wide studies of youth have been appearing in the literature, such as those by Stendler (1949), Hollingshead (1949), and Reed (1950), following the earlier pattern set by the Lynds in 1929 and 1937.

Ordinarily research in adolescent psychology is prosecuted without reference to systematic theory. The proposed Wright-Barker study (1950), partly based on Lewinian concepts, is in contrast to this, however. As a rule, also, research on adolescence has seldom appeared in the form of the classic experimental design of comparison of an equated control and experimental group following an interpolated situation. A survey of the current literature of adolescence reveals a tremendous number

of more or less interrelated facts, many of them based on exceedingly dubious research, a number of more or less tested generalizations, and a lack of integration and verification of existing findings in the area. Two of the most pressing needs for future research on adolescence are the selection of adequate and representative samples and the replication of studies.

A complicating factor in research on the adolescent period is the frequency with which findings become "dated" as changing times present new situations and new problems. In the quarter of a century that followed 1925 the adolescent living in the United States experienced a most extraordinarily wide and varied sequence of environmental changes. Immediately following 1925 he lived in a country characterized by prosperity and pervaded by optimism and the last dregs of the "jazz and gin" era. World War I was close enough in the past to be more than a mere historical memory, and the future held great promise as most people interpreted it. The early 1930's reversed this trend as the country found itself beset by a depression, and, with full justification, pessimism and uncertainty filled the air. Those were the days of youth movements, the CCC, the WPA, all shades and varieties of liberalism, the Lincoln Brigade, and wandering gangs of homeless and hopeless youth. It seemed to many people at the time that there could be no future worth living. Certainly the old securities and many of the old ways of life were gone. Then came the increasingly good times of the late 1930's with dawning hope for the future, marred, however, by increasing international tension. By the early 1940's the international situation had deteriorated to the point where the future, particularly for the younger members of the population, became once more a time of uncertainty and fear. World War II brought for youth, whether they were in military service or too young to serve, new ways of life, new values, and new problems of adjustment. Increased mobility, deterioration of family life, death, and, for many, new sources of wealth posed their problems. It was a time when American youth at Guadalcanal and on many another battlefield answered the contemptuous charge of "softness" and "indecision" that their upbringing was supposed to have engendered. Peace in 1945 brought new hope, and a fine future appeared to stretch optimistically ahead. Times were good, education was made possible for many, and the "veteran problem" seemed possible of solution. The dream faded in the midst of gathering international tension, and as youth faced a national draft and universal military service the future again became uncertain as Americans once more existed in a period of tension complicated by a new kind of prosperity.

It should not be assumed that youth living in the United States were alone in the transitions and difficulties which have been described. Youth all over the world have faced crises of the same period of history, and in many countries their problems have made those of children in the United States look simple and uncomplicated.

Of course, no single person was an adolescent during this whole 25 years of change and counterchange, but large numbers of living Americans as well as others all over the world did pass their years of adolescence in one or more of these periods and may be thought of as products of their times. Certainly the literature on adolescence since the 1920's records the impact of the times upon the children who lived during them. For that reason, much of the literature on adolescence is dated, and one must interpret it in terms of generalities rather than specifics. Thus, an article on adolescent attitudes written in 1932 has comparatively little significance for the

present except to indicate that "things are different." Such an article does, however, have a general significance, if one interprets it as a generalization as to how a given period or situation may affect behavior and attitude. On the other hand there are also many articles that cover aspects of adolescence little affected by time or condition, for example, interest in the opposite sex and various growth phenomena. It must be remembered, though, that even such apparently stable phenomena may assume new forms and means of expression, as in the case of interest in the opposite sex and the effects of changed diet and environmental conditions upon growth and development.

For these reasons the present discussion has attempted, wherever possible, to base its points upon the literature appearing after 1940. Earlier studies are used only because of certain insights and interpretations they provide in considering youth today, because comparable studies have not been made in recent years, or because they represent recognized landmarks in the literature. As a matter of fact the writer believes that a complete psychology of adolescence could be based entirely on studies made subsequent to 1945.

Definition of Adolescent Psychology

Adolescence has been defined as that time of life when an immature individual in his teens approaches the culmination of his physical and mental growth. Physiologically an individual becomes an adolescent with the advent of puberty and the ability to reproduce his kind. Chronologically puberty generally occurs in girls between the twelfth and the fifteenth years with a range of about 2 years on either side of these figures. For boys puberty tends to occur from 1 to 2 years later than it does for girls. Investigators differ in measures of variability and central tendency which they cite depending upon the nature and circumstances of their sample (Ellis, 1948, 1947; Hogben, Waterhouse, and Hogben, 1948; Crampton, 1944; Schonfeld, 1943; Dearborn and Rothney, 1941; Shuttleworth, 1937, 1939; Dimock, 1937; Hardy and Hoefer, 1936). Psychologically and chronologically adolescence ends with the attainment of a consistent and comparatively widespread level of maturity. The development of such maturity is a slow process, and there now exists no means whereby it is possible to measure whether an individual has attained such a level. It is ordinarily assumed that most individuals have attained at least a moderate degree of psychological maturity by the time they are in their early twenties and that they are then adults rather than adolescents. For some people, however, psychological maturity never does arrive, with the result that they extend their adolescence throughout their later years.

Hence, the beginning of adolescence is defined in physiological terms and its duration and cessation in psychological terms. However, since the definition and implications of psychological maturity are controversial and display wide variations from individual to individual it is unsafe to make generalizations about the end of adolescence. The permissive limits seem to rest on the assumption that most individuals can be expected to attain the necessary integration of maturity by the time they are well into their twenties.

As a matter of fact, the cessation of adolescence is in reality governed by the culture in which an individual lives. If the culture is such that it allows the individual to exercise responsibility early and to assume the rôle of an adult, then his maturity is hastened. If the culture is such that it denies responsibility and shelters the indi-

vidual throughout his teens, then maturity tends to be retarded, at least for the majority. In western culture people tend to attain maturity at a much later date than in less sheltered cultures or in earlier historical times when children assumed adult responsibilities at what today appears a fantastically early age.

Considerable psychological and anthropological writing has attempted to draw parallels between western culture and the various primitive cultures of the South Seas, Africa, the American Indians, and various other peoples. Such studies usually take as their base an investigation on a specific primitive culture which is then contrasted with selected aspects of western culture (Whiting, 1941; Lee, 1940; Erikson, 1940; Boas, 1938; Mead, 1928*a*; Malinowski, 1927). Such parallels began by drawing analogies between cultures and later were used negatively to question psychological assumptions growing out of observations of western culture. It became fashionable to speak broadly of "western culture" vs. "primitive culture." A danger in such broad comparisons was pointed up by studies such as those of Beaglehole (1940) and Evans-Prichard (1934), which emphasized the great complexity and diversity of primitive or preliterate cultures. One cannot properly speak of primitive culture per se but only of a specific localized aspect of a given primitive culture. Such is equally true for western culture. One cannot properly assume, for example, a given situation as being true of *all* the United States any more than one can assume a situation to be true of *all* Europe. Contrasts between American youth and German youth, for instance, are probably too broad. Intracultural differences may well be greater than intercultural differences among western culture as well as among primitive cultures.

Major Aspects of Adolescence

In general, wherever adolescents are to be found there are five major focal points around which problems of behavior and adjustment tend to cluster. They may be thought of as points of reference from which to view adolescent growth and development and may be summarized as follows:

1. Adolescence tends to be a time of seeking status as an individual. There is a tendency to attempt emancipation from childish submission to parental authority and in general a struggle against relationships with adults in which the adolescent is subordinated on the basis of inferiority in age, experience, and skill. It is a period of emerging and developing vocational interests and of striving toward economic independence.

2. Adolescence tends to be a time when peer group relations become of major importance. The adolescent is usually most anxious to attain status with, and recognition by, his age mates. He tends to desire intensely to conform to the actions and standards of his peers. It is also a time of emerging heterosexual interests that bring complexity and sometimes conflict to emotions and activities.

3. Adolescence is a time of physical development and growth that forms a continuous pattern common to the race, but idiomatic to the individual. During this period there is a rapid altering of the body and a revision of the body image and habitual motor patterns. It is during this time that physical maturity is attained.

4. Adolescence tends to be a time of intellectual expansion and development and of academic experience. The individual finds himself in the position of having to adjust to increasing academic and intellectual requirements. He is asked to acquire many skills and concepts useful at some future time but often lacking immediate motiva-

tion. It is a time when an individual is gaining experience and knowledge in many areas and is interpreting his environment in the light of that experience.

5. Adolescence tends to be a time of development and of evaluation of values. The quest for the controlling values around which the individual may integrate his life is accompanied by an increasing awareness of "self," a development of self ideals, and an acceptance of self in harmony with those ideals. It is a time of conflict between youthful idealism and reality.

In considering the foregoing points of reference it is well to recall that, even though the growth and development of all people follow a similar pattern, there are wide individual variations within the pattern. Such individual variations are often the most significant aspects in the consideration of any given individual.

Biological Aspects of Adolescence

Adolescence is a time of growth and differentiation. In some areas of development, it is just as much a time of cessation of growth or the initial attainment of maturity. For most of the growth processes, rapid growth in infancy and early childhood is followed by a plateau or a period of slow growth until just before pubescence. At that time there is usually a spurt of rapid growth succeeded by less rapid growth and gradual deceleration of the growth curve until middle or late adolescence. In late adolescence most growth curves reach an asymptote or in the case of functions such as mental development start a long, gradual decline that progresses throughout maturity. In some cases, such as the thymus, the decline is extremely rapid.

Physical changes have a great deal of influence upon social and psychological behavior. If physical change were simply a matter of changing structure and function, one could describe them and pass on to other topics. From the point of view of behavior, however, the matter is not so simple; actual structural or functional change is only the beginning, from which stem considerable changes in social behavior, in attitude toward self and others, and in those things which the adolescent feels have value for him. Bayley (1941) and H. E. Jones (1949) have indicated the effects of the rate and direction of maturing and of the development of strength upon an adolescent's social acceptance and status and upon his personal adjustment.

Various studies have revealed over-all patterns of growth and have cited their findings in terms of curves of growth and decline. One may speak of general curves of growth, as for example, height or weight, and even describe their course and general nature. However, there are great individual differences, and these differences are to be found not only in persons but also in groups. Studies sometimes cite growth patterns for a general population group and sometimes for a sample selected from a group of individuals deviate in one or more growth factors. Shuttleworth (1938, 1939) and Dearborn, Rothney, and Shuttleworth (1938) in the Harvard Growth Study divided their sample into a number of homogeneous groups in respect to the advent of first menstruation. In the analysis of data they considered each of these homogeneous groups as a separate and distinct population. Bayley (1943*a*, 1943*b*) and H. E. Jones (1949, 1939) in the California Growth Study dealt with early- and late-maturing samples based on skeletal age. Other investigators have used similar devices.

Findings indicate that there is no one standard growth curve. Different organs and different parts of the body grow and develop at different rates of speed, and the curves of their growth take different forms,

with considerable variations occurring from person to person. In twenty-two dimensions of growth used in the Harvard Growth Studies, Shuttleworth (1939) noted that each generated a characteristic pattern which was in most cases unmistakably different from the pattern of every other dimension. He further noted that the growth pattern for each dimension was recognizably similar for both sexes, for all menarcheal and age of maximum growth groups, and for children of North European or Italian stock. Certain common elements did exist in the growth curves of all twenty-two dimensions studied. Most important of these was the existence in each dimension of two major growth cycles consisting of accelerating and decelerating phases. However, the growth trends of the twenty-two dimensions were not synchronized in that the growth phases of the first cycle were initiated at different ages and were of different durations.

Physical growth has commonly been studied by measuring growth increments in the various internal and external organs of the body. Most common of the measurements is the linear measurement of the length and width of growth increments or dimensions. Such linear growth may be most clearly observed and compared in measurements of standing height and sitting height. Second of the measurements is areal or cross-sectional measurement, which concerns itself with areal increments or increases in body mass or volume. Such measurements most commonly include the areas of various surfaces of the body, chest dimensions, and girth of arms, legs, and hips. Third is ponderal measurement, which is concerned with growth in body or single-organ weight and mass. Over-all weight is an example of such measurement and is considerably influenced by deposits of fatty tissue.

Quite specific differences in growth patterns are observed when they are considered from the aspect of areal as compared to linear or ponderal growth. One of the more outstanding contrasts occurs in increases (in relative postnatal increments) which take place between birth and early maturity. For example, growth in stature, which is one-dimensional, is 3.5 fold; that is, an individual increases in height 3.5 times his height at birth. In surface area, which is two-dimensional, growth is 7 fold. And finally, in weight, which is three-dimensional, the increase is 30 fold.

Growth in Height and Weight. When ponderal increments of body weight are compared with linear increments of standing height, much the same course of growth is presented. Boys tend to be somewhat taller than girls and remain so until about 10 years of age, at which time girls begin to forge ahead, and from 11 to 14 girls are taller than boys of the same age. But from shortly after 14 boys begin to forge ahead, and they maintain their superiority in height from that time on. This is, of course, the average picture. There are always some boys who are shorter than some girls, and vice versa. There are also considerable differences in the ages at which different children have their growth spurts or attain maximum growth. In general there is an acceleration in growth about 6 months before the advent of puberty. In studies since the 1920's there has been a tendency to categorize subjects as early-, average-, and late-maturing, and to present data in those terms as being more representative of true individual growth patterns. Late-maturing children do not grow so fast as early-maturing children in terms of increments per year, but their growth period does extend over a longer period and continues after the growth of early-maturing children has ceased. There appears to be no correlation between final size and rapidity of growth either during the period of adolescence or before (Friend and Bransby, 1947;

Bayley, 1946; Bunak, 1940; Shuttleworth, 1939; Meredith, 1935; Boas, 1932; Davenport, 1926). Figure 1 presents average yearly increments of growth in standing height for early- as compared to late-maturing boys and girls.

1934; Collins and Clark, 1929; Pfuhl, 1928). Figure 2 presents the average weight of a sample of American boys and girls from a study by Shuttleworth (1939).

Thus, it may be seen that linear and ponderal curves of growth present a number of

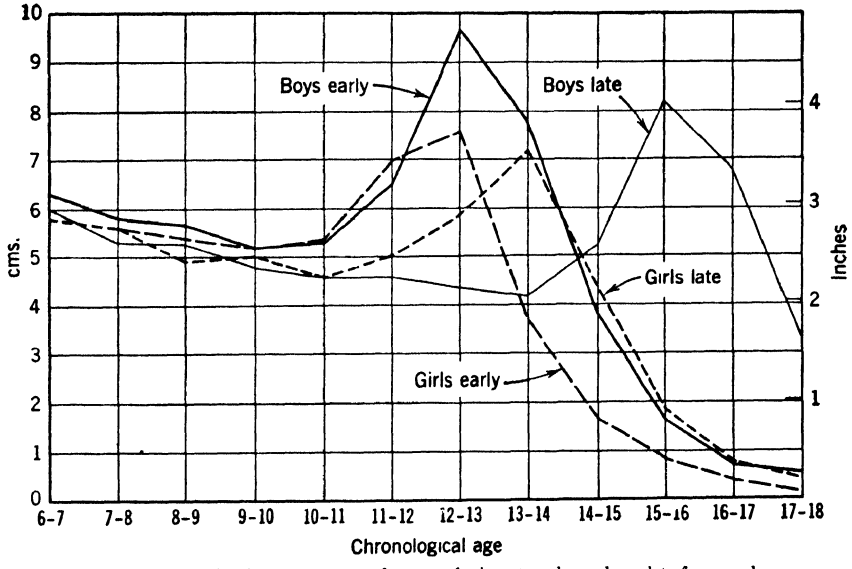

FIGURE 1. Average yearly increments of growth in standing height for early- as compared to late-maturing boys and girls (late and early categories determined by age of maximum growth). Adapted from F. K. Shuttleworth. The physical and mental growth of boys and girls aged 6 through 19 in relation to age of maximum growth, *Monogr. Soc. Res. Child Develpm.*, *4*, No. 3, 1939, pp. 245–247.

In respect to weight, boys and girls tend to follow the same general course of growth, but girls tend to be lighter than boys to prepuberty. In the early part of puberty girls become heavier than boys, after which boys once again become heavier, and they maintain their advantage of weight throughout maturity. The same prepubescent growth spurt occurs in both boys and girls, with girls averaging 1 to 2 years in advance of boys at that time. With weight as with height, age of maximum growth is an important factor in assessing a given individual's relative status (Ellis, 1947; Ni, 1947; Shuttleworth, 1939; McCloy, 1938; Wetzel, similarities. They both tend to follow the same double sigmoid curve of growth, but in ponderal growth there is a greater increase in rate and a number of minor variations preceding puberty. With both height and weight there are great individual differences. One may not predict any given individual's height or weight from his age, but it is possible to cite average heights and weights for any given age. It is the individual that deviates markedly from the norm who is most likely to experience difficulties of adjustment.

In addition to studies of standing or overall body height and of weight previously

cited, a number of investigations have been made of growth of sections of the body such as the arms, legs, trunk, neck, head, chest, hips, and thighs. Many of these studies are linear, but a number of them are areal; that is, they attempt to discover actual changes in surface area rather than in height or in width alone. Such areal studies are two-dimensional in contrast to one-dimensional linear studies.

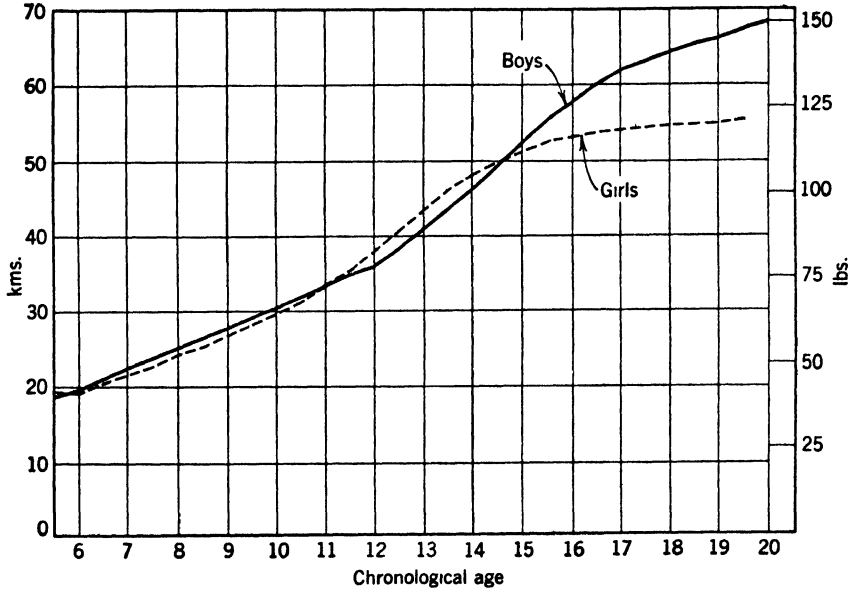

FIGURE 2. Average growth trends in weight of 1458 boys and girls from the Harvard Growth Study. From F. K. Shuttleworth. The physical and mental growth of boys and girls aged 6 through 19 in relation to age at maximum growth, *Monogr. Soc. Res. Child Develpm., 4,* No. 3, 1939, pp. 248–249.

Two things are to be remembered in interpreting studies of height and weight. One, as Gould (1938) points out, is that growth curves plotted from averages of different sets of individuals mask individual spurts and cessations of growth. A second is that it is dangerous to generalize from one sample to another since both height and weight are conditioned by many environmental as well as internal variables which may be present in one sample and missing explains how height and weight measurements may be made and interpreted.

Relationships between Various Bodily Dimensions. In considering the course of general growth a number of different parts and dimensions of the body are involved and must be taken into consideration. Bayley and Tuddenham (1942) note in their discussion of adolescent body build that the relative proportions of the different parts of the body which determine body form or body build are of as great interest to the psychologist as such characteristics as height or weight. They cite the possibility

of relationships between physique and the various components of personality and point out that "as a measure of nutrition, weight in relation to height does not take into account the wide differences which exist in skeletal build and in the proportions of the body and its extremities."

There have been various attempts at classification of body build, ranging from the *habitus phthisicus* and *habitus apoplecticus* of Hippocrates to the somatotypes and measurement ratios of modern workers. McCloy (1938) notes that such classifications generally attempt to arrange individuals along a continuum from a relatively tall, slender type at one extreme through an intermediate or "normal type" to a relatively short, stocky type at the other extreme. McCloy cites four general methods of classifying body builds which have found acceptance at one time or another. First is a general index number of body build derived by setting up a ratio between two different measures, usually with a measure of sitting or standing height as the denominator; for example: (chest circumference)/height, (head length)/height, weight/height, (weight ⅓)/height, (stem length)/height, (hip width)/height.

The second type of classification attempts to group individuals into two or more clear-cut categories. An example of this type of subjective classification is that of Stockard (1922–1923), who proposes three categories: linear, intermediate, and lateral. Classifications based upon such arbitrary, discrete categories differ markedly from those of the ratio type. The ratio type are subjectively arrived at, and presuppose that body type may not be categorized into a few separate types but exist along a continuum, and thus form a continuous distribution from one extreme to the other.

The third type of classification, according to McCloy, is that of Kretschmer, who proposes a thin type called asthenic, a stocky type called pyknic, and various mixed or intermediate types. Kretschmer also proposes a deviate type which he calls athletic. The Kretschmer classifications have exercised considerable influence in sociological and psychological thinking, although this type of classification no longer finds acceptance among scientific workers in the field of growth and development.

The fourth type of classification is that of Draper (1930) and of Draper, Dupertuis, and Caughey (1945), who attempt to classify individuals on the basis of predisposition to various kinds of diseases. Draper speaks of a tubercular type, a gastric-ulcer type, a gall-bladder type, and a pernicious-anemia type. Draper's system is a medical one and has not found use among psychologists in their studies of growth and development.

Typical of present classification systems are those of Sheldon, Stevens, and Tucker (1942) and of Reynolds and Asakawa (1948), Sheldon's endomorphic, mesomorphic, and ectomorphic classification being probably the best-known system since Kretschmer's. There are also various methods of appraising physical fitness which use physical-relationship categories such as the Wetzel grid, the Baldwin-Wood age-height-weight tables, the Franzen and Palmer ACH index, and the Pryor and Stolz age-height-hip-weight standards. In an evaluation of the various appraisal procedures in the use of body measurements in a school program Stuart and Meredith (1946) cited weight, stature, pelvic breadth, chest circumference, calf circumference, and subcutaneous tissue thickness as constituting the most useful indicators of physical status and growth progress.

Although the various body classification types have found specific diagnostic uses from time to time, the consensus appears to be that body typing is either not possible or is at best misleading and imprac-

tical. There is serious danger that our confidence in the validity of body typing and overgeneralization from data so obtained may lead to extremely unfortunate results. Bayley and Tuddenham (1942) observe that the quantitative treatment of body measures of large populations does not result in a series of discrete "types" but rather that such measures are "distributed normally throughout a range of magnitudes for any dimension measured." They further observe that, although there is a correlation among the various dimensions of the body, the correlation is "by no means perfect," and accurate predictions of an individual's proportions on the basis of a "type" classification is not feasible. From the psychologist's point of view the most profitable procedure is that of observing individual deviations from the average in terms of their effects, for that person, on behavior and social acceptance.

Interrelationships in Body Growth. In common with previously cited measures of the growth of weight and height, a marked prepubescent spurt is observed in the growth of many other bodily dimensions, a spurt which is characterized by sexual differentiation in the earlier and more rapid growth of girls. In girls there is greater growth in hip width, accompanied by sex differences in the distribution of fatty deposits, and the appearance of secondary sex characteristics. Boys, on the other hand, despite a slow start, soon exceed girls in shoulder width; this fact is partly responsible for the greater strength commonly possessed by boys, since their larger bony framework provides greater leverage for the operation of muscles. As previously mentioned, the tendency is to present growth data in terms of whether the individuals being studied mature late, early, or at about the average time. Studies report that different developmental rates and sequences exist where the rate of maturity is markedly accelerated. This appears to be particularly true of boys where bodily proportions are concerned, including the relation of sitting height to standing height, of width to length, and of hip width to shoulder width. The proportion of hip width and shoulder width is different for boys and girls. Girls are quite broad hipped; whereas the ratio between height and hip width in boys remains relatively constant, boys who mature late tending to have narrower hips than those who mature early. There appear to be no differences among girls in terms of the relation of early or late maturity to hip width, although quite definite differences exist between early- and late-maturing boys and girls in the relationship between shoulder and hip width. Late-maturing individuals tend to have broader shoulders than early-maturing individuals, although this tendency is more marked in boys than in girls. Hence, one finds broad-shouldered, narrow-hipped late-maturing boys as compared to narrow-shouldered, broad-hipped, early-maturing boys (Muhsam, 1947; Dublineau, 1944; Bayley, 1943*a*, 1943*c*, 1941; Simmons and Greulich, 1943; Schmidt-Voight, 1942; Bayer, 1940; Zeller, 1939; Stone and Barker, 1937; Carey, 1936).

Strength and Physical Development. Closely associated with an individual's growth and development are his physical fitness, physical coordination, and motor development. Such matters are of great importance to adolescent males. The typical adolescent boy is expected to fit the "manly," physically active, physically adept stereotype of boyhood. He stands to gain prestige and social acceptance through athletic ability in competitive sports. It is expected that a boy will be interested in participating in sports and physical activities and that he will have the stamina and ability to implement his interest. An adolescent who lacks such interest, ability, and

stamina is confronted by many difficulties of acceptance in his peer relationships and even in many of his relationships with adults. Where physical activity and interest are lacking the adolescent boy must compensate strongly in other directions, but such compensations have their limitations and overcompensation may even militate against him. Various investigators (H. Jones, 1948; Bower, 1940; Cowell, 1935; Thrasher, 1927) have pointed out the social acceptance value for boys of athletic skill, "gameness," strength, etc.

Various Means of Assessing an Individual's Physical Fitness and Strength Potential. Such measures are usually summed up in a descriptive index number representing an over-all picture of physical status or potential. Typically included are measures of grip, leg strength, push and pull, jumping, running, and other tasks which involve moving either the whole body or a part of it. Among such attempts at measurement have been those of Larson (1941), Cozens (1936), MacCurdy (1933), McCloy (1932), Brace (1927), Rogers (1927), Garfiel (1923), and Sargent (1921). No single test of physical fitness appears to offer a satisfactory index. Present procedure favors a combination of tests with emphasis upon dynamic measures such as field and track events.

Strength normally increases at a rapid pace during the first 20 years of life, but at varying rates from year to year. In general it is particularly accelerated after the sixth year. H. E. Jones (1949) notes that the development of strength during childhood and adolescence is more conspicuous than any other aspect of physique and that, whereas one-third of an individual's height is acquired after his sixth year, approximately four-fifths of his strength is acquired after that time. Jones hypothesizes that such rapid changes in strength possibly indicate that strength will show sensitive responses to accelerant growth factors in adolescence and may well have practical use as partial indicators of the status of other growth factors. Meredith (1935) notes that in the Iowa studies, with the exception of weight, strength possessed a coefficient of variation some 2 to 5 times greater than any other measures used.

In speaking of the acceleration of the growth curve for boys, H. E. Jones (1944) notes that boys are twice as strong at 11 as they are at 6, and that their manual strength increases 100 per cent from 11 to 16. This growth picture has been characteristic of most of the studies made of the development of strength of grip (H. E. Jones, 1949; Meredith, 1935; Metheny, 1941). In so far as the various studies reveal differences, the differences tend to be in levels of strength achieved at various ages rather than in the course and nature of the growth curve itself.

There appears to exist a general curve of growth for strength. Not only do the various measures of strength tend to show similar curves of growth, but there are also high correlations between the course of development of strength and the development of other physical features of the body. This last is not unexpected when it is remembered that strength depends upon the tangible physical features through which it operates and without which it would remain nonexistent. Meredith's (1935) finding, for example, that both strength of grip and weight displayed marked acceleration when the boys he studied reached 13 years may be taken as evidence of a functional relationship.

Since strength may be thought of as a function potential depending on various factors in addition to muscle size, it is reasonable to expect that knowledge of the anatomical growth of an individual's muscles alone would not yield a proper index of his strength. As a matter of fact,

because of the accelerated growth of the body generally around the time of pubescence, it has been found that strength tends to increase faster than the anatomical growth of muscle. Sex differences in the growth of strength are, of course, partly due to differences in weight, musculature, and the skeletal framework of boys as compared to girls, but they may also be due in part to the more frequent and vigorous use of the muscles which results from the customarily greater physical activity of boys. In this connection it is interesting to note that, at the age when differences in strength between boys and girls begin to increase markedly, girls are entering upon a more feminine cultural phase, during which their activities assume a more sedentary character than those of boys.

A summary of survey evidence (H. E. Jones, 1946; Bayley and Espenschade, 1944, 1941; Espenschade, 1940; Carpenter, 1938; Dimock, 1935; Atkinson, 1925, 1924) indicate that children who are taller, heavier, and older tend to be stronger and to display greater motor and physical proficiency than shorter, lighter, and younger children. It appears, although the evidence is as yet incomplete, that physiological maturity goes hand in hand with increases in strength and motor performance, and that the age of maximum growth, of physiological maturity, and of anatomical and skeletal maturity is more important than chronological age in this area. Body build as such has exhibited low correlations with motor performance during the years of adolescence. Differences in measures between the sexes are usually found, with the characteristic early development and early cessation of growth in girls contrasting with the later development and later cessation of growth in boys. In general, increases in motor performance tend to cease at about 17 or 18 for boys and at about 15 for girls. So far as sexual maturity is concerned there is a definite positive relationship with strength.

Physiological Development

Advent of Puberty. The phenomenon of sexual maturity with its accompanying behavioral changes and attitudes is one of the chief landmarks in the developmental sequence. The advent of puberty or sexual maturity is the most clear-cut and most dramatic line of demarcation between the child and the adolescent. Puberty is defined as that time in the life cycle when functional maturity is attained by the reproductive organs and the individual becomes capable of reproducing his kind. In girls puberty is marked by the gradual appearance of secondary sex characteristics. A gradual change in figure occurs which includes the deposition of fat on the hips, development of the breasts, a widening of the pelvis, and the appearance of hair on the pubes and axillae. The advent of puberty is generally judged in girls by the appearance of first menstruation. Before first menstruation a girl is classified as prepubescent; following that time she is classified as pubescent. However, the irregularity of the menstrual cycle in young girls indicates a certain amount of caution in using first menstruation as the only criterion of puberty. Greulich (1944) notes that, properly speaking, menstruation is a reflection of a physiological state which usually precedes the capacity to reproduce and which may occur in different individuals at different times during the pubertal cycle. Despite this caution, however, psychologists in their studies customarily accept menstruation as an indication of the advent of puberty and classify and analyze their data on that assumption.

A review of studies citing the average age of first menstruation indicates that

findings disagree, sometimes to the extent of 2 or more years. Such differences may be due to problems of inadequate or highly selected sampling, or to variations in techniques adopted by various investigators. The differences may, however, reflect real long-term changes in the entire population. There is evidence (Gould and Gould, 1932; Mills, 1937; Schaeffer, 1906; Neurath, 1932; Bolk, 1923) that average menarcheal age is decreasing in the United States as well as in central and northern Europe. Such general changes, if continuing over a period of time, may have important implications for education and problems of social and heterosexual adjustment where adolescents are concerned.

There is also evidence that environmental factors are related to some degree to the age of onset of adolescence. Greulich (1944) has pointed out that food and feeding habits, nutritional status, illness, and a favorable or unfavorable environment all operate to hasten or retard the onset of puberty. It would not be surprising to find a comparatively retarded average age of first menstruation in underprivileged as compared to highly privileged samples, or in inhabitants of a country suffering severe nutritional difficulties as compared to one which is more fortunately endowed. Two studies whose contrasted findings may offer partial evidence that the concomitants of socio-economic status affect age of first menstruation were made by Shuttleworth (1937) with a sample of higher socio-economic level girls living in Cleveland, Ohio, and Engle and Shelesnyak (1934) with a sample of low socio-economic level girls living in an orphan asylum in New York City. In his study Shuttleworth cited 12.5 years as the average age of menarche for his sample, whereas Engle and Shelesnyak cited the average age of menarche as 13.5. Of course, differences other than socio-economic status may have been operating, but the differences between these two studies represent a pattern that has been reported in numerous other studies.

Within the United States racial differences do not yield advent-of-puberty differences when groups are equated (Mills and Ogle, 1936; Boas, 1932; Engelmann, 1901), nor does the former belief that warm climate has a considerable effect upon the acceleration of sexual maturity seem tenable either in or out of the United States (Mills, 1937; Mueller, 1932). As a matter of fact Mills (1937) notes that "nowhere on earth do girls mature so early as they do in the central part of North America," and that, as one proceeds "south toward the Gulf of Mexico, east toward the Atlantic coast, or northeast into Canada, the menses tend to begin at later ages," and that a comparison of North and South America reveals an average retardation of 1 full year on the latter as compared to the former continent. Here, again, one might hypothesize environmental and nutritional rather than climatic factors. All investigators agree in reporting individual differences of several years in the attainment of puberty. In general it may be accepted that the average age of onset of puberty in girls in the United States is somewhere between the 12.5 years reported by Shuttleworth (1937) and the 13 to 14 years reported by Gould and Gould (1932), Boas (1932), and Lintz and Markow (1923).

The problem of determining the age of advent of puberty is more difficult for boys than for girls. The clear-cut line of demarcation provided by first menstruation in girls is missing, and the various physical or physiological landmarks by which the pubescent status of boys is determined tend to develop at different times. Dimock (1937), in a study of 1406 boys in a summer camp, reported the average age of pubescence as 13 years, 1 month, on the ba-

sis of the Crampton Criteria. The Crampton Criteria determine pubescence partly on the basis of the appearance of pigmented hairs in the pubic region and the gradual appearance of a kink or twist in the pubic hair and a wrinkled scrotum. Of Dimock's 1406 cases, 260 were pubescent. The 260 were from 10 to 16 years, with 1 per cent in their eleventh year, 14 per cent in their twelfth, 76 per cent in their thirteenth, fourteenth, and fifteenth years, and 8 per cent in the sixteenth year. Carey (1936) using the same Crampton Criteria reported that 49 of 259 boys from 11 to 18 years at St. Mary's Industrial School in Baltimore were pubescent. The mean chronological age of the pubescent group was 14 years, 3 months, with a standard deviation of 12.1 months. Most investigators (Schonfeld, 1943; Schonfeld and Beebe, 1942; Westbrook, *et al.*, 1934; Baldwin, 1916; Starbuck, 1899) cite the average age for the advent of puberty in boys as occurring somewhere between the fourteenth and sixteenth years, although occasional investigators (Dimock, 1937; Crampton, 1908) cite 1 year earlier.

In a study of sexual behavior in boys Kinsey, Pomeroy, and Martin (1948) cited the date of first ejaculation as the major criterion of the onset of puberty in boys, although they note that whenever there is "any development of any physiologic or physical character that pertains to adolescence" the investigator must recognize it as symptomatic of the onset of adolescence. They note that, when the year of first ejaculation is considered in conjunction with the appearance of pubic hair, the onset of rapid growth in height, and with the appearance of certain secondary sex characteristics, a definitive picture of pubescent status is obtained. Kinsey feels that, if physical development seems to be some years in advance of first ejaculation, it is better to determine the date of puberty by exterior physical changes rather than by the date of the first ejaculation. In the Kinsey study, however, 85 per cent of the subjects reported simultaneous acceleration in physical development and first ejaculation.

Kinsey, Pomeroy, and Martin (1948) also reported a positive relationship between social or educational level and date of first ejaculation with nearly a year's variation between different educational levels. The means cited were 13.71 for boys who go on to college, 13.97 for boys who do not go beyond high school, and 14.58 for boys who do not go beyond the eighth grade. They note that differences may well be due to nutritional differences, as they seemed to be in the case of female differences in mean age at menarche.

In addition to first ejaculation, puberty is also marked, as the previous discussion has implied, by the gradual appearance of secondary sex characteristics. In boys the larynx enlarges with an accentuation of the prominence called the "Adam's apple," the voice changes, hair makes its appearance on the pubes, the axillae, and the face, and the external genitals begin a period of rapid growth.

In summary, the time of the advent of puberty is a matter of individual growth. Differences are determined to some extent by heredity and to some extent by environmental factors including nutrition and disease. In general girls reach puberty before boys, the difference averaging from 1 to 2 years. As has been indicated, the exact age for the attainment of puberty depends upon environmental factors such as nutritional opportunities and disease incidence, and upon biological-genetic factors such as race, rate of anatomical growth, and state of health. In general girls reach puberty somewhere between the ages of 9 and 17, and boys between the ages of 11 and 18. Thus, although at 13 boys are found who

are already pubescent and girls who are still prepubescent, their number will be smaller than the number of 13-year-old pubescent girls.

Endocrine Aspects of Adolescence. Puberty is part of the normal growth process, closely associated with all the other factors and phenomena of growth. Among these factors are the glands of internal secretion, which are of considerable importance in preparing an individual for sexual maturity as well as in promoting other aspects of growth. Nathanson *et al.* (1941) note that the glands of internal secretion have three main functions: "to stimulate growth, to influence metabolic activities, and to regulate the physical metamorphoses of children." In general, it appears that some time before the onset of puberty the anterior lobe of the pituitary gland produces a gonadotrophic hormone (follicle stimulating hormone, FSH, prolan A) which tends to stimulate the growth of the immature gonads. Under the stimulation of the gonadotrophic hormone the gonads (ovaries in females, testes in males) accelerate their growth and the individual attains sexual maturity. At this point the gonads produce mature sperm and ova, as well as estrogenic (female) and androgenic (male) sex hormones. It is well to note, however, as Shock (1944*a*) points out, that relatively small amounts of hormone secretion do occur prior to the time the gonads begin their accelerated growth. Shock (1944*a*) notes that the initiation of puberty has as a probable mechanism "a gradual increase in pituitary secretion coupled with an increasing sensitivity of the gonads to the hormone." In both boys and girls estrogens and androgens (17-ketosteroids) may be traced in constantly enlarging amounts from the third year through puberty.

It may be observed that both androgens and estrogens are excreted by both sexes, but the excretion of androgen is more characteristic of males than of females, whereas the excretion of estrogens is more characteristic of females. However, an excessive secretion of the major hormone of the opposite sex in a boy or girl will tend to lead to at least a partial assumption of some of the secondary sex characteristics of members of the opposite sex. A drastic increase of the sex hormone appropriate to one's sex follows the ninth year, although androgen is secreted in relatively larger amounts than estrogen.

The amount of hormones present at any point in the growth cycle of an individual, and, by analogy, the rate of activity of the glands from which the hormones are secreted, may be determined by a quantitative analysis by measuring the amounts of pituitary, adrenal, and sex hormones to be found in the blood and urine. The methods used are still comparatively crude, and there appears to be no accurate way of determining the presence of sex hormones in the blood stream, although it is possible through chemical analysis to measure the amounts of the hormones secreted in the urine. Because this is a new field with uncertain techniques, there have been comparatively few studies in the determination of hormone levels in the urine and even fewer attempts to correlate the information derived to the human growth sequence. Most of the studies have utilized animals or very small samples of available children. One of the more important studies in this area is that of Nathanson, Towne, and Aub (1941), who used 104 normal children and made a total of 1100 hormone determinations. Other discussions and studies, all appearing after 1930, include those of Greulich, Dorfman, *et al.* (1942), Catchpole and Greulich (1940), Catchpole *et al.* (1938), Gustavson, Mason, *et al.* (1938), Frank (1935), Katzman and Doisy (1934), Neumann and Peter (1931), and Schörcher (1931). The results of the studies are usu-

ally not strictly comparable because of differences in the samples used, but there is general agreement that hormone seeretion increases with the advent of sexual maturity.

Other Physiological Changes. Among the many physiological changes taking place during adolescence are those in circulation, pulse rate, blood pressure, and the chemical composition of the blood; changes in energy metabolism and respiration; and changes in the excretory function. During adolescence the pulse rate tends to diminish, and though there is an increase following exercise, the rate of increase diminishes with age. The increase, however, tends to be greater in boys than in girls. Shock (1944*a*) notes that early-menstruating girls and children who experience an early adolescent growth spurt have a pulse rate which is characteristic of more mature girls. Among the studies of pulse rate are those of Shock and Schlatter (1942), Tuttle (1931), and Sutluff and Holt (1925).

In general, blood pressure tends to rise with age, although there is a tendency for a decrease to occur in girls after 16. Richey (1931) reported intercorrelations between systolic, diastolic, and pulse pressure at all ages. The correlation between systolic and diastolic pressure was positive; between systolic and pulse pressure, positive; and between diastolic and pulse pressure, negative. The correlation between systolic and diastolic pressure decreased with age whereas that between systolic and pulse pressure increased with age. Richey also found significant sex differences in actual pressures recorded. Between the ages of 10 and 13 the average systolic pressure was higher for girls than for boys. After 13 the systolic pressure for boys was greater, the amount of difference increasing with age. The average diastolic pressure was higher for girls than for boys between the ages of 11 and 16. The average pulse pressure for boys was higher than for girls after 13, the difference increasing with age. However, Richey notes that the blood pressure of normal children varies between wide limits, suggesting that the normal blood pressure for any age group might best be described as a continuum. Downing (1947) and Greulich, Day, *et al.* (1938) also mention wide day-to-day fluctuations. In studying blood-pressure changes as a function of exercise, Shock (1946) found that an increase in systolic pressure after exercise was greater in boys than in girls. Girls showed little or no change with age, whereas in boys the maximum systolic pressure increased with age. He also found that the rise in systolic pressure after exercise was greater in younger than in older children. There was a marked decrease in diastolic pressure after exercise which disappeared with increasing age.

Nylin (1935) sums up the situation with regard to respiratory changes when he notes that the total respiratory volume increases during adolescence. In a summary of the literature, Greulich, Day, *et al.* (1938) report that the average vital capacity increases about 3 times between the ages of 6 and 16 years. The volume of air in the lungs and respiratory passages at the end of a normal expiration (functional residue) increases during adolescence. The volume of tidal air (inspiration) increases during this period while the rate of respiration decreases. Shock and Soley (1939) found that the minute respiratory volume in boys increases between the ages of 12 and 14. This is attributed to an increase in body size. In boys aged from 14 to 16, respiratory rate decreases, tidal volume increases, concentration of expired air decreases, and expired carbon dioxide increases. In girls aged from 12 to 14, respiratory volume and tidal volume increase whereas in the age range from 14 to 16 changes are taking place that are not

clearly defined. Shock and Soley (1939) also note an increase in oxygen consumption in both sexes from 12 to 16 years. However, when this increase is considered with respect to body size, there is an actual decrease in oxygen consumption. They report that in 16-year-old girls most of the respiratory functions were similar to those in adult females. In contrast, 16-year-old boys breathed faster, had a smaller tidal volume, a higher concentration of oxygen and a lower concentration of carbon dioxide in their expired air and total oxygen consumption than did adult males.

During the adolescent period basal metabolism tends on the average to diminish following what Bruen (1933) calls "an independent pubertal metabolic acceleration." Greulich, Day, *et al.* (1938) in their summary also note a prepubertal change and state that such changes in metabolic rate are necessary for the maintenance of temperature. Shock (1943) notes that metabolic changes with age are greater in adolescent girls than in boys. Girls appeared to be more variable than boys. Shock reports that a rapid decrease occurs with the beginning of menstruation and that this decrease is more closely associated with menarche than with chronological age. Many other bodily changes take place during the adolescent period, including replacement of vellus by terminal hair in the pubic region with axillary hair making its appearance somewhat later. Immediately before adolescence there is also an increase in the secretory activity of the sweat glands located in the axillary region.

In discussing physiological changes, Shock (1944*b*) makes the point that an analysis of the growth curves for physiological variables presents two characteristics: "(*a*) In individual children sudden and rapid changes in physiological characteristics are frequent, and (*b*) the rate of physical maturation differs greatly for different changes." One difficulty in considering such curves is the fact that average growth curves of physiological variables tend to be smooth, thus concealing and averaging out the considerable individual variations present. It is also not enough to consider physiological functioning apart from other aspects of physical activity indulged in by the adolescent. One of the penalties of growing older appears to be slower recovery to a state of physiological and physical balance after exertion. Shock (1946) conducted a longitudinal study of the results of severe exercise upon a group of 100 children as they proceeded through the adolescent years. Recovery curves were plotted for pulse rate, respiration rate and volume, oxygen intake, and carbon dioxide elimination. Shock found that, whereas work output increased with advancing age, the rate of recovery with respect to the physiological factors studied decreased with advancing age.

For the most part, the outward manifestations of physiological change are acceptable enough in our culture for the average adolescent to adjust to them. One exception is acne, which often appears during adolescence and tends not only to cause embarrassment to the adolescent himself but sometimes calls forth an unfortunate reaction of distaste from those with whom he comes in contact. Lawrence and Werthessen (1942), Hamilton (1941), and others have attributed acne during adolescence to an imbalance between male and female sex hormone secretion and report successful treatment by use of hormones. Jolliffe, Rosenblum, and Sawhill (1942) and Straumfjord (1943) report dietary regulation and the administration of the B-complex vitamins as successful in the regulation of acne. Greulich (1944) notes that the increased activity at puberty of the sebaceous glands which appear in the skin and

which are particularly large on the wings of the nose may be an important factor in causing acne.

Skeletal Analysis. A number of measures, including chronological age and advent of puberty, have been used in determining an individual's level of maturity. There has, however, been a quest for a more meaningful basis of classification. Of the methods proposed, skeletal analysis has proved one of the more accurate. By the method of skeletal analysis the progress or status of ossification is recorded by means of X-ray pictures. Skeletal analysis has the advantage of providing a comparatively exact estimate of the individual's level of maturity at any point in his life span.

Unfortunately a problem arises in finding a standard with which to compare skeletal X-rays. There have been a number of attempts to formulate such standards, but those presently available are not in entire agreement, with the result that indices and ages computed by different systems are not directly comparable. The most widely used standards are those proposed by Flory (1936) and Todd (1937).

Todd (1937), in an X-ray study of a sample of over 1000 children, reported that in the period from 5 to 13 there appeared for girls a "minor progressive acceleration of female skeletal maturation" between the ages of 6 and 8, with a slowing up between 8 and 9, so that at 9 the maturation of males tended to catch up with that of females. At 10 years of age girls again accelerated, and by the time they were 13 they had arrived at a state of maturation not attained by boys until they reached their fifteenth year. There is a definite slowing down of skeletal maturation in girls following their thirteenth year, until, by the sixteenth to the seventeenth year boys have caught up with them. Todd reported increasing stabilization from 17 on in both sexes. Baldwin, Busby, and Garside (1928), after a longitudinal X-ray study of children from birth to maturity, also reported sex differences in times of acceleration and arrival at final maturity. Bayley (1943*a*, 1943*b*) reported similar findings. Sawtell (1929) noted a definite relationship between ossification and gross body size, and an even greater correlation between weight and height in relation to actual bone growth. Flory (1936) reported a definite relationship between ossification and puberty and noted that acceleration in skeletal development is generally accompanied by an earlier arrival at puberty. The relationship between rate of ossification and physical conditions, such as thyroid deficiency, metabolic disturbances, nutritive deficiencies, have been noted by Francis (1939), Sontag and Pyle (1941), Roberts *et al.* (1939), and MacNair (1939).

Intellectual Growth and Development

Age of Cessation of Mental Growth. The age of cessation of mental growth has occupied considerable space in psychological research. Early investigators estimated that the age of cessation of mental growth occurred sometime in the neighborhood of the thirteenth or fourteenth year of life. Later investigators, particularly since 1924, have gradually raised the estimate for age of cessation upward toward the early twenties. Most investigators agreed, however, that the increments of growth following the sixteenth year were relatively minor. Hart (1924), using the Army Alpha, reported growth approaching a point of cessation at 16 or 17 years. Dearborn and Cattell (1930) found mental ages and point scores on the Dearborn test greater at 18 than at any previous age. Sudweeks (1927) reported scores on the Terman group test increasing until age 19, and Burks, Jensen, and Terman (1930) reported scores at each

age to 19 higher than the preceding years. Woodrow (1928), testing the entire school population of a small town, reported no cessation of increase in test scores "at any rate up to 18.5 years." In a community-wide study H. E. Jones and Conrad (1933) reported that the curve of mental growth rose to about 16, displayed a negative acceleration after 16, and reached its highest point between 19 and 21 years. After 21 a long, slow decline began so that scores recessed to about the 14-year age level in the middle fifties. The Jones and Conrad study was particularly adequate in that it contained sufficient subjects in the late teens and in maturity to present a complete picture of growth. The majority of studies of intellectual growth have tended to include subjects of an age range that did not include people of late adolescent and adult status. The final answer is not yet certain, but present evidence agrees that the age of cessation of the growth of intelligence is certainly beyond the teens.

The implication of the age of cessation of mental growth for the education of adolescents is that in terms of mental ability or power the adolescent is nearing his peak. By the time he is 18 he has either already reached his peak or will show only a slight increase from that point on. Under the circumstances his learning ability is potentially as great as it will be during his adult years, and he may profitably be subjected to learning experiences that will challenge his capacities. The reason for withholding certain types of learning experience from an adolescent is not that he is not potentially capable of profiting from them, but that he may have had insufficient previous experience or training.

Rate of Mental Growth. The rate of mental growth has been studied by numerous investigators including Brooks (1921), Baldwin (1933), Jones and Conrad (1933), Freeman and Flory (1937), and Freeman (1938). The growth of intelligence does not proceed at a constant rate throughout its period of development. Mental ability grows rapidly during childhood and begins to decelerate in adolescence. In general, curves of rate of growth of intelligence show a much greater rate of development in early than in later years. The curve tends to show a diminishing rate from 8 to 15 with a greater reduction after 15, so that acceleration is negative in the middle or late teens. The rate varies at different ages in no predictable manner, but it is not highly variable or erratic despite the fact that each child tends to show a distinctive growth pattern. There appear to be no statistically significant differences in rate changes as the result of the onset of puberty, although Stone and Barker (1939, 1937*b*) reported intelligence test scores and IQ's of post- as compared to prepubescent girls somewhat higher.

Interpersonal Relations

Social Adjustment. One of the most striking tendencies of the adolescent is the great importance which he attaches to the attitudes and opinions of others, particularly those of his own age. The adolescent usually finds his social rôle a difficult one. He has recently passed through stages in social development during which both his accepted personal rôle and the rôle others expected of him were considerably different from the rôle he is now expected to play. He is an individual with limited experience, still in fact a child, who finds himself in what is to him a rapidly expanding adults' world. He finds himself with new physical urges, new physical growth, new interests and values, and new concepts of self. He finds that, unwittingly, he has turned his back on much that used to be important to him. The process of growing up is both difficult and strange, particularly in the

adolescent's relations with others, either contemporaries or adults. From his social explorations he must finally emerge with mature and adequate social attitudes, standards, and skills if he is to find any degree of social adjustment as an adult.

As an individual moves from childhood toward maturity his social development is a progression from the great egocentricity of a very young child to the outlook of a mature adult, who no longer regards himself as the center of the universe. This progress is marked by an increasing awareness and acceptance of others and by a redefining of a personal rôle to conform to a society where workable interpersonal relations are essential for economic and social survival and effectiveness. As the individual proceeds through the years of his adolescence he must expand his social consciousness to a point where he is sensitive to the rights and desires of others, and where he is willing, when it is appropriate, to subordinate his own wishes to the greater good of the greater number. Above all he must learn the techniques, the taboos, and the facilitations of social intercourse. Not all persons are successful in this phase of social development, and to the extent that they are not they will tend to encounter increasingly difficult problems as they grow older.

The older a child grows, the more he widens his social contacts, not only in terms of the greater numbers of persons with whom he comes in contact but also in the diversity of situations under which these contacts take place. Anderson (1939) has noted the fact that "one of the striking characteristics of normal development is an ever-widening circle of attachments." He also notes the "increasing differentiation with respect to social organization" with which the child must become familiar and in which he must learn to operate successfully. A central problem of adolescence is the fact that an adolescent often finds himself in social situations in which he must behave as an adult before he knows exactly how to behave. He has developed a sense of values which tends to overstress the social importance of certain aspects of conduct or appearance, and he may overreact to them if he cannot meet the standards set by himself or his group, because of either physical or monetary limitations.

The problems that present-day adolescents encounter in their social relationships have been reported, among others, by Lawton (1949), Remmers and Shimberg (1949), Wall (1948), Tramer (1947), Moraitis (1946), Partridge (1945), Fleege (1945*a*), Wolberg (1945), Howard (1941), Frank (1941), McGill and Matthews (1940), Curran and Schilder (1940), Butterfield (1939), Wexberg (1939), and Taylor (1938). Cheney (1949) has described a useful method for identifying problems of high school youth.

The Peer Group. The place in which the adolescent has his greatest opportunity of finding social acceptance or rejection and where it is essentially important to him is in the peer group. Acceptance is easier for the conforming adolescent and more difficult for the nonconforming. Adolescents tend to be clannish, to have fairly definite value judgments, and to sharply reject those persons who deviate from their patterns of behavior, dress, and systems of values. For that reason an adolescent who wishes to find acceptance must conform to the mores and the values of his peer group. Deviation means overt nonacceptance, or at best noninclusion or grudging inclusion, in the group's activities. With the great value an adolescent places upon group acceptance such rejection is very disturbing. In his endeavors to gain, to regain, or to hold the esteem of his fellows, the adolescent will often go to lengths that seem extreme to adults. Continued rejection will

often lead to aggression, possibly eventual withdrawal, and sometimes to overcompensation in some other activity where group acceptance is not an issue. But, whatever he may do, the peer-rejected adolescent tends to be unhappy and to be placed in a position where he loses many social contact opportunities that are important to him as a developing individual

Most studies agree that the personal qualities required for acceptance in the adolescent peer society are multiple. Williams (1923) in a study of delinquent boys cited the following as instrumental in the selection of friends: that the individual be of similar chronological age, be of about the same mental age, be fair, be fun to be with, be sportsmanlike, be athletic, be loyal to his friends, and never "tell tales" to those in authority. Dimock (1937) reported that boys tended to be acceptable to each other if they were cooperative, helpful, courteous, considerate of others, honest, unselfish, and self-controlled; if they never or rarely showed off, bluffed, bullied, quarreled, carried grudges, thought they were "picked on," alibied, made excuses, acted superior or domineering, or showed overdependence on others. Anastasi and Miller (1949) list in order of frequency the following six characteristics as being most preferred in friends for both college-entrance and noncollege-entrance high school groups: has many friends, is friendly, well mannered, cooperative in a group, enjoys hearing or telling jokes, and is loyal to friends. Differences occurred in some of the characteristics best liked in friends by the noncollege as compared to the college group. The characteristics chosen with greater frequency by the precollege group were: serious-minded, talkative, talented in arts and crafts, enjoys working on his own hobbies, enthusiastic. The noncollege group more often picked: good listener, athletic, enjoys practical jokes, "peppy," neat in appearance, grown-up, hail-fellow-well-met. Males preferred their friends to be grown-up and neat in appearance, to enjoy working on their own hobbies, and to enjoy practical jokes. Females preferred their friends to be serious-minded, assured with adults, and cooperative with a group.

In a comparison of the similarities and dissimilarities between pairs of friends of junior high school girls and boys, Wellman (1926) reported greatest similarities among girls in scholarship and least in height. Boys were most similar in height, IQ, and chronological age, and least alike in extroversion, scholarship, and mental age. Vreeland and Corey (1935) in a study of 30 pairs of "very" close friends reported high correlations in degree of neuroticism and social intelligence, but low correlations in social attitude. Both Hartshorne and May (1928) and Dimock (1937) found close similarity in moral insight and knowledge of mutual friends. Dimock reported low intelligence correlations between mutual friends, in contrast to an earlier study by Warner (1923), who felt that similarity of mental ability was the factor that maintained friendship between boys even though it was not important in bringing them together in the first place. Fleming (1932), Van Dyne (1940), and Allport (1920) have also discussed personality correlates of mutual friends. The foregoing studies present to some extent a picture of disagreement, probably due to different samples and instruments used. Possibly a more fruitful approach would be to study differences between popular and unpopular adolescents with more adequate samples. Kuhlen and Lee (1943) in a comparative study of least and most popular boys and girls note that age is an important factor in determining what characteristics will find acceptance or rejection in the peer group. For example, among sixth grade

boys, being active in games was important for acceptance, whereas liking the opposite sex was much less important. Among twelfth grade boys, liking the opposite sex had become important and being active in games had become considerably less so. However, more popular boys in both grades showed greater social interest than did the less popular members of the same grades Girls presented a similar picture, although age changes, as compared to boys, appeared to have less important implications. Kuhlen and Lee make the point, however, that there is a danger of emphasizing such differences "at the expense of essential similarities." In their study, for girls, three of the five traits (friendly, enthusiastic, popular) which characterized the most popular girls in the sixth grade also characterized girls in the twelfth. For boys, four of the five highest traits in the sixth grade (cheerful, enthusiastic, popular, friendly) retained their position in the twelfth grade.

Group behavior of children during adolescence has been studied by Cunningham *et al.* (1951), Hollingshead (1949), Furfey (1940), Dimock (1937), Punke (1936), and Partridge (1934). In general it has been found that adolescents who belong to peer groups tends to merge into the group and to assume the attitudes and points of view held by the group. However, participation in the activities of a group does not mean acceptance of the individual participating, nor does status in any given group mean equal status in other groups. There appear to be many different kinds of adolescent groups.

Some investigators report a trend toward the formalization of adolescent group activities, but the majority of adolescents still confine most of their activities to informal as compared to formal groups. The lower the socio-economic class, the less the likelihood of formal organization.

Most popular among group activities are watching and celebrating high school athletic contests, sitting and talking in soda fountains or other gathering places, going to movies, visiting, and dancing. In all these activities, but more especially in respect to dancing and visiting, considerable differences are to be observed between boys and girls, in school and out-of-school youth, and among socio-economic classes. Spontaneously formed groups tend to be more cohesive than artificially formed ones. The multiple-purpose group tends to have more cohesiveness than the single-purpose group. The size of the group appears to be important in group cohesiveness—more important than age, although advancing age appears to make for less intragroup cohesion. Definite sex differences appear in the solidarity patterns presented by male and female groups, although there are numerous similarities.

The study of leaders and followers appears to have been a major preoccupation of those investigating adolescent groups. In general, successful adolescent leaders use different methods of control from those used by child group leaders. The leader who takes into account the wishes and needs of his group is most successful. His methods must be comparatively subtle and must not depart too markedly from acceptable adolescent patterns of behavior. Typical of studies of adolescent group leaders and followers are those by Carter and Nixon (1949), Zeleny (1940), Remmlein (1938), Smith and Nystrom (1937), and Brown (1933).

A problem of concern to those interested in adolescent behavior is the formation of the gang, or the transition of existing adolescent groups into gangs. The gang, in contrast to other adolescent groups, is more highly organized and is usually the result of conflict or outside pressures against its members which throw them together for

mutual aid and support. Gangs have been reported as most likely to appear among more recent immigrant groups or in sections where there are racial or national tensions. A good proportion of juvenile delinquency finds its inception in the gang The reasons for joining a gang are often similar to those for becoming a juvenile delinquent. Gang membership is frequently a normal process rising out of environmental difficulties. Not all gangs are antisocial, but their chances of turning eventually in antisocial directions are greater than those of the clique or the crowd. Studies of gang behavior range all the way from the pioneer studies of Puffer (1905) and Thrasher (1927) to the present-day studies of H. Jones (1948) and Crawford *et al.* (1950).

Heterosexual Relations. One of the outstanding aspects of an adolescent's social development is his gradually growing interest in members of the opposite sex, an interest which normally leads him into expanding heterosexual activities after puberty. A complication of this process, as Stolz, Jones, and Chaffey (1937) note, is the acceleration of girls by 1 to 2 years over boys. During this period girls tend to make overtures to the point where the "dominant" male finds his rôle reversed and discovers attempts to drag him into heterosexual activities before he really wishes to participate. This developmental contrast is most apparent in the ninth grade, where, for probably the last time, girls are clearly placed in the dominant social rôle. Studies such as those of Kuhlen and Lee (1943) and Hildreth (1933) clearly reflect the increasing interest of adolescents in members of the opposite sex. Such new interests bring with them many questions and many problems. Adolescents are very much interested in finding out all they can about members of the opposite sex (Davenport, 1923; Blos, 1941), but the answers they receive are unfortunately limited and often from the wrong sources (Ramsey, 1943; Bell, 1938). Many problems of social procedure and facilitation arise. Hutson and Kovar (1942) report that many adolescents are not able to participate in heterosexual activities because of parental restrictions, geographical location, lack of money and suitable clothing, feelings of inferiority, and feelings of not belonging. Problems growing out of dating are many and complex, with many adolescents simply not knowing what to do, although there is evidence that this is not true of all or perhaps even the majority of adolescents, many of whom display more sophistication than adults ordinarily realize (Hollingshead, 1949; West, 1945; Blos, 1941; Lynd and Lynd, 1937; Finger, 1947).

Family Relationships. The adolescent's family is both a source of security and a difficult problem. It is a source of security in that it offers a refuge, a place of acceptance, and a place where material needs are cared for. It is a problem in that it interposes a barrier which retards acceptance as an adult and offers a fertile ground for difficulties of interpersonal relations. The adolescent's relationship to adults is a problem which requires, on his part, not only acceptance of a barrier to his own natural desires and strivings but also a certain willingness to subordinate himself to others and to accept their counsels and decisions as wise and just, even though, at any given time, he may be unable to appreciate either their reason or their necessity. This all-pervasive problem centers around the fact that the adolescent is a person who is approaching the culmination of his growth and is, in effect, passing from childhood into adulthood; he is sometimes more a child than an adult, sometimes more an adult than a child, but in reality he is neither one nor the other.

The adolescent is expected to obey and respect his parents; he must go to school and accept the child-adult student-teacher relationship; he is denied an adult's place and responsibility in the community; his sex and social life is circumscribed; and, above all, day after day, he is constantly dependent upon adults and must accept his inferior status, taking and carrying out orders. Much is forbidden him, and he is typically apt to grow impatient or perhaps resentful. Sometimes he may attempt, even overtly, to fight against his rôle and status, particularly as it appears to him to be prolonged against all reason. Thus, a desire and often an overt striving for independence are natural and common aspects of the adolescent period. The process of achieving independence is known as emancipation or psychological weaning.

As has been implied in the preceding discussion, for the adolescent the home represents, in the final analysis, the ultimate and definitive repository of adult authority, and its effect upon him is very great. Bossard (1948) notes that the development of personality is a constant series of choices, that such choices represent a person's values, and that such values "are in large part the result of family conditioning." Stott (1939*a*) in a study of city, town, and farm children reported that the two most important factors in family living and the social life of the home, as they affected the personality development of the child, were the "confidence, affection, and companionability" pattern and the pattern of "family discord" or "parental misconduct." Children from homes characterized by "good" patterns of family life as contrasted to "bad" were better adjusted and more appreciative of family life and were superior in their general personality development. In a study on the adolescent in the family conducted by the White House Conference on Child Health and Protection (1934) it was concluded that "the outstanding fact emerging from the study is the significance of the home for the personality development of the child." The most significant aspects of the stable home were found to be affection, confiding in parents, trust and loyalty of child to parents, and control by other means than punishment. Baldwin, Kalhorn, and Breese (1945), Symonds (1939), and Fitz-Simons (1935) all point to the importance of the psychological climate of the home, and Baldwin *et al.* and Fitz-Simons propose methods of identifying and classifying the psychological climate of any given home.

Extremes of parental reaction tend to have unfortunate effects on adolescent behavior. Indulgence up to a point makes an adolescent's adjustment considerably easier and gives him a real sense of security by creating a permissive atmosphere in which he may move toward personal independence and gradual emancipation. When indulgence becomes overindulgence, however, or when overprotectiveness appears, the consequences tend to be unfortunate. Hattwick (1936) notes the vicious circle and behavior ramifications which parental overprotection can engender.

The adolescent whose home history has been one of overprotection and overindulgence experiences greater difficulty than normal in adjusting to the outside world. Outside his home he endeavors, usually without success, to make himself the pampered center of every situation he enters. He constantly seeks parent surrogates in adults whether his teacher, his employer, or the person he eventually marries.

Among the many aspects of an adolescent's home that affect his behavior are whether he comes from a "broken" home (White House Conference, 1934), the number of siblings and his ordinal position in the family (Hayes, 1938; and Stott, 1939*b*),

socio-economic status (Davis *et al.*, 1941; Bossard, 1948), and geographic mobility (Carrington, 1940).

Interests and Activities

Interests. In the study of adolescent interests, play activities have usually been selected as an effective means of showing the kinds of things that appeal to an adolescent when he is "on his own" rather than under the direct supervision of an adult. Play may be thought of as the implementation of interest. It is the activity product of an interest drive, and it becomes a means of demonstrating interests through actually doing something about them. The most-often-cited study in the area of adolescent play interests is the comprehensive one made by Lehman and Witty in 1927.

The first questions in considering adolescent interests are what young people do and, more important, what they like to do. It is fallacious to assume that a normative study of adolescent activities would be an accurate indication of their interests and preferences. Owing to environmental, economic, and adult restrictions and limitations adolescents are often placed in the position of having to participate in activities which are either distasteful or which are, at best, comparatively far down on their preference list. Of course, other things being equal, many activities indulged in by youth are well liked and preferred, but an assumption that such is true for any given activity should be made with considerable caution.

The answers to the questions what adolescents do and what they like to do must, at best, be provisional. The questions might better be phrased, "What youth, when, and where–" Valentine (1943) notes that interests do tend to fluctuate and that there are enough intergroup differences so that one is not justified in treating "a company of youths of a particular age . . . as a homogeneous group." Pressey (1946), in a study covering a 20-year period, noted considerable changes in likes and dislikes, and reported that certain of these changes differed with age and sex. Horrocks and Thompson (1946), Thompson and Horrocks (1947), and Horrocks and Buker (1951) reported fluctuations in friendships, which, however, tended to grow less with increasing age, but which did exhibit sex and rural-urban differences. Jacobs (1949) in an analysis of secondary school students scores on the *Kuder Preference Record* cites some stability of interests in the latter years of high school but recommends repeated measurements during that period.

The variables which make for differences in interests during the adolescent period range all the way from the obvious differences (age, sex) to the differences caused by the less obvious factors of intelligence, socio-economic status, place of residence, physical endowment, opportunities and experiences, period in history, and parental restrictions and taboos. Snyder (1941) has summarized the findings of various studies of interests during adolescence. Among the studies reporting adolescent interests and activities following the depression of the 1930's are those by Peel (1948), Canonge (1948), Vickery (1946), Hammond (1945), M. C. Jones (1941), and Hotopf (1940).

One of the most frequently used avenues to the study of adolescent interests has been through the investigation of communication media habits, such as reading, listening to the radio, watching television, and attending the movies. In this area, as in perhaps no other area of behavior, conflicting and indefinite results have been obtained by various investigators. Why do studies disagree? A number of factors, none of them operating in isolation, are responsible. Among the most important are the following: the time in history; the season of the

year; whether the sample is from rural or small-town communities or from large cities; and, whether the sample accounted for variables (sometimes cited, sometimes ignored) such as sex, race, creed, family upbringing, opportunity, excellence of instruction, intelligence, aptitude, and experience. The conclusion to be drawn is that a normative survey of adolescent interests may impart information that is peculiar to a given time, a given group, or a given location, and hence may not be universally applicable in considering adolescent behavior in general—even within the limitations of a comparatively homogeneous culture.

Sterner (1947) notes that there appears to be little relationship among the various communication media when children's habits and reactions regarding them are considered. She reports that "from a knowledge of a pupil's activity in one medium one cannot predict how much time he will spend on another medium." It is her interpretation that "it is interest rather than the medium which attracts," and that no two media will be utilized to the same extent by a given child to satisfy his needs and interests.

Reading Interests. In general, adventure is popular in all grades (Brink, 1939; Cox, 1929), with reading being more popular in junior than in senior high school (Donahue, 1947). Abbott (1902) reported that although there is a tendency for older children to read more mature books, half of the selections read by high school freshmen were juveniles, humor being popular with both sexes, and action appealing to boys but being rejected by girls. Brink (1939) found that mystery, humor, and drama lost their appeal with advancing age, but Jordan in two studies, one made in 1917 and one in 1926, found that with advancing age fiction became more popular for both sexes. In a third study, in 1935, Jordan reaffirmed the earlier point of view by noting that there was little change in the reading tastes of high school students between 1918 and 1932. LaBrant and Heller (1939) reported that with increasing age abstract quality began to appeal more than narrative. Pearson and Center (1936) in their sample of 40,000 found that the tenth grade marked one of the most decided changing points in reading interests. They noted a definite increase in nonfiction reading in the upper grades. Pond (1939) feels that little growth is discernible from grade to grade but notes a transition from juvenile to more mature material between the tenth and eleventh grades. Ridout (1938) in his study of juvenile favorites feels that, by and large, children are more interested in the books adults are reading than children of a generation ago. Today's adolescent, as Ridout interprets him, has a critical taste. He is interested in adventure, but real characters are the criterion for every book he reads.

Adolescents appear to be avid readers of newspapers (Feingold, 1944), and their newspaper reading interests tend to be essentially a reflection of the times and hence mirror the focus of natural interest at any given period (Tangney, 1942). There appears to be a steady increase with advancing age in reading of the editorial page and the stories, but for the most part changes tend to be greatest between the tenth and the eleventh years of school, with ninth, tenth, and eleventh graders displaying more intergrade similarities. With advance in grade the daily newspaper is read more thoroughly; the comic section, the front page, and the sports section retain their popularity; although there is a comparative decline of interest in the comics in the twelfth grade, comics remain the most-read part of the paper (Donahue, 1947; Feingold, 1944; Fendrick, 1941; Grumette, 1937).

Possibly the two best-liked media for reading among adolescents are comic books and regular magazines. Both are read widely, and both tend to be preferred to other types of reading matter. Nasser (1941) reported that a sample of 950 high school students read more than 350 different magazines. Of these, the average student read 7.68 magazines regularly. Comic books tend to be less popular with older adolescents, but their appeal continues to be great throughout the teen years.

Radio and Motion Pictures. Youth are very enthusiastic about both the radio and motion pictures and indulge whenever they happen to have the opportunity. In a study of 2000 boys Fleege (1945*b*) reported that 3 out of 4 boys attended the movies once a week or oftener, the average boy attending 1.2 times per week, or 4.9 movies per month. Sterner (1947) in her study of the various communication media used by children notes that "radio had more titles listed for it than any other medium. This is the medium to which pupils devote most time each day." The popular status of radio with adolescents is particularly significant when one considers that radio is a comparative newcomer. There has been much discussion relative to the total and comparative influence of television. As of 1953 the medium is still too new and research is still too meager to permit any adequate generalizations. Typical of available studies on television are those by Gable (1951), Siepmann (1950), and McDonagh *et al.* (1950).

Vocational Interests. Vocational selection is another crucial point in adolescent development and adjustment. Adolescents, particularly boys, spend a great deal of time thinking and talking about what they will do after they graduate from school. They are continually confronted with the desirability of making a vocational choice. There is the further fact that for many a vocational decision represents a real step toward freedom from parental control. For some there is also the desire to get married and to be able to support a family. Various studies of the occupational preferences of adolescents have been reported (Myers, 1947; Cawley, 1947; Berdie, 1945; Bradley, 1943; Roeber and Garfield, 1943; Canning, 1941). A considerable amount of fluctuation occurs in vocational choice, although it tends to lessen with increasing age. Older adolescents are likely to become somewhat more realistic in their vocational choices; younger adolescents tend to select more exclusively on the basis of their interests or what they interpret as their interests. Sex differences are apparent. Girls tend to be somewhat more mature in their vocational choices than boys of the same chronological age, and they usually select more sedentary occupations. Proper vocational guidance seems to be desired and tends to lead, where available, to greater stability and more appropriate choices. Various studies have been made of factors related to vocational choice (Myers, 1947; Bradley, 1943; Peters, 1941; Williamson and Darley, 1935; Strong, 1934). Details and superficial selections may change, but basic elements such as curiosity and mastery tend to remain comparatively stable. Factors determining vocational choice are environmentally engendered. Parents and family are usually most influential in determining vocational choice, then friends, and then professional acquaintances. Sons of higher-income parents are more likely to want to follow in their father's footsteps than the sons of lower-income parents. Social prestige is often an important element in the adolescent's vocational choice. But, whatever the adolescent's final decision, personal advice is decidedly of greater importance in influencing choice than information from other sources.

Chapter 12

RESEARCH ON PRIMITIVE CHILDREN[1]

Margaret Mead

Introduction

The value of research upon primitive children to students of psychology is part of the whole larger problem of the relationship of researches made among primitive people to the hypotheses and theories of psychology. Therefore, the history of the uses to which psychology has put data about primitive children and data about primitive peoples when constructing theories of developmental psychology is a history of the changing relationship between anthropology and psychology.

The first use to which psychologists put ethnological data was in constructing biogenetic theories in which the postnatal behavior of the child was regarded as recapitulating the past history of the race. In a thorough examination of this position Hallowell (1939) has shown that any such theory involves these untenable positions: (1) an acceptance of the doctrine of acquired characters, (2) a direct equation between the type of culture found among our primitive contemporaries and previous stages in the history of more advanced cultures, and (3) a demonstrable correspondence between the behavior of civilized children and primitive adults. In its crudest form this old biogenetic theory continues to crop up in the literature, and psychologists continue to make investigations to disprove it (Schubert, 1930; Anastasi and Foley, 1936, 1938). More seriously, it lies, as Hallowell has shown, behind much current psychoanalytic thinking and therefore compromises investigations made among primitive people within the psychoanalytic frame of reference.

All the evidence which we have at the present time suggests that the only situations in which the savage adult can be compared with the child within our society are those in which primitive societies have failed to pattern some aspect of behavior which we have patterned extensively. In those cases, the thinking of the primitive adult, not trained, for example, in scientific logic, may resemble to a certain extent the thinking of civilized children *not yet* trained in the methods of scientific thinking. This resemblance, however, will be negative in terms of slightness of exposure to some cultural patterning and may not be attributed to a greater degree of "primitiveness" in the thinking of the savage adult than of the civilized adult in the sense that primitive means a simpler, a more rudimentary, or an earlier form. Similarly, the drawing of primitive adults who have *never drawn before* often resembles the drawing of civilized children who have *never drawn before*, but when the art of a primitive or non-European society has some positive characteristic—for example, the technique of phenomenal regression instead of perspective—this must be attributed either to the circumstance that the societies have developed and institutionalized different approaches to the problem of representation or to differences

[1] I am indebted to Miss Marion Marcovitz for her collaboration in preparing the bibliography and organizing the tabular statements on unpublished research. M. M.

in the cultural conditioning of perception (Thouless, 1933). There is the further possibility that, since types of thinking or ways of solving problems may tend to appear in a given order in the development of the child, different cultures may select an earlier ontogenetic tendency than others for elaboration (Mead, 1947*b*). When this occurs we can find elaborations in given primitive cultures of types of behavior manifested for a brief period and within a restricting and limiting frame in our own culture. In such cases there are available to the psychologist data upon ways in which potentialities of human thought, left unexploited or definitely overlaid or distorted in our culture, may develop.

This generalization holds in many fields. We can find cultures which develop the potentiality for animistic thought, as we can also find primitive societies which give their children a training that discourages animistic thought even more rigorously than does our own (Mead, 1932) and cultures which fail either to give encouragement and elaborate channeled forms or to discourage, but leave man's capacity to begin thinking animistically, in childhood, so unpatterned that it will survive merely as an idiosyncrasy in some adults confronted with a new situation (Mead, 1928*a*).

Róheim (1934*b*), working within the psychoanalytic frame of reference in the study of primitive children, continues to refer those aspects of primitive culture which are common to all primitive societies to a phylogenetic Oedipus situation, although allowing (Róheim, 1939) more and more for the specific elements in given cultural family situations which account for the particular form that the Oedipus complex takes in the character of members of a given primitive tribe. The most promising attempt to state the relationship between developmental phases in the emerging personality and the institutionalized cultural forms of contrasting societies is to be found in Erikson's (1939) theory of the social implications of *epigenesis*. He applies Freud's theory of pregenital zones and stages to problems of culture by pointing out that the successive emphases upon body zones in early childhood permit the particular modes of these zones to become established as basic social modalities. In a given society the oral-sensory, anal-muscular, and genital-locomotor zones are trained so that their modes (incorporation, retention, elimination, intrusion, and inclusion) become patterned to form a basic social grammar, consisting of such modalities as getting, taking, having, holding, letting go, and giving.[1] Within this theoretical scheme different cultures can be classified according to the extent to which they abbreviate or lengthen these stages, emphasize or deprecate the various modes of behavior associated with given zones, and so produce, as the standard cultural personality, a *monstrum in excessu* or *monstrum in defectu*, stated in terms of developmental possibilities. This approach permits, as did the discredited biogenetic theory, a stimulating cross-comparison between the behavior of children in any given culture, at any given stage, and the behavior of adults in other cultures.

The biogenetic theory and much of the thinking that has replaced it work with the concept of *the primitive*, a synthetic personality, built up partly deductively from a hybrid of sociological, pseudobiological theory and partly through a miscellaneous mass of detail collected and systematized by such comparative writers as Lévy-Bruhl and Frazer. This material was further systematized by psychologists like Freud,

1 Erikson handled this theory formally in a chart (Homburger, 1937) which was reproduced in the first edition of this manual. It has been omitted here as a much fuller treatment of this chart is included in Erikson's *Childhood and Society* (1950).

Wundt, and Stanley Hall, and "the primitive" as an analogue of "the child" or "the neurotic" or "the psychotic" became a theoretical counter in later psychological research (Piaget, 1924; Storch, 1924). Despite the enormous amount of ethnological research that has been done to demonstrate the great complexity and diversity of preliterate cultures (Evans-Prichard, 1934; E. Beaglehole, 1940) and the untenability of any such concept as "the primitive," this concept still recurs today with monotonous frequency in psychological writing. There arose, however, a counter tendency to document the extent to which primitive man must be regarded as an acculturated adult, subject to the patterning of his culture, and in no sense more archaic, or simple, in his methods of thinking than are we (Boas, 1938). The very great differences between cultures of the world appear then as comparable to the smallest local variations which obtain at home. This approach, in the hands of members of other disciplines, again tended to crystallize a conception of a series of synthetic primitives, as unreal as their single predecessor, members of a given tribe who were just like us except for a few conspicuous details; the Zuñi had a distaste for violence, and the Kwakiutl a freer exaltation of himself. These stereotypes have proved to be almost as mischievous an idea as that of the primitive who thought prelogically and represented the childhood of the race.

Current sophisticated treatments of the reports from primitive society tend to use, in one part of their argument, the data showing that primitive man is just like us in all the respects in which he has been accused of being most different and, in another part of their discussion, discrete items of difference as recorded for particular tribes, who become unreal counters for "nonviolence," "jealousy," "lack of knowledge of paternity," etc. This is the result of combining the generalized rebuttals of the older position, based upon a large number of miscellaneous instances, with a certain amount of data on conspicuous differences.

Neither stereotype is of any genuine use to psychologists; one leads to untenable theory, the other to mere dull disbelief, for the average student who is taught that a given kind of native is just like himself, except for a few conspicuous and striking differences of behavior of which he knows he would be absolutely incapable, very properly rejects the whole argument. To convert these stereotypes it will be necessary for psychology gradually to assimilate and reduce to useful form the more recent findings of ethnologists which stress that a fully acculturated member of a living culture differs in *every respect,* and *systematically,* from members of any other culture (Mead, 1934*a*; Bateson, 1936; Erikson, 1940; see also Köhler, 1937). Lee (1940) shows, for instance, that the Trobriand lack of recognition of paternity is not merely a prop for matriliny or an isolated piece of illogicality among a people who are just like us but that this nonrecognition stands in a systematic relationship to many other Trobriand ways of thought in a system of thought different from our own.

It is necessary to recognize that the growing child is systematically patterned in every detail, in posture as well as in gesture, in tempo as well as in speech, in his way of thinking as well as in the content of his thinking, in his capacity to feel as well as in the forms which his feeling takes and that only by an understanding of the extent and internal interrelationships of any of these systems of socialization can the psychologist operate usefully with "the Zuñi child" or "the Arapesh child." The use of isolated instances of cultural differences, in the most abstract form possible, so that for the statement "The Mundugumor na-

tive feels shame in the outside of his upper arm" the psychologist will substitute "The localization of specific emotions may be introspectively referred to different parts of the body, and parts so identified in one culture may be ignored in another," will enable the psychologist to keep his thinking from becoming culturally limited, but the effect will be negative. Such an abstraction keeps him from making obvious errors of the order of "All children are more animistic than adults," but it does not necessarily stimulate him to say anything new, to advance any more fruitful hypothesis.

Looking at the development of psychology's use of primitive data from another point of view, we find that in the first stage, that of *analogy*, there was an efflorescence of unprofitable and unsound parallels between primitive man and civilized children which led to a dead end in psychological thinking. This period was followed by the period of disproving the assumptions made in the previous period and using primitive material *negatively* to call in question psychological assumptions which had contained a western European premise (Malinowski, 1927*a*; Mead, 1928*b*, 1932; Benedict, 1934*b*). During this period it was further the function of the ethnologist who oriented his work to psychological preoccupations to phrase his material as "Yes, but among the . . . such and such is the case, and so your hypothesis will not hold."

The effect of this type of criticism is to drive the theorist toward higher degrees of abstraction. The Yale frustration-aggression hypothesis (Dollard, Doob, Miller, *et al.*, 1939) is a case in point. The hypothesis states that if a series of acts which would have led to a final satisfying act is interrupted, the subject will either turn toward some other analogous goal (substitution) or he will exhibit aggressive behavior. The critic replies: "Yes, but the Balinese do not see their own behavior in this way. They see their own behavior either as an infinite continuum leading nowhere or else as separate atomic pieces; they do not see life as we do, as composed of a series of acts punctuated with satisfactions." This criticism calls attention to the whole problem of "time gestalt" and "purpose," and it is now possible to look at the goal seeking and at the aggressive behavior in terms of this new abstraction and to see that both are alike in their punctuation, in that both end in climax. This leads us to the generalization: "If an individual has been conditioned to a certain time gestalt and if a sequence of his acts is interrupted, he will turn toward some other sequence in which a similar gestalt is implicit."

Our criticism has led to a higher degree of abstraction and so to a reduction in the number of entities invoked. In place of the alternative entities, "substitution" or "aggression," we now have only one entity, the "time gestalt" (Bateson, 1941). However, a correction of this order, introduced into a hypothesis which had been carefully framed in an attempt to allow for and rule out the cultural factor, can be introduced only on the basis of an exceedingly detailed study of character formation in other cultures. It is therefore to be expected, in terms of the continual cross-fertilization between psychology and anthropology, that, as the field worker takes more cross-culturally useful frames of reference into the field, he will return with material which will be relevant at a higher level of theoretical abstraction in psychology.

This most recent stage in the application of primitive material to psychological theory has a positive aspect, in which the ethnologist attempts upon the basis of primitive data to develop concepts that could not

be derived on the basis of any other data which we possess. The contribution of the ethnologist here may be likened to the contribution which a chemist might have made in discovering a new element *before* the periodic table was constructed. Because our theories of human nature must always be constructed on the basis of subjects who have been socialized, our progress is exceedingly slow in constructing any theoretical picture of the range of human potentialities and the systematic interrelationship of different parts of this range Until we have enough data to fill in the analogue of the periodic table for human development, it will be necessary to have more and better-detailed studies of the process of character formation and the resulting personality structure in different cultures. Erikson's (1950) chart makes it possible to make an intelligible statement about certain aspects of character formation in about half the primitive societies upon which we have relevant data concerning the way in which the zonal behavior is patterned. Bateson's (1942*a*) suggestion for the analysis of cultures in terms of types of *deutero-learning*, through which different types of learning identified in learning experiments in the laboratory may be seen to play different rôles in the expectations of members of different cultures, provides us with another such cross-cultural frame of reference, as does his formulation of *end linkage* (1942*b*). The Gesell-Ilg (Mead, 1947*b*) spiral concept of development provides another useful cross-cultural model less exclusively preoccupied with affective elements than are those theories of growth which derive from Freudian psychology. Renewed attention to forms of thought of the type which is found extensively in dreams, in schizophrenics, in ritual and art, and in the spontaneous productions of children is introducing new possibilities of cross-cultural analysis of *primary process* types of thought (Vigotsky, 1939; Schachtel, E. G., 1947; Lowenfeld, 1935). The development of psychosomatic theory has also introduced a new set of concepts within which child development may be seen culturally (Mittlemann, Wolff, and Scharf, 1942; Mead, 1947*c*; Wolff, 1947). Models for seeing child development in cultural settings as part of a circular system of communication between generations may be expected to come from the newly emerging approach of *cybernetics* (Wiener, 1948; Bateson, 1949; Mead, 1949*a*). This approach may be opposed to unrewarding discussion of the causal rôle of particular items of child rearing practices (Whiting, MS *b*; Orlansky, 1949). This newer framework makes it possible to look upon the child as acting within the whole social group and, by making the point of reference the regularities of the human growth process within a social group of all ages, eliminates artificial distinctions between the sequences of growth within the individual organism and the interrelationships among all the human beings within a society (Mead, 1949*b*).

So the psychologist will continue to demand from material gathered by the ethnologist data for correcting his hypotheses —negative material—and data for amplifying his hypotheses—positive material. Upon the formulation of significant cross-cultural hypotheses which the ethnologist can take into the field will depend the amount of significant materials of this sort which the ethnologist can bring back; and, if the science of human behavior is to proceed at maximum speed, the field ethnologist concerned with psychological problems must be working with hypotheses even before they reach the point of publication and not with the formal psychological statements of some years back.

The Psychologist among Primitive Peoples

We can now turn to the history of the attempts of the psychologist to work in the field, or to set specific problems or provide tests for the use of the field worker. His first contacts with primitive peoples, like his first use of primitive material, were cast in a biological mold. He wanted to study racial differences. Klineberg (1935) and Goodenough (1936) summarize the state of research here. Goodenough says:

> In view of the relatively small amount of information concerning the mental characteristics of various cultural and racial groups that is based upon direct measurement or simple functions, it is greatly to be regretted that up to the present time psychological interest has been so closely centered about the problem of classification on the basis of general broad assumptions the validity of which is uncertain.

The first research was done on the sense organs, and, as Goodenough (1936, p. 6) points out, psychologists were satisfied with the disproof of the extravagant claims of racial differences which had been made and ignored the differences which were found. There was then a very infertile period of applying intelligence tests to primitive children, usually in culture contact environments, which necessitated an equally infertile effort to refute the findings. Efforts are now being made (Porteus, 1937; Cattell, 1940; K. R. Stewart, MS *c*) to develop tests which can be standardized on the members of preliterate cultures and which will yield positive data on how the individuals think, not merely on how we may classify them. To date, no data have been advanced which actually call into question the basic ethnological assumption of the nonexistence of innate psychological differences between races. The principal importance of this type of research lies in its background relationship to other problems, for if there were significant and constant differences between all the members of one primitive group and those of another group, then any study of the socialized individual would have to take them into account.

A second attempt on the part of psychologists to collect primitive data has been prompted by problems which they themselves formulated and for which they collected supporting data. Porteus (1937) set out to test the theory that environment was responsible for the poor showing of natives in a culture contact setting. He made a study of primitive people in two differentially difficult *physical* environments, to find that, if anything, the individuals in the harder environment were superior but that, on the whole, the differences were unsystematic. Greater reliance upon ethnological data would have suggested that this investigation, as it was phrased, was not worth undertaking. Dennis (1940*a*) posed the problem of whether the cradle board affected the age of walking and tested it out in two Hopi communities, one in which the cradle board was still used and one in which its use had been abandoned. Setting aside the reliability of Indian mothers' reports on a problem that involved accuracy in months, the question, like Porteus's, was phrased in a way that tremendously oversimplified the problem. It is to be expected that infants subjected to a type of environmental pressure of which the cradle board is one expression will differ from infants differently reared, but not on such simple items as "age of walking." Rather will they differ in manner of walking, occasions when they walk, significance of walking for the personality, type of balance disturbance to which the individual is subject, etc. It is even probable that most of these effects would remain even if the cradle board itself dis-

appeared, as long as the whole complex of cultural behavior of which the cradle board had been a part survived (Erikson, 1939).

Recent elaborations of this type of earlier approach now occur in reverse. Some single item of behavior which has been described as providing useful clues to the understanding of the acculturation system of a given primitive society, as, for instance, the way in which a pattern of permissiveness or exactingness is expressed in the infant feeding situation, is then assigned hypothetical causal importance, and this hypothesis is either subjected to criticism (Orlansky, 1949) in the light of work done in our own society or uncritically imported as a basis for a pediatric program (Moloney, 1945; Moloney and Cammisa, 1947).

When the emphasis was upon the contribution of research in primitive society as a negative corrective to culturally limited hypotheses, taking a problem into the field, such as the incidence of conflict at adolescence (Mead, 1928*b*) or the effect of a harsh environment on IQ (Porteus, 1937), seemed to be an effective use of primitive material. From such oversimplified studies, however, we could not expect anything except negative, corrective, precautionary conclusions, and such an approach is now definitely out of date.

Approaches during the Period 1935–1940

These approaches (1935–1940) take as a focusing point, not a simple presence or absence, concomitance or nonconcomitance problem, but instead the investigation of the developing individual within the whole cultural matrix. The older approaches relied upon primitive societies to provide laboratories within which different sorts of children could be found whose behavior could be used to disprove or call in question some hypothesis. The value of primitive societies was regarded as lying principally in the fact that the culture was a different one and that special sets of conditions, such as cradle boards, prolonged suckling, nonrecognition of paternity, absence of formal schooling, and knowledge of graphic techniques, could be found and their "effects" upon the developing personality studied.

It was later felt that more was to be gained by asking another kind of question, and by utilizing two other aspects of primitive culture: (1) the circumstance that they represented varieties of social systems which we could neither produce experimentally nor derive by extrapolation from known forms and (2) the circumstance that in small groups of preliterate peoples sharing a common culture it is possible to deal with the individual within the whole society, in relation to his total culture, in a way that is not possible in large groups, in a stratified society, characterized by great heterogeneity of culture. The new questions that the psychologist or the ethnologist working in terms of psychology asked were positive questions: What is the mechanism of character formation within the new society? What sorts of learning are emphasized, and what are the results? How is a personality type which places no value on aggression developed, and how do individuals of this sort function within society? Emphasis was laid first upon collecting data upon the total socialization process, and then focal points within that process were studied.

This approach grew out of increased emphasis upon personality and culture (Malinowski, 1927*a*; Frank, 1931, 1938, 1939*a*; Fromm, 1933; Benedict, 1934*a*; Mead, 1934*a*, 1937; Lasswell, 1935; Bateson, 1936; Dubois, 1937*a*, 1937*b*; Horney, 1937; Maslow, 1937; Gorer, 1938) and out of an increasing rapprochement between psychoanalytic findings and cultural studies (Mead, 1930*a*; Glover, 1932; Róheim, 1932, 1934*a*, 1934*b*; Dollard, 1935*a*, 1935*b*; Horney,

1935; Mekeel, 1935; Opler, 1935; Eriksoń, 1939; Kroeber, 1939; Lasswell, 1939; Levy, 1939; Kardiner, 1939, 1945; Schilder, 1940). From this type of investigation we may expect data upon the whole socialization process within a given society which are sufficiently precise to give a greater understanding of specific aspects of socialization, such as types of learning (by conditioned reflexes, by "empathy," by different sorts of identification, by dependence upon verbal or nonverbal cues); patterning of interpersonal relationships in preponderantly symmetrical or asymmetrical terms; utilization of biologically given differences, such as sex differences, in building character; cultural patterning of rhythms of growth; minimization or maximization of hereditary defects or special abilities; development and utilization of symbolic forms; orders of congruence between sorts of character structure and politico-economic forms. Even further illumination is to be expected from using a series of such detailed findings in cross-cultural comparisons which will bring out general tendencies; and on the basis of these tendencies hypotheses, later to be tested in other ways, can be formed.

A first attempt at such a study was made in *Cooperation and Competition among Primitive Peoples* (Mead, 1937). Kardiner (1939) using suggestive data upon some of the formal aspects of culture indicated a series of formal ways in which such investigations might proceed. The most complete field work based upon his frame of reference, and upon which he has drawn in his later work (Kardiner, 1945), is that of Cora Dubois (1944). Whiting (1941) made a similar attempt to illustrate by field materials the applications of learning theory developed by Dollard and Miller (1941).

The period just before the war saw the collection of large amounts of field data, much of which will never be fully published, upon which psychologists, or anthropologists working with questions posed by psychologists, or the two working together may test and explore developing hypotheses.

Developments during World War II and the Postwar Period

Anthropological work was even more affected by the war than other disciplines, because field work became impossible in many of the more primitive areas. Since 1940 work has concentrated along two main lines: (1) the application of projective tests and other standardized testing and observational procedures to groups of children in culture contact situations, principally schooled or partially schooled American Indians, and (2) the application of theory based on previous work on primitive children to the new applied field of studies in national character. The most ambitious attempt at the cross-cultural use of projective tests, in mixed teams of anthropologists, clinical psychologists, and educators, was the work of the Indian Education and Administration Research represented in a large number of publications (Eubank, MS; Hallowell *et al.*, MS; Hassrick, MSS; Havighurst, Gunther, and Pratt, 1946; Havighurst and Hilkevitch, 1944; Havighurst and Neugarten, MS; W. E. Henry, 1945, 1947; Joseph, MS; Joseph, Spicer, and Chesky, 1949; Kluckhohn and Leighton, 1946; Leighton with Adair, MS; Leighton and Kluckhohn, 1947; Macgregor, 1946; Mordy, MS; Rannells, MS; Thompson, 1946, 1948, 1950, MS; Thompson and Joseph, 1944, 1947; Underhill, 1942, MSS; Warner, Havighurst, and Eubank, MS) ranging from discussions of the methodology of the cross-cultural use of a particular test (W. E. Henry, 1947) to reports in which the authors' extensive knowledge of a whole culture is integrated with some of the test results (Leighton and Kluckhohn, 1947;

Macgregor, 1946). Specific results of this very ambitious study, which was planned to meet the standards of cross-disciplinary research in child development, have been contributions to our knowledge of the usefulness and range of the tests employed rather than to the development of new conceptual schemes for dealing with the problems of culture change, for which we at present have no conceptual tools (Mead, 1949*c*). Cultural insights have been channeled back into the world of projective testing, increasing somewhat the possibilities of the inclusion of cultural concepts in the interpretation and use of the tests, but hardly calling into effective question the original culturally limited concepts on which the tests were developed. The unsatisfactory state of the relationship between Rorschachs and cross-cultural uses is summarized by Abel (1948). Individual anthropologists, particularly Hallowell (1941*a*, 1941*b*, 1942) and those working with him (Caudill, 1949; Coelho, MS *a* and drawings; Watrous, MS), have been able to use the lines of communication with clinical thinking to fertilize their thinking in areas where they already had great cultural knowledge, but the use of these methods, with the emphasis on comparability of method rather than upon cultural patterns, has on the whole yielded great masses of data and little theoretical advance

The field of national character developed as a wartime measure in which methods based on a combination of anthropological field work and clinical research were applied to attempt to delineate the character of enemies, allies, and native populations. A variety of theoretical formulations were developed (Bateson, 1942*b*; Gorer, 1943; Mead, 1943*b*, 1946, 1947*f*; Levy, 1947; Schaffner, 1948; Leites, 1948; Benedict, 1949; Dicks, 1950). All of them involved hypotheses concerning the importance of regularities in methods of child rearing as a clue to the character structure of members of a culture. They all invoked certain theoretical propositions of the order referred to above[1] about the nature of growth; the significance of certain types of communication (Mead, 1949*a*) between adults and children, such as those involved in feeding, weaning, teaching of control and bodily autonomy, regulation of bodily functions, etc.; and they drew also upon the theoretical work of learning and Gestalt psychologists. These studies have provided a rich body of hypotheses, the most recent of which are embodied in Gorer's set of hypotheses concerning the rôle of the child rearing practices, particularly swaddling, during the first year of life in the formation of the character of Great Russians (Gorer, 1949; Gorer and Rickman, 1949). But essentially this series of studies, even when made upon exotic cultures such as those of Japan, Burma, and Siam, have not been studies of children but rather studies of cultural practice, as reported by adult observers, which involve children, or deductions about childhood experience from the literary and artistic material or from the anamnestic materials of individual adults. This was inevitable given the conditions under which the material was collected, but the research worker is now left with a set of hypotheses concerning childhood hardly underwritten with any observations on the children of the countries to which these hypotheses apply, producing a period historically analogous to the period when Freudian hypotheses about childhood had as yet no supporting data from child analysis. The older workers in the field of national character have all done field work, but there is serious danger that in the absence of field work opportunities a new group of research workers may develop hampered by a lack of background of ob-

1 See page 739.

servation of children in a genuinely primitive or exotic cultural setting.

The combination of the national character research and the work done with projective methods, as exemplified in such investigations as Columbia University Research in Contemporary Cultures set up by Benedict (La Barre, 1948), opens up again the possibility of combining data on actual childhood behavior with other types of cultural data from arts, myths, religious ceremonials, and dreams, so as to illuminate the way in which preverbal psychological mechanisms continue to operate throughout life. K. R. Stewart's study of primitive dreams (MSS *f*, *g*) which records and analyzes dreams of children and adults in three native cultures—in a society which interdicts the use of dreams, in a society which neglects dreams, and in a society which turns them into instruments of social control—is a significant field addition to this area. Further analyses of prewar field work on adults and children (Bateson and Mead, E; Belo, E; Tschopik, E) may be expected to provide data on this same set of problems.

The most extensive set of interrelated field studies having at their disposal most of the hypotheses developed during the war are those which have been under United States naval auspices in Micronesia (Barnett, 1949, E; Burrows and Spiro, 1953; Gladwin, E; Joseph and Murray, 1951; Lessa, E; Luomala, E; Rauch and Tolerton, E; Schneider, MSS, E; Spiro, MS, E). These studies should be expected to reflect greater theoretical sophistication in new forms of field observations.

The emphasis upon the study of the total socialization process and the investigation of the development of the personality within the whole culture does not obviate the need for precise psychological studies within the primitive societies which will use more controlled methods for the study of small, delimited problems. Without these basic cultural studies, however, the precise investigations are meaningless. The psychologist who used anthropological data in the past was inclined to pick at random illustrative details torn from the context (Miller, 1928) or recorded in the absence of context, or to content himself with insisting that more precise methods should be used without formulating the interrelationships between the problems which the precise methods were to solve and the delineation of the total socialization process (Bartlett, 1937).

Once this is recognized, it will be possible to take more precise psychological methods into the field. For example, in Bali, it may be observed that the incidence of fatigue seems to be much lighter than in other societies In the absence of other data, for the psychologist to make a precise determination of the degree of fatigue under different sorts of tasks among the Balinese would get us absolutely no further than the original observational statement It would back up the original observation but would not add any further understanding. However, a study of the total picture in Bali shows: the way in which learning takes place, by direct manipulation of the learner's body or by participation by the carried infant in the rhythm of the mother's acts, by observing what others do, but with a minimum of verbal teaching of any sort; the way in which the child's behavior is controlled by the affectively toned exclamation accompanied by the invocation of one of an assortment of fear symbols—wildcat, witch, scorpion; the way in which gradual detachment from other persons and a decrease in, and finally the disappearance of, bids for personal attention takes place in the Balinese child whose responsiveness is continually played upon by adults and older children; the absence of overt manifesta-

tion of guilt or remorse; the high degree of hypochondria, coupled with a great preoccupation in playing upon one's own body; the way in which a craftsman uses only the particular muscles absolutely essential to a given task, so that there is no spread to total involvement; the premium that the Balinese put upon orientation in space, and their objection to drunkenness; their interruptibility and apparent lack of perseveration; the absence of goal-oriented behavior.

When these and a great number of comparable motifs have been identified and documented, the psychologist skilled in the measurement of fatigue could go in and make significant, precise studies of the amount of fatigue shown by the Balinese in various relevant contexts—in the presence of strangers, in a strange environment, under exhortation to make an effort, in dangerous occupations involving a threat of personal injury, when given verbal instruction as compared with a demonstration of the task, etc.—and from such an investigation a real addition to our knowledge of fatigue might be made.

This general principle holds true of all precise measurements of individuals in primitive society; differences in visual acuity are of merely academic interest and lack any theoretical significance unless they can be correlated with a total behavior picture in which they may be shown to play a systematic rôle. Ability to solve a maze, endurance, perseveration, discontinuity of learning, etc., are important to measure if it is possible to show that these identified mental habits have a systematic relationship to the type of character standardized in that particular culture. (For example, K. R. Stewart (MS *b*) found that Ainu women showed a definite inability to tackle new problems which could be correlated with the special circumstances of older women's social rôle.)

If the field worker is trained in both psychological and ethnological techniques, both aspects can be developed together; the areas in which precise measurement or contrast groups would be useful can be identified in the field, and the necessary tests given. Alternatively, ethnologists in the field can carry out various suggestions given them in consultation with psychologists, either before they set out or, more fruitfully, after they have identified the foci of their problem. Examples of such cooperation are Nadel working with Bartlett's suggestions (Nadel, 1937*a*, 1937*b*); Mead working with the Abel Free Design Test (Abel, 1938); J. Henry and Mirsky working in cooperation with Levy (Levy, 1939; J. Henry, 1940*a*); and, conversely, K. R. Stewart, as a testing psychologist, using techniques of hypnotism, dream analysis, maze testing, Goodenough test, etc., and working with a knowledge of the cultural background provided by Noone (K. R. Stewart, 1951, E); Erikson making his observations among the Sioux with cultural orientation provided by Mekeel (Erikson, 1939) and among the Yurok with cultural orientation provided by Kroeber (Erikson, 1943); and Dennis making extensive use of the manifold published Hopi cultural material (1940*b*); as well as the extensive team work of the Indian Education and Administration Research (Thompson, 1948).

With the recent elaboration of technique of recording and observing, single-handed field work is becoming steadily less rewarding, and expeditions in which scientists trained in different disciplines cooperate on the spot will have to take the place of the single worker.

Methods of Research

In discussing methods of field research, certain absolute requirements will be taken

for granted and not discussed in detail.[1] In the primitive culture studied, the investigator must have an especially detailed knowledge of the data most immediately relevant to childhood: prenatal care, care of children, family structure, children's play patterns, both formal and informal (Mead, 1931; Flannery, 1936), age grades, initiation system, rituals associated with *rite de passage* (Van Gennep, 1909), etc. He must furthermore have a systematic understanding of the whole culture—the sociopolitical system, the economic arrangements, etc.—so as to be able to place this detailed material in its context. Such an understanding can, of course, be gained in several ways: by direct ethnological research, by the use of existing ethnological sources, by cooperation with an ethnologist in the field, or by working with the cooperation and advice of an ethnologist who has been in the field. Work must be done either in the native language or in a contact language in which the children and the investigator have facility (Mead, 1939*a*). The direct use of an interpreter is not adequate, but educated natives may be used to give tests, record results, etc. The subjects should be known as individuals, so that at no time will an individual's behavior on a test, in a social situation, or as recorded in a photograph have to be interpreted without reference to that individual's known personality and status within the family, the age group, and the community. As most research on primitive children is highly qualitative and utilizes a very limited number of subjects, this condition is not difficult to meet. The research should be done with a closed group, a village, a clan, a locality, a horde, as the case may be, so that the total social situation within which the individuals live can be accurately stated (Moreno, 1934). Observations of "forty Indian children gathered from twelve different tribes at a government school," etc., are relatively valueless until an enormous amount of work has been done on the twelve tribes involved, and then it would still be more rewarding to study forty children within one of the twelve tribes.

We may now consider the more specific methods by which children's behavior can be studied and by which the implications of the cultural setting as expressed in the behavior of the growing child can be evaluated.

The Natural History Approach. This method is based upon careful observation of primitive children within ordinary life situations: infants in their mother's arms; siblings struggling over their mother's breasts; children's behavior at the death of a parent or during a quarrel between their parents; behavior of individuals during initiation; etc. In such an approach the investigator is minimally present, effaces himself or her camera as much as possible, and records the surrounding context of behavior as well as the actual behavior. So a struggle witnessed between an old woman and a child, in which the old woman seems to be putting excessive energy into attempting to drag the child with her, is given retrospective illumination by the circumstance of the old woman's death three hours later (Bali). A child's display of fear in the arms of a young girl nurse which is not paralleled by similar behavior in the arms of a different nurse may be placed against the knowledge that the nurse has just quarreled with her guardian and been expelled from the temple society of unmarried girls (Bali). A child who has never been observed refusing food before may suddenly refuse food from his mother with an accompanying temper tantrum. This behavior becomes relevant if the investigator knows that the child was adopted

1 For practical consideration, see Mead (1931).

a short time before, had been taught that his mother was not his mother, and that the adoption arrangement had been abruptly terminated the preceding night as a result of a quarrel among the adults (Iatmul).

There are various stages of refinement with which these methods can be used. The records kept may be taken at random whenever significant behavior is observed (Mead, 1928*b*, 1930*b*; Hogbin, 1931; Firth, 1936; Gorer, 1938); a large enough sample of different types of observation—for example, daughters with fathers in mothers' absence, mimetic play immediately following a cultural spectacle, etc.—may be taken at definite intervals (Bateson and Mead, E, for Bali and Iatmul; Brown, E; Kluckhohn, E, for definite periods, once a year). The records themselves may be *retrospective*, that is, written down after the observations have been completed, or *simultaneous*. Simultaneous records may be of many types: running verbal records of behavior (varying in value depending on whether the recorder has to look at the medium of recording, so that writing methods like touch typing and stenotyping are superior to methods of recording which require visual attenton, such as stenography); records made by one observer or by several observers who concentrate on different aspects of the situation and synchronize against a time scale; records made with a parallel still photographic record, varying from illustrative photographs (Figures 1, 2, 3, 4, 5) giving a general setting to a short series of photographs in a sequence (Figure 6); a sequence of photographs taken with a miniature camera permitting more lavish expenditure of film and automatically giving a permanent sequence record (Figure 7); a sequence taken with a rapid winder, presenting a far more detailed record (Figure 8); or a set of stills taken simultaneously with a cinematograph record. Cinematograph records represent the most complete behavioral record (exclusive of sound), and vary in refinement from short Ciné sequences interspersed with verbal records and short Ciné sequences interspersed with verbal and still records through the final refinement of two 16-mm. Ciné cameras, staggered so as to give a complete record.[1]

There are two further possibilities of obtaining photographic records which have not yet been tried out. The first is the use of a motor-driven camera and the inclusion of a sound recording apparatus. Such a method would be very costly and would require three persons, one for the Ciné camera, one for the sound apparatus, and one to keep a verbal situational record which the sound record would not replace. If it were desired to expand in the direction of equipment rather than in the number of investigators, it is probable that a 35-mm. Ciné camera, equipped with a foot release, a device for taking single frames, and an automatic clock device, might permit a single investigator to approximate, but not to equal, the record kept by two investigators, in which one makes the photographic record, the other the verbal.[2]

1 Bateson, Mead, and Belo have experimented with all the various methods described above. Costs of still photographs are enormously reduced by using bulk film and loading it into cassettes in the field, and by supplementing the use of Ciné film by much less expensive series of stills. The use of two Ciné cameras and two miniature cameras makes it possible to record simple behavioral sequences without any break, if it is possible to have an operator for each Ciné miniature pair. This method, however, necessitates *three* observers, for it has been found that even Ciné records are of very limited value without a complete simultaneous verbal record.

2 All records made by more than one observer must be made against a time scale, and all records, even by a single observer, are enormously improved by the use of a time scale, not only for behavioral sequences but also for single bits of behavior observed out of any known context, as the context may later be filled in or the interval before an observed bit of behavior may become significant.

FIGURE 1. Expression of fear of foreigners by Balinese children. Bajoeng Gede, Bali. G. Bateson. Reading from left to right and from top to bottom:

Doemoen, aged ca. 18 months, in her mother's brother's wife's arms. (Dec. 12, 1936. Leica, 3V-34.)

Patera, ca. one year, in his father's arms. (Dec. 8, 1936. Leica, 3T-9.)

Karbo, 310 days old, in his mother's arms. (Dec. 11, 1936. Leica, 3T-34.)

Badera, girl ca. one year, in arms of a neighbor child. (Oct. 10, 1936. Leica, 3A-21.)

FIGURE 2. Contrasting ways of handling children. Reading from left to right and from top to bottom:

Arapesh, New Guinea. Bischu's ca. week-old baby, carried in a net bag, in which the infant's body gets all-round support as *in utero*. (1932. M. Mead.)

Iatmul, New Guinea. Kalugwaimali's 11-day-old infant on mother's outstretched arm. (May 31, 1938. Leica, 23P. G. Bateson.)

Lepchas, Sikkim. Tafoor's two middle daughters. The Lepcha child spends nearly all waking hours securely fastened to the back, in which position it has to yield passively to every move of the carrier. (1937. G. Gorer. [Gorer, 38 Pl. 23.1)

Manus, Admiralty Islands. Ngamel's wife with ca. 8-month-old baby on her back. (1929. M. Mead.)

Pilagá, Argentina. Carrying child in sling. (1936–1937. J. Henry.)

Bajoeng Gede, Bali. Lenjad, carrying her 42-day-old infant girl. Balinese babies are suckled in the sling. (May 6, 1937. Leica, 8E-4. G. Bateson.)

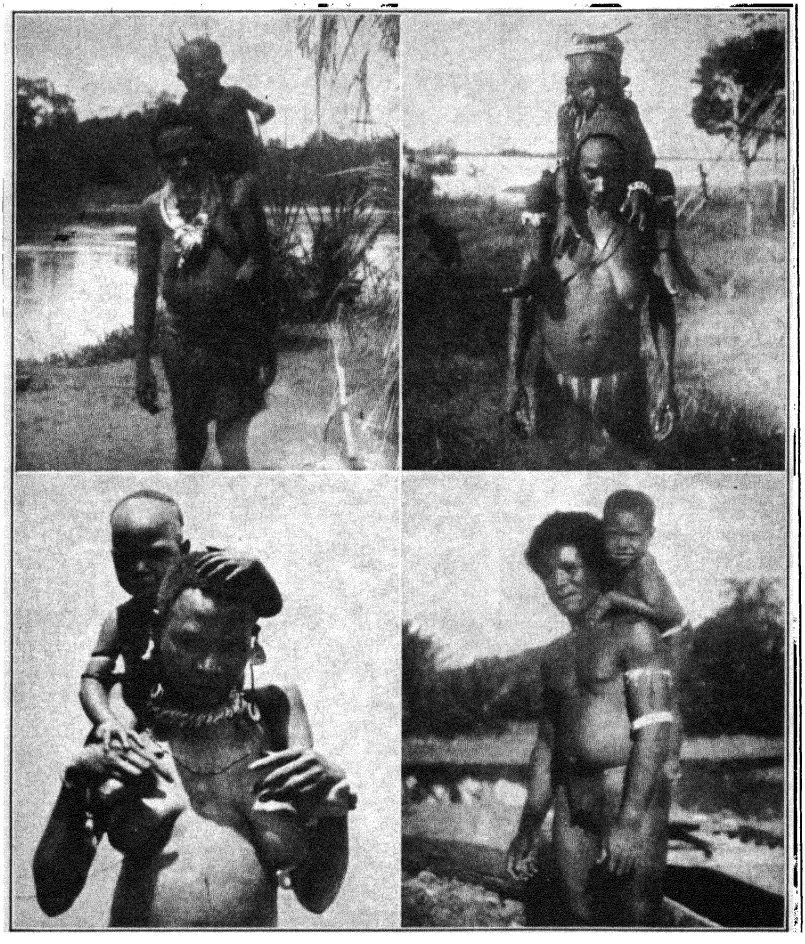

FIGURE 3. Contrasting ways of carrying older children. Mandated Territory of New Guinea. Reading from left to right and from top to bottom:

Mundugumor, Sepik-Aitape District. Kwenda, carrying adopted twin girl, ca. 2 years. Child is given no support by woman whose hands hang idle. (1932. M. Mead.)

Tchambuli, Sepik-Aitape District. Woman of Wompun hamlet carrying child in ceremonial dress. No support given by hands of woman. (1933. M. Mead.)

Arapesh, Sepik-Aitape District. Kamawon, ca. 2-year-old girl, on the back of a young girl, Wadjubel. Both of child's legs supported. (1932. R. F. Fortune.)

Manus, Admiralty Islands. Piwen, aged ca. 2½ years, on the back of her father, Luwil, holding on herself. (1929. M. Mead.)

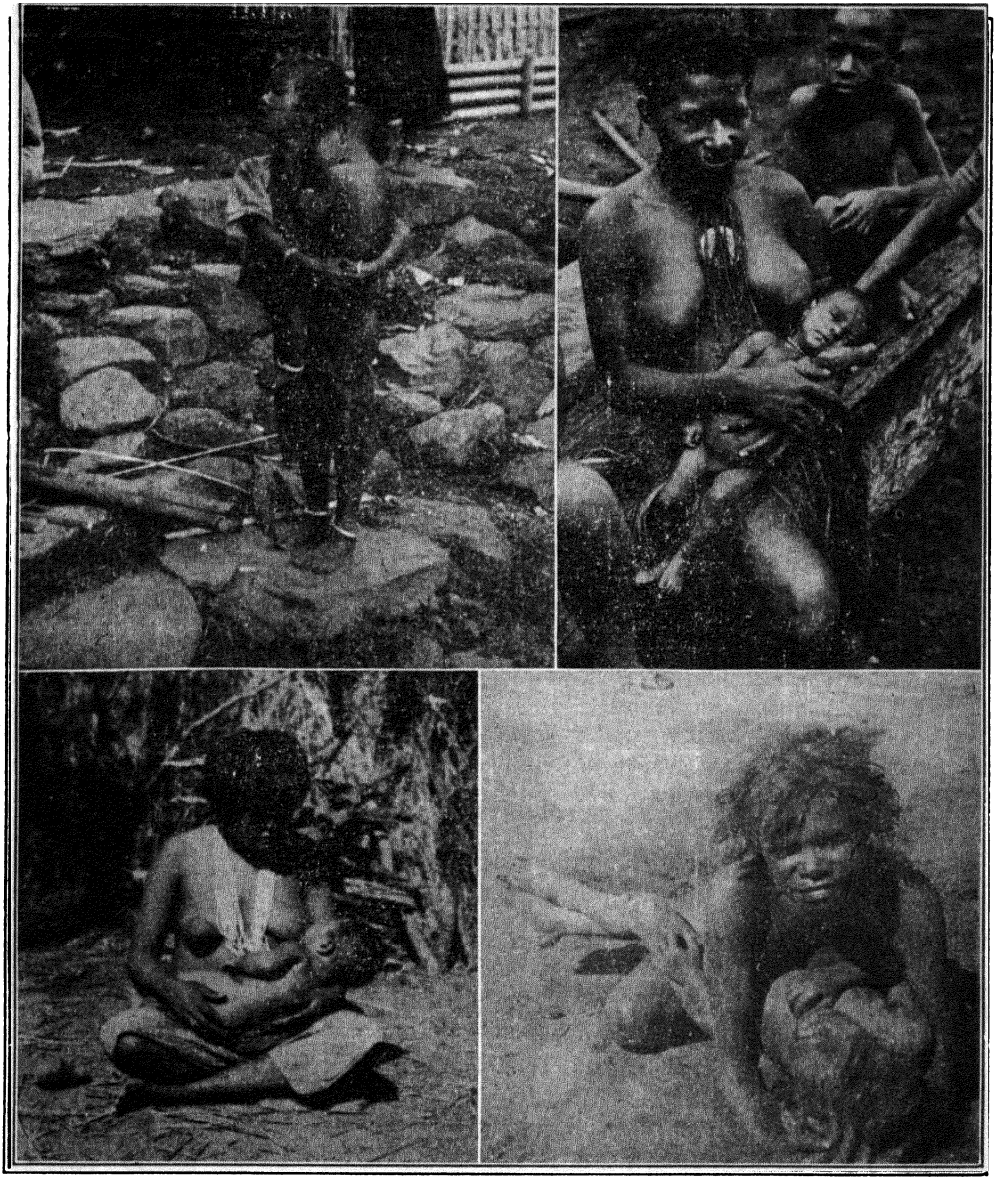

FIGURE 4. Sleep postures. Iatmul, Balinese, Pilagá, Pitjentara. Reading from left to right and from top to bottom:

Bajoeng Gede, Bali. Kenjoen, 266-day-old baby girl, in arms of elder sister, Gati, aged ca. 5 years. (Dec. 24, 1936. Leica. 3Wa-35. G. Bateson.)

Iatmul, New Guinea. Pulembelua, seated on a log, with her ca. 3-month-old baby girl on her lap. (Oct. 5, 1938. Leica, 32A. G. Bateson.)

Pilagá, Argentina. Child asleep at breast. (1936–1937. J. Henry.)

Pitjentara, Central Australia. Tuma, wife of Kanakana, demonstrating how mothers sleep over their children. (1929. G. Róheim.)

FIGURE 5. Children's symbolic play. Reading from left to right and from top to bottom:

Siwai, Bougainville, Solomon Islands. Girls dancing in imitation of women. (1938–1939. D. Oliver.)

Iatmul, New Guinea. Kowi and Wanggi, boys ca. 12 years old, making play pots by pouring water into mounds of sand. (Aug. 26, 1938. Leica, 29C-45. G. Bateson.)

Pilagá, Argentina. Naicho and Tapeni, girls making themselves clay breasts. (Henry, 1940*b*.) (1936–1937. J. Henry.)

Bajoeng Gede, Bali. Karni, ca. 10 years, preadolescent girl, with hair still cropped short, wearing false hair made of grass. (April 14, 1937. Leica, 6V-21. G. Bateson.)

FIGURE 6. Child behavior sequences. Reading from left to right and from top to bottom:

Bajoeng Gede, Bali. Raoch, 312-day-old boy, in mother's arms, while ethnologist medicates his skin. Mother brings child in typical limp fear state; covers his eyes during medication; offers breast to crying child; finally child actively sucks. (Oct. 24, 1936. Leica, 3A-2-5. G. Bateson.)

Pilagá, Argentina. Mother teaching child to walk. Before standing the child up, the mother raises and lowers the baby, never lifting it from the ground, just flexing and unflexing its legs. (1936–1937. J. Henry.)

The most significant cleavage among these methods lies between the *retrospective* and *simultaneous* types of records. As this difference applies both to completely "natural," that is, nonexperimental, situations and to behavior within experimental set-ups, it will be discussed in detail here. Examples of retrospective records are the following:

[Dennis, 1940*b*, p. 145. Observation of 1939 within a contrived set-up among the Hopi.] Joe seems sleepy and cross. He cries easily. He was sitting on Etta's lap and protested when she tried to get him to sit alone. When he cried, she hugged him and rocked him back and forth. Then she reached to the window and brought along a half-consumed sucker which apparently had been brought along with such a use in view. This quieted him, but he remained on her lap.

[Mead, E 1929. Field notes. Observation in natural set-up on a Manus child,

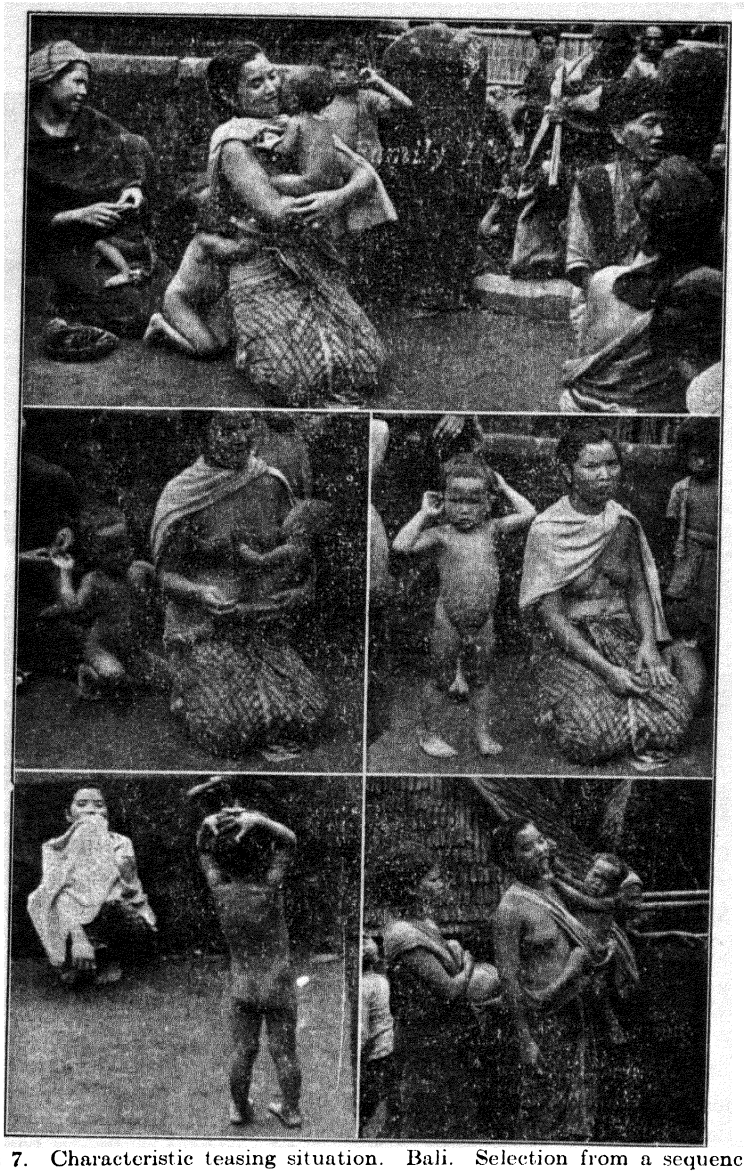

FIGURE 7. Characteristic teasing situation. Bali. Selection from a sequence of 23 frames (Leica, 5A-3-28), covering about 10 minutes of scenes among wedding guests in Bajoeng Gede. March 1, 1937. G. Bateson. Reading from left to right and from top to bottom:

Karsa, unweaned boy ca. 3 years, crouches laughing behind his mother, Men Singin, who holds her sister's crying baby girl, Meres.

Karsa begins to show anger when his mother gives her breast to the baby.

Mother has returned the baby to her child nurse but is unresponsive to Karsa's continued temper tantrum.

Mother covers her mouth; Karsa still in a temper.

Mother finally picks up Karsa, who pushes her face away.

aged 2½–3 years.] Ponkob, 43–4 (place in numbered households in village census). Ponkob was in a canoe alone, a fairly shallow one, punting. A great pig started to attack the canoe. He screamed with fright, but nevertheless didn't lose his head, and kept pushing the pig off with his pole and slithering the canoe around for about five minutes. No one came to his aid. Finally the pig gave up, and he, still wailing, made for his house. This happened right behind his own house.

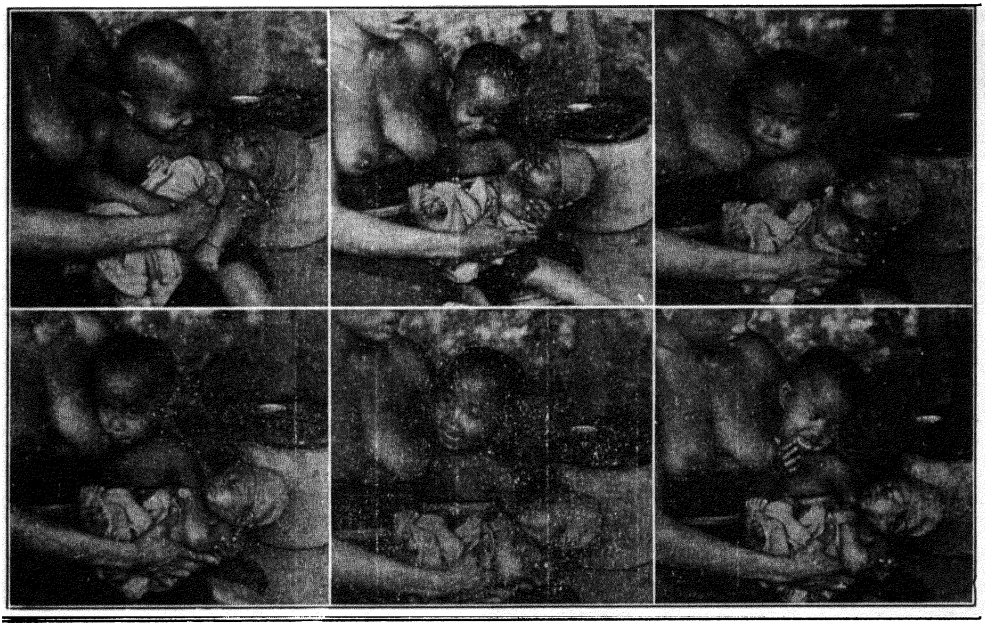

FIGURE 8. Sibling behavior sequence. (Bajoeng Gede, Bali. April 30, 1937. Leica, 7V-34-39. G. Bateson.) Reading from left to right and from top to bottom:

Njawa, girl ca. 3 years, infant brother, aged 30 days, in mother's arms, at a birthday feast for another child. End of a 14-frame sequence. At the beginning of the incident, the mother puts the baby in Njawa's lap, a standard way of making children show off. In the frames shown, the mother's attention wanders and the weaned older child absently steals to the breast, then grins back at the baby.

We may compare such records with simultaneous running records of behavior:

[Fortes, 1938, p. 31. Observation of three Tallensi children who had been building a play cattle kraal which had collapsed in the course of their play.] Suddenly, with a shout, Gomma began to scramble off the baobab branch, followed by Zoo, calling out, "Let's swing." For a minute or two they rocked back and forth on the branch and then descended. Now Gomma remembered his cows. Vehemently he accused his sister of having taken them, and when she denied this challenged her to "swear." "All right," she said placidly. Gomma took a pinch of sand in his left hand and put his right thumb on it. Zoo licked her thumb and pressed down with it on Gomma's thumbnail. He stood still a moment, then suddenly withdrew his thumb. (This is a children's play ordeal.) Gomma examined his sister's thumb and found sand adher-

ing. "There you are," he said, rapping her on the head with a crooked finger.

[E. and P. Beaglehole, 1941. Account of weaning of a Pukapuka child.] Mata, a childless married woman, is minding her sister's baby, William (aged 8 months), for the day, while his mother works in the taro gardens. The child is soon to be weaned and has already started to eat taro and nuts. Mata's keeping the child for the whole day is part of the weaning process. The child gets restless and fretful, so Mata picks it up in her arms and rocks it violently, cuddling it fiercely, bumping it about, and patting it with no gentle hand. To soothe the child further she gives it her dry breast to suck. The baby sucks hard, and then, when he can get no milk, he stands up and suddenly bites Mata's neck. Then he returns to the breast and ends by giving her nipple a severe nip with his teeth. Mata slaps the child on the head. The child cries hard, throws itself about in her lap. It is given some coconut flesh to eat but continues to whimper for some time.

[Mead (Bateson and Mead, E). Field notes. Excerpt from a record called "Karbo and His Parents." Bajoeng Gede, Bali, October 11, 1937. Karbo is 19-months-old; natives speaking Balinese.]

11:32 A.M.
K. comes to step, sits, and wiggles on his bottom.
N. Oera (father of Karbo) rattles some money on the cement.
K. turns and looks at him.
K. drops a piece of banana skin.
K. takes an enormous mouthful (of banana).
N. Oera exclaims in alarm then, "There, chew it."
K. pounds with bracelets on the cement.
K. takes banana and pounds with it.
N. Oera, "Eh! Eh!" (mild exclamation of pain) "Throw it away!"
K. pounds again and throws it away as ordered.
K. pounds another piece.
N. Oera, "Throw it away!"
11:35 A.M.
K. "Away," and throws it away also. (Repeating the last syllable of the Balinese *koetang,* "throw away." This form of syllable clipping is culturally standardized for baby talk, and between intimates.)

A record of this sort can be compared in detail with the following:

[Mead (Bateson and Mead, E). Field notes. Excerpt from "Scaring Children," November 10, 1937, in which Karbo, aged 20 months, is carried by Moespa, a girl of about 11, onto my veranda. Natives speaking Balinese.]

9:50 A.M.
K. reaches toward my papers, out of Moespa's arms.
M., holding him, says, *"Aroh"* (an exclamation of fright or pain), *"aroh,* contains worms."
K. puts a marble into his mouth.
M., "Spit it out. Contains faeces, contains faeces" (omitting the initial *t* in the word *tae,* faeces, standard baby talk).
K. spits it out.
K. puts marble in his mouth again.
I say "Aroh!" as closely imitating Moespa's tone as possible.
K. takes marble out and *then* spits.

We may now consider the advantages of the two types of records. The retrospective type of recording is only as valuable as the questions which were already formulated in the investigator's mind. The investigator selects for later recording certain aspects of the behavior, and later he makes generalizations based upon these illustrations. They may suggest new problems, but they will rarely yield answers to problems which the investigator has not formu-

lated. Therefore, the publication of such protocols, except illustratively to show the type of data used, is hardly justified, in terms of publication costs, because they will already have been squeezed almost dry of theoretical implications. Simultaneous records, on the other hand, although inevitably somewhat affected by the frame of reference also, contain a great deal more spontaneous observation and may yield to analysis and reanalysis not only by the investigator but also by other investigators. Records of this type permit detailed comparisons between many aspects of the behavior of children of the same age, of the same child at different ages, and between children from different cultures. Retrospective recording is an efficient method for solving the negative type of problem which has now been outdated. For the new approach, what we need is a mass of very detailed material about the way in which the individual child develops within his culture; simultaneous records which are ultimately to be made available in full are an absolute requirement.[1]

A further advance in the natural history approach is made when the same situations are recorded for a number of children, for the same child over time, and in different cultures. Advances in this respect have been due to practical considerations which rather limit the number of comparable situations among cultures, for example, bathing a baby, and to theoretical considerations, mainly contributed by various psychoanalytic frames of reference, which have suggested that some situations (suckling, weaning, cleansing after excretion, handling of genitals, sibling rivalry, etc.) were specially significant in the process of character formation and therefore important to observe in detail. Although materials for cross-comparison become immediately much more usable if such standard observations have been made, it is possible to overemphasize the importance of these crucial situations. Erikson's more abstract statement suggests the need for recording tendencies which find many different expressions during the socialization process. Because the simplest way to demonstrate a type of child training is to give a vivid illustration, as Róheim's (1932) illustration of the way in which a Normanby Island mother sings a song as she suckles her child, which is accompanied by pulling the nipple out of the child's mouth at the end of each phrase, it is necessary to guard against the tendency to oversimplify the problem and say that such an experience as this in itself produces the type of character formation observed in the adult (Mead, 1947*b*).

A more discriminating and accurate way of stating the matter would be to say that in the illustrative incident there are a number of details—for example, the rhythm, the deprivation, the returning of the nipple, etc.—and that of these some one or more are specially significant inasmuch as they are backed up by innumerable other small habitual details of daily life. An identical sort of behavior where, however, it was the rhythm and not the deprivation which was the more typical element, might be found elsewhere, associated with quite different character structure. Similarly, in Iatmul, the nipple is frequently pulled out of the child's mouth in order to transfer the child to the other breast, hoped to contain more milk. Such a deprivation will have a very different effect from that produced by interrupting a child's sucking before it has finished because the mother dislikes suckling, as Mundugumor mothers do (Mead, 1935*a*). Similarly, in the Iatmul

1 Such records need not necessarily be printed. They may be mimeographed and given a small library circulation, or they may be put on microfilm or microprint. The latter technique, however, is not very fully adapted to methods of detailed cross-comparison between sets of data.

custom by which the mother subjects the child to a mock weaning, wreathing her nipples with human hair for 15 hours or so, and then going on nursing the child again, until, a month or so later, she finally weans it with a hair wreath, the significant element is the false alarm, which ties up with many other aspects of Iatmul behavior, whereas the use of human hair as a weaning mechanism, although found in many societies, has no very important tie-up in Iatmul.

If we emphasize too heavily a formal set of data, on suckling, weaning, sphincter control, etc., some of the most important nuances are likely to be lost. So, while continuing to collect as much material on these standard situations as possible, in order to assure comparable masses of data, we need to make simultaneous, detailed, and, if possible, multiple-observer and multiple-technique records of large sequences of behavior in normal situations. Such sequences will be valuable in direct proportion to their length, continuity, and the amount of detail recorded. From long records of the interactions of about three human beings in a culturally natural context we may be able to answer great numbers of questions not yet formulated; we can attack such points as cadence and tempo of behavior, proportion of symbolic to nonsymbolic activity at different age levels, and the sequence in which one type of activity is substituted for another.

Recording of Verbal Behavior. The various American schools of anthropology and the Malinowski school have all insisted upon the value of collecting ethnological materials in text, that is, literally recorded in the native language. Text collection has usually been regarded as a corrective for overenthusiastic interpretation, and very little emphasis has been given, except by Malinowski (1935, Vol. II), to the extent to which a record of words spoken in sequence is a record of behavior. Even without a photographic record of the posture of the individual, and with no formal system for recording tone of voice, large masses of spoken or written (where writing has been introduced) comment from native children is an especially usable form of data.

[Mead, E. 1928–1929 Field notes. Monologue—directed toward the investigator—of a Manus girl, Kawa, aged 4–5 years. February 19, 1929]

I am called [i.e., someone is calling me].
My tobacco is in the box of Kopal.
There is no paper, but someone will get some in the house of mourning.
Give me some paper to smoke.
Pwailep is at the house of Katu.
Pwailep is the niece [*kaka,* literally, sister's daughter].
Ponap and Posuman have gone to work for the white man
Topal [her brother] wants to take my tobacco to the Usiai [members of another tribe with whom the Manus trade].
[Someone calls.]
We have no food, it is all in the bush [i.e., not yet traded for].
The ghosts are about. [There has been a death in the village, and the presence of inimical ghosts makes going about, and trading, dangerous.]
We haven't a big canoe.
Ngawa wants to go to make a ceremonial exchange in Dropal.
Do you want to buy it?
[I say "What?"]
Some paper. My tobacco is in the box of Kandra in our [exclusive possessive pronoun] house.

It is also possible to get children from about 9 years to adolescence to dictate material, sometimes quite lengthy texts.

[Mead, 1928*b*. Portraits of themselves dictated in Samoan by two adolescent girls. 1926.]

I am a girl. I am short. I have long hair. I love my sisters and all the people. I know how to weave baskets and fishing baskets and how to prepare paper mulberry bark. I live in the house of the pastor [p. 255].

I am clever at weaving mats and fine mats and baskets and blinds and floor mats. I go and carry water for all my household to drink and for others also. I go and gather bananas and breadfruit and leaves and make the oven with my sisters. Then we [herself and her sisters] go fishing together, and then it is night [p. 256].

[Bateson (Bateson and Mead, E, Iatmul, 1938). Field notes. Informant Kowi, boy, aged 12. October 22, 1938. In the presence of Mbetna, aged 14.] In the Agamora Reach [of the river] there she went to *undumbu* [Land of the Dead], they took her. They brought [her] to the village. Having put [her] in the house, they wept. Then "turn pancakes" when he had said and looked [and there were none], he hit [her with] adze. Here [holding his own wrist] the spirits put her heart he hit her. She went to *undumbu*. They wept for her. What [shall I say now]? In the morning, going in the top of a malay apple tree he went and hung himself. He —first having tied it badly he fell. Having fallen with a good rattan having tied it he fell. He hanged. Djaneimbuangga [and] Ambwanembindo undid him. They buried him.

Text records of conversations between children and parents, or between children, are also much more valuable than translations, but the problem of getting down more than brief exchanges is very great, whereas in dictated texts or slow, dreamy monologues the recorder has a chance to keep up with the child.

[Mead, E, Manus, 1928–1929. Field notes. Conversation between Kawa, girl, aged 4–5, and Tjokal, boy, aged 11–12, immediately following the monologue recorded above. February 19, 1929.]

Tj. Kawa, your father is calling you.
K. I have no canoe.
Tj. The child-of-Ngandiliu has one, go on.
Tj. [To me.] Her father is calling her. He says: "This evening all the ghosts will emerge."
[Kawa comes back.]
K. We haven't any food in our house. They didn't go to the bush. Tomorrow we'll go.

The Cross-Section Method. The investigator of primitive children is usually limited to a brief period, seldom exceeding a year, and if he wishes to describe the way in which children develop within that culture he must perforce use the cross-section method, that is, construct a picture of the total socialization process by reference to the observed behavior of groups of children at each age level. Many criticisms of the limitations of the cross-section method as it applies specifically to the study of the individual, culturally seen, have been made (Mead, 1928*b*, pp. 261–262; Dollard, 1935*b*, p. 4; E. and P. Beaglehole, 1941). Supplemented by the *retrospective* and the *simultaneous* (see below) life history, however, cross-sectional methods are likely to remain one of the principal standbys for the study of children in other cultures. Two methodological devices can increase their usefulness. The first of these is maximum and detailed attention given to the behavior of individuals in periods of maturation, *defined as transitional* for purposes of the investigation. So, if the adolescent girls have been classified by the usages of the culture or by the investigator into groups of preadolescent, adolescent, and postado-

lescent, there will be certain individuals who stand conspicuously, in physique or behavior or status, whatever the criteria are, at transitional points. The task of the investigator will then be to define the central tendencies in the group which the transition individuals are on the point of leaving and the central tendencies in the group toward which the transition individuals are moving. These individuals will then be observed in the greatest detail, and every alteration or variance of behavior relevant to the defined behavior of the two groups will be recorded, analyzed, and subjected to immediate scrutiny in terms of situational, constitutional, or social-structure factors which might make it atypical.

This transitional behavior will furthermore be utilized to get introspective comments from the preadolescents and adolescents about the behavior, and to get the adults to make retrospective and valuational comments of the order of "I remember when I reached menarche, my mother said . . . ," and "She is just about to reach menarche; she should stop dancing," or "Yes, he refused to carry her even though she had a sore foot because he is not *sapta*" (brave enough to raise a momentarily nubile girl above his shoulder). A year usually provides enough time to study a significant number of transitional cases, whether it be a suckled child through weaning to postweaning, a child with an unpregnant mother through the mother's recognition that she is pregnant, a child with all milk teeth through loss of several milk teeth, a child who is still too young to go anywhere alone through the period when he is entrusted with his first older-boy tasks, etc.

The second method, invented by Lasswell (1937), requires a greater refinement of data and knowledge of age level than are usually available in a small primitive group. It might, however, be applicable to an alien culture with a large population, if the observer had a limited amount of time but almost unlimited resources for observation. By this method the observer keeps under simultaneous observation, in terms of a detailed schedule of behavior items, a series of overlapping age or status groups, so that the transition from *a* to *b* to *c* is recorded for two different groups, when the group in stage *a* is entering *b*, and when the group in stage *b* is entering stage *c*. The detailed utilization of this method is dependent upon knowledge of age of subjects or the substitution of some physiological criteria which are systematically related to behavior, for example, classification according to change of voice in one culture or height in another. Criteria other than age are difficult to handle cross-culturally but would not detract from the adequacy of the method within a given culture. In a general way this method may be utilized in any cross-section study of individuals in a living culture and provides the technique for correcting any error which may come from observing individuals from one point of view; it avoids, for instance, the group in period *b* being thought of more in terms of having left period *a* than as approaching period *c*.

Other Methods Which Can Be Combined with Cross-Section Studies. The field worker is always under far greater pressure than the psychological investigator working within our society. He usually has a definite and very inadequate time allowance; he is working in the medium of a foreign language with subjects unaccustomed to any sort of routine or discipline; and even if the main outlines of the culture are known he has to pay constant attention to the unraveling of the cultural implications of the simplest acts. Furthermore, a great deal of time has to go to subsistence and supporting activities: buying food, medical care of the natives, maintaining rapport,

etc. Any techniques which can short-cut this problem are doubly useful.

I shall discuss four: Fortune's handling of *events*, my own method of utilizing the *deviant case*, an adaptation of Levy's method of *pure cases*, and Wolfenstein's method of *paired child-parent interviews*. In the use of *events*, extensively developed by Fortune (1935) and also reported in my Arapesh diary (Mead, 1947*a*), events of a certain type—illness, misfortunes, quarrels, etc.—are taken as focusing points for the study of the behavior of all individuals involved in that particular situation. This method, applied to the study of children, means that at the end of a field trip one would have a systematic account of the behavior of children of given age and sex when confronted with comparable situations within their households, such as births, death, quarrels, and major *rite de passage* ceremonials. If this method is to be used systematically, a type of event must be chosen which is likely to occur often enough to provide a real sample; for example, quarrels would be a suitable selection for a 6-month investigation among the Iatmul, but no large sample of quarrels could be obtained in a 2-year study of Bali.

In my method of the *deviant case*, individuals who vary from the observed norm, owing to either environment or personality, are selected for study. These cases are analyzed in terms of generalizations already made about the group behavior and the factors identified as significant. For example, individuals from biological families are analyzed to show whether hypotheses made about the influences of large households can be supported (Mead, 1928*b*, pp. 141–143); or single cases of early weaning are examined to see what light they throw on the rôle of late weaning (Mead, 1935*a*, p. 38); or the behavior of little boys whose fathers are dead is examined in cultures where the father plays an important part in education (Mead, 1930*b*, pp. 112–116). Then, as a related method, deviations in behavior, such as the individual child who has temper tantrums beyond the customary age limit (Mead, 1935*a*, p. 51) or the girl who bursts out with a suicidal wish at a funeral ceremony in a society where all such outbursts of emotion are disallowed (Bateson and Mead, 1942) or the child who steals in a society where stealing is most unusual (Mead, 1928*b*, pp. 178–180), are analyzed to discover what elements in the social background or experience of the individual may explain the behavior. The fullest published material on cases of this latter sort is that of J. Henry (1940*b*), in which three Pilagá children who refused to speak were analyzed to show the emotional deprivation which the children had undergone. A final use of deviant cases is the study of the behavior of individuals whose personality approximates least accurately the type approved by the group for the given age and sex, as a device for illuminating the functioning of the more successfully acculturated individuals (Mead, 1935*a*).

Levy (1938–1939), in his method of *pure cases*, selects from a large set of full case records a series of cases, all meeting several hypothetically significant criteria, and then analyzes these cases in detail to show a pattern of interaction between the developing personality and the social environment. This method can be applied in the field by making the criteria of "purity" a series of items of conformance to the cultural ideal, for instance, or of conformance to the statistical norm. So a series of cases which are "pure" because they are ideal, or "pure" because they are statistically usual, could be analyzed to show what sort of personality develops under the circumstances which the culture postulates, and under those which actually obtain in the culture. For the Mountain Arapesh, for instance, this would mean studying a series

of children from families where the father and mother had been betrothed in childhood, the mother had grown up in the father's parents' home, there had been no other wife, and both father and mother were mild personalities; these would be the pure cases of the cultural ideal. Such a series could be set against children in homes where there were two wives, at least one of whom had not been "grown" by the husband during a child betrothal, which is the statistically usual condition.

Wolfenstein (1946) has developed a method of *paired parent-child interviews,* in which a parent and one or more children are either interviewed along carefully paralleled lines or subjected to the same sort of evocative material, such as a story. This method further localizes the mass of observational data in a situational context and makes it easier to separate out behavior which should be referred to "family culture" or—in dealing with modern ethnic groups within a complex society—to "home ways" (Mead, 1944*b*) characteristic of subcultural groups within a wider culture. Although an informal use of this method has characterized most field work on primitive peoples, as the field worker inevitably worked with families, it meets many of the requirements, specifically emphasized by Lasswell, for a more precise definition of the observational situation.

The Life History. The significance of the life history in the study of the development of personality within a cultural setting has been most fully stated by Dollard (1935*b*). Kluckhohn (Gottschalk, Kluckhohn, and Angell, 1945) has systematically discussed the variety of methods used, and I have outlined a further set of problems in my record of the verbal productions of one Arapesh informant (Mead, 1949*e*). The most satisfactorily annotated published life history of a member of a living native culture is Gorer's life of Kurma (1938). Radin's *Crashing Thunder* (1926) is still a classic in this field.

It is usual to characterize the life history approach as dynamic and involving time as an active dimension, and the cross-section approach as static, but actually the use of transitional cases in cross-sectional studies shows the individual acting in time, whereas time is merely an implied dimension when the individual relates past events as they appear to him in the present. Life histories may be distinguished in respect to what point in the individual's life is taken as the focus. In the *retrospective* life history, or autobiography, adults relate the story of their lives as they now appear to them; in the *simultaneous* life history a section of the life of an individual capable of introspective comment is recorded, both in terms of actual events and of the individual's comment upon those events. Parallel with this utilization of introspection are *longitudinal* methods, designed especially for the study of young children, in which the behavior of individuals is observed over a period of time or tests are applied at stated intervals with wide gaps throughout a period of development.

Much has been claimed for the *retrospective technique* as restoring the organic locus to the study of personality. It is undeniable that an adult's account of his early memories and childhood experiences furnishes valuable data on the way in which adults see childhood experience, their own and other peoples'. However, these are essentially data upon how the narrator feels and what significance those experiences have for him in the present, not data upon his actual development in the past. This distinction has been lost sight of because for therapeutic purposes a false memory is often as good as a real one. When our object is the study of the growth of personality, data derived from these introspective accounts must be taken with the greatest

caution. This is particularly so when the material is gleaned from the memories of survivors of an earlier cultural era and there are no living children against whose experiences these memories can be checked (Eastman, 1902; Michelson, 1918–1919, 1932, 1933; Radin, 1926; Linderman, 1930. 1932; K. R. Stewart, 1951; Devereux, 1937; Landes, 1938).

The survivors of an earlier period may well give a record of their childhood training which jibes perfectly with the data they give on their attitudes as young men and women, with their accounts of cultural values and emphases, and with their present attitudes toward life. There is, however, no guarantee that this internal consistency has not been imposed by the narrators upon the actual facts of their experience; and, whereas consistency among a large number of unrelated observations on individuals of different ages within a living society can be regarded as strengthening the presumption of accuracy for any one observation (if the observations are of such an order that the coherence which might be introduced by the investigator can be ruled out, as in, for example, myths, formal rituals, literal texts, and photographic records), such consistency in retrospective life histories is not of any such value.

The only circumstance under which life histories from members of broken cultures, unsupported by any observational data, can be of value is when there are several histories, with systematic differences among them and sufficient data about the personalities of the narrators so that some day these personalities may be placed in a theoretical frame of reference and we may be able to say, "The formal culture, as seen through the eyes of three individuals of type x, two of type y, three of type z, etc., appears to be of type x, and the differences in the versions given by the various narrators confirm this hypothesis." It is probable that by the time that we know enough to make any such systematic statement we shall not need to reconstruct the childhood experience of members of cultures for which only this very limited kind of data is available. Because there is a possibility that we might need it, however, investigators are urged to get as many data as possible on the present personality of their informants (including moving pictures showing posture and gesture, or at least long continuous portrait sequences; literal records of responses to situations which can be standardized for all informants; disease pictures, if any; performance on projective methods such as the Rorschach).

In the meantime, retrospective life histories are useful mainly in the study of the parents of children who are also being studied, and they may throw valuable light upon the way in which the child's behavior is being interpreted and reacted to by the parent. They are especially valuable if the informants combine memories of their own past with a running comment upon their children's present behavior and if such records can then be put beside observational records of the children's behavior. Children's own accounts of their pasts are even more valuable.

However, such records as these become, in effect, what I propose to call *simultaneous* life histories, in which the emphasis is on the individual's comment, whether it includes retrospective material or not, upon current events, the substance of which is known to the investigator. If such records stretch over several months and are carefully correlated with events in the real life situation, very valuable data can be obtained on the behavior of parents and also on informants' own behavior when the material is gathered from adults' memories combined with their present behavior and comments on that behavior by adolescents and young children. This method was ex-

tensively pursued among the Iatmul. Such simultaneous life histories can be continually checked against the events which have stimulated the memories,[1] and the memories themselves can be compared with other individuals' memories of the same event and with the way in which similar situations are being handled in the lives of contemporary children. So an adult's comment on his own adoption, made at a time when he is giving back, in a fit of petulance, a name owned by his adoptive father, may be placed against the actual circumstances under which a child of 3 is at the moment being adopted.

Longitudinal Studies. It is generally recognized that all the above methods—cross-sectional studies and various types of life history techniques—are imperfect compromises and substitutes for the on-going life history in which the course of individual lives would be recorded, within the full social setting, from infancy to maturity. The Beagleholes are committed to the absolute necessity of such a measure and, on the basis of a 7½-month study of Pukapuka children (E. and P. Beaglehole, 1941*a*), assert that, no matter how great the mass of data accumulated in a short-time study, these data cannot be interpreted without a study of selected children over a longer period. I have just completed a study in which I followed a series of Balinese mountain children over a period of a year, with some interruptions over a second 9 months, and during a check-up visit a year later, so that there are records of their behavior over a period of 33 months. Placing the data of this study against intensive cross-sectional studies made in four other cultures, I do not find that the advantages of a longitudinal study are anything like those which the Beagleholes predicted. There is obviously a richer body of material collected over 33 months than over periods of 7 to 9 months (the periods of the other studies), and for purposes of exposition it is useful to be able to show a film of a 33-month spread in the same child's life. An analysis (Mead and Macgregor, 1951) of a longitudinal series of 4000 still photographs of eight Balinese children in terms of the Gesell-Ilg concepts has demonstrated that longitudinal studies, by defining each observed type of behavior in reference to a given individual, increase the certainty with which hypotheses can be constructed. If the proper checks are used in the cross-sectional method, as outlined above, and the field worker has a theoretical framework within which individual behavior can be translated into an understanding of the dynamics of socialization, the increased insight to be derived from work in two cultures, rather than from the time spent on a longitudinal study of one, is usually more rewarding. To obtain material from a longitudinal study which will justify the time spent, observations of great precision, of which the most important is either a knowledge of chronological age or detailed physical records of dentition, pubescence, etc., are needed.

Kluckhohn (1939; and Leighton and Kluckhohn, 1947), working on the same assumption as the Beagleholes, has followed the same group of Navaho children over a period of 13 years with consistent observations at intervals of 6 months (except during the war period). For the success of such a plan, consistency and objectivity of records, holding the rôle of the observer constant, and not too great cultural change are all desirable and difficult to attain.

1 This method was used by Gorer (1938, p. 403) in checking on Kurma's belief, not shared by the rest of the group, that his brother had been murdered. The excerpt from Bateson's notes on Kowi's account of his father's suicide (see p. 759) is taken from a check series of eighteen accounts of a suicide in Iatmul, in which the fourteen lengthy and detailed versions fail to agree upon any point except the fact that the man killed his wife and hanged himself, after the rope broke once.

Projective Methods. Projective methods are a suitable form of test for use in the study of primitive children, and the results are excellent expository devices. The general discussions of projective methods (Homburger, 1937; Lerner, 1937*a*; Frank, 1939*b*) have to be supplemented by a few further remarks when the methods are to be used not primarily to study children as individuals but to throw light upon cultural processes (Abel, 1948). The projective techniques should be as free from culturally limiting elements as possible. For example, Stewart's metal maze tests (K. R. Stewart, MS *d*) are less culturally limited than is the Porteus maze test; and the Goodenough "draw-a-man" test, administered flexibly, is more useful than forcing children to draw a white man so as to make it possible to score it. Methods which do not require isolation of the subject are preferable to those that do, for any method, such as Levy's sibling rivalry test, which requires privacy will be definitely ruled out for some cultures. Surprise and bizarre elements are undesirable because the news of the tests will be spread too rapidly through the group, and standards of behavior will be imaginatively elaborated outside the test situation. Tests which require complicated but recordable responses will be valuable in proportion to the amount of response they elicit; tests to which motor responses are important should be avoided unless they can be given in front of a camera, as our vocabulary for describing motor responses is not capable of any sort of cross-cultural accuracy.

At the same time, the simpler the situation to which the children are asked to respond, the more probability there is that the responses will reveal a high proportion of cultural patterning. For example, in the use of toys a small series permits a great number of repeats as every child is likely to use all three or four of the toys presented; a large assortment permits each child to make an idiosyncratic choice, and the underlying pattern is less apparent. As the number of cases will always be few, any test which encourages range is more difficult to deal with. It is also desirable to eliminate tests in which the prompting given by the experimenter is stereotyped.[1] Some projective methods, like the Rorschach, depend for their interpretation upon the compiling of cultural norms for age and sex groups.[2]

The use of projective tests in which a verbal response is expected as in the Rorschach (Abel, 1948) and the Thematic Apperception Test (W. E. Henry, 1947) is less rewarding than the use of tests such as drawing tests, Margaret Lowenfeld's World Test, or her Mosaic Test, in which the actual construction of the child can be kept or reproduced. All tests involving verbal responses introduce misunderstanding by the translation of multidimensional nonverbal thinking into words, by the translation of the words into another language, and, when culturally limited concepts have been incorporated into the method of scoring or interpretation, through the further complication of inapplicable clinical concepts.

Caution must also be observed in interpreting as validation of clinical concepts developed within our own culture what simply amounts to the fact that when field

1 In giving the Weigl test to Balinese boys, Belo followed the prescribed procedure and stopped the test when they had sorted for form and content, these being the two usual responses for individuals in our society. A later analysis of test results showed that many Balinese used other categories, such as position, and place in a color pattern, as categories of equal importance with form and color, so that, in stopping the test when form and color had been sorted for, a culturally limited "right answer" had been forced upon the subjects.

2 Doctor Dubois tells me that the analysis of her series of thirty Rorschachs, all on adults, shows this number to be insufficient, and that the collection of Rorschachs on children, when the adult standards are not known, would not in the opinion of her consultants be rewarding.

workers from our culture, making judgments on the "hostility" or "aggressiveness" of a primitive people, agree with a blind analysis made by a Rorschach specialist they are merely demonstrating the fact that Rorschach indicators and other behavioral indicators, when observed in another cultural system, by research workers with the same cultural frame of reference, will be interpreted the same way.

Useful projective methods may be classified by the type of response permitted by the experimental situation, varying from the presentation of a simple situation in which responses are recorded (for example, Japanese paper flowers which open in water, Mead, 1932) through stylized situations, of which the Levy sibling rivalry test is the best example (Levy, 1939; J. Henry, 1940*a*), to free play with a series of toys.[1]

Children's drawings are perhaps one of the most generally usable projective materials (Figure 9). They are the simplest to collect. It is necessary to keep a record of the composition of each drawing group, the date, the sequence of sheets if a child does more than one, and interpretations, either spontaneously given or systematically elicited. However, the bulk of the data is provided by the children's work, which can be analyzed at leisure out of the field. The material, if white paper and a black pencil or crayon are used, is easily reproduced and very comparable from culture to culture. To make any use of such material, further than to say that each set of drawings betrays a definite style [which shows up sharply in K. R. Stewart's (MS *a*) enormous collection of Goodenough drawing tests from different tribes], it is necessary to have a proper record of the adult art style and particular knowledge of the children's own art styles as portrayed in sand drawings, mud sculpture, scratching on walls, etc. With such a collection of drawing types, more positive problems can be attacked than the old biogenetic theory permitted. (Relationship of children's drawings to this theory is summarized in Hallowell, 1939. Compare also Anastasi and Foley, 1936; Schubert, 1930; and Dubois, 1944, Appendix.)

Examples of such problems are the extent to which personalization is characteristic of the children's thought (Mead, 1932), the formation of style (Mead, E; Belo, 1937), emotional attitudes (K. R. Stewart, E, drawings of dreams; Mead, E, "draw a man and woman"), and the identification of basic patterns of symbolism. The contrast between drawings by Balinese and Iatmul children is extremely interesting in this connection. The Balinese way of life is exceedingly formal, stereotyped, and static; interpersonal relations are conducted with a minimum of emotional expression, the minutiae of etiquette govern every act; Balinese children's drawings are full of activity, with free-flowing lines and the depiction of vigorous movement. The Iatmul way of life is in the strongest contrast to the Balinese. Interpersonal relations of great vigor and assertiveness are the rule, quarrels and reconciliations a continual feature of village life. The Iatmul children's drawings, however, are static and scattered aimlessly over the page; there is no movement and no relationship between one design element and another; when told to draw two men fighting they would draw a figure of a man and say, "He is dead." When it is realized that Balinese children are persistently discouraged when they attempt to bring human relations to a climax, whereas Iatmul children are taught to exert maxi-

[1] In visual terms, these types of specificity are represented by picture interpretation (Mead, 1928*a*), by the setting of a problem [Draw something you are afraid of (K. R. Stewart, E); draw a man killing a man (Mead, E)], or by cutting the drawing paper to specified shapes (Mead, 1940*b*), or by permitting the children to draw whatever they like.

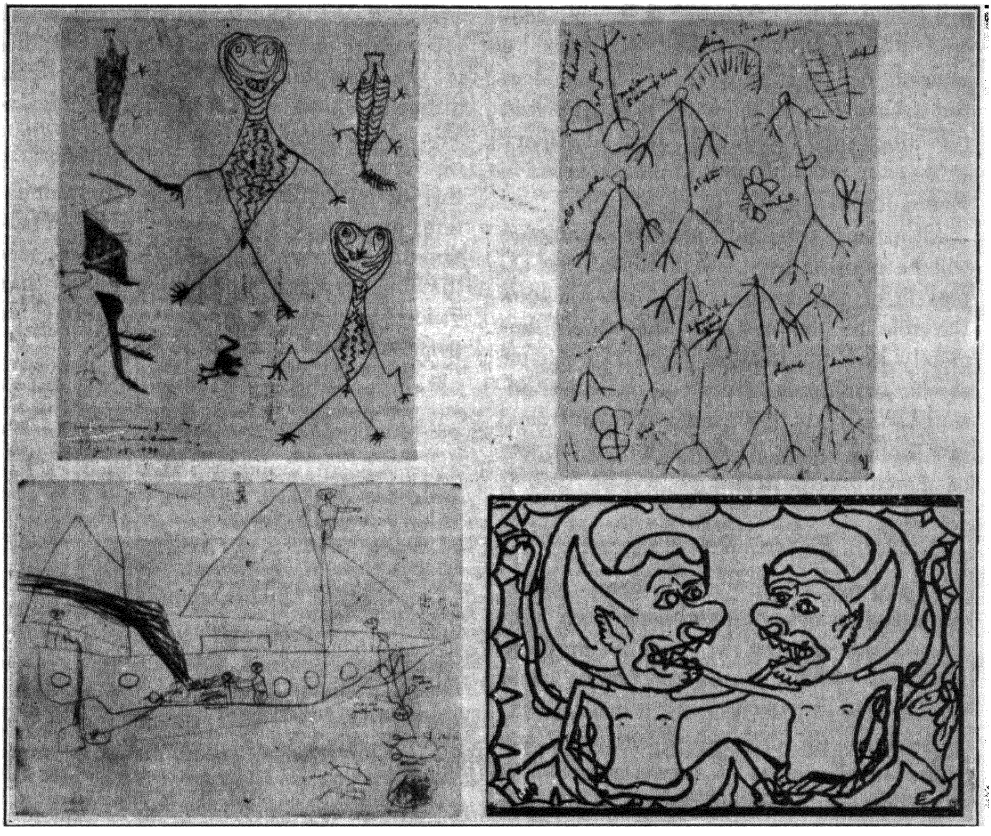

FIGURE 9. Children's drawings showing stylistic differences. Reading from left to right and from top to bottom:

Iatmul tribe, Sepik-Aitape District, New Guinea. Man, woman, and animal figures. Gambukundiavwan, boy, ca. 12 years. (July 28, 1938. Collected by M. Mead.)

Arapesh tribe, Sepik-Aitape District, New Guinea. Human beings, lizards, trees, houses, moon and stars. Nigimarib, boy, ca. 7 years. (April 4, 1932. Collected by M. Mead.)

Manus, Admiralty Islands, New Guinea. Fishing for turtle from a European schooner. Loponiu. (February 24, 1929. Collected by M. Mead.)

Sajan village, Bali. Two figures from shadow play. I Gandir, boy, ca. 6 years. (1934. Collected by J. Belo.) (Belo, 1937.)

mum personal pressure in order to induce others to satisfy their demands, the importance of these materials becomes evident.[1]

1 Iatmul children's use of toys in free play is congruent. They construct tableaux and state, for example, that "The snake has killed the child [a female]. The 'possum [who represents the male child] has killed the snake, and the 'possum now mourns [a female activity] over the dead child."

Extensive use of play technique among primitive peoples was first made by Róheim among the Central Australians and on Normanby Island; he found the Australian children dominantly interested in genital play, the Normanby Islanders in mother-child play in which the same characters become alternately mother and child and hus-

band and wife. Róheim, however, controlled the plot of his play situations by interjecting such remarks as "What does the husband do to the wife?" I have used toys among the Iatmul, and J. and Z. Henry (1944) have published a most extensive record for the Pilagá.

All attempts to use projective techniques will be fruitful to the extent that the attention of the invesigator is focused upon the rôle of the culture. He should not merely look for isolated types of behavior similar or different from our own in situations which are experimentally controlled but should try to see the behavior as part of the culture pattern.

Future Research

The general trends in research among primitive children have already been indicated above as being (1) increased emphasis upon the study of the developing child within the culture seen as a whole; (2) possibilities for detailed psychological exploration of aspects of development which a preliminary study of the total situation has shown to be relevant; and (3) accumulation of masses of simultaneous records, verbatim accounts of behavior, photographic records, multiple-observer records, performance on tests of the projective type, etc., which will be amenable to subsequent analysis as our hypotheses become more refined. If problems are to be taken into the field, they should be problems of the constellative type rather than problems which seek to isolate the effects of one factor. The large amount of existing unpublished material on primitive children, some of which is summarized in the table below, provides another source for research. Psychologists may phrase their problems in such a way that field workers may be able to provide relevant material from their existing notes.[1] Nothing, however, is so pressing as more intensive detailed studies of the development of children in living primitive societies. These data are invaluable in extending our knowledge of the possible range of human behavior. Only with this sort of material can we lay the foundations of a psychology free from the limitations of our own cultural bias; and, once the few surviving primitive societies have yielded to culture contact, we shall have no possible way of replacing them.

Work for this revised chapter was begun January, 1949, and completed in early June, 1949. No subsequent additions to the text have been made, so that it describes the state of theory and research at that time. The few bibliographical items bearing a more recent date than June, 1949, are simply those that were in manuscript or in press at the time this chapter was revised and have since been published.

Bibliography

Prefatory Note

Publications in anthropology differ from publications in psychology, where short, formal summaries of masses of concrete observations are the acceptable form for presenting detailed investigations to the student. In anthropological research, a full account of the background against which the individual is studied cannot be omitted in a final statement of the material, and publication is delayed until facilities for complete monograph publication are available. As a result, a large part of the work, sometimes done as much as ten years earlier, may still be unpublished. I have therefore adopted a procedure rather different from that used in other chapters and attempted to gather, by inquiries and questionnaires, material on unpublished work.

Manuscripts to which I have had access are listed in the regular bibliography. Field work on children upon which there are no publications has been listed as Expeditions (E) under the name of the field worker. As an appendix to the bibliography, I have presented a summary table of the information which has been supplied to me in response to these requests. Where the information which I have received is merely that a given worker has used such and such a method in such and such a tribe, but no manuscript or supporting evidence has been forwarded to me, I can only publish this statement without taking any responsibility for the extent and

1 See Introduction to *Cooperation and Competition among Primitive Peoples* (Mead, 1937) for discussion of this point.

fullness of the results. By including this list of unpublished materials and completed but unorganized field work, I hope to encourage the use of these materials by workers interested in collecting as much comparative material as possible.

TABLE SUMMARIZING THE RESEARCH METHODS AND MATERIALS REPORTED BY 85 INVESTIGATORS [1]
(The investigators are listed in the bibliography with addresses in case they have not published.)

	Legend (used in questionnaires: 1940, 1949)
General	1. Observations of children in ordinary life situations. 2. Detailed material on the standardized treatment of and training of children. 3. Time samples of child behavior. 4. Studies of group behavior. 5. Tests of any sort. 6. Experimental methods of any sort. 7. Childhood material obtained from adults by life history method. 8. Life history materials obtained from children or adolescents
Projective Methods	9. Children's drawings, modeling, or carving. 10. Rorschach records. 11. Tests of the Levy Sibling Rivalry Type. 12. Tests involving cognitive processes of the Nadel (1937) type. 13. Intelligence tests used as projective methods, for example, Porteus Maze or Goodenough 14. Use of free play techniques.
Miscellaneous	15. Collection of children's games and songs. 16. Intelligence tests. 17. Tests of sense perception. 18. Collections of children's dreams.
Photographed	19. Typical treatment of children, for example, suckling position. 20. Standard activities of children's games, etc. 21. Studies of parent-child behavior. 22. Studies of individual children. 23. Studies of series of children in any standard set-up. 24. Body-build pictures.
Language Development	25. Baby talk or special children's language. 26. Records of the way in which children learn a language. 27. Material on the formation of concepts by children.

Aginsky, B. 1, 2, 4, 7, 8.
Barnes, F. 1, 7, 8, 10, 19 (stills), 20 (stills).

Coelho, R. 1, 2, 7, 9, 10.
Colson, E. 1, 2, 7-9.
Copeland, P. 1, 4, 5 (Sociometric tests), 9, 20, 23.
Dazey, E. 2, 7.
Dennis, W. 1-5 (Dennis and Russel Animism Tests), 9, 15, 25, 27.
Devereux, G. 1, 2, 5 (Finger-painting), 7, 8, 9, 15, 18, 19, 25, 27 (Mohave children's ideas of death).
Dubois, C. 1, 2, 4, 5, 7, 9, 11 (modified Levy Sibling Rivalry Test), 13 (Goodenough "Draw-a-Man" Test), 14.
Dyk, W. 1, 7.
Eichhorn, E. 1, 7, 9, 10.
Flannery, R. 1, 2, 7, 15.
Foley, J. P., and A. Anastasi. 9.
Fortes, M. 1-5, 7, 8, 9, 13-16, 19-24, 26, 27. (Perceptual tests based on Spearman: Lowenfeld Mosaic Test. Sex life and moral development, economic activities of children.)
Friedl, E. 1, 7, 8, 10.

[1] This table was compiled in the spring of 1940, on the basis of a questionnaire sent to all workers in the field, and revised in 1948, when similar questionnaires were sent to the original respondents and to all workers whose names I could obtain by inquiry in those institutions and in those departments most interested in this kind of research. The list of unpublished work is neither exhaustive nor can it be selective, but in an area of research where the need for speed in the development of concepts and methods is paralleled by the speed with which the culture of communities valuable for study is being destroyed this, nevertheless, seems worth doing.

Gladwin, T. 1, 2, 5 (TAT, Kohs Block for adolescents), 7, 8, 10, 13, 15, 16, 18.
Gorer, G. 1, 2, 7, 8.
Hallowell, A. I. 1, 5 (TAT), 9, 10.
Hambly, W. D. 4, 8, 9, 15, 21.
Hanks, L. M. and J. R. 1, 7.
Harper, B. W. 1, 2, 4, 7, 15. (Material on sex play.)
Harris, J. S. 1, 2, 15, 27. (Concepts of property.)
Hassrick, R. B. 1, 2, 5 (Grace Arthur Point Performance Scale), 10, 13 (Porteus Maze Test, Goodenough "Draw-a-Man" Test), 16.
Havighurst, R. J. 2, 5, 7, 8, 9, 10, 16.
Hawley, F. 1-4, 7, 8.
Henry, J. and Z. 1, 2, 4, 5 (toys used to test logical approach to a problem), 6 (Piaget type of question), 9, 10, 11 (modified Levy Sibling Rivalry Test), 14, 15, 19-23 (stills), 25, 27.
Hilger, I. 1, 4, 7, 8, 9, 15, 19-22, 26.
Hogbin, H. I. 1.
Honigmann, I., and J. J. 1, 2, 4, 7, 10, 18, 19, 20, 22, 24 (deposited with Dr. F. F. Tisdall, Toronto; negatives at Dept. National Health and Welfare, Ottawa).
Joseph, A. 4, 5 [Grace Arthur Point Performance Scale, Goodenough "Draw-a-Man" Test, Stewart Emotional Response Test, Bavelas Test of Moral Ideology, the Story of the Stolen Melon and the Axe, Free Drawings, TAT (revised), Bender Gestalt], 7, 9, 10, 16 (Grace Arthur Point Performance Scale, Porteus Maze Test, Goodenough "Draw-a-Man" Test), 17 (Bender Gestalt).
Kaplan, B. 10.
Klineberg, O. 5 (speed and accuracy), 6 (photographs of emotions expressed by adults, submitted to Chinese children), 16.
Kluckhohn, C. 1-11 (Levy toys), 13-16, 18, 19-22 and 24 (stills and Ciné), 25, 26 (reaction of child to cradle; development of attitudes of modesty and of attitudes and practices with relation to excreta), 27.
Kuper, H. 1, 2, 4, 5 (Porteus Maze Test, Goodenough "Draw-a-Man" Test), 7, 9, 13, 15, 18, 19-22, 25, 26.
Labuschagne, A. S. 5 (intelligence tests), 16 (perceptual tests after the analogy of Raven Progressive Matrices).
Landes, R. 1, 2, 4, 7, 8, 9, 13, 15, 16, 18, 20-22.
Layard, J. 15. (Attitudes of adults towards children, particularly in regard to the concept of the soul; attitudes of novices and initiators in initiation ceremonies.)
Lee, D. 27.
Leighton, D. 1, 2, 7, 8, 9, 10, 16 (modification of Grace Arthur Point Performance Test).
Lessa, W. A. 1, 5 (TAT), 7.
Lipkind, W. 1, 7, 9, 19, 20, 24. (Stills.)
Macgregor, G. 1, 4, 5 (Grace Arthur Point Performance Scale, Goodenough "Draw-a-Man" Test, Kuhlmann-Anderson Intelligence Tests, Stewart Emotional Response Test, Bavelas Test of Moral Ideology, TAT), 7, 9, 10, 13, stills: 19, 20, 22.
Mandelbaum, D. 1, 2, 7 (material on sex play, drawing test), 14, 15, 19, 20 (stills), 25, 26, 27.
Marwick, M. G. 1, 2, 4, 5 (local version of TAT—using posed photographs, Raven's "Controlled Projection," Dramatic Productions Test—Murray and collaborators), 7, 8, 9, 10, 16 (Labushagne's modification of Raven Progressive Matrices), 18, 20 (Ciné and stills), 22 (stills).
McPhee, C. 4 (studies of group behavior in experimental musical organization).
Mead, M. 1-4, 5 (animism tests, ink blots, Bender Gestalt Tests), 7-10, 11 (toys), 12, 13 (Goodenough "Draw-a-Man" Test).
Mekeel, S. 1, 2.
Murray, V. F. 4, 10, 16, 17 (Bender Gestalt).
Oliver, D. and E. 1-4, 5 (animism tests used by M. Mead), 7, 8, 9, 15, 19-22 (stills), 25, 26, 27 (concepts of kinship, totemism, status, supernaturalism).
Opler, M. E. 1, 2, 4, 7, 8, 15, 19-22 (stills), 27.
Paul, B. D. and L. 1, 2, 7, 8, 14, 10-22 (stills).
Pearsall, M. 2, 7, 15, 25-27.
Rauch, J., and B. Tolerton. 1, 2, 4, 7, 8, 10, 18, 19-23 (stills and Ciné), 26.
Read, M. H. 1, 2, 4, 7, 8, 9, 15, 19, 20 (stills). (Special studies in relation to nutrition.)
Róheim, G. 1, 7, 8, 14, 15, 18, stills and Ciné: 19, 20, 22. (Day dreams.)

Chapter 13

CHARACTER DEVELOPMENT IN CHILDREN—AN OBJECTIVE APPROACH

Vernon Jones

Definition and Distinctions

Any attempt at the objective study of character development is beset with many difficulties, such as the varying concepts as to what is meant by character, the extreme complexity of the phenomenon, and the subtle manner in which nature and nurture exert their influences upon it. Recognizing this, let us attempt at the outset to eliminate as many unnecessary difficulties as we can by delimiting and defining the area of study. The concept of character is related to, and sometimes confused with, such concepts as moral or ethical behavior, temperament, and personality. Impossible as it may be to draw hard and fast boundary lines between these conceptual areas, working distinctions can be made which may help to avoid confusion.

In any strict interpretation of character it is clear that it is not coextensive with ethical or moral behavior. Morality concerns itself with conformity to existing standards of a given time or place. Character does not necessarily imply such conformity. Often in history the individuals who have been rated greatest in point of character have been nonconformists from the point of view of certain existing standards of their day. Moreover, conformity to existing standards sometimes demonstrates not so much character as behavior along lines of least resistance. This does not mean, of course, that character is not related to morality. It means that character is a more dynamic and more inclusive concept. In character development much more attention is given to volitional factors and to individual creativeness in the realm of goals to be achieved than is true in moral or ethical growth. If we add to morality the ability to reconstruct one's values and the volitional powers sufficient to direct conduct progressively toward such evolving values, then we have character as we shall think of it in this chapter.

The area of temperament is perhaps less often confused with character than morality is but illustrations of such confusion are not hard to find. Whether a person is good-tempered, sanguine, phlegmatic, melancholic, or choleric is certainly of interest to anyone rating him for practical purposes of living or working with him, and no claim can be made that such characteristics have no relation to character. Strictly speaking, however, the readiness and capacity of an individual for such relatively prevailing affective experiences are not central to the problem of his character. As Roback (1952) says, the influence of a man's character has a farther reach than his temperament. The value of a man's character, he says, does not fluctuate with our nearness to him in time or space, but his temperament is a matter of only "passing interest." "That Carlyle

was bilious, choleric, or grouchy," he says, "is certainly deplorable, but Carlyle's temperament, which counted so much with those he came in contact with, does not determine our estimate of the man from the point of view of character." Whether or not we agree fully with Roback that temperament is of only passing interest, we can readily agree that character is different from temperament in that character concerns itself more with the volitional powers of the individual and the directions and goals of his striving.

Finally we come to the confusion of character with personality. Personality, of course, is a very broad concept, being thought of by Murray and Kluckhohn (1948) as "the organization of all the integrative processes in the brain" of the individual, and as having for its functions self-expression, reduction of aspiration tensions, and the reduction of conflicts by appeasement of major needs and by social conformity and identification. If we may judge by such a formulation and by traditional research emphases in personality, too little interest is manifested in the problems of moral behavior coupled with the allied problems of values and of volition. The student of personality is interested in the adjustments or maladjustments which individuals make to tensions and conflicts, and the goal of his therapy is adjustment. The student of character is not so much interested in the mechanisms of adjustment or maladjustment adopted or in the types of personality developed by the individual who feels frustrated, or deludes himself, or becomes introverted, or develops various stereotypes; he is much more interested in what values underlie the individual's feelings of tension or frustration and stimulate him to attempt to maintain his status and self-esteem by such mechanisms as the students of personality are uncovering.

The main objective of personality development is adjustment to the existing environment; the objective of character development is the growth of the individual toward higher personal and social values and toward conduct consistent with them. Aspiration, striving, and all the volitional factors related thereto are considered to be aspects of character which are never outgrown. Instead of adjustment being an end in the character development of an individual, the kind of adjustment which he makes (whether, for example, by honesty and cooperation, or by deceit and intolerance) is a measure of his character.[1]

In making a distinction between character and personality, we do not wish to give the impression that the two areas can be completely separated. There is, of course, overlapping and interdependence between the two concepts, and the recognition of this is beginning to manifest itself in a rapid rise in attention to the interrelationships between personal values and ethical behavior in individual and social situations, on the one hand, and feelings of acceptance, security, and personal worth—and their opposites—on the other. However, one has only to look at the major research and theoretical interests in personality in the past to see that until recently[2] relatively little interest

1 For an elaboration of some aspects of this point, see Josey and Snygg (1950).

2 Interest in these problems, and particularly in the problem of values, has been growing rapidly, as can be illustrated by the writings of certain eminent scholars in neurology, sociology, and psychology, to take only three fields. Space will permit reference to only one representative in each field. Herrick (1946) says that the popular slogan "Science knows no values" is shortsighted and incorrect, for "If science had no interest in human values, there would be no science at all," because science has developed on man's valuing of the search for the truth and demonstrable fact over falsehood and magic. The social sciences must point the way, he believes, to better methods of solving problems of human adjustment in the light of the highest human values. Sorokin (1950) has brought together papers from spe-

has been manifested in the problems of individual and social conduct in relation to values, volition, and the integrity and growth of the self-ideal. These are the very problems in which the student of character is most interested.

If, therefore, character is not coextensive with morality, or temperament, or personality, or the sum total of these, how shall we think of it? Character is the sum total of the attitudes and overt ways of behaving of the individual which are the correlatives of his regulative habits, developing values, and volitional drives. It is a dynamic concept involving inner creativeness and psychocultural determination.[1]

In this chapter on character development, as character is here defined, it will be the aim to include the maximum of experimental data consistent with the attempts to point out integrative threads and with the search for meanings and generalizations. If one is interested in theory construction or in interpreting facts in terms of some theory tentatively accepted, there is ample opportunity for such in the interpretation of the responses of children in situations involving persistence, feelings of guilt, values, and the like. There are, for example, the very difficult but important problems of the source of values and the genesis of volition. With these particular problems little scientific progress has been made. However, it is easy to point to many areas in character development which have been attacked by experimental methods. A variety of devices have been used to study the behavior of children in situations involving cooperation, generosity, honesty, persistence, self-control, truthfulness, levels of aspiration, and the like. Various psychocultural studies have been made which have factual implications for character development. There has also been a large amount of statistical and experimental work done in comparing the responses of delinquent and nondelinquent children. The contributions of various nurtural-cultural and native-biological factors to character development have been studied. It will be the aim of this chapter to bring together the most significant facts from these and similar studies and to interpret them in as meaningful a whole as possible.

cialists in a number of fields, particularly from psychology, on the problem of the value concept of "altruistic love" in its relation to the integration and direction of behavior. Cantril (1950) maintains that man's outstanding characteristics are his capacity to sense values in the quality of experience and his tendency to improve the value aspects of experience. He believes that the value approach in psychology will greatly enhance understanding of individual and social conduct. These writers obviously are not thinking of values as narrowly defined within the framework of existing personality theory. To them values, and their conduct correlates in character, are pervasive and central in human life. They are concerned, therefore, with the study of values and character as basic problems in themselves.

[1] For a more detailed treatment of these distinctions and definitions, see Jones (1950).

Measurement of Character

In an objective approach to character development one of the first problems which arises is that of measurement, for the results of research in a field are no more objective and dependable than the measurements upon which they are based. Are there techniques of measurement, therefore, which are sufficiently valid and reliable in the field of character to supply a factual basis for present evaluation and future study and research? The answer seems to be one calling for cautious optimism. There are several very promising methods which when used with great care have yielded what seem to be dependable results, and newer, more subtle, and more ingenious methods are constantly being devised.

The techniques which have been the most successful in the past and seem most prom-

ising for the future can be grouped under eight headings: (1) observation and rating methods, (2) measurement of actual conduct, (3) physiological methods, (4) interview methods, (5) projective techniques, (6) measurement of attitudes, (7) psychodrama, sociodrama, and other rôle-playing devices, and (8) sociometric techniques.

Observation and Rating Methods. One of the oldest and best methods for measure of character is careful observation and rating. The validity and reliability of observations and ratings will, of course, vary with the traits or other aspects of conduct rated and with the training and care of the raters.

The reader who is interested in an extensive review of the methodology of objective observation and rating is referred to Cronbach (1949) and Greene (1952). Suffice it to say here that the best results in character measurement have usually been obtained when the observer-raters have been thoroughly trained, when the ratings were based on aspects of conduct which could be accurately observed, when special attention was given to the avoidance of "halo effects," when final ratings were based on the observations and ratings of several competent judges, and when graphic rating scales and other devices were employed to encourage raters to distribute their ratings widely over the scale range and thus avoid undue bunching of scores.

Test of Actual Conduct. Among the most interesting measures of character have been the tests of actual performance. In such tests the subject does not know that he is being measured in character. Voelker (1921), a pioneer worker in this field, devised several tests which measured the trustworthiness of children. He measured such behavior as the following: whether or not children would return borrowed property and overchange, the degree to which they would cheat in marking their own test papers, the extent to which they would make overstatements about knowledge possessed and books read, and whether or not they would receive a tip for small favors.

The most extensive work in the devising and using of concealed tests of performance has been done by Hartshorne and May, who worked with large samplings of school children. They employed the best tests available at the time and devised many new ones for the measurement of honesty, self-control, cooperativeness, and allied traits. Extensive statistical data were obtained concerning the validity and reliability of such tests, the intercorrelations among different measures of behavior in these fields, and the relation of various factors, such as intelligence and home background, to such behavior. For detailed discussions of tests of this type, the reader is referred to Hartshorne and May (1928, 1929), Hartshorne, May, and Shuttleworth (1930), Jones (1936), Greene (1952), and Cronbach (1949).

Another trait in which performance tests have been employed is persistence. An extensive review of the methods and results of testing in this field has been made by Ryans (1939*a*). He (1938*a*, 1938*b*) has experimented rather intensively with a test battery including a test of the amount of consecutive effort at a task in learning, endurance in the face of physical discomfort, and the like. French (1948) describes the use of a persistence test in increasing the predictions of school success from a multiple R of .58, based on aptitude and achievement tests, to .65, based on such tests plus the character trait of persistence.

Physiological Methods. In attempts to measure certain character responses, notably truthfulness and deceit, several physiological measures have been tried. Changes in blood pressure, pulse, respiration, and galvanic skin reactions have been the re-

sponses most frequently studied in their relation to deception. Lombroso, as early as 1912, refers to his use of the hydrosphygmograph in proving a suspect guilty of stealing. Since that time there has been a gradual development of instruments designed to detect deception by the measurement of several physiological reactions simultaneously. Probably the most successful instruments of this type to date are those devised by Keeler, by Lee, and by a group at the Ohio State University. Results from the Keeler (1934) "polygraph" (or, more exactly, pneumo-cardio-sphygmogalvanograph) were permitted as evidence in a jury trial in Wisconsin in 1935. This was the first time that such physiological measures were accepted as evidence before a jury in the United States, although a few earlier cases are on record where such results had been presented directly to judges in nonjury trials. Imbau (1946) reports that such devices are proving to be increasingly useful instruments in crime detection laboratories.

The key problem in the use of such physiological measures for research or for practical purposes of detection of deception or guilt is one of validity. One question that is particularly significant concerns the probabilities that an honest or innocent person may, in the face of the excitement involved in taking such tests or under suggestion effects from the tester, react as if dishonest or guilty. The measurement of several physiological reactions simultaneously and the use of only thoroughly trained testers are designed to reduce the probabilities of such errors; but the attitude of the more careful experimenters concerning the validity of present instruments is illustrated by Keeler, who said in the Wisconsin case that he recommended his findings as only one element in the evidence and that he would not convict upon such results alone.[1] Similar caution is suggested by the study of Bitterman and Marcuse (1947), who report certain negative evidence in the use of the Keeler polygraph in an attempt to solve a problem of theft in a college dormitory.

Interview Methods. One of the oldest approaches to the measurement of character is interview methods. Such methods cover a wide range of devices extending from the spontaneous uncontrolled interview to the use of more or less standardized interviews, and more recently to the use of projective techniques like the Thematic Apperception Test and the Rorschach Test, which are sufficiently specialized to demand mention under a separate heading. In character measurement the uncontrolled interview still yields good results in the hands of some clinicians and experimenters. Healy and Bronner (1936, pp. 88 ff.), for example, for a long time have used the "child's own story" among other devices in their study of delinquents. They carefully avoid any claim that these intensive interviews are psychoanalytical in nature, although they use informally some of the same techniques as those used by psychoanalysts for diagnosis.

Havighurst and Taba (1949) use the interview extensively for probing into the impact of the community upon the child's value systems and into his reactions to this impact. Künkel (1938) gives a good demonstration of the possibilities of this method for studying the relation of the character development of a child to the total integration of his mental and emotional life. From such studies we get challenging suggestions as to the possibilities of the use of the intensive interview in evaluating character responses at a depth where such responses

[1] See Imbau (1935*a*, 1935*b*, 1946). For a good historical treatment of the use of physiological methods for detection of deception and guilt, the reader is referred to Marston (1946).

are viewed not in isolation but in relation to genetic factors and to fundamental patterns of motivation.

Projective Techniques. In the field of personality measurement the projective techniques are attracting a considerable amount of attention, and their use in character measurement is definitely on the increase. There is need in character measurement for techniques which will reveal the dynamics of conduct. In the hands of thoroughly trained and experienced clinical psychologists some of these tests, notably the Thematic Apperception Test by Murray (1943), the Rorschach Test (see Beck, 1945; and Klopfer and Kelley, 1942), the World Test by Bühler and Kelly (1941), and the Rosenzweig (1949) Picture-Frustration Study, may yield valuable insight into basic motivation and frustration of a child or youth as they relate to the present organization and future development of his character.

Measurement of Attitudes. In attempts to measure certain aspects of character, numerous tests of attitudes and opinions have been employed, involving such devices as ranking offenses, marking suggested responses in situations as right or wrong, giving cause-and-effect relations, predicting probable consequences of acts, and the passing of judgment upon nationality or racial groups and upon economic, political, and religious issues. The obvious weakness of such tests is that measures of knowledge and verbally expressed attitudes do not accurately reveal to what extent such knowledge and attitudes will be translated into action. Of course, it might be maintained that such tests are of value because knowledge of, and proper attitude toward, desirable conduct is a prerequisite for such conduct, even though they are not guarantors of it. There is much cogency in this argument, especially as it applies to the use of such tests for revealing points at which education in knowledge and attitudes might be profitably applied. It is quite possible that research in the future may reveal ways of measuring attitudes and aspirations at depths which are nearer the mainsprings of action than present methods which lean so heavily on the verbalized and censored reports of subjects.

Psychodrama, Sociodrama, and Other Rôle-Playing Devices. Among the techniques that purport to measure the individual in relation to others in semicontrolled social situations the psychodrama and sociodrama are proving to be especially interesting and valuable. The psychodrama seeks to measure interpersonal relations and individual attitudes and motivations, whereas the sociodrama deals with intergroup relations and individual-group ideologies. Moreno (1947), to take one example, reports the use of psychodrama in the study and remedy of certain social tensions in a community. By means of this device, not only did the experimenter gain helpful information but also the parents and children who served as subjects gained insight into their own underlying feelings.

As an example of the use of the sociodramatic method, mention might be made of the study and demonstration by Lippitt, Bradford, and Benne (1947), who used the sociodrama as a means of identifying leadership qualities of individuals in a group and as a starting point for leadership training.

The potentialities of both the psychodrama and the sociodrama would appear to be particularly great in the psychocultural investigation which seems destined to play so large a rôle in character research in the near future. Moreno (1943) was one of the first to envisage this possibility in his contributions to measurement methods.

Sociometric Techniques. Sociometric techniques are designed primarily for obtaining peers' evaluations of each other. One of the more interesting of these techniques is the sociogram, developed by Moreno (1934, 1947), which is serviceable for revealing cliques, hierarchies of popularity, leaders, isolates, and the like in social groups. In an assessment program during World War II, the Office of Strategic Services (1948) used sociometric methods extensively to measure personality and character traits of potential officers. The Guess Who Test developed by Hartshorne and May (1929) in the Character Education Inquiry was one of the earliest and simplest of the sociometric methods. Like the sociodrama and the psychodrama these techniques will probably be of increasing interest to the student of character because of their promise as dependable measures of the individual, not in isolation, but in a dynamic social setting—the place where character actually functions.

Violations of Society's Standards. Finally, mention should be made of serious violations of social standards as measures of character. In such social institutions as the law enforcement agencies, the school, the home, and the church, certain minimum standards are set up, and any individual who falls below them is looked upon as a social offender by those interested in maintaining these standards. The standards set up by civil law particularly are quite generally accepted, and consequently any serious violation of these is usually considered indisputable evidence of inferior character development. All studies of juvenile delinquents have proceeded on the assumption that these young people have been measured and found deficient by one of society's most widely accepted tests. We mention this crude yardstick particularly because its verdict is taken so seriously and uncritically by society, when as a matter of fact it is but a rough measure of character and is in need of all the supplementary measures which research with more exact and penetrating methods can reveal.

Individual Differences in Character

One of the first facts which is noted in the inspection of the character responses of children is that the individuals do not fall into dichotomous groups: the strong and the weak, or the persistent and the nonpersistent, or the honest and the dishonest. There are individual differences in character just as truly as there are individual differences in general intelligence or in the knowledge of history. In tests of persistence, for example, Ryans (1938b) and Edmiston and Jackson (1949) find that persistence scores made by a group of subjects spread from very low to very high with no gaps in the distribution. Harris, Gough, and Martin (1950) find prejudice scores among children to vary widely. Similarly in tests of honesty, where dishonesty responses are easily accessible and where motivation for such responses is strong, children have been found to distribute themselves all along the scale. Figures 1 and 2 illustrate this point.

Figure 1 is based on the results of Hartshorne, May, and Shuttleworth (1930) on 21 tests of honesty-dishonesty of children in school and play situations. Figure 2 is based on the original data of Jones (1936) on one test of cheating in school. Both figures represent results for children ranging in age, for the most part, from 12 to 15. It is important to emphasize that the results in both these studies are based not on what children's attitudes toward honesty seemed to be, or on what they said they would do in different situations, but on tests of what they actually did under rather

well-controlled conditions. In both figures the distributions are seen to be continuous.

At first glance one might be inclined to say that the individual differences which are spoken of here apply only to the degrees of dishonesty among the dishonest, and that the honest students are still in a class by themselves. This view, although

DISTRIBUTION OF HONESTY SCORES FOR 265 CHILDREN, EACH SCORE BEING MEAN OF 21 TESTS

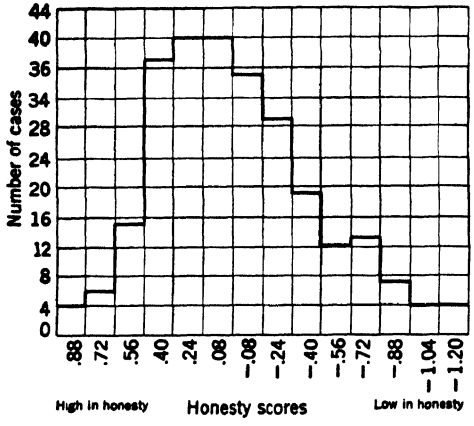

FIGURE 1. Based on data from *Studies in the Organization of Character*, by H. Hartshorne, M. A. May, and F. K. Shuttleworth. New York: Macmillan, 1930, pp. 480, 486.

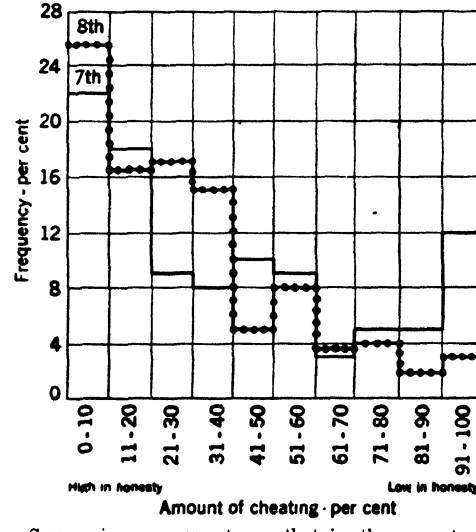
seemingly logical enough in the case of a given set of data, runs into difficulty when it is found that an individual may be completely honest in one situation, or under one degree of motivation, but he may show a considerable number of lapses from perfect honesty in another situation or under a higher degree of motivation. Gross (1946), for example, found much more dishonesty among seventh grade children in scoring their own test papers when their answers were slightly in error than when the errors were large.

To appreciate the fact that honest-dishonest behavior varies with the nature of situations and the motivation involved, at least among children, one has only to think how different so-called character traits get in one another's way. Truthfulness at times conflicts with loyalty to one's group; truthfulness to one's host or benefactor may run counter to courtesy or gratitude; truthfulness to the sick may come into collision with tact and helpfulness. Thus, if a child deviates in a given situation from "the truth, the whole truth, and nothing but the truth," shall we think of him and treat him as belonging in a separate category from the honest? It seems more con-

DISTRIBUTION OF SCORES ON MALLER SELF-MARKING (CHEATING) TEST FOR 191 BOYS AND GIRLS IN SEVENTH AND 133 IN EIGHTH GRADE



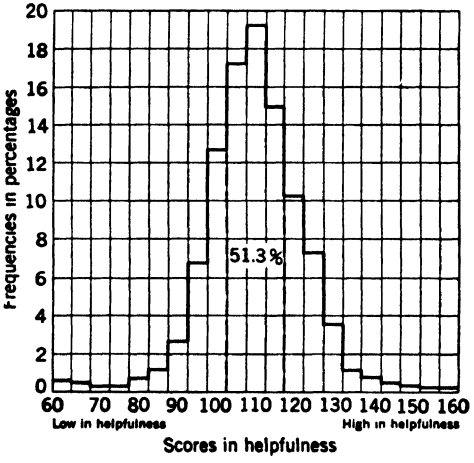
Scores given in percentages, that is, the percentage that the number of cheatings bears to the number of chances to cheat.

FIGURE 2. From original unpublished data of Vernon Jones.

sistent with the experimental facts—and also sounder from the point of view of education and therapy—to say in a case like this that the child's inhibitions against dishonesty and deceit have weakened un-

der the particular motivation or particular conditions of conflict with other "traits," and that in spite of a certain amount of dishonesty some degree of the organization of behavior which we call honesty remains intact. It is in this sense that we may think of a given individual in different situations or different individuals in the same situation as differing in degrees of honesty.

DISTRIBUTION OF TOTAL HELPFULNESS SCORES



Frequencies given in percentages. Number of cases = 800.

FIGURE 3. Adapted from *Studies in Service and Self-Control*, by H. Hartshorne and M. A. May. New York: Macmillan, 1929, 109. By permission of the publisher.

From the point of view of genetic development of honest behavior in a child, there seems to be much merit in this concept of degrees of honesty, because it is consistent with the basic hypothesis of the gradual development and organization of behavior and it assumes neither a sudden springing into perfection of patterns of behavior, or "traits," on the one hand, nor the sudden and complete collapse of such patterns, on the other.

What has been said about individual differences in honesty seems to apply to all other traits that have been measured. Space, however, will permit the giving of only one more distribution. Figure 3 represents a distribution of scores in helpfulness.

From a study of Figures 1, 2, and 3 it is not possible to generalize about the shape of the different distributions further than to say that they are continuous from the low to the high end of the scale and that the dispersion in all cases is wide. Figures 1 and 3 show a tendency toward normality of distribution, but this is not borne out by Figure 2, where the units of measurement are the simplest. In addition to the statistical fact that the shape of distributions may be affected by the units of measurement employed, it is known that it will vary with different degrees of motivation. It is also quite possible that the shape will differ in groups of different ages and different amounts of training.

The Contribution of Native-Biological Factors to Character Development

Having considered briefly the question of individual differences in character development and their measurement, we come now to the problem of the factors contributing to such differences and to general development. Does a child of a given age show up poorly in character because he is deficient in those biological factors which supply the potential base for character development, or because the conditioning and learning which his environment afforded were faulty? This raises the age-old controversy of nature and nurture, and it raises it in a most complex field of behavior.

If one were starting out, at the present stage of knowledge, to discover the percentage contribution of nature and nurture in accounting for individual differences in

character development, he would be doomed to failure. Such a multitude of unmeasurable variables is subsumed under each of these concepts, and they interact in such intricate ways, that the crucial experiment to determine the exact relative influence of each is at present out of the question. However, data are available to indicate that at least intelligence, age or level of maturation, sex, and certain emotional and volitional factors are sufficiently related to development and individual differences in character to justify their discussion, if we can accomplish that difficult task of treating one of these factors at a time without losing sight of the fact that none of them operates singly or in isolation from environmental and cultural forces.

One fundamental thesis of this chapter is that character development of an individual at any given time is an integration based upon certain native and biological factors on the one hand, and upon certain conditionings and learnings stimulated by the environment and the over-all cultural matrix, on the other. It is hoped, therefore, that the following discussion of some of the native factors which influence character development will never become so involved in particulars that it seems to lose sight of this larger framework of interrelationships.

Influence of Intelligence. The relation of intelligence to character development is probably most readily seen in the rôle which intellect plays in selecting the environment and in orienting the individual in it. The dull and the bright intellectually are not alike in their ability to foresee the consequences of their acts; neither are they alike in their capacity to sense when greater advantages inhere in remote goals than in immediate gratifications. The more able the individual, the better can he select his environment and mold it in accordance with the ends he would achieve. The same environment does not produce the same total organization of learned conduct and values in the bright and in the dull. Indeed, differences in intellect make of identical physical environments different psychological environments. Of course, this does not mean that superior intellect can so alter inferior environments as to guarantee strong character under any and all circumstances. Good intelligence, however, other things being equal, should enable one to achieve the skills, knowledge, and values that will help him to make the most of a superior environment, on the one hand, or to resist efficiently the restricting effects of a poor environment, on the other.

With these preliminary remarks concerning the meaning of any relation found between intelligence and character development, let us turn now to a consideraton of some of the objective studies. The statistical facts which are available on the relation between intelligence and character can be summarized under three headings: (1) the comparison between intellectually gifted children and unselected children on certain tests of character; (2) the correlation between general intelligence and scores on certain tests of character; and (3) the intelligence of serious offenders or delinquents.

Terman *et al.* (1925) in their classic study, compared a group of 532 children having IQ's over 130 with an equal number of unselected children by means of a battery of 7 tests of character. They found that 85 per cent of the gifted group equaled or exceeded the mean of the unselected, or control, group. The results for each age group are given graphically in Figure 4. It is seen that the gifted boys and girls exceeded the unselected by a significant amount at each age level. Terman also had teachers rate the children of the gifted and the control groups on 25 traits. If we select out of his list those

traits most closely related to the problem of character development and compare the ratings assigned to the two groups, we find that 73 per cent of the gifted boys and 74 per cent of the gifted girls exceeded the respective means of the control groups. The five traits upon which the above figures are based are conscientiousness, truthfulness, sympathy and tenderness, will and perseverance, and prudence and forethought.

MEAN TOTAL SCORES OF GIFTED AND CONTROL CHILDREN, BY AGE, ON SEVEN CHARACTER TESTS

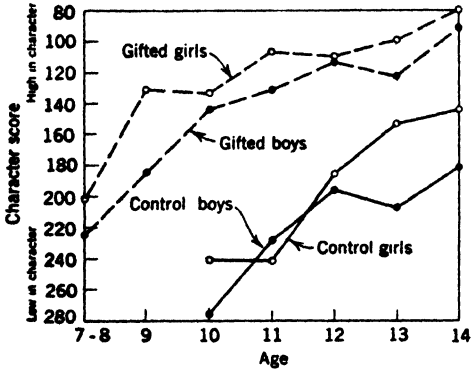


FIGURE 4. Adapted from *Genetic Studies of Genius,* by L. M. Terman, *et al.* Vol. 1. Stanford University, Calif.: Stanford University Press, 1925, 515. By permission of the publisher.

From the results on the tests and the total ratings, Terman concludes that intellectually gifted children surpass unselected children in tests and ratings of honesty, truthfulness, and similar moral traits. As he points out, the gifted are not free from faults in character development; indeed, he says that one out of five of the gifted has more faults than the average of the general population. However, the average difference between the two groups on the basis of total scores is striking. From it we conclude that children who are gifted intellectually, and who possess all the other advantages of environment and heredity which go with such giftedness, are placed in a better position to achieve superior character than the less gifted. From the point of view of assessing the relative contribution of intelligence alone to character development, this conclusion is useless; from the point of view of studying the clustering of factors as they affect character development in the realistic interrelations between nature and nurture in the culture in which the child actually lives, it is indicative of thinking in terms of the interaction of the factors of nature and nurture which will characterize this chapter.

A significant point growing out of a detailed analysis of Terman's data which the above composite results do not reveal is that some values in the culture are responded to more strongly than others by the gifted. Terman's data reveal only one such difference, but future research may reveal many. The gifted were found to surpass the average more in traits and values directed to self-success than to traits and values directed to social responsibilities and service. Taken as a group the gifted children exceeded the average in every trait measured, but they exceeded the average most in "will and perseverance" and least in "sympathy and tenderness." In the volitional, aggressive traits 85 per cent of the gifted exceeded the mean of the unselected; in the sympathy-service traits only 59 per cent of the gifted exceeded the mean of the unselected. When one considers the much greater capacity of the gifted to achieve power over others, this difference between their standing on ego-directed and on alter-directed traits takes on considerable social significance. These results of Terman are based on only one investigation and, of course, need verification in other studies before too much

stress is placed upon them. However, the results of Spaulding (1938) and of Wilson (1938), working in the field of education, may be interpreted as supplying at least complementary evidence. Spaulding made an extensive study of the social-civic knowledge and attitudes of high school students and found that, whereas the abler students had mastered factual material much better than the average, their insight into and concern about the social problems of their community or nation were far from commensurate with their mental abilities or general scholastic achievements. Wilson, in a similar study, found that young people with high IQ's consistently surpassed the average in comprehension of social terms, knowledge of history, and the like, but that these same students differed from the average very little in knowledge of or attitude toward such community affairs as relief, health, and recreation.

Phillips (1950), in studying intellectual and personality factors associated with social class attitudes of junior high school youth, finds that relative brightness, when coupled with good personality adjustment, tends to be positively associated with acceptance of the typical social class attitudes and behavior patterns of the class group of which the individual is a part.

So much for the relation of intelligence to character development as revealed by studies which contrast the bright and the average. These results can be summarized by saying that the gifted exceed the average on all composite tests and ratings reported, but that there are some definite signs that many gifted children in our present culture are developing their superiority in those character traits making for individual success rather than in those making for social responsibility and progressive social change.

The second line of evidence concerning the influence of intelligence on character development involves results from correlational studies. The most comprehensive investigation of this type to date is that of Hartshorne and May (1928, 1929). They used an extensive battery of tests with elementary school children, and found correlations which average about +.50 between intelligence and honesty in school situations. They attempted to measure the home background of their subjects and to partial out this factor by using the partial correlation technique. The partial r between intelligence and honesty, with home background constant, was found to be +.40. Jones (1936), working with honesty tests similar to those of Hartshorne and May, found correlations ranging from +.32 to +.43 with seventh and eighth grade pupils who were rather homogeneous in home background. The correlation between intelligence and helpfulness was found by Hartshorne and May to be +.16 and that between intelligence and cooperative behavior was found by Jones to be +.09.[1] These are samples of the correlations found between intelligence and tests of actual performance in situations where the subjects did not know that they were being tested in ethical behavior.

If we may judge from the rather wide range of correlations extending from +.09 for cooperation to +.40 for honesty, it seems that intelligence is related in different ways to different aspects of character. Nowhere in the literature do we find the relation to be really close. On the other hand, we almost never find it to be zero or negative.

The third source of evidence on the relation of intelligence to character development is the studies of juvenile delinquency. Healy and Bronner (1926) in their classic

1 The correlation ratio between the cooperation test and intelligence was found to be +.37. When this is compared with the Pearson r of +.09, it is clear that the regression is curvilinear.

study reported that 13 per cent of the 4000 delinquents examined by them in Boston and Chicago were feeble-minded, that is, below 70 IQ. This should be compared with 1.5 to 2 per cent, which is the percentage of feeble-mindedness in the general population. More recent studies tend to substantiate these findings of Healy and Bronner. Indeed Glueck and Glueck (1934, 1940), working with 1000 delinquents, found exactly the same percentage.

These results on the incidence of feeble-mindedness among delinquents are interesting and relevant as far as they go, but it is clear from the absolute size of the percentages that feeble-mindedness cannot be considered a factor in the large majority of cases. It is the dull and the dull-normal groups, not the feeble-minded, that are the chief sources of juvenile delinquency. Lane and Witty (1935) reported that 80 per cent of their group of 700 delinquent boys were below the average of unselected children in intelligence. Glueck (1935) found 58 per cent of her group of 1000 delinquents to be below 91 IQ as compared with 21 per cent of unselected school children. Armstrong and Heisler (1945) obtained an average IQ of 83 for 200 white delinquent boys in New York City. The average IQ for an equal number of Negro delinquent boys was 79. Owen (1937) made a summary investigation of 21 studies of delinquents and found a mean IQ of 82.4.[1] These are but a few of the many studies of the intellectual status of delinquents, but they give results that are typical.[2] There is no need to multiply the evidence. It shows clearly that intellectual dullness or backwardness is much more frequent in delinquent than in normal populations.

In presenting these three lines of evidence to the effect that intelligence is related to character, care has been exercised to avoid any intimation of a single-line causal relationship. Nothing could be further from the point of view held in this chapter than the concept of superior or inferior conduct, including delinquency, resulting from any single factor or a simple summation of single factors. The systematic position taken here is that such conduct results from a most intricate combination of factors which are usually anything but independent one of another. However, it is believed that the best understanding of this multiple causation can be achieved by a consideration of some of the more important factors, one at a time, and by a gradual approach to the integrations which the evidence seems to justify.

Our first conclusion is that dull and dull-normal children will, on the average, be more likely to be brought before juvenile courts for serious antisocial conduct than average or bright children, if everything else, including the environment, is left alone to work itself out as it will. The second is that, although good intelligence does not guarantee normal or superior char-

1 Eckenrode (1950) reported results based on the testing of 345 delinquent boys on the Stanford Achievement Test from which we estimate that the average educational quotient was 70 or less, indicating that delinquents' efficiency in school is appreciably lower even than their intelligence scores would lead one to expect. Ninety per cent of these boys reported that they disliked school.

2 For a review of this and certain other correlates of delinquency, see Metfessel and Lovell (1942). The position taken by these writers is essentially the same as that taken in this chapter, namely, that neither feeble-mindedness nor dullness in and of itself produces juvenile delinquency. There are always mediating factors. It is probable, for example, that low mental ability leading to difficulties and frustrations at school is one important mediating factor. It is possible that abilities to foresee consequences of one's acts are dimmed and the capacities to visualise possible punishment ahead are weak as a result of dullness. This may be a second factor. Moreover, when dullness is combined with the inferior home background that ordinarily accompanies it, the training is likely to be defective, the prestige of the family as a restraining force is likely to be negligible, and the individual aspiration level is likely to be low.

acter development, good intelligence, plus all the other advantages and opportunities that usually go with it in our culture, does give one a better chance to avoid or counteract the stimuli leading to inferior character, on the one hand, and to select more worthy stimuli and more socially acceptable goals, on the other.

Influence of Age or Level of Maturation. The influence of level of maturation upon character development, like the influence of intelligence, cannot be studied in isolation from certain other variables. In a strict sense, therefore, it may be maintained that maturation as such cannot be investigated here at all, for it cannot be divorced from improved ability to learn and increased experience. However, the influence of age, coupled with all the attending advantages in ability and learning opportunities, can be studied. Attention can be given, for example, to the problem of whether the manner in which the culture affects the individual is dependent partly on his level of maturation and experience. Attention can also be given to the evidence for physiological and other changes with age in determining the types of drives and motivations which will affect conduct.

Slaght (1928) compared younger and older boys on their ideas as to whether it was wrong "to cheat if you can," "to lie to keep a secret," and "to lie to get even with someone," and found that a significantly greater percentage of the younger children condemned each of these as wrong. Apparently the younger children had not faced the conflict between the virtue of honesty and the virtue of loyalty in some of these questions as squarely as the older ones. Probably, also, the younger boys were more willing to accept the general rule and hand it back as given to them than the older, who may have seen more clearly what the culture actually requires and what exceptions it really makes.

Tudor-Hart (1926), working in collaboration with Bühler, found that lying from a social motive was considered wrong more often by younger children than by older ones. These experimenters also reported that, although selfishness might change in its manifestations, its amount did not seem to decrease with age or advancement in school. In the study of gifted and unselected children, mentioned earlier in this chapter, Terman *et al.* (1925) reported a clearly defined tendency for total character scores, as determined by an average of 7 tests, to increase with age (see Figure 4). A study of the separate distributions for the various tests, however, revealed the interesting fact that the older children obtained their advantage very largely from verbal tests in which knowledge of the most acceptable answer counted most, such as tests of reading preferences and social standards and attitudes. On the tests of overstatement with respect to books read or knowledge possessed, there was no perceptible increase in honesty with age. Also on the "peeping," or cheating, test there was no consistent tendency for the older children to be more trustworthy than the younger. From these and similar results it seems safe to say that the mere process of maturation will not, on the whole, decrease the amount or seriousness of dishonesty and deceit of children. The types of untruthfulness and dishonesty which are practiced at different age levels will be different, but they will vary with the amount of experience and foresight possessed and with the pressures of the peer culture.

The results on tests of moral knowledge and of persistence are more favorable to the older children than are those on tests of honesty and truthfulness. All studies are in agreement that children as they grow older learn better what the accepted standards of society are, both those that are

practiced and those that are preached. It also seems definitely established that children, on the average, increase somewhat in persistence as they grow older, at least up to age 14. Hartshorne and May (1929) found a correlation of +.33 between test scores on persistence and chronological age in an elementary school population. Ryans (1939*b*), however, working with young people ranging in age from 14 to 22, did not find any consistent increases in persistence with age. This indicates that perhaps by early adolescence this trait is pretty well established in the make-up of the average person.

Attending the process of maturation there are frequently definite changes in the manifestations of conduct. With the onset of adolescence, for example, the sex drive influences not only the interests of young people but also their conduct and their inhibitions and controls. Fox (1946) finds several evidences of offenses paralleling certain age ranges among delinquents and criminals.

So much for the sketchy results on the influence of age on character development. They do not tell us what part maturation alone plays. They make no pretense of revealing how much of the difference (or sameness) from age level to age level is due to increased learning ability and experience and how much is due to conscious training by parents, teachers, and others. The results, although unanalyzable along these lines, do indicate conclusively that increase in age, plus all that ordinarily accompanies it, does not produce large improvements in any of the aspects of character that have been investigated, except in moral knowledge. They support the conclusion that children do not "naturally outgrow" their earlier faults as they become older. They lead one to believe that there is no age level which can be properly referred to as the "age of discretion," before which children's actions may be relatively unsusceptible to training and considered unimportant or insignificant for character development, and after which conduct rather suddenly begins to yield to education and the conditioning of the culture.

Influence of Sex. Our culture does not expect the same character patterns of girls that it expects of boys, and the training that it gives them is different. Whatever differences are found, therefore, in experimental studies between boys and girls in character development should be recognized as not necessarily native. Having granted this, however, we wish to call attention to at least one line of evidence which argues for a biological or native contribution to sex differences in certain aspects of conduct. The glandular systems of boys and girls are obviously different, and there is much evidence to indicate that differences in glandular balance and functioning are related to differences in character and personality. It would take us far afield to attempt to review here the extensive evidence on this, but two very relevant studies will be mentioned in passing. Bize and Moricard (1937) gave injections of testosterone to young boys and found a definite increase in aggressiveness in all social relations. Clark and Birch (1945) administered male and female sex hormones to a male chimpanzee and found that social dominance of the animal was increased by the former hormone and that subordination resulted from the latter. These and many other studies lead to the conclusion that one example of a character difference between the sexes which may result in part from native factors is the greater aggressiveness of the male, other things being equal.

Most of the gross differences that have been found in the comparison of the character development of boys and girls are probably the resultant of a very intricate

interaction of a few native differences, such as greater aggressiveness on the part of boys, and a host of environmental differences.

Tudor-Hart (1926) asked a large number of young boys and girls in Austria and in America to name any cases which they could think of where lies were necessary. She found, in comparing the answers of boys and girls, that the girls gave a much larger number of conventional lies, such as "Mother is not at home," "Glad to see you," or "I've had a fine time at your party." An appreciable difference was found in all lies which might be grouped under the heading of social, including lies to keep secrets, to conceal surprises, to protect others, to keep from offending, and the like. Thirty-two per cent of all the lies named by the girls, as compared with 18 per cent of those by the boys, were of this type. Hartshorne and May (1928) found that on the basis of averages on several tests there was no significant difference between the sexes in honesty in school, but the girls cheated more than the boys on a "party test" where cheating consisted of peeping in order to make a good showing in a social situation. Terman *et al.* (1925) also found, on the basis of a peeping test, that gifted girls were a little more dishonest than gifted boys, although on all honesty tests combined the girls were slightly more honest than the boys. Jones (1936), employing several tests of honesty in school, found no appreciable sex difference at the initial testing, but the girls tended to show somewhat more improvement during 9 months of instruction in character and citizenship than the boys.

With regard to possible sex differences in volitional behavior, the evidence is rather meager and not conclusive, as it is particularly difficult here to control for differences in motivation and early conditioning. In a study of approximately 800 boys and girls, ranging in age from 9 to 16, Sheehy (1938) found that boys are more aggressive, dominant, fearless, and boastful than girls, whereas girls are more suspicious, more fanciful, and more amenable to social controls than boys. Ryans (1939*b*) found no sex difference in his test in persistence.

On cooperative and "helpful" behavior, Hartshorne and May (1929) reported that boys and girls differ very little on the average, but, wherever small differences do occur, the advantage is usually on the side of the girls. On the average, the girls were found to be consistently more generous than boys in voting money for charitable causes, although in any given social grouping it is not unusual to find that it is a boy who shows the greatest aggressiveness in leadership and action.

In studying the incidence of serious misconduct in school and delinquent behavior among boys and girls, we find the evidence to be conclusive. More boys than girls are found guilty of antisocial behavior. Olson (1930, 1949) found by means of a behavior rating scale that boys have more tendencies toward serious conduct disorders than girls. Rundquist (1938), working with large samples of boys and girls in the first and second grades in school, came to the same conclusion as Olson. It is a well-known fact, of course, that many more boys than girls fall so far below the minimum standards of moral conduct that they run afoul of the law. Schwartz (1949) of the U. S. Children's Bureau reported, on the basis of returns from 76 urban juvenile courts, that the ratio of boys to girls among juvenile delinquents averaged between 6 to 1 and 4 to 1 during the years from 1938 to 1947. In New York Maller (1937) found the ratio to be 7 to 1.

When a study is made of the types of offenses for which boys and girls are arraigned before the courts, significant dif-

ferences are found. An investigation by the Children's Bureau of the Federal Security Agency (1946) showed the usual results, namely, that girls were referred to the courts most frequently for sex offenses, for running away, and for being ungovernable, whereas boys were arraigned most often for stealing and other crimes against property. (See Table 1.) Dollard *et al.* (1939) interpreted such sex differences in crime largely in terms of the greater aggressiveness of boys.

Of course, the facts concerning sex differences obtained from the study of juvenile court cases cannot be interpreted apart from the differences in ethical standards set by society for boys and girls. One might say, for example, that the fact that the greatest percentage of offenses among girls are sex offenses does not represent so much a sex difference in character as it does a "double standard" set by the culture for judging the "morality" of boys and girls. These facts, however, are very relevant to the question of sex differences if we think of them as differences in adequacy of response to situations where this adequacy is judged in terms of existing standards and practices in our present culture.

TABLE 1

OFFENSES AND FREQUENCIES OF OCCURRENCE AMONG 111,939 DELINQUENCY CASES OF 374 COURTS FOR THE YEAR 1945

[Taken from *Social Statistics*, Supplement to Vol. 11 of *The Child* (November, 1946, Supplement), *Juvenile Court Statistics*, 1944 and 1945, U. S. Children's Bureau, Federal Security Agency.]

Reason for Reference to Court	Number			Per Cent		
	Boys	Girls	Total	Boys	Girls	Total
Stealing	38,610	2,269	40,879	42	12	37
Mischief	17,779	1,462	19,241	19	8	17
Traffic violation	9,659	193	9,852	10	1	9
Truancy	6,164	2,517	8,681	7	13	8
Running away	5,652	3,655	9,307	6	19	8
Being ungovernable	5,542	4,298	9,840	6	22	9
Sex offense	2,579	3,411	5,990	3	18	5
Injury to person	2,828	396	3,224	3	2	3
Other reason	3,858	1,067	4,925	4	5	4
Totals	92,671	19,268	111,929	100	100	100

It is hazardous to attempt to draw any broad generalizations from the above results, but for the purpose of bringing some of the lines of evidence together we submit the following two tentative conclusions.

In the first place, it seems from the results of Hartshorne and May, Terman, Tudor-Hart, Jones, and others that girls may be more submissive than boys and more influenced by what they think is expected of them by adult society. Second, it seems that boys are more aggressive than

girls If these two conclusions are correct, we would expect the same degree of lack of socialization in boys and in girls to manifest itself in more serious, aggressive forms among boys. This we find to be the case as mentioned above. We would also expect a larger amount of aggressive leadership for superior conduct among boys than among girls. The evidence on this is not conclusive, but it is at least a possibility that deserves objective testing.

Accidents and Diseases Affecting Brain Functioning—Their Relation to Volition and Certain Other Character Traits. Among the unlearned factors which are known to influence character development at least negatively are injuries and disease which interfere with the normal function of the higher cortical centers. The most interesting point to be emphasized here concerning these studies is that in not a few cases the injury or the disease seems to operate[1] to upset the organized patterns of character responses. If such factors can interfere with the character pattern which had been achieved up to a given point, then we may infer that probably such factors can also retard and set limits to the character development achieved per unit of learning time or cultural exposure in the first place.

Many individual case histories are on record to show that after a cerebral injury the individual has been left not only with reduced intellectual ability but also with greatly altered patterns of inhibition and control. Aita (1948) found among other residuals of brain injury an increase in instability and a disturbance in the "capacity for interpersonal relations." Newell (1937) made a study of 20 children who had had brain injuries and reported that the most frequent effect of the injury was an increase in irritability with "a general decrease of inhibitory functions." Ten of these children showed neurotic symptoms after the injury and 5 were found guilty of delinquent behavior. Rylander (1937) studied 32 patients after brain operations had been performed. Changes in intellectual ability appeared in 21 of these cases, whereas in 25 cases diminished inhibitions of affective responses occurred, and in 22 notable changes in volitional powers.

In the case of severe mental disease it is well known that changes in the character of the victim occur. Baruk (1947, 1949) finds evidence for believing that disorders of the anterior hypophysis are related to lowered volition powers. Subjects suffering from such disorders, he says, while preserving in large part their judgment of right and wrong, display volitional weakness in the form of nonchalance and lack of control. The disease which has attracted most attention in recent years as a result of its relation to character changes is encephalitis. Many writers, including Greenbaum and Lurie (1948), Levi (1930), Stertz (1931), and Ciampi (1937), have cited cases showing notable changes in character following this disease. Sometimes the change in the behavior occurs soon after the onset of the disease; sometimes it appears in a serious form much later. The chief offenses noted are disobedience, lying, stealing, sex irregularities, cruelty, and violence. These occur in individuals who were, presumably, well adjusted previous to the contraction of the disease. Heersena (1940) stresses the point that the effects of the disease, and any attending infections, are more pronounced in children,

[1] Of course not all the total result is necessarily attributable directly to the injury or disease, for important character results may come from an individual's emotional reactions to the injury or disease. The point is, however, that a certain type of injury or disease has these effects whereas others which would seem to be similarly emotionally disturbing do not.

whose personality and character are still undergoing rapid development.

Such changes in moral behavior attending disease present interesting theoretical problems. They suggest possible limitations to character development as a result of hereditarily or biologically determined defects. Moreover, if we knew the mechanisms by which satisfactory moral behavior was rather suddenly replaced by definitely unsatisfactory behavior in such cases, then perhaps we should have a better idea about just what happens in the organism in the development of character. Unfortunately, however, the studies shed little light on this. The most promising hint which we get is that the disease may so affect neurological functioning as to throw out of equilibrium, so to speak, the integrations which the individual has achieved. Some evidence for this is presented by Bond and Appel (1931), who state that they find in the postencephalitic condition not only lying and stealing but also heightened feelings of insecurity, stronger regressive tendencies, and more intense introversion or extroversion. We should expect that, attending these signs of increased inner conflict following this disease, the integration in behavior which had been previously achieved would be unsatisfactory and that changes would appear. We should also expect that remnants of old integrations might remain and that the victim might alternate, as he usually does, between the new patterns of conduct and remorse for having forsaken the old.

The Problem of the Inheritance of a Moral Sense. In any discussion of the native, or nonlearned, factors connected with character development, the old question arises as to whether or not a moral sense can be inherited. The intuitionists of the seventeenth and eighteenth centuries postulated an intuitive faculty, presumably hereditary, which could perceive without training what was moral and what was not. The concept of a sort of innate moral deficiency, which is found in the literature from time to time, harks back to this thinking of the intuitionists. This view is illustrated by Betke (1944), who says that delinquency is often due to defective "moral reasoning," and especially by Tredgold (1937), who maintains that a certain proportion of delinquents and criminals are fundamentally lacking in moral sense. The term "moral deficiency" is used frequently in reports of the Mental Deficiency Committee in England.

This concept of a moral sense or moral deficiency is inadequate and misleading; it is mentioned here primarily for the purpose of sharpening the distinction which should be made between saying, on the one hand, that inherited nature affects the substructures upon which character is built and maintaining, on the other, that inheritance affects character directly.

The view represented in this chapter, and the only one which seems consistent with the data presented, is that children do not inherit their character. They inherit capacities for responding to stimuli and for profiting by experience; probably they inherit or biologically develop certain glandular and volitional strengths and weaknesses; and possibly they inherit some propensities toward overdevelopment or underdevelopment of certain impulses or drives. They gradually acquire their character, within the broad limits set by their native make-up, by responding in certain ways in the situations which the environment affords.

The Influence of Nurture

The environmental factors which relate themselves to the character development of a child are legion. Indeed, it would be difficult to name a factor in the environ-

ment calling forth a psychological reaction which might not have some relation to character development. All that can be done here is to group under a few headings what seem to be the most potent factors for the majority of children and treat each of these groupings rather generally to illustrate some principles of character development. Those which will be discussed briefly are: home influences, associates, church schools, day schools, recreational activities, and the over-all culture.

Influence of the Home. The first and most important place in a list of environmental factors influencing character development must be assigned to the home. As Groves (1940) says, the home, itself enmeshed in a cultural milieu, is the most powerful transmitter of the culture of the group. It complements such institutions as government, education, sex status, and religion, but it begins its work long before the child is conscious of these other institutions. In the early ages it is in almost complete control of his social acceptance and rejection, of his joys and sorrows. Parental precepts and example get in their conditioning long before conscious teaching of other institutions of society can reach the child, and they are continually reinforced as long as he is under the home influence. Parental acceptance and affection, or the opposite, determine the psychological atmosphere surrounding him before he understands scarcely any of the words spoken in his presence. L. K. Frank (1948) says that it is the family which is the essential agency for the socialization of the young child and for introducing him to the culture in which he is to grow up and live. Lacking the necessary warmth of parental affection, the young child continues too long his egocentricity, develops fears, and begins putting up his defenses in the form of distrustful and revengeful attitudes of mind.

Allport (1950) maintains that children and youth need warm affectionate relationships and at the same time need a respect for and a defense of their own self-esteem. When bids for affection or belonging are rebuffed or self-esteem is threatened, hostility is the usual result in outward conduct while sensitiveness and frustration are the inner correlates.

Liu (1950), in an extensive experimental study comparing Chinese and American children, concludes that strong emphasis on filial piety in the Chinese culture does not seem to interfere with the development of mature and critical judgment in Chinese children in situations involving moral issues. Instead it appears that the close and affectionate family ties, with the patriarchal management in the home, help to provide security and freedom from apprehension for the child or youth.

Stern (1949), in working with uprooted children in Europe in the wake of World War II, concludes that the lack of normal home life and parental identification has prevented many of them from developing their superegos in the normal way, and he senses difficulty in training them to develop proper attitudes of responsibility and service.

Stott (1950) finds juvenile delinquency frequently to be an escape from an emotional situation which is too much for the child, such as domestic disharmony, parental ill health, lack of feeling of security, and emotional estrangement from parents. Cooper (1950) considers inadequate affection in the home and diffidence of parents concerning the social, emotional, and moral development of their children as being the conditions most likely to lead to delinquency. Wallenstein (1937) studied 3000 school children with a battery of character and personality tests to determine the influence of broken homes on measurable conduct. A comparison of the children

from such homes with those from normal homes leads him to conclude that inferior development in several aspects of character could be attributed directly to broken homes.

The relation of children's prejudices and idea of right and wrong to those of their parents have been studied by several investigators. Frenkel-Brunswik (1948, 1951) finds a strong positive relationship between the values and prejudices of young people, age 11 to 16, and those of their parents. However, she finds the prejudices of youth to be more flexible and more subject to change by training than those of the parents. Hartshorne, May, and Shuttleworth (1930) correlated children's ideas of right and wrong with the ideas of each of the following: parents, friends, club leaders, day school teachers, and Sunday school teachers. They found the correlation between child and parent to be the highest, with r equaling .55, and that between child and Sunday school teacher to be the least, r equaling .002. Within the home it was found that there is a closer relation between the ideas of child and mother than between those of child and father.

The influence of the size of family on the moral behavior of children has received some attention from experimenters, but no general conclusions can be drawn. If a child gets the impression that he is not wanted by his parents, or if the presence of a younger brother or sister is interpreted as detracting from the affection and attention which he was receiving, he has greater difficulties in making satisfactory personality adjustments. Whether the adjustments finally made, however, will lead to stronger or weaker character development remains an open question. Probably it will depend both upon the individual child and upon the degree to which he feels that he is rejected.

Symonds (1949), after an extensive study of parent-child relationships, came to the conclusion that if one or both parents strongly reject a child he tends to become overaggressive, or hostile, and may resort to truancy, lying, and stealing. If, on the other hand, the parents exercise overprotection with a child, he tends to become overdependent, relatively helpless for his age, and noncooperative in situations requiring give and take. Different observers report different results relative to the reactions of children to overstrictness and overinhibitive treatment in the home. Some report that the child tends to become overaggressive and rebellious; others that he becomes submissive and strait-laced with an overstrong superego. Havighurst (1952) introduces a new note, based on results in an 8-year study, in which he maintains that consistency of discipline is positively related to the development of ethical competence including self-control and self-direction in the child. He advocates teaching children and youth through consistent discipline that there is moral orderliness in the world and that a reasonable degree of social conformity is realistic and desirable.

Several research studies have been made on the effect upon the family situation of one member who is or becomes neurotic or otherwise emotionally disturbed. The study of Berman (1948) is illustrative of this type of investigation. His results indicate that such a person will tend to bring about disequilibrium in the psychological atmosphere of the home. It seems reasonable to expect changes to result in both the emotional adjustment and the character organization of some or all members of the home.

The economic situation in the home is an important factor in the moral development of children when all the other variables correlated with it are considered. If, however, one may judge from the trends in de-

linquency during the depression years, it seems that the effect of economic status is small when such factors as parental supervision and level of a child's associates are held constant.

Carr-Saunders, Mannheim, and Rhodes (1944), working in England, equated delinquent and nondelinquent children for neighborhood and school district, and Healy and Bronner (1936), working in the United States, paired delinquent and nondelinquent children of the same family. In both studies the attempted equating of home background decreased the apparent importance of formal sociological factors as contributing causes of juvenile delinquency, but such equating did not eliminate the psychological factors. Even in the same home Healy and Bronner found that the delinquent child felt more often discriminated against and thwarted, more often disliked by one or both parents, and more subject to general emotional stress than did the nondelinquent child.

Jones (1932) and Dawson (1938) have shown that in the state of Massachusetts juvenile delinquency did not rise during the economic depression of 1929 to 1937. Adult theft increased, but crime on the part of children and youth below 17 decreased slightly. The Federal Children's Bureau showed a decrease of 16 per cent in the number of juvenile cases handled in a sampling of the courts of the United States from 1929 to 1937. This should be compared, however, with the rapid rise in juvenile delinquency beginning in 1942 when the economic situation in homes was much improved but when the psychologically disrupting conditions attending the war had made themselves felt. After 1945, as Schwartz (1949) has shown, there was a rather rapid decline for a time, which paralleled the improved supervision of children and youth following the war.

Influence of Associates. The influence of home and of associates cannot, of course, be separated because the place where a child's home is located often sets limits to the neighborhood and the range of cultural backgrounds from which he will select his friends. Granting these interrelations, it seems justifiable, nevertheless, to treat the influence of associates separately. Some of the clearest evidence of the influence of associates on character growth or decline comes from the studies of juvenile delinquency. Burt (1925) and Healy and Bronner (1936) stress the fact that there are few other factors comparing in strength with that of intimate companions in determining whether or not an individual will commit a crime, and, if he commits one, what the crime will be.

It is interesting to note in these and in other studies that there has been a shift in the direction of greater emphasis upon intimate friendships as contrasted with larger groups such as boys' gangs. Thrasher (1927) stressed the great power of the gang to mold the conduct of its members, and there is no gainsaying that such effects are very real. There are, however, intimate loyalties and counterloyalties even within the most solidified gang, and many students of delinquency today are stressing particularly the power for good or ill of the relationships among intimate pals—the twos and threes. There is no intention, in stressing this point, of implying that the influence exerted upon a boy by one or two intimate companions detracts from the power of the gang upon him. On the contrary, one may supplement the other. However, some of the influence which was formerly attributed to the gang in molding conduct may really belong to smaller groupings of intimate companions.

Hartshorne and May (1928) have made the interesting, although not surprising, finding that the influence of one's asso-

ciates upon his conduct is greatest when they are actually with him. They found that the correlation between children's standing on tests of deception and that of their best friends not in the same classroom was .23, whereas the correlation between best friends in the same classroom was .66. These results justify the conclusion that the effect exerted upon one by his companions is greatest when they are present and in a position to influence his behavior through immediate example, suggestion, and favorable or unfavorable reactions to his attitudes and behavior.

This leads to the mention of the influence of group morale. In small intimate groups, the standard of behavior accepted in the group molds the behavior of all its members at least while they are together. This phenomenon is frequently noted in schools and especially in individual classes. If a class group remains fairly well intact for a year or two, certain habits and attitudes toward neatness, cheating, courtesy to teachers, etc., may gradually be developed. These habits and attitudes are usually rather specific, however. A case is known, for example, where a whole school developed a sort of taboo against cheating, but extreme snobbishness was condoned if not actually encouraged by the group. In a given class in school a good group spirit may develop under one teacher and manifest itself in a high degree of honesty and cooperation in her room and in her presence, but under another teacher the conduct of the group may be very different.

Jones (1936) has found that improvement in measurable character made under the conditions of good group morale is largely dependent for its permanence upon the maintenance of the group intact. He used eight classes of seventh- and eighth-grade students in his experiment and gave instruction in character and citizenship over a period of 1 school year. The class with the best group morale made the greatest gain. But a few months after promotion time, when the previous class groupings had been dissolved, the students of each class were brought together again for testing. It was found that the original gains were maintained most poorly by the students of the class which had developed the best group morale, and they were maintained best by those students who improved in spite of the weakest group morale. The experimenter refers to the gains made under the very favorable conditions of good group morale as *group-linked gains*. They were, in other words, largely dependent for their operation upon the total group and the spirit which welded it together. This concept implies that, if a child rather suddenly shows improved character responses in a social setting where the group morale favors superior conduct, it does not necessarily follow that such conduct has become firmly interiorized at this level. Similarly, if an individual suddenly displays an abrupt drop from his customary level of conduct when in the company of companions where the group morale favors such retrogression, it does not necessarily follow that his individual habits and standards have crystallized at this lower level.

It seems that group-linked gains and losses become interiorized gradually. For education or rehabilitation this would seem to mean that a child who rather suddenly deteriorates under bad influences may be saved from much of his loss by speedy removal from these surroundings. In the case of a child whose conduct has improved under the impetus of superior surroundings, it means that provision should be made for rather protracted exposure to such conditions to allow the gains to become integrated into individual standards and habits.

Influence of Church Instruction. Historically, the problem of ethical instruc-

tion has been intimately associated with religious instruction, and no discussion of children's character development would be complete without at least a recognition of this relationship. There is, however, a notable scarcity of objective data on certain crucial questions.

Ligon (1939) has effectively raised many of these questions and has given a plausible account of the influence which well-directed religious education should have upon the character and personality development of children and youth. Theoretically, the opportunities for religious instruction gradually to interiorize the controls of conduct of the individual and to provide emotional toning for such controls would seem very promising, especially if such instruction could be directed more to actual conduct and if it could be integrated more closely with complementing activity in home and school.

A few studies have been conducted in which comparisons have been made between church or church school attendance and character, as measured by resistance to delinquency, by tests of honesty and cooperativeness, and by correlation studies between knowledge of the Bible and character ratings.

Wattenberg (1950) made a study of 2137 delinquent boys to determine the relation, if any, of church attendance to conduct improvement after one offense. He found fewer recidivists among the church-attending boys, and he concludes that church attendance is a part of a mode of living which tends to reduce juvenile misconduct.

Woodruff (1945) found that religious experience has an important effect on the value patterns of young people. Hartshorne and May (1928), working with large numbers of children in public schools, compared the amount of cheating done in a group attending Sunday school and in a group not attending. In their first sampling the percentage of cheating in the former group was 31 as against 40 in the latter group. In their second sampling the percentages were respectively 38 and 43. The same experimenters (1929), working with another group of 84 children, found that those who attended church schools obtained somewhat higher scores on tests of helpfulness than those who did not, and those who were regular in attendance did better than those who were irregular. Maller (1930) found on the basis of objective tests that the honesty of a group of Jewish children increased appreciably during attendance at religious schools.

All these differences are rather small, but they are consistent in their direction. Of course, it can be argued that any differences noted in favor of the groups under church influence may be due not so much to church or church school attendance as to factors in the heredity and homes of children whose parents are sufficiently concerned about their welfare to send them to such schools. Unfortunately, the accuracy of such an argument cannot be proved or disproved because of the past failure, perhaps unavoidable, to measure or control all relevant variables. The fact remains, however, that the children who attended church schools, and who had all the other advantages that might have gone with church school attendance, did better on the tests than those who did not attend.

It would be interesting to determine for homes equated for socio-economic backgrounds whether there was any relation between interest in religion and church attendance on the part of the parents, on the one hand, and the psychological atmosphere of the home for good child upbringing in personality and conduct, on the other. Our hypothesis would be that a positive relation would be found. Manwell and Fahs (1951) maintain that there is a definite relationship between the spiritual

and religious health of children and their mental and emotional health. On the problem of interest in religion among college students Allport *et al.* (1948) found in a study at Harvard and Radcliffe colleges a rather high interest in and "expressed need of" religion in relation to development of personal values.

With regard to the influence of Biblical knowledge on the moral conduct of children, it is impossible to draw any definite conclusions at present. Taylor and Powers (1928), working with school children, correlated the results on the Laycock Bible Test with character ratings based on the combined judgments of teachers and found a correlation of .50, whereas the correlation between the character ratings and intelligence was only .24. Hightower (1930), however, made a study of the same problem and found little or no relationship between Biblical knowledge and the different phases of moral behavior tested. The differences in the results of these two studies serve to stress the difficulty of controlling all relevant variables and getting to the bottom of the matter. Until the interrelationships among intelligence, Biblical knowledge, home influence, and various aspects of moral conduct are known, we cannot hope to draw any conclusions about the relation of Biblical knowledge to character.

Influence of the Day Schools. The influence of day schools upon the character and development of children and youth has been studied under three headings: first, the influence of teachers upon individual children and groups; second, the influence of group spirit upon the members of the group; third, the total impact of the school as measured by changes attending advancement to higher grades in the school. Many of the studies have been concerned primarily with the influence of teachers in their contact with individuals and groups. Space will not permit more than bare mention of this problem. Anderson *et al.* (1946), to take only one example, found that children's behavior in school tended to vary with different teachers. Inferior conduct, however, once begun under one teacher tended to spread over to other situations. The effects upon children of varying degrees of authoritative and democratic classroom management have come in for a good deal of study, but the control of variables in these studies has left much to be desired. It seems probable that the personality and character of the teacher and the manner in which a management method is executed are more important in affecting children's character development than the method as such. The evidence seems clear that in classes or schools where the management is ineffective the attitudes and conduct of the students deteriorate.

The group spirit of a class in which a child is a member is certainly one important condition influencing his conduct. Jones (1936) found this to be the most significant condition differentiating the classes which improved most in conduct from those which improved least in an experimental learning situation. It is impossible to say how much contribution to good class spirit is made by the teacher in his teacher-pupil relations and how much is made by the pupils in their own interrelations, but if we consider these two together we have the sets of factors in the school situation which are most clearly related to character development.

Level of advancement in school in itself does not seem to be a significant determiner of character, at least not in the grade range from 5 to 8, which has been most extensively studied. Jones (1936) found no significant difference in character development between grades 7 and 8 with which he worked, and Hartshorne and May (1928, 1929) found no consistent improvement

in grades 5 to 8 which could be attributed to level of advancement alone. Conduct changes in the different grades, but there is no evidence that it systematically improves except under the conditions already noted, namely, through individual teacher leadership and through the establishment of good class spirit supporting certain superior standards of conduct.

Influence of Recreational Activities. The main objective studies in this field have been made on club activities, motion-picture attendance, radio and television entertainment, and reading. Consequently, the discussion here will be confined to these four.

1. *Club membership.* The pioneer investigation of character development employing controlled test situations was made in the field of club activities. This study was conducted by Voelker (1921) for the purpose of determining the influence of Boy Scout work on trustworthiness. He worked with 57 boys, ranging in age from 10 to 14. At the beginning of the experiment he gave a series of performance tests. Then, during an experimental period of 7 weeks, two groups of boys were given intensive work on trustworthiness, and two other groups, having about the same scores on the initial test, were given the regular training prescribed by the Scout organization; two groups not belonging to the organization and receiving no training were held as controls. At the end of the experimental period all six groups were retested with a test battery similar to the initial one. It was found that most progress had been made by the two Boy Scout groups receiving the intensive training, and that the least progress was made by the two groups which received no Scout training. Apparently both the club membership and the special intensive training had some effect. The special training seems, on the surface, to have been the more important, but the favorableness of the social situation in which the training is given is coming more and more to be recognized as of very great importance, and in this study we have, possibly, an interesting illustration of this point.

Hartshorne and May (1928, 1929), working with their extensive test data, made a comparison of the scores obtained by children who were members of clubs and those who were not. They found that club members, no matter what the organization, were more cooperative than nonmembers; but club members did not consistently exceed nonmembers in honesty.

Numerous results, based on studies of delinquency in urban areas after club activities have been organized or expanded, have appeared to show that clubs providing good recreational programs and capable leadership have accomplished striking results. In such studies, however, the factor or factors accounting for the improvement have not usually been rigorously isolated. Frequently increased club activities in a community are accompanied by better leadership, better housing, etc. It is easy to believe that any opportunities that are provided for children to engage in club activities under supervision and to practice desirable conduct should contribute to their character development, but evidence on just what contributions are made by each of the interlocking variables would require many more controls than have been involved in these studies in the past.

2. *Motion-picture attendance.* The effect of motion-picture attendance on character development of children and youth has been the subject of a considerable number of research investigations. One topic of study has been the frequency of attendance. In urban areas in California, Shull (1940) found, 73 per cent of children between the ages of 9 and 14 attended the movies at least once per week. Fleege

(1945) in a study of boys in 20 Catholic high schools found that 75 per cent attended at least once per week, the average frequency of attendance being 4.9 per month. These results are in close agreement with the earlier results of Dale (1935) in the extensive Payne Fund Study in which it was found that 71 per cent of high school boys attended motion pictures at least once per week. There are, of course, wide variations in different areas of the country and in different sections of a given community. It is interesting to note that in some crowded areas of cities a substantial percentage of children begin rather regular attendance at the movies by or before age 8, and in such sections it is not uncommon to find children attending as frequently as 4 or 5 times a week.

Several studies have been made of what children see at the movies. The studies of Fleege (1945) and of Dale (1935) are good illustrations. One result of these analyses which is of interest in the study of character development is the great frequency of crimes, violent death, overdrawn love and sex scenes, and horror themes. The lack of reality in the films is also emphasized in these studies.

Success is depicted in the movies as coming fast and often easily. In the interest of making the story compelling, there are few normal and average people depicted in average homes. Extremes are the rule. The rich are lavishly rich; the poor are desperately so. Luck and physical strength, beauty and prowess, are out of proportion to their true place in reality. For adults who have experienced life widely, and can easily distinguish between the unreality of a good story and the reality of life, this is not serious. But for children who start their motion-picture attendance at young ages and see life depicted in this manner year in and year out, it may be serious, especially if the home, school, church, or some other institution of society does not correct these warped impressions.

The influence of motion pictures upon emotional responses and upon restlessness during sleep has been studied by Renshaw, Miller, and Marquis (1933). It was found that the restlessness after seeing motion pictures increased 26 per cent on the average with boys and 14 per cent with girls. Using measures of change in pulse rate as a measure of emotional response, Dysinger and Ruckmick (1933) found that while seeing a picture children 6 to 11 years of age displayed responses which averaged three times those of adults.[1] The effect of movies on muscular tension and body temperature was studied by Kleitman (1945), who found that both increased during attendance at many pictures. He says that movie attendance, although looked upon as "relaxation" in the sense of escape from the humdrum of everyday existence, is certainly not always relaxation in the physiological sense.

Many studies have been made to determine the influence of motion-picture attendance on delinquency and crime. The results are conflicting. In general, the investigations which have employed interviewing and questionnaire methods with delinquents have reported that motion pictures were direct causal factors in 10 to 20 per cent of the cases. Blumer and Hauser (1934), for example, have concluded that the movies were important factors in directing 10 per cent of the boys studied and 25 per cent of the girls into delinquent and criminal careers. Cressey and Thrasher (1934) interviewed 139 delinquent boys, age 15 and below, and concluded that 17 per cent of them "were clearly influenced by the movies toward delinquency."

1 Of course a given change in pulse rate is not so serious with children as with adults, but such wide changes are certainly worthy of note.

On the other hand, such specialists in the study and treatment of delinquents as Healy and Bronner (1936) find much smaller percentages. They are inclined to discount much that delinquent boys and girls say in interviews and questionnaires about the "cause" of their delinquency and seek for objective evidence beyond the delinquent's self-analysis. Healy and Bronner conclude that only about 1 per cent of their cases were clearly motivated in their acts of delinquency by motion pictures.

With such conflicting results before us it is impossible to generalize concerning the percentage of delinquents who were stimulated toward their misconduct by motion pictures. All investigations agree, however, that some motion pictures have deleterious effects on delinquents and near-delinquents. It seems probable that the greatest effects of movies do not appear suddenly and in such ways that they can be accurately measured by existing methods. Probably any detrimental influences are most likely to manifest themselves through gradual and cumulative effects on attitudes over a long period of time, and through supplying to individuals and small groups just enough added stimulation to serve as "trigger action" when they already have rather strong antisocial inclinations or pent-up resentments.

The potentialities of motion pictures for improving standards and conduct have received less attention than their potentialities for harm. However, positive values have not been entirely overlooked. As examples of studies showing gains in moral attitudes and standards, we may mention those of Rosen (1948), Raths and Trager (1948), Thurstone (1931), and Jones (1936). The first two investigators studied the influence of pictures stressing the evils of intolerance. The effects in both studies were in the direction of increased tolerance as measured on attitude questionnaires. Thurstone found that attitudes toward gambling were changed in a desirable direction as a result of seeing a film. Jones in a study of four films found that ethical standards of children could be raised or lowered as a result of seeing specially selected films. The films which were most effective in raising standards were those which unqualifyingly condemned specific types of undesirable conduct. A large factor in determining whether undesirable conduct was really being condemned in a given picture was the attitude taken toward that conduct by the actor with whom the spectator identified himself.

3. *The radio and television entertainment.* A considerable number of objective studies have appeared concerning the relation of radio to attitudes and conduct of children, but much less material of a conclusive nature has appeared relative to television. Siepmann (1950) has discussed in an extensive report the history and some of the social implications of television and radio, including a chapter on the present and potential use of these media in education and in propaganda. Riley, Cantwell, and Ruttiger (1949) studied matched television and nontelevision homes. They concluded that television is proving to be responsible for new family interests, is providing something for family members to do together, and is stimulating a wider circle of friends in the home.

There is sufficient evidence now available to enable one to say that the radio listening of children and adolescents is very great indeed and that probably most of the programs are neutral in their effect upon the character of children. Some of these programs, such as discussions of current topics, the speeches of prominent leaders, some of the news broadcasts, and the higher grade musical programs, may make positive contributions to the character and citizenship of the listeners. In fairness to

the radio as a medium of communication these deserve more attention and investigation. However, the greater number of objective studies have centered on such questionable programs as those with crime, horror, or murder mystery themes to which children listen. On the question as to whether such programs tend, on the average, to throw their weight on the positive or negative side of the scale in the character development of children, we end up with two sets of answers in the main. Some writers, usually with clinical or psychiatric backgrounds, see in such programs desirable outlets for "pent-up emotions" like hate and feelings of aggression. They believe in the beneficial results of emotional release and the cathartic effects of vicariously experiencing the emotions which these programs stimulate.

The other point of view, and one supported by several investigations, is illustrated by Rowland (1944) and DeBoer (1939). Rowland studied the nature and frequency of various crime themes in radio programs and concluded that crime programs distort the truth about crime and the functions and methods of law enforcement agencies. "Crime and violence in drama," he says, "lose their cathartic value when there is a constant habituation to overdoses . . . and may contribute to those frustrations which bring about aggressive behavior." DeBoer reports that such programs as these caused very strong emotional responses in children.

These, and other studies, lead us to conclude that to the extent that children see or listen to overemotionalized, unrealistic, and antisocial programs day after day they are probably subject to cumulative conditioning effects which are not good from the point of view of either mental hygiene or character development.

4. *Reading of books, magazines, and newspapers.* Reading is believed by many writers to be one of the foremost methods which can be employed for character development. The great stress on Bible reading in church schools and the confidence which many writers have expressed in the values of reading biography and great fiction are illustrations of this belief. Jones (1931*b*, 1952) prepared biographical episodes and tried these out as reading and discussion material in school. In comparing results in trained groups with control groups, he did not find a statistically significant difference on a test of moral knowledge, although subjective judgments seemed to indicate that there may have been some positive gains which the tests were not sensitive or comprehensive enough to detect. Child *et al.* (1946) have analyzed over 900 stories from third-grade readers and, on the basis of a careful and thorough thema analysis (in Murray's sense), conclude that such reading should if properly arranged encourage the development of certain motives and discourage others on the part of the young child. Gray (1947) has reviewed the literature on the social effects of reading, but he does not so much answer some of our basic questions as reveal that more controlled investigations of various aspects of the problem with children and youth in natural situations are definitely needed.

With regard to the deleterious effects of inferior reading matter, there is more evidence. Healy and Bronner (1936), who base their conclusions on wide experience with delinquents, are very emphatic in their claim that cheap novels and magazines dealing with bandit and underworld life act as a pernicious influence upon the character development of young people. Their conclusion is based on the verified confessions of boys and on the fact that many delinquents were found to have among their possessions a well-fingered book or magazine article which described

crimes bearing marked resemblances to the ones committed. In condemning such reading, Healy many years ago made the following insightful statement (which needs expanding to include the newer means of entertainment and excitement of today's youth): "A definite habit and craving for this type of reading is developed just as the individual develops a habit for alcoholic stimulants. The fires of the spirit of adventure are not only kindled but are kept going by this fuel." [1]

Novels and magazine articles are ordinarily sufficiently long and read under such conditions of relaxation as to permit suggestion effects to be at a high point. Particular parts of the written story, as contrasted with the drama, can be turned back to by the reader and reread for more stimulation or specific details. These are doubtless some of the features of the bandit, underworld, and amatory types of stories which contribute to the effects which Healy and others emphasize.

Comic books and strips have come in for considerable study and discussion. The results are rather conflicting. J. Frank (1949) says that comic books follow to some extent the same general pattern that children's cheaper reading has followed in the past except that much crime and horror material has been added. She reports that 50 million copies of comic books are sold monthly and that each copy usually has several readers. She calls for vigilance on the part of parents, teachers, and specialists in child development in scrutinizing marginal material, but sees no occasion for suspecting much, if any, damage from most of the current comics. Hoult (1949) finds what seems to be conclusive evidence that delinquents read more questionable and "harmful" comics than nondelinquents. Bender and Lourie (1941) came to the conclusion that comic-book material often fits the needs of the child in his striving to solve problems involving the attitudes of others toward him and his own impulses toward others. They do not consider the value levels at which some of the more questionable comic books may meet these needs. Jersild (1947) interprets the evidence which is available more seriously. He stresses particularly the point that the comics sometimes act as forces which contradict the teachings of the home and school. The young readers often find ends gained by force and violence in the comics, while they are taught elsewhere to live by more civilized principles; they sometimes find retaliation and cruelty defended, while the home and school try to educate away from such conduct; they sometimes find crime made into adventure and criminals made into heroes of action, while the home and school try to impress them with respect for law and order.

These are illustrations of the state of conflicting opinions and interpretations of the data relative to the effect of the comic book on the character development of children. The studies and discussions of the problem have served to indicate the extent of such reading, to sharpen up the issues involved, and, we hope, to stimulate more research upon it. We suspect that different comic books have very different effects on different children. A few may be actually beneficial to some children. Most are probably neutral for most children from the point of view of character. A few are almost certainly marginal if not harmful to all or most of those who read them. The over-all effect is probably small, except possibly in a cumulative way and in combination with other factors.

The studies of newspaper reading of children and adolescents have centered mainly on their interest in various parts of the paper, on the effects of newspaper reading on knowledge of current events, and on

[1] See Healy (1915, p. 305).

attitudes toward delinquency and crime. Feingold (1944) and Burton (1946), investigated the newspaper tastes of high school students and came to essentially the same conclusions, namely that front-page news, the sport page, and the comic strips ranked highest. The radio section and the motion-picture section were very frequently consulted. Feingold reports that approximately 20 per cent of the students in his study read the crime news very regularly. He also finds that three-quarters of these high school students report that they read the newspaper to keep up with local, national, and international news and that such reading is an advantage to them in their school work. Doob (1948), on the basis of a careful study of propaganda, says that, although some systematic bias undoubtedly exists in newspapers, and is very strong in some, it is usually an outgrowth of the cultural orientation and sincere belief of the owners and editors of the papers or of the reporters or feature writers who write specific articles or stories. He concludes, therefore, that much of the so-called propaganda in most newspapers is in this sense unintentional. However, he advises young and old to read two or more newspapers, each representing a different systematic position, in reaching conclusions on important issues.

The treatment of delinquency and crime in various newspapers differs greatly. Some newspapers feature crime and delinquency and make of the criminal something of a hero and daring adventurer in the minds of children and youth. Some go so deeply into the details of the crime and the methods used by the law in attempts to capture the offender that the delinquent or near-delinquent is educated in the techniques of both crime and escape. Many newspapers see the potential dangers to their communities in such overplaying of crime news and make their reports less sensational and more factual. Baker (1943) described some interesting practical experiments in which editors and publishers of newspapers in certain cities with high delinquency rates agreed to place crime news in the inside pages of their papers and to reduce the headlines. In each case, he says, there was a gradual reduction in the delinquency rate.

Influence of the Culture. Each of the factors discussed thus far in this section are a part of what might be called the *personal environment* of the child. It is a personal environment because within rather broad limits each person has a certain freedom of movement as to the nature and extent of his exposure to each factor. There remains the very important problem of the influence of the totality of the culture in which the child is born and lives. This problem is different only in degree from that of the influence upon the child of, say, the family or the associations of peers in the personal environment where certain norms of conduct are thrown about him and where with only limited consciousness of the existence of any other alternatives he takes these for his standards.

If the group is large enough and the identification with that group as compared with any other is strong enough so that there is only distant or disdainful recognition of other alternatives, then we have the *class stage* in cultural determination. Applying the concepts of class to the problems of character development of children, Havighurst and Taba (1949) have sought to determine what attitudes and values characterize the upper-class child, the middle-class child, and the lower-class child. Working in what seems to have been a prevailingly middle-class city, where there was a considerable amount of mobility in class affiliation, especially in the schools, they have not been very successful in discovering differences except at the extremes.

However, this study is doubtless a precursor of much research that will be directed towards the determination of what attitudes, values, and conduct are held up as the desirable norms and passed on to the children of different groups and "classes" in America. In a study of 1100 white men ranging widely in socio-economic status, Centers (1949) found that those of top occupational and economic strata strongly believed in maintaining the status quo, think that things are about right as they are, and identify themselves with those above them in position or rank. Those in the different levels of the lowest strata have more radical attitudes and identify themselves with those of equal status or with those at levels below them.

Overarching the subgroup or class there is the *over-all culture*. Here the opportunities for mobility and for seeing or accepting alternative standards in other cultures is reduced to practically zero. This is the national or regional culture or civilization typified by such broad cultural designations as "American cultural patterns," "western civilization," "Christian culture," and the like.[1] Every child is born in such an over-all cultural matrix and is influenced by it through every individual and social institution with which he comes in contact. All the factors which comprise the personal environment and all the ramifications of class structure operate within this larger frame of the over-all culture. Customs, standards of conduct, attitudes, aspirations, and values of every new generation are tremendously influenced by the culture in which it is born and reared.[2] This influence, we believe, is both piecemeal, in the sense of the separate contributions of each of such factors as were discussed under the personal environment, and global in the sense of a totality of orientation.

In emphasizing this sociopsychological approach to character development, we should not overlook the potentialities of the individual human mind in its creativeness to see beyond the culture of a given time and place and set its goals accordingly. But these moments of creativeness are probably rare in the history of individuals and peoples. In the practical problem, therefore, of understanding the most crucial fact about character development of children in different classes and cultures, we can probably do no better than follow the conclusion of Margaret Mead (1949), who says that many of our human frictions in society today arise from a failure to understand differences in culture that make it "natural" for people to think and act differently.

Motivation in Moral Behavior

Up to this point the discussion has been confined largely to phenomena upon which objective data are available, and it is not our intention in this chapter to venture far from such objective material. However, when we come to the question of motivation in character we are confronted with the choice of ignoring the problem altogether or of attempting to discover what the general theories of motivation in psychology have to offer that will apply here. In the face of this dilemma it seems best to adopt the latter course, even though the

1 Nixon (1952) develops the interesting idea that even truth has meaning only within the framework of an agreed context of fundamental values, and that we lack such a context in some of our thinking today in light of the conflict between democracy and its basic value system, on the one hand, and the enemies of democracy and their value systems, on the other. Dechesne (1950) says that the social institutions functioning in western civilization today have not succeeded in developing and maintaining the altruistic sentiments necessary for their own successful operation and high destiny. He believes that conscious attention to the development of such sentiments is the only solution to the social crisis of our day.

2 For an extensive discussion of this point see Kuhlen (1952).

limitation of space will necessitate a sketchy treatment.

The points of view found in the literature concerning the dynamics of conduct are varied. There are writers who believe that all behavior springs from many inner drives or urges; there are those who believe in one or two native or biological roots from which all specific motives can be derived; and there are those who deny the theory of innate drives and stress learned wants and the motivating power of the on-going organism in preparatory and consummatory activity.

The clearest and boldest treatment of motivation from the standpoint of innate tendencies has been given by McDougall (1918). "The human mind," he says, "has certain innate or inherited tendencies which are the essential springs or motive powers of all thought and action . . . and are the bases from which the character and will of individuals and nations are gradually developed under the guidance of intellectual faculties" (p. 20). He lists among instincts: curiosity, pugnacity, self-assertion, self-abasement, reproduction, gregariousness, acquisition, etc. The chief difficulties which have been faced by those who hold this view are: first, the inability to demonstrate what tendencies belong in this list of unitary drives and, second, the failure to show the degree to which the manifestation of a tendency which is noted at any given time is native and the degree to which it is acquired. With the advance of the researches on the processes and results of conditioning, on the one hand, and the growing interest in the integrative behavior of the organism, on the other, the belief in an hereditary equipment consisting of rather independent, broad, unitary tendencies to action was appreciably undermined.

In the fields of psychoanalysis and of individual psychology there has been a tendency to look for the dynamics of behavior in two or three native or unlearned roots. Freud (1924) regarded the sex tendency and the self-preservation tendency to be the main elements in human motivation, at least on the side of the "life instincts" as he later called them. The sex tendency encompassed all the direct and indirect derivatives of the sex motive whether conscious or "repressed in the unconscious." The self-preservation tendency included among other things the protection of all of one's moral and social standards. Adler (1927) postulated two universal tendencies: first, a desire for personal power and superiority; and, second, a "social feeling which binds man to man." "With these two points of view," he said, "we can understand how the relation between human beings is conditioned by the relative degree of their social feelings, as contrasted to their strivings for personal aggrandizement, two tendencies which are always in opposition to each other. It is a dynamic game, a parallelogram of forces whose external manifestations are what we call character" (p. 190).

Murphy, Murphy, and Newcomb (1937) suggest for descriptive purposes the following four groups of "human motives": visceral drives, activity drives, aesthetic drives, and emotions. They do not think of these as instinctive, however. They stress the point that there is no separation of the fundamental drives from the means which serve them. The process of motivation they think of as going on unremittingly, and they believe that the patterns of habitual responses are as fully motivated as unlearned responses. Coghill (1936), pointing to the relation of maturation to motivation, holds that as long as the nervous system and brain are changing and developing as a result of maturation there is at least some motivation which must be considered internal. Olson (1949)

says that "children, under the influence of appetite and homeostatic mechanisms, tend to seek according to their needs . . . [and] there are strong probabilities that growth has internal factors which constitute drives to action. From the environmental point of view, the child tends to produce in his behavior those things valued by the culture, if they are within the repertoire of possible successful responses. Within a roughly comparable set of values and experiences, there remain differences among children which are too large to be accounted for by nurture" (p. 157).

Numerous other views have been held, such as Dunlap's theory of "fundamental desires," Woodworth's theory of preparatory and consummatory activity as the essential feature in drives, and Stern's concept of pheno-motives and geno-motives. Space will not permit a discussion of these here, but the reader may find a rather extensive treatment of most of them given by Allport (1937).

These conflicting theories serve to illustrate the difficulty of arriving at a comprehensive and integrated concept of motivation in character. However, a few suggestions will be given as proposed guides in the search for such a concept. The first suggestion is that the attempts to reduce the motivation for conduct to two or three pervading tendencies have probably oversimplified the native equipment of man. Such attempts have derived, in what often seems a forced manner, too much from a very few tendencies and have not given sufficient consideration to the possibility that there may be a multitude of unlearned patterns of response, rather than just two or three, which may form the cores for broad tendencies. We know that the child can without training make the responses of sneezing, coughing, and crying to appropriate stimuli. It seems no less certain that the human organism after a certain degree of maturation has an unlearned capacity to experience a tension-expulsion impulse on genital stimulation. This may be the core of the structure which, when elaborated, has been called the sex instinct. Thus it seems quite possible that there is a multitude of fine patterns of actions in the innate structure of individuals and that around these patterns motivations are built up. It is possible also that these patterns differ in strength from individual to individual and that they are integrated in different ways. Thus two children raised under the same evironmental circumstances might not be similarly motivated in the same situation.

A second suggestion to be offered is that the innate tendencies given by McDougall and others, and the "fundamental desires" given by Dunlap, and all the supposedly unitary factors in lists like these, are probably products of an intricate combination, elaboration, and integration of a multitude of simpler urges. The mainsprings of moral behavior are probably not few and simple, but many and complicated, and genetic psychology may in the future show us how these tendencies develop and from what biological nuclei. The more recent work on conditioning and on culture leads us to believe that the influence of training begins much earlier and has much more to do with the manifestation and relative potency of "wants" than the classical treatment of innate tendencies and biological drives has indicated.

Third, motivation for superior and inferior character responses is probably not static, but is evolving. This is, of course, in one sense simply a corollary of the conclusion that the motivation of behavior at any given time is dependent partly on conditioning and training. But, besides this, it seems probable that some of the innate patterns, such as the sex impulse, change with age because of the process of matura-

tion in the nervous system. Such a study as Gesell and Thompson's (1929), which indicated that growth in climbing ability among young children is partly a process of maturation in neural patterns, suggests that such a possibility is well within reason. The change in motivation with age is well illustrated by the work of Piaget (1932), who studied the nature of the rules made and followed by children in their own games and the reasons why they followed them. He distinguished what he calls two moralities among children. One he found in all very young children: an egocentric type of behavior characterized by a tendency to follow rules because they are handed down by elders. He found no tendency for the child, regardless of amount of training, to think of revising rules in games for mutual advantage, and he found nothing upon which he could build a desire on the part of the child to do this or that because of any "mutual respect of child for child." The second type of morality he found to have its beginning later in the life of the child than the first, but not suddenly to replace it—indeed it is not infrequently crowded out or prevented from appearing by the first. It is a morality motivated by a desire to change the rule in a game if in its working some child is not being treated as he himself would like to be. It is the beginning of the desire for creativeness, as opposed to conformity, in character.

No one probably would contend that Piaget's "two moralities," which we have used to illustrate our point of the changing nature of "wants," are due purely to differences in maturation. But Piaget's observation that the second one never precedes the first, coupled with the common observations concerning growth in cooperative play among children and the change in interests of youth with the maturation of the sex functions, leads one to believe that the "wants" of children change not only through training but also through maturation in neural patterns.

A fourth point which should be made is that motivation for character responses is not some potential power existing somewhere, unrelated to what the organism is doing at the moment, and waiting to be turned on like a starter in an automobile. Woodworth (1934) has particularly emphasized this and has pointed to the fact that any activity in progress may be a motive for the time being. As an illustration of this in the area of character, one would say that a child's motivation for truthfulness or honesty, lying or cheating, at any given time is a part of a chain of on-going activities; that is, his motivation is not unrelated to what he is doing and where he is.

Fifth, emotional conditioning may pronouncedly affect motivation. This is one of the interesting leads in research in character development which has not been followed up by much research. Leeper (1948) has given some careful attention to the interrelation between emotion and motivation in an attempt to achieve a testable theoretical formulation. Bekhterev (1928) has found in working with children afflicted with kleptomania, "in which the emotion of satisfaction is associated with theft," that reconditioning can take place in just a few sittings so that the feeling of extreme annoyance instead of satisfaction is associated with theft. Watson (1926) has found that the emotion of fear may be connected by a conditioning process with situations to which it was not previously connected, and that it may, by the same process, be disconnected from situations to which it was connected. It is surprising that so little attention has been given to this problem in studies of character development, especially in view of the fact that the church has made use of it to such a great extent, as have also primitive tribes,

particularly in connection with adolescent initiation ceremonies. It seems probable that one of the chief effects which literature, drama, oratory, and other arts may have upon character development is to link strong emotionally toned reactions to certain motivating forces of the individual.

Our sixth suggestion concerns conscious and unconscious motivation. It is a matter of common observation that very small children misrepresent facts oftentimes not as a result of any conscious desire to deceive but rather as a regular part of their wishful thinking and imagining. Among older children and adults a very large part of their honest behavior is a matter of habit, where it would be impossible to say that they are consciously motivated to refrain from lying or stealing. Moreover, the psychoanalysts have emphasized what they call unconscious motivation in cases where thwartings in certain lines of activity have led to "repressions," which in turn have led to undesirable acts which do not seem to fit in logically with any conscious motivation of the subject. Cases have been cited, for example, where a youth who has been thwarted in certain desires derived from the sex impulse may turn to stealing. From a practical point of view there seems to be no doubt that the genesis of stealing in particular, and other forms of immoral behavior to some extent, may often be traced back to some important conflict or thwarting. It is possible, however, to lay so much emphasis on this type of explanation as to make it seem that almost all character responses are motivated by what "escapes from the unconscious." It would seem a more inclusive and less mysterious explanation to say that conflicts play their part, as do all experiences, in affecting the on-going activity of the individual, but that it is the on-going activity at any given time, including conscious processes, reactions to frustration, and habit mechanisms, rather than some entity in the "unconscious," which provides the motivation for action.

The final suggestion which we wish to make is that verbalized concepts may motivate character responses. This point is implied in much that has been said about activity motivating further activity. Those who subscribe to the view that no behavior, regardless of how much it may benefit society, can be described as moral unless the motive of the agent is consciously moral will say that all motivation in moral behavior *must* depend on verbalized and conscious concepts. This problem has led to an age-old controversy in philosophy which cannot be reviewed here. Suffice it for our purposes to emphasize the contention that verbalized concepts do motivate moral behavior at times. As will be shown later, generalized principles and ideals are gradually built up in accordance with the laws of learning out of experiences which are verbalized. Once these verbalized principles are acquired, they become tools not only for considering the present but also for reconstructing the past and planning the future. Through them, the distant and the past are made a part of the here and now. With them, we build the goals we would achieve. By them, individual characters of the past and present, both great and small, may exert motivating influences upon us.

Such a verbalized concept, for example, as cheating-is-a-form-of-stealing may, under some circumstances, act as one motivating factor for honesty in an examination. In the presence of conflicting motivations the ideal of acting-toward-others-as-we-would-have-them-act-toward-us may become for the individual the prepotent "drive" in the situation. It would be a mistake, of course, to assume that the major part of the motivation in the character of children is dependent upon the prepo-

tency of such a highly complex concept or principle as the last one named. The goal of character development, however, is in that direction. The striking gap which so frequently exists between verbally expressed principles and actions has so impressed some observers that they seem to doubt or belittle the motivating power of ideals. The frequency of the gap must, of course, be granted. However, any account of character development which underestimates the potential motivating power of ideals and other verbalized principles, because they seldom if ever produce action completely consistent with them, would be short-sighted indeed. It would be guilty of discerning nothing in a direction of striving except the goals achieved and of minimizing worthy intentions that do not eventuate in full accomplishment.

Knowledge, Conscience, Aspiration, and Volition in Relation to Ethical Behavior

Knowledge. In popular analyses of ethical conduct it is often assumed that knowledge of "right" and "wrong" and the will to follow the right when it is known are the *sine qua non* of moral responsibility. This assumption is shown most interestingly in attempts made in courts and homes to decide upon punishment for misconduct. Roscoe Pound (1930) says, "Our traditional criminal law thinks of the offender as a free moral agent who, having before him the choice whether to do right or do wrong, intentionally chooses to do wrong." This clearly assumes, in the first place, that the individual knew which act was right and which wrong, and, in the second place, that the individual "willed" to do the wrong. Before the courts, an individual, whether child or adult, is considered to be either responsible for his acts or irresponsible. There are no in-betweens. If it can be established that an individual's powers have not developed sufficiently for him to know the difference between right and wrong or for him to have adequate "will power" to control his acts, then he is pronounced irresponsible for his acts. In many states, children under 6 or 7 years of age are considered irresponsible if they commit serious offenses, but children slightly older are considered responsible and are punished accordingly. In the home, too, it is sometimes assumed that young children should not be held very strictly accountable for their acts because they have not reached an "age of discretion."

One purpose of this section is to point to the oversimplification in the above concepts. In the first place, there is no point in the development of a child at which he suddenly passes from the age of irresponsibility to that of responsibility. Study after study has shown that children develop gradually in their moral knowledge as well as in conduct. Two or three such studies which deal primarily with moral knowledge may be cited by way of illustration. Written descriptions of 64 childhood situations were presented by Jones (1929*a*) to 177 children in grades 7 and 8. The instructions were that the proposed action in each situation should be marked as "right," "excusable," or "wrong." There were only 9 situations out of the 64 where as many as 90 per cent of these children agreed as to the rightness or wrongness or excusability of the proposed action. The same situations were presented to several hundred school teachers and prospective teachers, and among these there were only 12 situations where as many as 90 per cent agreed. These findings were subsequently corroborated by Maller (1932).

Even at the college level the question of cheating on quizzes and examinations seems to be a moot issue with many. An intensive study by Katz and Allport (1930), at

Syracuse University, revealed that 26 per cent of the college students examined considered "cribbing" to be as bad as lying or stealing, but that 22.5 per cent definitely condoned it. The remainder took stands in between these two positions. From these and similar studies it seems certain that persons cannot be divided into two categories, those who know the difference between right and wrong and those who do not. There is no time when one is suddenly endowed with ability to discern right from wrong. Strictly, there is no age that can be called "the age of discretion." Throughout life one is continually learning and modifying his views of the right and wrong, or, perhaps more realistically, of the "bests" and the "second-bests," as he faces new situations.

This leads to a second point of oversimplification in many assumptions about character and character development. It is that character is a matter of rather routine conduct and that problem solving and creativeness are not required. This is a serious error in conceptualizing on the problems of character and especially serious in educating for character development. Character cannot properly be conceived of as a mere repetition of learned responses.

New issues must be faced by every developing child, and with increasing maturity he must make his responses more and more independently of parents, teachers, or other counselors. In life, virtues not infrequently run counter to each other, and one has to choose among them. How does the individual arrive at his conception of what is the "right" course of action in a novel situation? The view subscribed to here is that ethical knowledge is derived by a process of generalization from past experience and that, the more the child is taught to generalize from his knowledge and conduct in those stages of development when he has guidance from parents and teachers, the more will he be able to use effectively the process of problem solving in novel situations. A young child who is properly taught learns that it is wrong to steal jam at home, a pencil at school, and candy in a store, but he may gradually generalize that stealing in any situation is wrong. Thus a hierarchy of values is built up. Any line of activity in a novel situation which in his judgment involves stealing will, therefore, be considered wrong.

As an illustration, consider a boy who for the first time faces the situation of not having his fare collected on a train, owing to the oversight of the conductor. He is confronted with the choice of keeping quiet and retaining his fare or of paying for the service which he is obtaining. In deciding what is right and what is wrong in this new situation, the boy may consider the paying of the fare as linked up with honesty, and the retaining of the money or ticket as associated with dishonesty. If this happens, he is no longer faced solely by the specific choice between paying and not paying, but he is faced by the choice as it has allied itself with the "honesty constellation" or the "dishonesty constellation." If, as a result of development and of training, the honesty constellation is greatly preferred to the dishonesty one, the choice between paying and not paying is largely made. Following this same reasoning there may be further interlinkages. The boy may look upon honest behavior as a sort of subhierarchy in the higher hierarchy of respect for rights of others and dishonesty as a violation of these rights for selfish interest. The simplest choice may be made, therefore, by an individual in the light of his most fundamental values. We call this choosing on "principle." But the principle is not some mysterious and suddenly acquired power for knowing right from wrong; it is an acquired generalization based on specific experiences.

A third oversimplification concerns inferring too much from the oft-repeated observation that knowledge of the right does not insure right conduct. The possible error involved is in underestimating the value of knowledge in character development of children and youth. Granted that knowledge of the right or the best does not guarantee action consistent with it, nevertheless, knowledge is important because one cannot choose the right in a situation except by utter chance if he does not have the proper knowledge or habit patterns. In all conscious choice, knowledge is a prerequisite both to wise and to ethical action. One has as much ethical obligation to keep informed, so that his actions may be rightly geared to changing needs in society, as he has to convert the ethical knowledge which he has into action. It is not alone the converting of ethical knowledge into action that we need in the realm of character and citizenship today; it is the converting of *better* ethical knowledge and values into better action.

Conscience. At this point we come to the crux of the age-old problem of conscience. We cannot hope to do justice to this very complex problem here, but we do wish to recognize it as a problem worthy of psychological study. Most psychologists today are very circumspect about the use of the term *conscience*, but they recognize that tensions accompanying the consciousness of an individual of a serious gap between what he thinks he ought to do and what he does are among the chief sources of personality conflicts.

Freud freely uses the word conscience, and we are indebted to him for what is probably the most systematic attack on tensions growing out of moral values that has been made from the point of view of instinct theory. To Freud, guilt and a sense of inferiority are manifestations of the tensions between the ego and the superego. But how is this superego or conscience built up? Freud (1930) thinks that the superego develops by the child's gradual "internalizing" certain controls upon himself, motivated by his early helplessness and dependence upon others. Thus, according to Freud, conscience grows out of child-parent relationships which go back fundamentally to instinctive bases. The child identifies himself with the parent and gradually the superego develops, taking over certain controls and exercising the same aggressiveness toward the ego that the father would have exercised toward the child. Out of concepts such as these, Freud builds a systematic structure of urges, controls, and tensions. French, Miller, and Riesman (1950), in discussing the relation of psychoanalysis to ethical values and conduct, maintain that psychoanalysis should aid the patient to find his own moral values. They believe that psychoanalysis contributes to ethical behavior in several ways, in its emphasis on absolute honesty.

In some of the more recent work in anthropology and psychoanalysis less stress is being placed on instincts than characterized Freud's own writings. More emphasis is being placed on early conditioning and cultural influences. Sherif (1948), for example, says that there are acquired motives related to the genetically developing ego values of the child which are not derivations of biogenic needs. "These ego values," he says, "which collectively may be referred to as *conscience*, are incorporated from the prevailing values or norms of one's group; they are imposed by parents, school, church, play group, clique, etc. These ego values thus derived . . . are not, in many cases, conducive to the satisfaction of biogenic needs or the 'derived drives' traceable to them" (p. 36).

Kardiner (1939), maintains that Freud's explanation falls short in that it does not give sufficient recognition to the depend-

encies, affections, and values which are built up from the earliest age by direct conditioning and learning from the social environment. He says: "In his orientation on instinct, Freud left little room for the operation of societal influences."

Horney (1937) also stresses the cultural basis of many of the wants, values, and aspirations of individuals, and contrasts this approach with the more purely instinctive and biological approach of Freud. This author particularly emphasizes the important rôle played in anxiety and other neuroses by the conflict between what the individual does and what he feels is expected of him, and illustrates (1948), in the case of vindictiveness, how therapy should help the individual to avoid or overcome ethically unacceptable behavior in the interest of his adjustment.

There is much to be said for extending the sources of moral standards, values, and ideals along the lines suggested by Kardiner, Horney, and others. That one has the power to acquire conscience is a gift of nature. The limits to which one's conscience can be made sensitive to intricate and subtle distinctions are probably dependent at least in some measure on native endowment. There may even be certain biological conditions or prepotent impulses which influence the kind of conscience which an individual develops. But, within certain very broad limits, children and adults acquire their consciences by reacting to the stimulation which such factors as the home, friends, church, school, and the over-all culture afford.

Level of Aspiration. The nearest approach which has been made by laboratory experimentation to the above problem is the work on *aspiration level.* Hoppe (1930), who did pioneer research on this problem, defined level of aspiration as the goals, the expectations of a person, or the claims on his future achievement. In his experiments he was not concerned with aspiration in any ethical sense. Some of his results and conclusions, however, like those of others who have worked on the problem, are suggestive in the present discussion. He found, for example, that success on the part of a subject in reaching his aspiration level encouraged him to try harder tasks, whereas failure had the opposite effect.

Child and Whiting (1949), working in real-life situations, also find that success generally leads to a raising of the aspiration level and failure to a lowering. Moreover, they find that shifts in the levels of aspiration of a subject are a function of changes in his confidence in his ability to attain the goals. Weber (1946) adds the finding that excess of level of aspiration over performance is often associated with aggression and emotionality. Gould (1939) concludes that different subjects react differently to the gap between level of aspiration and performance. Some subjects react to feelings of failure by trying to do better; others by becoming discouraged and losing the desire to go on; others by overcoming the consciousness of the gap by dreaming of success, making excuses, etc.; and still others by various combinations of these.

Volitional Factors. In many treatments of character the gap between knowledge of desirable conduct and action consistent with such knowledge is attributed to weaknesses in volitional factors. Indeed, not a few writers consider volition to be the central problem of character and maintain that strong characters are strong primarily in will and that weak characters are weak in will. Stephenson (1935), for example, says that it is "in the sphere of volition and conation that we hope to find the secrets of character." With the concept of character held in this chapter we cannot accept the thesis that character is a function of volition only, but there is no question of

the importance of volitional factors in character and in character development.

Attempts to study the phenomenon of volition and to show its relation to conduct fall under two headings: (1) studies involving factor analysis which reveal clusters of related or similar behavior in different situations, and (2) studies of conduct resulting from damage to certain physiological bases of volition due to drugs, toxins, etc. The latter studies indicate the importance of giving attention to the biological and emotional constitution of the individual as well as to his environment in the investigation of character development.

Among the factor-analysis investigations we may mention especially those of Webb, Spearman, Reyburn and Taylor, and Cattell. Applying factor analysis to tests and ratings of character, Spearman (1927) and Reyburn and Taylor (1939, 1943), for example, have obtained evidence for what they call a *w* or will-character factor. Cattell (1946) gives an extensive review of factor-analysis research and cites many studies as revealing a close clustering or "factor" in this area. Some of the characteristic forms of behavior which are found in a cluster, and on which the individual tends to be consistently high or low, are: persistence, perseverance, stability in pursuit of objective, resistance to distraction, determination to carry through what has been undertaken, resolution, strength of purpose, and the like.

The important point for our discussion here is not so much whether the clustering is close enough to justify the concept of a general factor of *w* but rather that close clustering has been found indicating a relatively high degree of similarity in the conduct of an individual in different situations involving volitional factors.

In many discussions of volition the implication seems to be that the contributions of early conditioning and general nurture are being underestimated. This is not the implication intended here. Our search is for the factors which, with any appreciable degree of consistency, motivate, limit, guide, or influence character responses of children. Conditioning and other learning influences which affect volitional behavior are recognized here as having already made their contributions to the volitional behavior as we see it at any given time in the life of the child. Any consistency in behavior which is found, therefore, may be as indicative of consistent conditioning and learning of a given individual in his environmental and cultural setting as it is of possible native factors upon which the culture and training operate.

A second line of research in this area to be discussed is that concerned with the physiological bases of volitional behavior and the influence upon such behavior of changes in or disturbances of these bases. Numerous studies have been made which throw light on the effects of drugs such as Benzedrine, Pervitin, sodium amytal, marihuana, and alcohol on persistence, resistance to fatigue, strength of inhibition, and other evidences of willing behavior. One or two illustrations will suffice to indicate the relevance of such researches to the problem at hand. Cuthbertson and Knox (1947) studied the effects of Benzedrine and Methedrine on subjects whose activity had been greatly reduced by fatigue. They found that both drugs increased output on the ergometer under such conditions, Methedrine being the more potent. It was as if certain volitional powers had been increased. We do not know, of course, that the change in behavior was mediated directly by any changes in volitional factors, but the connection is close enough to indicate that investigations of this type should be undertaken by the student of character development for possible clues

concerning this important but elusive factor of volition.

Charen and Perelman (1946) have made a clinical study of 60 men addicted to marihuana. They conclude that marihuana weakens the "controls of the superego." Baruk (1949) has experimented with a drug and a toxin and reports that part of their effect is to reduce voluntary powers.

So much for a very brief review of some of the objective results on volitional factors and their relation to character development. That the ground has scarcely been scratched in this complex area is very apparent. It seems safe to say at least tentatively that, on the one hand, physiological and other unlearned factors and conditions of the individual so affect his volitional powers that these can never be ignored in character development; and that, on the other, the volitional habits, the motivations, and the goals of striving which the individual acquires greatly influence the effective strength of his volition and largely determine the directions in which it manifests itself in conduct.

Consistency and Inconsistency in Ethical Behavior in Relation to Trait Theory

One of the most interesting theoretical problems in the study of character is the problem of the consistency or inconsistency in the behavior of an individual in different situations involving honesty, cooperativeness, persistence, and other so-called traits. There is a considerable body of evidence on this problem, most of it consisting of correlational studies in which children's scores on one measure of a "trait" are correlated with their scores on another measure of the same trait. As will be seen from the few typical results on actual performance tests given below, there is relatively good agreement among the statistical results obtained by the different experimenters. Jones (1936), working with 185 seventh-grade pupils, found an average inter-*r* of .35 among three performance tests of honesty in school situations. Hartshorne and May (1928, 1929), using elementary and junior high school children as subjects, found an average inter-*r* of .39 among four tests of honesty. Crutcher (1934) reports a median inter-*r* of .47 among six persistence tests on children ranging in age from 7 to 16.[1] Gross (1946) conducted an experiment involving 229 seventh-grade pupils in honesty under several different conditions and found that only two-thirds of the students who were dishonest on one occasion were dishonest on another. These, we believe, are fair samples of the results that have been obtained, and we need not multiply the evidence.

What does all this mean so far as specificity or generality of traits is concerned? On the face of it, it means that an observer cannot predict very accurately what a child's unanalyzed behavior will be in one situation involving a supposed trait from his behavior in another situation presumably involving the same trait or trait name. For example, a child may be honest on a test where he has a good chance to cheat, and yet he may dishonestly get an advantage over other pupils in a prize contest by peeping when he has promised to compete with his eyes closed. Moreover, a child may cheat under one teacher but not under another.

In studying lying among children, Blatz (1952) distinguishes four types of lies, and the implication is that a child would

[1] It is interesting in passing to compare these inter-*r*'s among different tests within the same "trait" with inter-*r*'s among different "traits." Jones found an average inter-*r* of .15 between each of his honesty tests and a test of cooperation. Hartshorne and May found an average inter-*r* of .21 among tests of honesty, helpfulness, self-control, and persistence.

not necessarily behave consistently in situations involving the different types. The types which he mentions are: (1) lies of fantasy, involving imagination and partly unconscious and partly conscious misrepresentation; (2) lies of distortion, including conscious and unconscious omissions, overemphases, and underemphases; (3) lies of loyalty, deriving from the desire to belong, to be accepted, to be loyal to an individual or group; and (4) lies of self-protection involving deceit to avoid the consequences of one's behavior. From such observations and statistical results some are led to question the concept of generality of traits and stress specificity, much as Symonds (1928) has done. "It has been found," he says, "that no one acts perfectly consistently with regard to a trait as would be the case if conduct was an expression of inner traits" (p. 320). He admits that conduct under a given trait name may be generalized by responding to the likenesses and differences in situations, but he concludes that this generalization of conduct does not extend as far as the advocates of a generalized trait theory suppose.

Allport (1937) and Cattell (1946), starting with the same statistical results as Symonds, come out with a very different interpretation from his. Allport calls attention to a correlation of .13, found by Hartshorne and May, between stealing small change and the telling of lies about cheating, and he admits that the "dishonest habit aroused by one of these situations is quite independent of the dishonest habit in the other." He maintains, however, that under this surface specificity there are generalized traits. He admits that a given child who is tested may not steal money and yet may cheat in school and lie about the cheating. But he interprets this as showing not so much the lack of a general trait of honesty as the presence of a general trait of timidity. "Each of these children," he says, "behaved as he did toward these tests, not because of specific habits but because he had some deep-lying and characteristic trait" (p. 251). Cattell follows essentially the same line of reasoning in asserting that back of observed inconsistency in behavior there must be a trait. He says: "Just what degree of consistency—i.e., what reliability or consistency coefficient—one should demand in behavior manifestations to justify a trait is an arbitrary matter, best left for discussion when more data have accumulated on trait consistency" (p. 128). This concept of traits is so elusive that any hope of testing its reality in relation to conduct seems very remote.

These are illustrations of the different interpretations based on the same facts. Without ignoring the factual data involved in the low correlations among different aspects of behavior usually classified under the same trait names, it seems possible that we may avoid the morass of complete specificity, on the one hand, and the elusiveness of traits at any cost, on the other, by going back to an analysis of the behavior of the child. First, we should make a distinction between the behavior of a child as seen by an observer or revealed by a test, and the behavior of the child as looked at from his own point of view. If we could put ourselves in the child's place there seems little doubt that we should see much more consistency than his unanalyzed behavior reveals. This would be true because a situation which is designed from the point of view of the examiner to test honesty may not test honesty—and nothing but honesty—from the point of view of the subject. A child, for example, who refrains from cheating with one teacher but cheats freely with another may not think of the two situations as comparable at all. He may not cheat in the one case because he feels that he is on his honor not to try to "put anything over" on someone who treats him

fairly and whom he likes; he may cheat in the other because he considers it an opportunity to "steal a march on," or to get even with, someone whom he dislikes or distrusts. As observers of only the honest-dishonest aspects of these situations, we might well conclude that honesty for this child is not very highly generalized. If, however, we view the total situations from the child's position we see more clearly how the behaviors that become classified by adults under a trait name are not necessarily one thing psychologically to the subject but perhaps several things.

Another point to be considered is that generality or specificity of traits probably varies with the age and training of the individual. There is no clear-cut statistical or experimental evidence which can be given here to demonstrate this, but all that we know of early conditioning as well as later learning of children leads us to believe that there should be greater specificity of conduct at the lower levels of learning and greater generality at the higher level.

One of the main theses of this chapter is that development in character should be away from specificity and in the direction of generality. When a child at a very young age makes a response which is judged to be undesirable or wrong in a situation, there come along simultaneously from the parent disapproving gestures, facial expressions, vocal tones, or such words as "no-no," "that's bad," "that's wrong," "that's not yours," "that's being a tattletale," "that's dishonest." By repeatedly experiencing annoyance in connection with a response or class of responses the child is conditioned against it. On the other hand, if the child makes a response which is judged to be the proper one, his action is rewarded by a smiling countenance, approving gestures, and such words as "that's a good boy," "that's right," "that's being honest." He has similar experiences on every side, and, just as he learns gradually the names and uses of objects, he learns that certain acts are looked upon with approval and others with disapproval. This is the beginning of the process of generalizing, but his generalizations are based on only a very few acts which he has learned are not approved of and which he pronounces in a parrotlike fashion to be bad. At this stage of development a child's conduct seems to be highly specific.

But, as time goes on, the child finds that there are approved-of or not-approved-of aspects in a large number of situations; he learns that such words as "right," "wrong," "ought," "mustn't," "truthful," "untruthful," "honest," "dishonest," "loyal," "disloyal" refer to certain common factors in many situations. No other behavior of his is so violently responded to by adults as that where questions of right and wrong are raised, and consequently no other becomes so quickly and so thoroughly emotionally toned. With the increasing ability of the child to use verbalized concepts goes increasing use and understanding of the generalizations of right and wrong, good and bad, honesty and deceit, loyalty and disloyalty. He experiences what is referred to by various trait names in a great variety of situations. Gradually there develops whatever consistency of behavior occurs under trait names for him. These trait names assist him to generalize further, and emotional accompaniments become increasingly attached not only to specific acts but also to classes of acts. This process continues into adulthood.

However, even when an individual reaches his highest stage of maturity we cannot say that his traits are completely generalized in the sense that we can predict with anything like absolute certainty how he will behave in a relatively new situation involving a "trait" in which we rate him highly. When we describe a youth or man as hon-

est, for example, we do not mean that we have observed any unitary or generalized trait of honesty on his part. We mean only that we have observed honest behavior in his case in a variety of situations and that we predict that in further sampling of situations he will respond similarly. This prediction is made partly on the assumption that in new situations involving honesty which he will face he will have systems of detailed habits that will make highly probable such and such conduct and partly also on the assumption that he has a certain orientation, a certain hierarchy of values, which will tend to insure behavior consistent with it.

Unfortunately, experimental facts are not available by which to test the above hypothesis that generality increases with growth in character. Taking all things into account, however, it seems that neither thoroughgoing specificity nor generality is likely to be adequate in any universal sense. The degree of specificity or generality characterizing an individual's conduct will depend, we believe, on his maturity and character development. Thus in attempting to fit our concepts of traits and trait names to the facts of child behavior we conclude that the degree of generality of a "trait" is dependent upon what is subsumed under the trait name and upon the stage of development of the individual.

Some Practical Observations on Character Development

In concluding this chapter a few practical suggestions concerning character development in home, church, and school may be in order.

The Importance of Early and Continuous Training in Character Development. In some of the older doctrines, before the advent of modern research on child development, great faith was placed in sudden changes in the character development of children and youth. The old notion that a child rather abruptly reached an age of moral responsibility after which time he could be "reasoned with" is one illustration of the belief in sudden changes. It is not our purpose here to maintain that rather sudden changes in the values and moral outlook of individuals never occur. Sufficient psychological data are not available on the dramatic cases that are usually cited in support of sudden changes to enable us to judge, but such cases are at least rare in comparison with the multitude of individuals who develop gradually from day to day.

The parent or the teacher who waits for the sudden dawning of an age of discretion seems, in the light of research results on mental growth, to be doomed to disappointment. While parents wait for their small child to be "old enough to understand," certain preliminary orientation of the child is achieved about the relative importance of truthfulness and of not getting caught. Young children have often learned a great deal before their parents stop recounting with amusement their "cute" escapades and "white lies."

Teachers, also, often delay too long or overlook good opportunities in giving early training. Such a simple lesson, for example, as the distinction between mutual helpfulness among classmates and cheating is frequently put off or taught only sporadically until serious confusion develops. The result is that many children in our elementary and secondary schools do not consider cheating an ethical question at all. It is rather a question of what one can "put over on" the teacher and what one can "get by with" in general. What an older child subsumes under the concepts of honor, cheating, tattling, or being a goody-goody or a thief, and what his emotionally toned attitudes toward these are, at any given

age, are dependent in no small degree upon his conditioning and learning which began very early. Ethical concepts and behavior are continuously in the process of formation and revision throughout life, of course, but the earlier a child is oriented toward desirable conduct and generalizations, the earlier does he begin to internalize the controls upon him and to evolve his own sense of relative values.

Motivating Character Development. A child learns desirable character responses (1) in accordance with the principles of goal seeking and (2) by experiencing satisfaction in connection with those responses which are ethically and socially acceptable and annoyances with those which are undesirable. Thus meaningful goals, rewards, and punishments are basic in character development as in all learning. Probably in no other form of learning however, is it quite so important that they be adjusted accurately to the stage of development of the child.

Much evidence is accumulating to indicate that reward is usually more effective than punishment in character development. Punishment is being found to be valuable mainly as a deterrent to specific forms of undesirable behavior, since it lacks the constructive qualities to reveal or motivate desirable conduct except in the very simple situations where the right response is the opposite of the wrong. Evidence is also tending to indicate that intensity of rewards and punishments is less important than the promptness and consistency of their occurrence, especially in the early periods of development of the child.

Tangible awards for desirable character responses are sometimes valuable means for making such responses satisfying, but they are ordinarily valuable only in so far as they become progressively unnecessary as the child grows older. If at any age tangible awards tend to establish and perpetuate desirable conduct only as responses to these artificial stimulants, thus failing to internalize the motives, they are to that extent undesirable, as Dimock and Hendry (1929) have interestingly demonstrated.

The types of rewards which seem to be most universal and permanent are those involving social acceptance and approval. Manifestations of genuine approval in the form of compliments, personal acceptance, and added responsibilities are among the strongest satisfactions for a child when they come from an adult or an associate whom he admires.

As an individual becomes older, he never becomes insensitive to social approval, but a more and more important place may gradually be taken by goal seeking and by the satisfaction accompanying the consciousness of self-approval or inner harmony in one's strivings. As Dewey says, "The community without gradually becomes a forum and tribunal within."

Thus, in the most advanced stages of character development, the most important function which the teacher can perform is to show the learner how each new problem in conduct is related to his existing patterns of generalized responses which already have strong emotional attachments and satisfactions connected with them. Once an act is viewed as being in harmony with one's ideals and values, it becomes satisfying in its accomplishment and in its anticipation; once it is viewed as out of harmony, it becomes annoying. Perhaps most of the choices of life are made at lower levels of ethical consciousness than this, but the choices with the greatest significance to character are probably made in this manner. All teaching of youth should make provision for the development of such inner goals and satisfactions. Without such internalized motivation character would always depend upon the short-range stimulation of more or less externally de-

rived rewards and punishments and would lack the sustained pull of goal seeking in the pursuit of ideals and values.

Generalization and Transfer of Training. In character development, as in all other aspects of development where learning plays an important rôle, one of the major practical problems is the degree to which training received in one situation will function outside the narrow confines of that situation. Much research has been directed to this problem, and a review of it would be rewarding, but space limitations prohibit it. Suffice it here, therefore, to draw from this research two observations which bear particularly upon character development. One is that the learner in developing the responses which are called by any trait name should, in the interest of consistency in the application of this trait, be led to practice such responses in a variety of situations. To provide such a variety of situations for the common learnings which society demands, there should be the greatest possible joint planning and cooperation to this end among all the institutions of a community which are concerned with the character development of children.

The second observation is that, in the interest of generalization and transfer, learners should be stimulated and assisted to respond to the *relations* among the various manifestations of a trait in different situations. The potential power of children to generalize has been repeatedly emphasized in this chapter. However in learning honesty, for example, unless the child is assisted in culling out the honesty "element" in a variety of situations and in generalizing the honesty concept, he is left without the most promising bridge between one honesty situation and another, and his concept of honesty is in danger of becoming or remaining an unorganized, unintegrated collection of "do's" and "don't's."

The synthetic process of gradually building up trait concepts and other generalizations, and the analytical process of seeing "elements" in new situations to which these generalizations apply, should go hand in hand. The most realistic and challenging education in character which is supplied by home, school, and church functions largely in the area of stimulating children and youth, on the one hand, to generalize, and thus evolve the goals and values they would achieve, and, on the other, to analyze out of the ever new and increasingly complex problems of their everyday world the ethical issues at stake and to solve these problems in conformity with the highest principles and values which they have attained.

Conclusion

The aim of this chapter has been to raise some of the main psychological problems involved in character development and to present evidence or clues wherever possible toward their solution. Character has been considered as a dynamic concept involving both psychocultural determinants and inner creativeness. It involves the sum total of the attitudes and those ways of behaving of the individual which are the correlatives of his regulative habits, values, and volitional drives.

Both native and environmental-cultural factors have been studied, the central thesis of the chapter being that the child acquires his character in conformity with the principles of conditioning and learning, but that the possibilities for such acquisition and the broad limits thereto are provided by nature. Thus character development has been studied in as naturalistic and realistic a setting as possible. However, it has not been thought of in any narrowly deterministic fashion which rules out the possibilities of creativeness in the evolution of values to which one gives allegiance. The

environment conditions but does not control either conscience or values. It is this very independence and creativeness of the human being in passing judgment upon his own conduct and the goals he would achieve that gives character development its chief interest as a field of study and holds out the possibility that it is in this area that the most important integrating and regulating forces of personal and social conduct will be found.

CHAPTER 14

EMOTIONAL DEVELOPMENT

ARTHUR T. JERSILD

INTRODUCTORY

This account draws heavily upon studies of children but it calls upon other sources. The content of this chapter has been influenced by behavioristic and gestalt psychology and by academic psychologists who are not identified with either of these schools (e.g., McDougall), and it represents also an effort to integrate findings of developmental psychology with fruitful developments in psychoanalytic psychology.

The first few paragraphs which follow are not documented in detail. They deal with elementary matters, but they are a necessary introduction to the conceptual framework of the chapter as a whole.

THE MEANING OF EMOTION

To be emotional means to be moved. "Emotion" is a label for a vast range of psychosomatic states. When these states occur, it is by virtue of the fact that something is occurring in the external environment or within the organism itself which thwarts or threatens, furthers or enhances, the process of living.

On the subjective side, an emotion involves *feeling*. The feeling may be quite clearly defined (as when one feels a surge of anger and is aware of it), or it may be vague and difficult to describe (as often is the case when one is anxious). Feelings not only fall on a scale of varying degrees of pleasantness and unpleasantness, but they occur also in indefinitely numerous qualities.

Also on the subjective side, emotion usually involves *perception* or awareness of an event or circumstance which the individual has feelings about or to which he attributes his feelings. It is necessary to say "usually," for strong feelings may occur without a clear perception of what brings them about. This is especially true of feelings that occur by virtue of "hidden" motives and "inner" conflicts and other subjective conditions which the individual is unable clearly to define to himself.

Emotion also involves a more or less clearly defined *impulse* or disposition to action, such as an impulse to fight or flee, or a striving to attain or to sustain a condition that produces joy, or a quick mobilization of one's defenses if something threatens one's pride.

The bodily features of emotional behavior involve *visceral* activities, including a variety of reactions of the glands and of the circulatory, respiratory, and digestive systems, as well as activities of the *skeletal muscles* such as occur when an individual strikes out or retreats or makes subtle postural adjustments, or displays subtle changes in the expression of his face. Muscular activities also include those of the vocal organs that come into play in weeping, outcries, and laughter.

The total response that takes place or that emerges during emotional behavior may be of a highly explosive, *disorganized*

character, or it may, at the other extreme, take the form of highly *organized*, well-coordinated behavior that is nicely adapted to cope with a disturbing event or to take advantage of a joyful opportunity.

As already implied, the term emotion, as here used, covers conditions of both a "positive" and "negative" character, conditions in which the organism may be described as being eager, zestful, jubilant, and *moving toward*, as well as conditions in which it is disturbed, distressed, and *moving against* or *away*. It is necessary to emphasize this rather simple point, for often in psychological writings emotion is treated primarily as a form of disorder and distress. Indeed, much of the literature has treated emotion as though it were a rather sinful state, or at least a nuisance.

WHAT GIVES RISE TO EMOTION?

Emotion is involved in the whole business of living. The most obvious occasions for emotion are those involving bodily harm or threat of violence or of being overwhelmed. But emotion may also be elicited by any condition which thwarts or threatens or which furthers or enhances the gratification of a person's needs, as he perceives them, or the realization of his goals, or which blocks or expedites a disposition to action or behavior tendency (recognized or unrecognized, "conscious" or "unconscious") which he has acquired in the process of adapting himself to the demands of life. Emotion is involved in anything in which a person sees himself involved. For this reason, to understand the child's emotion it is necessary to take account not only of the objective stimulus situation and of his overt behavior to this situation but also of the subjective system known as the self which, while not directly observable by others, is to the person himself the most important reality of his existence.

MOTIVES AND NEEDS

To understand emotional development we need a theory of motivation that takes account of elementary needs for safety, sustenance, and shelter which all creatures have in common, and of the particular needs that develop in the life of the individual child because of the capacities he possesses and the kind of person he turns out to be.

Writers in recent years have stressed the need for a broad conception of human motivation. Many of the "propensities" which McDougall (1926) listed before behaviorism was in full cry have stolen back into the literature, although mostly under new names. In addition to primitive needs for sustenance, shelter, and safety, many writers have emphasized tendencies within the organism to realize itself, to utilize its capacities, to exercise its powers. There are just as many potential impulses as there are potential abilities. Goldstein (1947) speaks of the organism's tendency to *actualize* itself as the basic drive. Man does not strive merely for self-preservation but is moved to manifest spontaneity, according to Goldstein.

Murphy (1947) similarly emphasizes the tendency of human beings to utilize their powers by virtue of motivation other than that involved in the need for physical survival. Maslow (1943 and 1948) speaks of needs as arranged in a hierarchy of prepotency, ranging from physiological needs to the needs for esteem and self-actualization. According to Maslow, when the most prepotent need is satisfied, the next higher need emerges, so that man is a "perpetually wanting animal."

In the psychoanalytic field, many writers have stressed a view of human motivation which emphasizes the broad range of human potentiality. Horney (1945), for example, stresses the importance of relation-

ships with others and of the attitudes of others as factors in the development of a person's "real self" and of his fictitious "idealized self" and the intrapsychic needs and defenses which are mobilized in connection with the maintenance of the self-picture. Fromm (1947) speaks of man's efforts to become what he potentially might be. Saul (1947) and Fromm speak of the normal person as one who uses his powers in a *productive* manner. F. Alexander (1948) follows Freud in speaking of both love and play as erotic phenomena, but he goes beyond this to speak of these phenomena as not designed merely to save energy, but to expend it in creative and progressive ways that lead the organism toward new ventures and experiments. The energy children expend in an experimental and playful manner is not simply being used for homeostatic stability or survival.

In listing human motives, the common practice is first to name physiological drives that are directly connected with *physical survival* and *bodily comfort*—the need for *food*, for *drink*, for *air*, for protection from extremes of heat and cold, and the need for excretion of waste.

Another need or drive in this category pertains to sex. Although the sex drive does not reach its "mature" form until puberty, there are many indications, as will be pointed out below, that erotic behavior of some sort is manifested in early infancy and that it appears in various forms throughout childhood years. Later we shall refer to behavior which, according to surface indications, is erotic in character but which functions as a symptom of or vehicle for other motives.

Under this heading, we probably should also include a *parental drive*, although this drive does not define itself as clearly as the hunger drive. Evidence from the study of animals (Warden, 1931), and observations of adults (see, e.g., Thorndike, 1913) indicate that at least on occasion and in certain individuals the drive or drives that lead a parent to be with and to care for an offspring are very powerful. Whatever is "primitive" or visceral about the drive will, of course, in the human being, be embroidered and perhaps even be clouded by other motives. The parental drive cannot, of course, operate in children as it can in a mature person who is capable of begetting children. But the writer believes that, if we grant that such a drive exists at all, we must also assume that it, like other features of human nature that sooner or later emerge in the life process, probably has a developmental history extending back into earlier youth or childhood.

The drives named above have sometimes been called physiological or visceral drives. Some writers have unkindly referred to them as "lower" drives. They have also been called "primary," "vital," or "prepotent" drives.[1] Although we can speak of a person having cravings when hungry, cold, or thirsty, or subject to other visceral needs, there is not a clearly defined set of emotions paralleling each of these drives. However, the way in which the child is permitted to satisfy these needs, and perhaps, to an even greater extent, the rules, restrictions, and restraints which surround these needs, frequently arouse emotional response from early infancy onward. Probably also from a rather early age thwartings or deprivations connected with these drives take on a larger meaning. To a child who is able to formulate an idea of the possible *intentions* of others, denial of food when he is hungry may mean a denial or rejection of *him*.

Apart from drives such as the foregoing which are important for bodily preservation, reproduction, and repair, the organism is equipped also with *activity* drives,

[1] For accounts of motivation, see, e.g., Young (1943), Tolman (1932), Maslow (1943 and 1948), Murphy (1947), O. Klineberg (1940), H. A. Murray (1938).

drives to *use* and *exercise* its capacities. These drives appear in ways too numerous to permit classification, but certain broad categories can be noted.

There is a drive for *muscular activity*. This is especially prominent in young children, who are notoriously "on the go." Muscular activity is the vehicle for many joyful experiences of childhood, and enforced inactivity is a fruitful source of frustration. A drive to use muscular coordination often is especially noticeable when the child is in the process of making a new hurdle in his motor development, such as walking or climbing (Shirley, 1931; Damann, 1941).

There also are drives leading to the use of the *sense organs*. The child feasts upon sights, sounds, cutaneous contacts, and other sensory experiences. In speaking of the "sensory drives," Murphy (1947) points out that they may be intermingled with the "visceral drives," as when appetite for food is influenced by the color of the food.

The gratification of sensory drives probably accounts in part for the emotional content of intense esthetic experiences.

Under the broad heading of activity drives we may also include the *drive to use the intellect*. Moore (1948) states that "Every mental ability, every function, has a native tendency to set itself in action" (p. 108). In due time, the normal child is eager to find out, to explore, to discover. Many children go through a period of avid questioning about the what, how, when, and why of things. We might call this a drive for *cortical activity*, or, in more commonplace language, simply the exercise of curiosity, which is an abundant source of satisfaction. Shand (1920) named curiosity as one of the important impulses on his list. McDougall (1926) listed curiosity as one of the principal instincts and named the emotion of *wonder* as linked with this instinct.

Needs which overlap those described above have also been referred to in such terms as the need for *achievement*, for *discovery*, for *new experiences*.

Another group of needs which can be observed but which are not easily defined are needs for *love, affection*, and *belonging*. Whether these needs are "primary" in the sense that a child needs love as such, or whether his need for all that love brings and all that it implies springs from his initial helplessness or develops as a "conditioned" product of treatment he receives from loving parents, need not be debated here. Whatever may be the conditions that spur an infant to need love, he shows in countless ways in the process of his development a need for affection as coin that has value in its own right regardless of the source from which it derived its value.

As the child matures, he not only exhibits a need for receiving affection but also manifests affection for others.

Other needs that develop in a child's relations with other persons have been described in various terms, including the need to *belong* and various forms of *gregariousness* which are influenced to a large degree by learning, but which lead a person to be a joiner, cooperator, imitator, dominator, competitor, or a follower or a leader, or, at different times, all of these. Drives connected with his relations with others may also take the form of *need for approval, need for recognition*. These needs pertaining to a child's relationships with others, his link with the society in which he lives, have been emphasized as being of crucial importance in the development of the subjective system known as the self (see, e.g., Mead, 1934; Horney, 1950; and Sullivan, 1947). Sullivan's account of the social (interpersonal) origins of the self are especially persuasive and provocative, and they raise

a host of research questions for the worker interested in developmental psychology.

According to some writers (notably Sullivan, 1947) a child is capable of responding emotionally, through a process of empathy, to the attitudes of a significant person who has charge of him. However, this is a speculative matter, and it represents one area, of many, that requires research of a kind that deals not only with the objective environment but also with the subjective environment represented by the child himself.

The needs for approval and recognition overlap with needs associated with the growing child's developing concept of himself. As the child develops and acquires an increasingly differentiated idea of himself, he also acquires a need for satisfactory feelings about himself—a need for self-esteem, a desire, as Maslow (1943) puts it, for a "stable, firmly based, high evaluation of himself . . ." (p. 381). In commenting on this, T. V. Moore (1948) states that whatever convinces one of his excellence and importance ". . . awakens a satisfaction which once experienced is ever afterwards craved and so constitutes a powerful driving force of human nature . . ." (p. 244). Anything that enhances the self-idea may lead to feelings which are experienced as a form of exaltation, or strong feelings of self-confidence, whereas anything that leads in the opposite direction, or threatens so to do, may cause depression, gloom, "feelings of inferiority," discouragement, or fear. McDougall (1926) anticipates these observations on his list of instincts, which includes an instinct of "self-assertion" (or self-display) and, tied to this, a primary emotion of elation or positive self-feeling. We shall have occasion to discuss below conditions that give rise to feelings of joy and satisfaction relating to self, and conditions that lead to gloom or anxiety may occur not only as a result of a need for approval and esteem in the eyes of others but also, as the child grows older, from a great need for self-approval.

The needs associated with a person's idea and appraisal of himself include both desires for enhancing his self-esteem and also strivings to preserve the integrity or consistency of the self. The classical concepts regarding protection of self originated with Freud, who spoke of the ego and its defenses. The struggles a person may undergo to live up to, preserve, and vindicate an idealized version of himself have been described by Horney (1945, 1950) and others. Snygg and Combs (1949) maintain that the "basic human need" is the "preservation and enhancement of the phenomenal self"—the self of which a person is aware (p. 58). The rôle of the concept of self in emotional behavior has been set forth by several authors, including the writer (Jersild, 1947). The ideas a person has about himself, his attitudes and ideas as to what a person such as he should be expected to like or dislike, do or not do, accept or hate or fear, will be important in determining whether a certain happening is a threat to be warded off or a temptation to be feared or an occasion for joy or a cause for remorse. The position that pleasant and unpleasant emotions are especially likely to occur in connection with circumstances that threaten or challenge or help to unify the self has been set forth in a book by Lecky (1945).

Earlier Accounts of "Primary" Emotions

Many students of emotions have tried to identify what might be regarded as primary or original emotions which all creatures have in common and which might be regarded as providing the basis for the countless mixtures, nuances, and gradations of

emotion which we identify in the language of everyday life. Lists of emotions that have been proposed as the primary emotions are of historical interest.

Shand (1920) listed seven emotions: fear, anger, joy, sorrow, curiosity, repugnance, disgust. Ribot (1903) described the "primitive" emotions as fear, anger, affection (from which later are derived the "social" and "moral" emotions), self-feeling or egoistic emotion, and sexual emotion. McDougall (1926) listed seven pairs of instincts and correlative emotions, including: flight–fear; repulsion–disgust; curiosity–wonder; pugnacity–anger; self-abasement (or subjection)–negative self-feeling; self-assertion (or self-display)–elation (positive self-feeling); parental instinct–tender emotion. Watson (1919) and Watson and Morgan (1917) confined the list to three: fear, rage, and love. Hollingworth (1928) suggests that these reactions, as distinguished from the more highly differentiated emotions of later life, might be designated as startle, resistance, and content, and that a fourth form of response, gloom, be added.

Changes in the Conception of What Constitutes an Emotional Stimulus

In connection with past efforts to identify distinct emotional states there have been efforts also to describe what constitutes the primary or original stimulus situation for each emotional state.

One of the simplest and most inadequate formulations was that given by J. B. Watson (1919) when he proposed that the original or natural stimuli for fear were noise and loss of support. Actually it is necessary to take account of the total situation in which the individual finds himself, including both the context in which this or that detail of the *external* stimulus occurs, and, as we have already pointed out, the *internal* situation: the individual's mental set, his expectations, values, hopes, desires, aspirations, attitudes of defensiveness, and any and all prevailing attitudes toward self and others. The need for taking account of the entire psychological field applies not only to the study of the emotions of a child at a given time but also to the understanding of changes in his reactions as he matures.

EMOTIONS AT BIRTH

According to some psychoanalysts, the child is capable of profound emotional experiences at the time of birth and perhaps even before birth. If we may believe one writer (Sadger, 1941), experience of pleasure and pain, and sensitivity to attitudes of acceptance and rejection by parents, may befall not only the embryo but even the spermatazoon and ovum. Freud (1936) implies that the unborn child is subject to feeling: "The fetus can be aware of nothing beyond a gross disturbance in the economy of its narcissistic libido. Large amounts of excitation press in upon it, giving rise to novel sensations of unpleasure" (p. 96).

The event of being born, according to some writers, represents not only a drastic physical upheaval but also a traumatic psychic experience.

Rank (1932), in speaking of the trauma of birth, maintains that the newborn child is subject to anxiety, and he claims that there is a relationship between the child's earliest phobias and the impression which the birth experience made upon him. Freud (1936) questions this conclusion, but he comments that the human infant "is sent into the world more unfinished" than the young of other animals, and that it is the "biological factor of helplessness . . . [which] brings into being the first situation of danger and creates the need to be loved

which the human being is destined never to renounce" (p. 130).

In speaking of the infant, Isaacs (1936, p. 16) says that "knowledge is lacking, understanding has not yet begun: but wants and wishes, fears and angers, love and hate are there from the beginning." According to Bender (1939, p. 582), "When a child comes into the world he comes in lonely, and he is afraid."

Statements such as the foregoing must be regarded as conjectures rather than as descriptions of observed facts. It is interesting to observe how Freud, and perhaps to an even greater extent some of his followers, on the one hand speak of the child's incompleteness at the time of birth and yet, on the other hand, seem to take for granted that the equipment involved in the experiencing of emotion is well developed.

In discussing the beginnings of emotional experience, Stern (1930, pp. 75–76) expresses the opinion that all we can justifiably assume is ". . . the presence of a dull undefined foreshadowing of consciousness in which the sensorial and emotional elements are so inextricably intermingled that they might be designated either as 'sense-emotional states' or 'emotional-perceptive states.'" Whether this describes the situation no one can say. But certainly the notion that the child at birth has (as some writers imply) practically an adult capacity for emotional experience, even though he is very "unfinished" (as Freud puts it) in other respects, can be questioned both on the basis of biological theory and on the basis of observed facts.

It should be recognized that the fact that the cerebral cortex is as yet undeveloped (which means that the cognitive capacity for perceiving danger or thwarting also is restricted) need not, in itself, be regarded as a bar to emotional experience. Observations of apparent emotional excitement as a consequence of direct stimulation of, or interference with, the hypothalamus, suggests the possibility that emotional reactions may occur apart from functioning of the cerebral cortex (see Masserman, 1943; Clark *et al.*, 1938; and a review by Moore, 1948). If such reactions can occur independent of functioning of the cerebral cortex in a mature person, it is conceivable that an infant might experience emotion by way of lower centers before the higher centers are mature. If the hypothalamus can be regarded as a seat of emotion, then, to the extent that the hypothalamus matures and functions earlier in life than the cerebral cortex, the infant might have something in the nature of emotional experiences while his higher centers are yet undeveloped. We would still have to establish a means by which emotional response through the "lower" channels alone might be brought about.

Masserman (1943) summarizes his own work and the earlier work of others by saying that the clinical and pathological data of the rôle of the hypothalamus in emotional experience are inconclusive. It is safest to assign the hypothalamus a rôle in reinforcing and coordinating the mechanisms involved in *expression* of emotion and to leave for further proof the theory that the hypothalamus is the dynamic source or seat of experience of affective states. On the other hand, there is evidence, according to Masserman, which indicates that an emotion is a highly integrated, conative, cognitive, and affective-somatic reaction in which the central nervous system and the entire organism function as a psychobiologic whole.

There are findings which indicate that emotional states may be influenced by drugs (see, e.g., Collins, 1946). But the reactions shown by adults or older children to an abnormal chemical condition (as when drugs are administered) do not tell us what might

be the situation as it operates in a normal, immature child.

As it happens, writers who have made the most categorical pronouncements concerning the capacity of the infant to have profound emotional experiences while he is yet in other respects very immature and highly restricted in his capacities for responding have not troubled to make clear what is the medium or machinery, organic or "psychic," which would make such experiences possible.

Studies dealing with the overt response of newborn children to situations designed to produce emotion indicate that emotional behavior at birth is quite diffuse and lacking in differentiation much as is true of the neonate's behavior in general.

OVERT REACTIONS IN EARLY INFANCY

Evidence of Lack of Differentiation

In a study by Sherman (1927) it was found that no clear-cut emotional patterns could be detected in the overt responses of infants to situations such as delay of feeding, sudden loss of support, restraint of head movements, being pricked with a needle. Adult observers, when informed concerning the stimulus that had been applied, tended to name the overt responses of infants in conventional terms. But when they saw motion pictures of the behavior of the children, without knowledge of the stimuli, they failed to guess what the provocation had been or to agree among themselves as to what emotion was being expressed. Adults similarly showed little agreement in identifying the cries of children who, behind a screen, were being subjected to various stimuli calculated to produce hunger, pain, fear, and rage.

Sherman noted that there were no specialized, uniform, or characteristic overt reactions or cries on the basis of which one "emotion" could be distinguished from another. Rather, there were was much uncoordinated, unspecialized, and diversified response.

This lack of differentiation in early emotional reactions has been emphasized also by Bridges (1932). Bridges states that the most common response to highly stimulating situations seems to be one of general agitation or excitement.

Investigations of overt reactions soon after birth to provocations that presumably should produce anger tell a similar story. In one such study by the Shermans (1925) restraint of movement was imposed through pressure upon the chins of infants by means of the experimenter's forefinger. No coordinated defense movements appeared during the first 24 hours after birth, but defensive movements did appear by the fifth day.

In a study by Pratt, Nelson, and Sun (1930) of children during the first 2 or 3 weeks of life, infants were observed when their nostrils were compressed in such a way as to prevent breathing (for periods ranging from 5 to 15 seconds), and when their arms were pinned to their sides. The findings did not substantiate Watson's earlier statements regarding defense reactions in the newborn child. It was observed that generalized reactions predominated over specific reactions in early childhood and that distinctive patterns were difficult to detect. Lack of differentiation in early emotional reactions has been emphasized also by Taylor (1934) in a study of 40 children aged 1 to 12 days.

Restraint of movement as such does not produce negative reactions in the newborn, according to observations made by Dennis (1942*a*), but any form of intense and prolonged stimulation, including rough restraint of movement, can elicit crying and restlessness. In due time stimuli calculated to

restrain activity can elicit negative reactions if such stimuli interfere with customary sequences of behavior. In other words, the arousal of emotion depends not simply on the external stimulus as such but upon the impact this stimulus has upon an internal condition.

In most of the voluminous work on emotion in infancy that was precipitated (or influenced) by John B. Watson's pronouncements, attention has been focused almost exclusively on the external stimulus and on overt behavior (except to determine, in advance of stimulation, whether the child was awake or asleep, wet or dry). A vast amount of research on emotional development beyond the infancy period has suffered from this tendency to pay attention primarily to objective and overt features without proper regard for subjective factors which, from the individual's point of view, are the most crucial feature of the psychological field.

Infants in a study by Irwin (1932) were quite placid in a situation which seems rather drastic from an adult point of view. Twenty-four infants under the age of 1 month were observed in a situation that might be expected to produce fear. They were held above the experimenter's head and were dropped and caught after they had fallen a distance of 2 feet. In only 2 instances out of 85 did the infants show the response of crying in reaction to sudden loss of support, and in 12 per cent of the trials no overt responses could be detected. In 46 per cent of the trials in which overt movements were observed these movements were confined to the arms alone.

A more definite pattern of response, which has been designated as the "startle pattern," has been noted by Landis and Hunt (1939), in studies of infants and older individuals by means of high-speed motion pictures. The authors do not describe this as an emotional response but rather as a response that might be called a pre-emotional reaction to sudden or intense stimulation. It is more simple in its organization and expression than the so-called emotions, and it may or may not be followed by emotion proper. The response may be elicited by sudden or intense stimuli from any sense modality but it was found to appear especially as a reaction to sudden, sharp noises.

This startle pattern is described as "a complex, almost invariable, involuntary, innate reflex response." It includes elements such as blinking, closing of the eyes, a thrusting forward of the head and neck, and flexion of the bodily musculature resembling protective contraction or shrinking, involving forward movements of the trunk, contraction of the abdomen, and pronation of the lower arms. Not all the elements of response were found to be present in response to a given stimulus. The response ranges in duration from 0.3 second to 1.5 seconds and is not easily observed with the unaided eye. Landis and Hunt point out that more study is necessary to establish the relationship between the startle pattern and the Moro *Umklammerungsreflex*.

The fact that this startle reaction was revealed by a high-speed motion-picture technique supports M. C. Jones' conjecture in 1933 that finer methods of recording might reveal features or patterns of emotional response early in life that cannot be detected by ordinary observation.

The findings we do have indicate that emotional behavior is highly undifferentiated at birth, and that during the first days or weeks of life many infants not only fail to show a patterned response but even are unperturbed by treatment which, from the point of view of an older person, would seem to be quite provocative or threatening. In addition, the fact that some infants sometimes respond to a certain prov-

ocation while others do not suggests that there are large individual differences in susceptibility from the time of birth.

Most of the findings that are based upon empirical research come from studies with a behavioristic slant. Different findings might emerge from studies by psychologists with a different theoretical orientation.

Genetic Studies of Emotional Differentiation during Infancy

As a child matures, emotional responses emerge that correspond roughly to the emotional behavior of adults and to which such labels as anger, fear, and joy, can be applied. Gesell (1928) reports, for example, that at the age of 1 month a child will give different cries for hunger, pain, and discomfort, and that the beginnings of what perhaps might be regarded as delight or pleasure appear in smiles and vocal expressions of apparent feelings of pleasure at the age of 3 months. Blatz and Millichamp (1935) note the progressively expanding repertoire of emotional behavior which becomes more adaptive with age.

Accounts of differentiation of emotional behavior during early months of life have been given by Bühler (1930) and Bridges (1932). At birth, Bühler noted restless, aimless, excited movements which she regarded as signifying "active displeasure." She also observed what she regarded as evidence of fright and actions of flight and defense by way of aimless movements and crying. At 1 month, according to her account, characteristic hunger cries can be noted, as well as further signs of active displeasure. Bridges reports that distress is differentiated from a general state of excitement at about 3 weeks. At 1 month, Bühler notes also signs of "displeased astonishment," and of pleasure (eyes gleaming, corners of mouth drawn up, eyes looking up). At 2 months the expressions of earlier feeling states show further elaboration, and at this age her infants showed "function pleasure" (a form of response earlier named by Karl Bühler to designate pleasures that accompany the organized course of a succession of movements).

Bridges reports that delight is differentiated at a later time than distress. She found that, under 1 month, the child is either excited or quiescent; he may kick and cry when his feeding is delayed but show calm rather than signs of delight when desired food is given to him. According to Bridges, the beginnings of delight start at 2 months, as manifested by fleeting smiles in response to being nursed, patted, or cared for, but this emotion is more clearly differentiated at 3 months, and more active signs of delight, such as loud laughter, smiling in response to another's smile, and efforts to raise the body in approach to an attentive person, are noted at 4 months.

Additional responses described by Bühler include lively expressions of joy at 5 months and laughing as a general reaction, slapping of the hands, crowing, and smacking and spreading of the fingers at 6 months.

It can be noted that there are many points of similarity in the accounts given by Bühler and Bridges, but there are differences also with respect to the time when some responses are reported as first appearing. Both note what appears to be pleasure in activity or achievement sometime during the first year.

Although these accounts cannot be regarded as definitive, they represent a developmental approach that is much needed in the study of early emotional behavior.

Theories Concerning Emotional Hazards of Infancy

The idea that happenings during the infancy period might have an important bear-

ing upon a person's emotional well-being during the rest of his life has occurred to many observers on contemplating how vulnerable the infant is. He is completely dependent upon others for food, warmth, and physical care. Within a short time after birth he is subject to many frustrations. The satisfaction of his elementary needs is surrounded by restraints. A vast number of regulations are brought to bear upon the child before he is able to see the reason for things and long before he has reached a level of intellectual development that enables him to formulate his experiences in terms that can be remembered in later life. He is called upon at an early age to distinguish between what is approved and disapproved. He has to acquire a vast range of voluntary control. Apart from ordinary trials, he may face special difficulties. He may come into a home where he is unwanted, and, whether wanted or not, he will be subject to the backlash of emotional frictions within the home.

Even if all is quite serene on the surface he may be the victim of the almost endless variety of "mistakes" such as are made by parents who, being human and imperfect, are more or less anxious and uncertain. The tensions, pressures, unresolved problems, and conflicts which have accumulated in the lifetime of his parents will sooner or later, to some degree, directly or indirectly, be visited upon the child. He is bound to be touched by repercussions of the struggles his parents may be undergoing in dealing with their own issues, which may include competitive strivings and power drives; a tendency to sacrifice spontaneity in order to conform to cultural stereotypes; irrational self-rejecting attitudes which they harbor with respect to their own misdeeds, their forebears, their upbringing as children, their social origins, their physical appetites; unrecognized grievances and grudges against their own parents or other authority figures; an unwitting tendency to project their own feelings upon others; irrational and unperceived endeavors to try to make amends, through their behavior as parents, for circumstances that have struck them as hurtful in their own lives.

Emotional Implications of Infant Care

The bearing which the handling of a child's feeding, weaning, and elimination and his early erotic tendencies might have upon his emotional well-being has received much attention. Studies in child development have emphasized the importance of maturation in determining the level at which children are ready to progress from one mode of behavior to another in their feeding and elimination. Studies of the response of babies to a "self-demand" feeding arrangement have indicated that the child's own desires may provide a good guide to the timing of his feeding and the amount and nature of what he is fed. As already indicated above, psychoanalytic theories have also drawn attention to these aspects of child care.

Theories regarding Early Sexual Hazards. According to the Freudian conception of early development, the infant is faced with possible "aberrations and maldevelopment of the sexual function" (1933, p. 135). Such maldevelopments may occur in connection with what Freud has described as the *oral* and the *anal* phases of *pregenital* development (and also during the phallic phase which comes later). In speaking of the *oral* phase, Freud states that the "erotogenic zone of the mouth dominates what we may call the sexual activity of this period of life" (p. 135). In the *anal* phase, "anal and sadistic tendencies come to the fore," according to Freud (1933, pp. 135–136). Freud and his followers (see, e.g., Fenichel, 1945) have described various outcomes which they regard as likely to occur

if the infant is unduly deprived or frustrated in connection with his oral and anal tendencies.

Unfortunately, for a period of many years the followers of Freud were more inclined to reiterate these ideas or to draw logical deductions from them than to bring evidence to bear upon them. There are, however, some statements that can be made that touch more or less directly upon the issues just raised, and related matters.

The importance of various aspects of early sexual development and of various features of child care, including feeding and training for bladder and bowel control, can best be understood if we see each aspect not simply as a segment of development that might have a peculiar significance of its own but as a feature in the larger relationship between the child as a growing self and significant people in his environment. It is by way of their attitudes toward the child's early sex interests, his desire to suck his thumb, his tendency to soil and wet himself—as well as by way of their attitudes toward all other aspects of his development and behavior—that parents communicate approval or disapproval, express their tendency to be prudish, anxious, harsh, perfectionistic, and impatient, or kindly, accepting, and willing to let the child be himself and develop in his own good time.

According to this view, the basic underlying attitude of the parent is more important than this or that practice which they adopt in bringing this attitude to bear in their dealings with sex, or cleanliness, or oral activity, or other aspects of child care.

Oral Activity. From the time of birth, most infants exhibit oral activity beyond what is involved in getting food from the breast or bottle. Many children (perhaps nearly all) suck their thumbs more or less during early months of life.

As time passes, all children use their lips, their tongue, and sometimes their teeth in exploring the world about them. For a time they try to bring almost everything into contact with their mouths. They use their mouths to examine the taste, the texture, the contours, and temperature of things. The mouth is for a time, like the eyes and ears, an important means of exploring the environment.

There clearly is a drive, inherent or early acquired, to use the sucking and mouthing mechanism for purposes other than food-getting. It is reasonable to assume that interference with this absorbing enterprise would be frustrating. To interfere with his sucking and mouthing is a way of blocking self-expression or (in another manner of speaking) a way of opposing his ego. To say also that such oral behavior is related to sexual development is another matter. We can, of course, include oral behavior under the heading of sexuality by the simple linguistic device of defining sexuality so broadly that it arbitrarily includes oral behavior, but that merely begs the question.

It has been observed that an increase in finger-sucking may occur if a child is deprived of the customary amount of sucking that he has enjoyed in connection with getting food, as when a bottle feeding is dropped from a schedule (Levy, 1928). But there are thumb-suckers among children who have been given the freest possible opportunity to suck. Moreover, deprivation of sucking in connection with food-getting does not invariably result in thumb-sucking, as shown in studies reviewed by Orlansky (1949). In other words, in dealing with this aspect of "oral" satisfaction, we are faced with something far more complicated than what is involved in depriving or not depriving a child of oral activity in connection with his feeding.

We do not have to saddle a sexual significance on to oral behavior in order to establish its importance. The very fact that the child undertakes sucking and mouthing so assiduously is enough to establish its importance from his standpoint. And now if we bring sharp disapproval, punishment, and forcible restraint to bear upon the child to curb his eagerness for oral activities we are, to a degree, punishing and thwarting (and perhaps even rejecting) *him*. Something very important in the child's relationships with significant people in his environment occurs by way of their response to his sucking activities. Sucking in a sense becomes the focal point of unpleasant interpersonal relationships (if we may borrow terminology from Sullivan, 1947). Again, a child's sucking activities may become the object or target of the kind of harsh treatment from his elders which may operate as a factor in the causation of anxiety. What thus is done to the child in the context of his sucking activities is the significant thing, this writer believes, whether or not we also choose or refuse to regard oral activity as something tied to a so-called "pregenital" phase of sexual development.

Breast Feeding. According to one school of thought, breast feeding is more conducive to emotional health than bottle feeding. Anna Freud and Burlingham (1944) put it quite simply: "Breast fed babies are, of course, better off than bottle-fed babies" (p. 12). According to Harnik (1930), bottle-fed babies are frequently liable to suffocation during feeding and suffer anxiety as a consequence. In a review of numerous studies bearing upon this problem, Orlansky (1949) points out that, although a baby who receives individual care from his mother has obvious advantages, the assertion that breast-fed babies are invariably better off than bottle-fed babies remains unproved.

It has also been proposed that breast feeding might have a bearing on a child's emotional development on the theory that the practice of cutting out breast feeding might be a form of rejection. The evidence on this matter, as reviewed by Orlansky (1949), is not unequivocal. The fact that a categorical answer is unwarranted on the basis of present evidence is emphasized by findings in a study of 60 babies in three groups of 20 each, one fed by cup, one by bottle, and one by breast, during the first 10 days of life (Davis, Sears, Miller, and Brodbeck, 1948).

If we could get to the bottom of this, we probably would find that it is the overall quality of the parent-child relationship rather than the particular feeding practice as such that is the important thing. It is possible for a breast-feeding mother or a bottle-feeding mother to be affectionate or lacking in affection; she can be relaxed and able to enjoy her child, or tense, anxious, and impatient. The feeding situation, perhaps more than any other single situation, brings the child into frequent close contacts with the parent, and it is by way of contacts that a mother communicates her attitude toward her child, whether the manner of feeding happens to be by breast or bottle.[1]

Weaning. We can assume that weaning must be a frustrating and, at least for the time being, a very unpleasant experience. For this reason, weaning from either breast or bottle might be regarded as possibly having an important bearing on a child's emotional development. According to Pearson (1931), when the breast is withdrawn the nursing infant fears it will never be

[1] One more point regarding this: according to one theory, a woman's refusal to breast-feed (when otherwise all is opportune) may be a symptom of an attitude of rejection of her female rôle and thus a symptom of self-rejection. But in these terms, again, it is the underlying attitude, not the manner of feeding, that is crucial.

returned. In commenting on breast feeding and weaning, Orlansky (1949) speaks of the lack of experimental data.

Training in Bladder and Bowel Control. The work of McGraw (1940) and of Gesell and Ilg (1937) emphasizes the fact that it takes time for the child to mature organically to the point where he is able and ready to exercise voluntary control over his bladder and bowels. In the light of such studies, advice to the effect that toilet training should begin at the age of 3 months or 6 months, or even earlier, is absurd. It is reasonable to suppose that many children have suffered ill effects when parents have tried to establish "early control" by coercive methods. A study by Huschka (1942) of problem children in a hospital suggests that children who have been "coercively" trained might tend to show symptoms such as constipation, fear, and rage more than children who have been trained with better regard for their comfort.

But here (as in connection with feeding and sucking) the effects of methods of training should be considered in the light of the total situation of which they are a part. When we find parents who insist on trying to hurry the child's bowel and bladder control we probably also will find that this is only one detail in a larger pattern of insistence on cleanliness, orderliness, and conformity to a variety of rigid cultural standards. Some such parents probably also try to hurry other features of development. The parent's desire to hurry the child in the process of getting housebroken may represent, for example, an expression of an attitude of self-rejection on the parent's part: he cannot tolerate the part of his nature that is, as he sees it, filthy with excrement, and so he must hurry the child over the hurdle of being a soiled child. Again, the parent's compulsion to hurry the child may be an expression of a larger compulsive tendency to prove that he can get things done in a hurry. It is possible, even, that this pressure may be an expression of a compulsive competitive tendency in the parent: if ordinary babies can get the dry habit by the age of 2 or 3, his child should be able to beat this average by several months.

Mothering. Writings about early development repeatedly reiterate the age-old belief that mother love is an important thing for the child From the time of birth babies show a desire for human company and human contact beyond the contacts that are incidental to feeding and other aspects of physical care. Levy (1936) has used the expression "primary affect hunger" to denote a child's need for maternal love and other feelings involved in the mother-child relationship. The fact that under certain conditions infants may show extreme symptoms of depression when suddenly separated from their mothers has been noted by Spitz (1946). Studies bearing on the large subject of parent-child relationships will be noted in a later section, but we are interested here briefly in mothering from the point of view of the special hazards of infancy.

The view that lack of proper mothering may have dire consequences in the child's life has been emphasized by Ribble (1943), who reiterates a number of concepts which Freud forcefully set forth several decades ago. Brodbeck and Irwin (1946) found that even during the first 6 months of life children in an orphanage made fewer and less varied speech sounds than children of high or low socio-economic status who were being brought up by parents in their own homes. Other studies, which will be referred to at a later point, indicate that other features of development also are likely to proceed best in a situation in which friendly human relationships prevail.

Moreover, as Bühler (1933) observed and as Spitz and Wolf (1946) later pointed out,

there is likely to be an emotional coloring in the infant's first awareness of discrimination of a fellow human being. In connection with the development of auditory perception, according to Bühler ". . . there occurs from two months on a specific reaction to the human voice in all its modifications, and that is smiling. The two-month-old infant, in fact, smiles occasionally at the sound of the human voice, even though at this age he does not smile in response to other stimuli" (p. 376).

In a study by Dennis (1938, 1941) two babies from birth to the age of 7 months were kept under conditions of extreme social isolation. Human contacts were restricted to a minimum, and no one played with the babies, or fondled them, or talked to them. These babies showed a record of early development very much like that of infants in a normal environment. They even responded affectionately when a stolid experimenter came to observe them. A study by Danzinger and Frankl (1934) also suggests that babies may show a high degree of social responsiveness when given the opportunity even though they have spent several months early in life in a situation that provided less human contact than babies usually enjoy in our culture.

The studies just cited leave several questions unanswered but they suggest that the effect on a baby of being deprived of his mother (at an age when he is old enough to notice) may be influenced by several variables. The child's response may depend in part on what he has become accustomed to expect or to go without. The disturbing effect of separation from the mother probably also will be influenced by the extent to which the child already has a disposition to be anxious. Babies seem to differ not only in the extent to which they become accustomed to much or little contact with *one* person (the mother or mother substitute) but also in the extent to which they are given much or little opportunity, from an early age, to learn to expect affectionate treatment or unkindness when in the care of *many* different persons. The disturbing effect of loss of the person who hitherto has played the mother rôle, as described so movingly by Spitz (1946) and Ribble (1941), should probably be interpreted in this light. It seems to the writer that we need to be guarded in our interpretation of the limited systematic data we have on this extremely important topic.

Important recent contributions concerning the bearing of emotional relationships with others on the emotional health and personality development of the young child have been offered by Horney and Sullivan. We will refer to these later.

Observations regarding Fragility and Hardihood of Infants. The fact that the child is physically weak and helpless is obvious, and many writers take it for granted that he is also *psychologically* more *fragile* than an older person.

The young child is weak, it is true, but there also are certain protective features in his make-up.

He is defenseless against many of the calamities of life, but it is also true that the infant does not have the intellectual ability to perceive their implications to the same degree as does an older person.

While the infant can be aroused to intense excitement by an immediate threat, he can also stage a quicker recovery. He seems to be able to shift more readily than an older person from anger and tears to affection and laughter. Infants do not appear to have as strong a *perseverative* tendency in their emotional behavior as older persons.

Although the infant does not have the ability of an older person to protect himself from harm, it also is probable, on the other hand, that he has a greater capacity

for self-repair. Anderson (1948) reviews findings which indicate that the healing rate of physical wounds is faster in children than in adults, and he suggests that there is no reason to assume that the opposite would hold true with respect to psychological wounds.

Moreover, there are many findings which show that the infant, even at a tender age, is not a creature whose emotional life is completely at the mercy of episodes occurring in the environment. Several studies have shown that children show a high degree of consistency in the individual or characteristic ways of responding that mark them as distinct personalities, and that there is a great deal of toughness in their ability to preserve their integrity (see, e.g., Shirley, 1933, 1941; Gesell and Thompson, 1941; and reviews by Anderson, 1948; and Jersild, 1947).

Most important of all, from the point of view of the child's safety, is the dynamic nature of the life he lives from day to day and of the forces of growth that are constantly at work. He is continually interacting with his environment. His life from day to day involves a vast amount of learning, a vast amount of forgetting. New abilities emerge; new experiences befall him; and different currents in his life interact upon each other in changing ways. His curiosity leads him into experiences that bring him to grips with his fears. New impulses that come into play as new abilities emerge make old satisfactions obsolete or give new powers that take the sting out of old frustrations and enable him to satisfy continuing needs in new ways.

While these factors help the child in defending himself against harsh features of his environment, circumstances may interfere with the process of learning by which the child normally revises his emotional attitudes in keeping with the changing realities of life. This can be seen when an emotional attitude keeps persisting even though the occasion which aroused it has long since passed, as when a child retains an attitude of hostility, suspiciousness, and defensiveness even after he has come into friendly hands. Circumstances which produce an overwhelming emotional reaction in early childhood may singly, or cumulatively over a period of time, have a profound and long-continued effect on the child's way of life. At an early age, for example, as documented in a striking manner by observations in an orphanage (by Skeels *et al.*, 1938), children who have to shift for themselves without parental affection and protection may acquire attitudes of distrust and defensiveness which carry over into their responses to friendly people. In observations of older children Redl and Wineman (1951) graphically show how difficult it is for children who have suffered from neglect and abuse to become accustomed to the opportunities offered by a friendly environment.

It seems reasonable to assume that, the more strongly an emotional attitude (such as reacting to others with hostility or fear) has become established, the more difficult it will be to modify it, the more difficult it will be to apply the attitude discriminatingly, and the stronger will be the tendency to take the attitude for granted, to defend or rationalize it, and to build a consistent character structure around it. Moreover, as time passes, a vicious circle is established, for if a child is suspicious and hostile toward other people many of them will respond to him in kind and thus prove (as he sees it) that his defensive attitude is well grounded.

The fact that the experience in infancy may leave a strong trace is shown in studies of animals. J. McV. Hunt (1941) found that rats subjected to feeding-frustration in infancy were more likely to hoard food when again subjected to such frustra-

tion as adults than rats which had been frustrated at a later stage of "childhood," or not at all. Effects of infantile experiences on the way adults respond under stress is shown in another study of rats by Wolf (1943). When required to compete for food (after previously being fed individually) animals that had been *deafened* for a time in infancy frequently lost in competition at the adult level when the signal was a *sound,* and those that had been *blinded* for a time frequently lost when the signal was a *light.* In other words, depending upon the kind of limitation they had suffered in infancy, the animals now, under stress, were inhibited in their hearing or seeing. They retreated, so to speak, to an outmoded form of behavior (not seeing or not hearing) which had prevailed for a time during the infancy period.

FACTORS INFLUENCING EMOTIONAL RESPONSE

There are certain broad considerations which must be taken into account in studying the emotions of children at any age level.

Individual Differences

Practically all studies of young children directly or by implication emphasize the fact that children differ greatly in emotional susceptibility and responsiveness. Shirley (1933), for example, describes differences in timorousness and irritability that appear early in infancy and persist throughout later months. A later study by Neilon (1948) of the children originally studied by Shirley indicates that there is a very strong likelihood that temperamental qualities which a person displays in early childhood will continue to characterize him in later years.

The Rôle of Maturation

Many studies have stressed the fact that a child's susceptibilities change as he matures and that the concept of conditioning alone does not explain these changes or the emergence of new or changed emotional responses as a child grows older. Bühler (1930), for example, describes the manner in which new occasions for delight occur as the child becomes able to undertake new performances. Similarly, the development of a child's ability to discriminate and perceive will render him responsive to stimuli to which he was impervious at an earlier time (Shirley, 1933; Jersild and Holmes, 1935*a*).

Gesell (1929) describes the manner in which fear "waxes and alters with growth"; he maintains that "this pattern is as much the product of organic growth as the various stages in the elaboration and perfection of prehension" (p. 656–657), and he illustrates with a description of reactions shown at different age levels by an infant confined in a small pen. In an earlier study, H. E. Jones and M. C. Jones (1928) noted changes with age in response to a large harmless snake. They point out that ". . . the arousal of fear depends not only upon situational changes, but also upon the individual's general level of development. . . . As a child develops . . . new things startle him because of his new perception of the fact that they are new and unusual" (pp. 142–143).

The varying effects of a given event as children grow older can also be noted in occasional shifts in emotional response. At about 5 to 8 months, for example, a hungry but hitherto relatively calm infant may show signs of anger if there is a momentary delay in his feeding after he has caught sight of the bottle, but at about 8 or 9 months and in the same circumstances a child may show signs of pleasant anticipa-

tion rather than anger (Bühler, 1930) if the delay is brief. Other examples of changes that occur in the process of maturing will appear in later sections.

Obviously, learning is one factor in changing reactions such as those described above. The point remains, however, that the reaction to a situation will depend not simply upon the cumulative or spreading effects of specific emotional stimuli that have gone before but upon the changes in capacity and changes in scope of behavior that are associated with growth.

Differentiation of Early Expressions as Related to Growth

The development of facial expression of emotion offers an opportunity to study inherent and acquired features of emotional patterns. In a study by Goodenough (1931*a*) judges were shown photographs of a 10-month-old child. These photographs were taken under relatively mild conditions designed to elicit various emotional states The judges correctly identified the situation or emotion depicted by various photographs in 47.4 per cent of the instances, as against a chance expectancy of only 8.3 per cent of correctness. According to Goodenough, "The findings suggest that however greatly the overt expression of emotional states may be inhibited, modified or intentionally assumed in the social relationships of adult life, the language of expression is nevertheless built upon a core of native reaction patterns which appear at so early an age that can hardly be ascribed to training" (p. 101). Findings in keeping with this conclusion are also reported by Goodenough (1932) in a study of a 10-year-old child who had been blind and deaf from the time of birth. Darwin (1913) earlier reported that the expressions of the blind resemble those of persons who can see.

Photographs snapped at opportune moments were utilized by Thompson (1941) in a study of the facial expressions of emotion exhibited by 26 blind and 29 seeing children aged 7 weeks to 13 years. Patterns of emotional response similar to those designated as anger, sulkiness, annoyance, and sadness in seeing children were also exhibited by blind and deaf-blind children, but such responses did not occur as uniformly among the blind as among the seeing. Thompson concludes that the facial expressions exhibited by the blind "seem to be maturational since there is no other obvious way in which they could have been brought about." On the other hand, the effects of mimicry, as distinguished from maturation, appear in certain stylized expressions exhibited by older seeing children.

In a study by Fulcher (1942) brief motion pictures were taken of 118 seeing and 50 blind children while they were voluntarily expressing happiness, sadness, anger, or fear The seeing differentiated more sharply than the blind between expressions of different emotions, but the differentiations the blind did show were like those shown by the seeing.

The Rôle of Learning

The fact that emotional behavior is modified through learning and that emotional responses become associated with new situations through the process of conditioning is obvious from everyday observation, and it has been emphasized in experimental studies. The classic study in this field is Watson's work (Watson and Rayner, 1920) with a little boy called Albert. When first presented with a white rat, Albert showed interest and curiosity, but as his hand touched the animal a loud noise was sounded which caused Albert to be startled and to withdraw. After several repetitions, Albert no longer reached for the rat but

shrank and showed evidences of fear at the sight of the animal.

The concept of conditioning as applied in research work with children so far does not, however, *per se* provide a guide for predicting under what circumstances conditioning is likely to "take" in a laboratory setting or in everyday situations (Valentine, 1930; English, 1929; Jersild and Holmes, 1935*a*; Bregman, 1934).

Widened Scope of Effective Stimuli

The younger the child, the more his emotions tend to be aroused by tangible events that impinge directly upon him. As he grows older he becomes increasingly responsive to signs and symbols that betoken furtherance or hindrance of his welfare and his wishes, and more and more of his emotional reactions concern anticipated events. Also, of course, as a child grows older, emotions become associated with an enlarging repertoire of activities, plans, and interests, and he becomes increasingly able to entertain lingering or recurrent fears, joys, and resentments. As Lund (1940) puts it, with added maturity there is an increase in objects and situations that have emotional value.

When the child is on the threshold of new experiences or achievements he may for a time react emotionally to situations that subsequently are "laid by." Each new hurdle in the child's development, or in his impact with new environmental conditions, may for a time provide a thrill or offer a hazard.

Differentiation in Expression

Differentiation of overt expressions of emotion is especially noteworthy during the first year of life, but there are many further elaborations after the first year in nuances of facial, vocal, and postural expression.

In the display of anger, for example, Goodenough (1931*b*) notes that: "With advancing age behavior during anger becomes more overtly directed toward a given end. At the same time the primitive bodily responses of the infant and young child gradually become replaced by substitute reactions of a somewhat less violent and more symbolic character."

The lengths to which the substitution of other forms of expression have gone by the time of maturity are indicated in a study by Richardson (1918), who found that, in about 600 instances of anger reported by 12 adults, no blows were struck "except with those persons who have the correction of children." A shift from overt expression to more subtle or disguised reactions is noteworthy also in the case of fear. As a result of such changes it becomes increasingly difficult to detect and to understand the child's emotions as he grows older.

The fact that a child sometimes will reveal his feelings in make-believe settings or play situations has increasingly been taken into account in the use of projective methods and play technique in the study of children.

The decline with age in frequency of emotional outbursts does not, of course, depend solely upon the development of the inhibitions, gradations, and the substitution of less overt responses. It arises also in part by reason of changes in the character of the emotion. Persisting apprehensions, resentments, and pleasant anticipations cannot so appropriately be expressed by outbursts such as may occur in an episodic response to a concrete happening.

Decline in Crying as an Expression of Emotion. Crying at first usually occurs in connection with bodily movement, but by the age of 6 months crying may occur without the accompaniment of such movements (Bühler, 1930). In a study of 61 children during mental and physical examinations

throughout the first year of life, Bayley (1932) found that children cried an average of 15 per cent of the total examination time. In the early months crying resulted mainly from internal causes, but in later months factors in the external environment, such as strangeness of place or persons and continued handling, became increasingly potent.

A sharp decline with age in crying in connection with preschool children's social contacts and in their conflicts with one another has been noted in several studies (Brackett, 1934; Jersild and Markey, 1935). It has also been noted that at the preschool level crying occurs less in response to the child's own falls and bruises than as an expression of anger when a child is hurt or thwarted by someone else (Ding and Jersild, 1932). Ricketts (1934) found in a study of preschool children that crying occurred relatively more often in connection with anger at home than at school. Blatz, Chant, and Salter (1937) found a relatively high incidence of crying in a situation for the feeble-minded where there was less disapproval of crying in public than usually prevails in other situations.

In a study by J. Bell (1943) in which about a hundred children aged 3 to 8 years were observed during dental treatment, crying was displayed by only 25 per cent of the children, and 51 per cent of them smiled or laughed. There were no significant differences between boys and girls in their tendency to cry during dental treatment. At the adult level, however, Landis (1924) found that women cried more often than men in trying experimental situations.

DEVELOPMENTAL CHANGES IN THE INTERLPAY OF THINKING AND FEELING

Although thinking and feeling are intricately interwoven it is useful in studying emotional development to make a distinction between them. One of the most baffling problems in connection with the development of human beings is the problem of achieving a harmonious and productive integration of the individual's intellectual powers and his emotional capacities. Failure to achieve such integration appears, for example, when a person is subject to irrational emotional states, lacks insight into his fears and hostilities, or is governed by "unconscious" forces. In the present chapter we cannot presume to go deeply into this important topic, but we will touch upon certain aspects of it that pertain especially to the growing child.

Theories Regarding the Priority of Thinking and Feeling

Here we may properly elaborate a bit on an issue raised at an earlier point, namely, whether we may regard emotion as the prior and psychologically more primitive form of experience in human development. As noted previously, there are writers who assume that the child has a practically unbounded capacity to feel while he still has a very limited capacity to perceive or to think. Searl (1932) speaks of the child as one who is frequently, easily, and completely overwhelmed by his own feelings before he has anything but a weak sense of any other reality and before explanation or reasoning is possible and while means of communication are lagging behind the strength of his desires. This doctrine is strongly reaffirmed by Isaacs (1933) when she maintains that "the sense of guilt, or, more strictly, the deeper anxieties that represent the primitive forerunners of the sense of guilt, *do* develop spontaneously in the child's mind whatever be the precise nature of his educational experiences . . . in its essence, the sense of guilt is inherent in the fundamental interactions between human

mental structure and inevitable early experiences" (p. 371).

The most systematic presentation of the view that the ability to use the intellect by way of sustained thinking, awareness of one's own mental processes, and reasoning in terms of cause and effect lags behind a more primitive form of mental activity in a child's development has been offered by Piaget (1928, 1930, 1932). In accord with Freud, Piaget maintains that *Lustprinzip* is prior to *Realitätsprinzip;* thought serves desire before it serves truth (1928). There is an inborn unconsciousness of thought toward itself, according to Piaget. For many years the child is incapable of detached awareness of his thought processes; he is not bound by logical necessity; he is not conscious of guiding factors in his own thoughts. Piaget distinguishes between *logical* thought, which is *social,* communicable, and guided by a need for adapting to others, and *autistic* thought, which is *incommunicable,* indifferent to truth, and unconscious to itself and of the affective factors by which it is guided, and states that the child's way of thinking occupies a place situated between the autistic and the social (1928, p. 205). Piaget calls this way of thinking "egocentric."

It is not until after the age of 7 or 8 that a child begins to grow conscious of his reasoning process, according to one of Piaget's studies. Until this age the child's picture of the world is always "moulded on his immediate sectional and personal point of view" (1928, p. 248). According to the same report, it is not until age 11–12 that "formal thought" appears when the child "comes to reason about pure possibility" (p. 251). According to Piaget, a child's egocentrism not only makes him unconscious of himself (under the age of 7–8) but also keeps him from being aware of the phenomenon of thought as a subjective phenomenon and it prevents him from establishing the exact limit between his own ego and the external world.

Although Piaget's discussion centers primarily on the nature of the child's logic rather than on the feelings involved, we may probably infer, if Piaget's account is true, that the child would have just as much difficulty, if not more, in understanding his feelings as he has in understanding his thoughts. So construed, Piaget's conclusions lead to a gloomy view of the ability of the human being, in his formative years, to achieve an integration of intellectual awareness and feeling and to bring cognitive processes to bear on forces which influence his way of life.

In discussing what he calls egocentricity in children's thinking, Piaget has identified important truths, but he has overstated them by far. "Egocentric" thinking of the kind described by him occurs in children at all age levels, and also in adults. But, as many investigators have shown, Piaget greatly underestimated the capacity children have for *logical, causal,* and *socially communicable* thinking from a relatively early age (see, e.g., Dennis, 1942*b*; Deshaies, 1937; Deutsche, 1937; Hazlitt, 1929; McAndrew, 1943; Oakes, 1946).

The possibility that a prelogical stage of thinking, such as has been proposed by Piaget, might exist but at an earlier age than Piaget has set or than has been covered by other investigators who have tested Piaget's conclusions was explored by Dennis (1942*b*) in a study of a bright child from the time the youngster began to talk until the age of 6 years. Dennis found that at the age of 3 the child gave many answers concerning the nature and cause of things that conformed to Piaget's expectations, but by the age of 6 many of these had been changed.

In other words, we may conclude that children at an early age (probably from the time when they are able to reveal the na-

ture of their thoughts) are capable of logical and socially communicable thought about things and the nature of things to a far greater extent than Piaget has proposed. These findings do not tell us at what age and to what extent the young child is able to think about his own feelings.

Here is an area where there is great need for research. Stated in broad terms, we might ask, at approximately what level of development is a child able to be aware of himself, able to examine his own feelings, able to begin to bring his intelligence to bear on emotional currents in his life? With this we might raise another question: At about what level of development is it possible to help the child to cultivate his ability to take stock of himself? These questions have fateful implications for human happiness. A vast amount of human misery would be obviated if children could be helped to understand themselves and others—if they could be helped to achieve better understanding of emotional forces in their lives. As matters now stand, a large number of children do not seem to achieve a healthy integration of their cognitive and affective resources. Many from an early age use their intellectual abilities (including their capacity for imagining) to support or defend irrational attitudes of hostility, anxiety, and inferiority. The intellect often serves the purpose of self-deception rather than self-enlightenment.

Lag in Self-Inquiry. Even if we could establish the position that children have more capacity for understanding their feelings than we have generally assumed, we would still have the problem of finding how best this ability might be cultivated and put to use. Elsewhere the writer has set forth the view that in our training of children at home and at school we tend to encourage them to ignore and to evade opportunities for testing and cultivating whatever capacity they may have for growth in self-understanding (Jersild, 1951, 1952).

In the normal course of events, it occurs to very few children until about the time of adolescence to mention a desire to understand or to cope with their own emotional problems when they reveal wishes or what they are interested in studying or learning more about (Jersild, Markey, and Jersild, 1933; Jersild and Tasch, 1949). Even at the high school level, an expression of such an interest in self-understanding is rare unless the school has encouraged it. So it is, for example, that even late in childhood it will not occur to children who suffer from troublesome fears to wish for the strength or insight to cope with them or to express an interest in finding out what makes people afraid.

Interaction of Intellect and Feeling. Some writers take the position that emotion is the forerunner, the pacemaker, in intellectual activity. Here again we may cite Isaacs (1933): "It is the child's first experience of instinctual frustration, of unsatisfied longing for food in the intervals between satisfaction, which provides the first stimulus to his appreciation of the external world" (p. 288). This particular statement may be true, but, in the judgment of this writer, it is only part of the truth. A child's emotions influence his perceiving and thinking. But a child's ability to perceive and to think also influence his emotions.

A child's fear of unfamiliar things when he has reached the ability to discern what is strange illustrates the impact of perceptual development on emotional behavior. It might be argued that this illustration is not sound: the response to the stranger may not be in the form of a sequence of perceiving and then fearing, but, rather, the perceiving and fearing perhaps should be regarded as features of a larger unitary response. Even granting this, it would be

arbitrary to reverse the order and assume that the primary response to strangeness was fear and out of this arose the perception of strangeness. Children often give evidence of new forms of intellectual discrimination without revealing fear. In other words, unless we arbitrarily read fear into the response, or perform a linguistic trick, we could not state that fear is here antecedent to perception.

Many studies have shown that what a person perceives is influenced by his needs and values. When shown ambiguous pictures a hungry person may see them as pictures of food. The perceiver tends to select or to notice the features that are in line with his attitude. For example, a person who would like to move to another place reads advice from a friend in that place as though it said, "Stay here," instead of the actual words, "Stay there" (meaning where he now is).

Among those who have studied these phenomena are Bartlett (1932) and Edwards (1941). Lund (1925) found high relation between belief that a proposition was true and a wish that it should be true.

According to a summary by McKillop (1952), the following generalizations concerning the effect of attitude seem reasonably well established, at least under certain conditions: (1) perception reflects the individual's attitudes; (2) material that conforms to one's attitude is more easily learned and retained than material that is in opposition to one's attitude; (3) attitude influences one's judgments and one's ability to reason logically; (4) the more ambiguous and unstructured the stimulus, the more important is the rôle of attitude.

In a study of the relationship between the reader's attitude and certain types of reading response, McKillop used 512 eleventh-grade students in 22 classes in three high schools in the New York area, representing a heterogeneous population with people differing in socio-economic status and in racial composition, and she presented passages dealing with Negroes, Communism, and Israel. The topics were presented in a biased way but in a manner that appeared more or less plausible. She found that when the questions in the tests dealt with exactly the specific details presented in the passages the students as a group were able to look for the right answer and to give answers based upon what the passage said. When the questions required the reader to make inferences, to read a little between the lines, most students were still able to answer on the basis of the passage, but exceptions became more frequent and wrong choices tended to be in the direction of attitude. When, however, the questions were so worded that there was no "right" answer and there was an opportunity, for example, to make a judgment regarding the justification for Arab objections to Israel, or to make a prediction concerning the results of overthrow of the Communist government, attitudes of the students became important factors in determining their answers. "Although the spirit of the passages was quite clear with regard to these issues, and although students were directed to answer on the basis of the passage, it became increasingly difficult for the students to distinguish between the general spirit of the passage and how they felt about it" (pp. 80–81).

The influence which emotion may exert over thinking has been expressed very effectively by Murphy (1945), who states that, whenever the task is objective and intelligence free, man can remake the order of his world. "Yet on points concerning his own nature, where his impulses have beclouded the process of his thinking, he still relies on exhorting, moralizing and argument. . . . The towering genius of a great scientist often lapses into childish babblings as he turns to problems in which

his personal desires give structure to his thoughts" (p. 2).

Examples of the way in which children's intellectual grasp of a situation influences their emotional response to it are offered by observations concerning the reactions of older and younger children to events connected with war (Kimmins, 1915–1916; Despert, 1942; for a review of other studies, see Jersild and Meigs, 1943). Children of about beginning school age react to war more on a *perceptual* level than do older persons. As children become older, they react increasingly on a *conceptual* level. The older child, for example, is able to appreciate the effects of an air raid not simply in terms of the destruction that lies before his eyes but also as a frightening sign or omen of a policy of destruction which the enemy might carry out in the future.

The bearing of intellectual development on emotional behavior is also shown in the fact that there are certain differences in the emotional behavior of bright and dull children. F. B. Holmes (1935) found that brighter children at the age of 2 or 3 were susceptible to conditions which eventually arouse fear in many children to a greater extent than less intelligent children of the same age. Holmes found correlations ranging from .50 to .53 between IQ and "fear scores" (the more fear shown, the higher the score) in the age range from 24 to 35 months; in the range from 36 to 47 months, the correlation was .18; and at the 4-year level, it was .10. She pointed out that her findings indicate that the more intelligent child seems to develop certain fears earlier than the less intelligent child.

Evidence that brighter children at older levels might also be more sensitive to things that might endanger them is reported in a study by Boston (1939) of children under 9 years of age, including a group with an IQ range of 90 to 104 and another with a range from 115 to 154, whose records were studied from the point of view of a psychiatrist's opinion concerning each child's fantasies and fears. A few of the bright children fitted the theory that superior intelligence is accompanied by greater awareness of danger. Moreover, in the average children, the negative factors in the home that seemed to contribute to fear (such as rejecting or neurotic parents, conflict between parents, frightening experience, or physical factors around which fear centered) were more pronounced and more overtly apparent than in the brighter children.

The relation between intelligence and anger has been examined by Meltzer (1937). He found that anger and intelligence were closely related in a feeble-minded group (the correlation was .65). Imbeciles were more susceptible to anger than idiots, and morons were more susceptible than imbeciles. On the other hand, in a college group with an intelligence range from low-average to near "genius" the correlation was practically zero. The anger reactions of individuals at all levels of intelligence were found to be largely nonadaptive. When after-effects of anger were examined from the point of view of finding trends toward "dissociation" or "integration" the differences between groups at different levels of intelligence were small.

Other things being equal, we might expect the child with greater intellect to have more emotional scope. He is better able to perceive both the tragic and the comic in life about him; more able to sense and to fear the omens of future calamity and more able, also, to anticipate in feeling and in thought the future consummation of his hopes. He is able to acquire a wider range of interests which the circumstances of life may block or bless. But other things are not equal. The bright along with the dull may acquire attitudes at any stage along the course of development which put walls around their intellect. The child with a

high IQ, like the professor with a Phi Beta Kappa key, may use his intellect to defend a bias and thus close the door to experiences that might enlighten or enrich his emotional life. Again, the bright person may be as vulnerable as the dull to circumstances which interfere with his spontaneity. Smith (1932) found, for example, that "feelings of inferiority" were quite uniformily distributed through the whole range of intelligence.

These considerations deny the view that the relation between emotion and intellect is one of uniform dominance and priority of the former over the latter. The fact still remains, of course, that a child's emotions may dominate his thoughts, and the fact also remains that he will have emotional experiences in early childhood which he cannot at the time review and examine with his intellect.

Memory of Early Emotional Experiences

Child psychologists and psychoanalysts, alike, have shown much interest in the study of early childhood memories. A "Note on Early Memories" was published by G. Stanley Hall in 1899. In 1893, Miles questioned people concerning the earliest things they were sure they could remember and the age at which these occurred. V. and C. Henri, in 1895, published a questionnaire devoted to early memories. Numerous other studies in this area have been reviewed by Dudycha and Dudycha (1941).

The average age of the person at the time of his earliest remembered experience has varied somewhat in different studies. Dudycha and Dudycha (1933), in a study in which the data consisted only of memories which could be quite accurately placed or traced, concluded that the average age of the earliest memories reported by college students is 3 years, 7 months. Investigators are not unanimous as to the degree to which pleasant and unpleasant experiences prevail in early memories, although earliest remembered experiences usually have an emotional tone. In the Dudycha study cited above, fear was reported in connection with 30.4 per cent of the memories; joy, 27.9 per cent; anger, 10.3 per cent; wonder and curiosity, 8.1 per cent; pain, 5.2 per cent; shame and guilt, 2.6 per cent; miscellaneous emotions, 3.8 per cent; no emotion indicated, 5.2 per cent.

A question might be raised as to what might be the relation, if any, between the number, nature, and timing of a person's earliest memories and his emotional adjustment. Studies by Crook and Harden (1931) and Child (1940) give varying reports with regard to this matter. More intensive clinical investigation would be necessary to provide an adequate answer.

One thing that complicates the study of early memories is the factor of *selective recall*. What one remembers from his past will be influenced not only by what happened in the past, for in the ordinary course of development there is a vast amount of forgetting. Why does a person remember certain things from his early childhood while forgetting so much else? One theory is that some things are remembered not simply because of their intensity or impressiveness, *as such*, at the time of the original experience but because they fit into or are congruent with certain personality tendencies which now exist and which have a history extending back into earlier years. On this theory, a person's early memories may tell us more about his present mood and attitude toward self and others than about the factual events of his childhood. If he is a person who has a strong tendency to feel abused, for example, a tendency to look upon life and fate as being unjustly against him, his early memories may include recollections of times

when he was (in reality, or according to his interpretation) treated in a harsh and unfair manner. If he has a strong tendency (now) to disparage and blame himself, he may also have a tendency to recollect experiences in his life when he did something that made him feel especially guilty or unworthy. If he is preoccupied (now) with sexual conflicts or is convinced that sexual difficulties provide the key to human conflicts he is more likely (according to this theory) to have recollections of sexual experiences among his early memories than a person who does not happen to be consciously preoccupied or "unconsciously" troubled by sex to the same degree.

Another factor that needs to be considered has already been alluded to above, namely, the "memory" that is reported may represent something that actually occurred but which at the time involved a great amount of subjective elaboration. There may be an essential element of reality in the "memory" even though the experience was, at the time, subjected to a biased interpretation. In other words, a recollection dealing, say, with sex may mean that a child was actually caught unawares and frightened by a sexual advance from an older person, or it might mean that the child, by reason of already-existing feelings of anxiety or self-disparagement relating to sex, *interpreted* a certain happening (such as being followed) as though it had a threatening sexual significance.

Another factor, in keeping with the foregoing, is suggested especially by Horney's account of ways in which people often tend to "externalize" their inner difficulties. The process of externalizing may take the more or less familiar form of attributing to others (projecting on others) moods or attitudes resident within oneself (as when one who is hostile sees others as hostile but is quite oblivious of his own hostility). Now, one way of externalizing present difficulties is to project them on to or attribute them to one's own past environment and experiences. To avoid facing himself as he now is, and to avoid taking responsibility, as it were, for his *present* state, the individual may place responsibility upon happenings in his early childhood and he may be able to piece together plenty of "early memories" to support this position. The early memories he reports may, in reality, be true, but they represent only that part of the "truth" which happens to fit the individual's need for finding an explanation for his present problems.

Factors Influencing Recall and Reconstruction of the Past

At a given moment children and adults are likely to be able readily to recall more pleasant than unpleasant events from their immediate past (Wohlgemuth, 1922–1923; Flügel, 1925; Jersild, 1931).

A discussion of the concepts of suppression and repression would be in order here, but these concepts have been applied to the study of children largely on the basis of formulations arrived at through work with adults. The writer has not found any study which deals systematically with suppression and repression in a way that gives an adequate and plausible account of what these processes involve and how they undergo changes at various maturity levels.

Apart from consciously forgetting an episode in its totality, there are processes by which an experience may become modified or distorted in a child's recollection. Northway (1936) has shown, for example, how children, when called upon to recollect stories, tend to recast the contents into familiar terms and settings. She noted further that the younger children (the age range in her study was 10–15 years) by omission and addition molded the materials into a form nearer their interests to a

greater extent than did the older children. She found also that, the more foreign the material is to the child's "psychological field," the more he tended to substitute a story of his own invention.

A somewhat similar tendency has been noted in a study by Hildreth (1941, 1944), who found what she called a "difficulty reduction tendency" in children. When children, for example, attempted to reproduce designs they tended to substitute something meaningful for something meaningless, to "close" the design, to add conventional proportions when they were lacking. When confronted with a difficult problem, the child, according to Hildreth, unconsciously remakes it to fit his immature mentality. He reworks it to fit his grasp, getting out of it only what his limited insight and experience permit. This finding is not confined to children, however. Morgan (1944) found that logical thinking of adults may be warped not only by emotional bias but also by simple habit patterns.

Needed Research

The foregoing section touches upon many factors which make it difficult, and in some respects impossible, for the growing child to acquire an intelligent appreciation of what has happened or is happening in his emotional life. We have noted also that children before adolescence and even during that period often show a conspicuous lack of interest in inquiring into the nature and origins of their feelings.

Teachers and even psychologists have a tendency to take this lack of interest in self-understanding for granted, as something obvious, natural, and inevitable. But it is possible that the average child, with proper guidance, could learn, to a far greater degree and at an earlier age, to gain understanding of psychological problems. This is demonstrated in the success which workers have achieved through play therapy, group therapy, and other therapeutic procedures with troubled children at various age levels. The likelihood that children at the preschool level can learn to appreciate, at least to some degree, the psychological nature of some of their problems, and to deal with them, is indicated not only in clinical studies but also in studies conducted in educational settings. Chittenden (1942), in a study of selected nursery school children, found that children showed a decrease in "dominative" behavior (including aggressive methods of domination) without at the same time becoming more inactive or subdued after a training series in which they had a chance to study what happened when dolls used quarrelsome and cooperative methods of handling social problems such as those that arise in the play of young children. Another suggestive finding is reported by Appel (1942), who found that one of the most successful of the techniques used by teachers in dealing with the fights and quarrels of nursery school children was to try to interpret the wishes and feelings that came into play.

Findings such as these suggest that even at the preschool level children probably have a greater capacity for understanding and for using applied psychology than customarily is assumed in connection with their training at school. The studies do not give answer to the queston as to how early and how well a child might learn to bring reason to bear in understanding his own emotional experiences. But the writer ventures the hypothesis that much of the child's lack of understanding of psychological processes which we ordinarily encounter is influenced by cultural factors and is not due solely to constitutional limitations.

The writer (1951*b*, p. 122) has advanced the theory that human beings, from an early age, have more capacity for learning

to face and to understand and to deal constructively with the realities of life than we have hitherto assumed in our psychological theories or in our educational practices. To test this theory would require research of a kind that now is largely lacking in the literature on development. Apart from recognized obstacles within the child himself, many circumstances in our culture, including, in this writer's opinion, many of the things that go under the name of education at school, are calculated to divert and hinder a child from getting into contact with reality.

EMOTIONAL MATURITY

Before going into more detail concerning characteristics of various forms of emotional behavior that emerge as a child matures, it will be well to consider briefly what sort of yardstick or standard we might apply in judging what constitutes more or less "mature" behavior. The concept of "emotional maturity" figures prominently not only in accounts of older people but also in accounts of normal as well as disturbed children. This concept is implicit in the much-used idea of *regression,* or responding to stress by reverting to an earlier, more infantile form of behavior. The concept of emotional maturity is also involved in the idea of emotional *adjustment* and of emotional *stability.* Mitrano (1939) points out that forms of behavior conspicuously shown by children who are judged to be unstable include many "immature" forms of behavior. In line with this observation was a finding by Durea (1937) that delinquent children are emotionally less mature than normal children of similar age.

Many of our prevailing concepts of maturity are colored by cultural expectations which may or may not be well geared to the natural course of development. Notions of maturity that are applied to young children when they are urged to be "big," not to cry, not to be so afraid or so angry (which means, in effect, not to *show* that they are afraid or angry) often seem to be very false and very pernicious. Even at the adult level the pose of maturity which some people assume and fear to depart from may be a dangerous sham. But, even so, within broad limits, it would be useful to have a more systematic measuring rod than now is available.

To give meaning to the concept of emotional maturity as applied to children, it would be necessary to take account of maturity at various developmental levels leading up to the mature adult level. Even at the adult level there should be gradations, for as the science of gerontology progresses it probably will be found that there are pronounced differences between a "mature" adult of 25 and a "mature" adult of 45 that are just as truly *developmental* in nature as the differences, say, between the "mature" 6-year-old and the "mature" 10-year-old.

In her classical discussion of emotional maturity, L. S. Hollingworth (1928) calls attention to the fact that many of the tests of fitness for manhood or womanhood in ancient pubic ceremonies were tests of capacity to suffer, carrying the implication that emotional maturity consists of fortitude. In proposing her own criteria, she mentions first that the emotionally mature person is (1) *capable of gradations or degrees of emotional response;* he does not respond in all-or-none fashion. He keeps within bounds. If his hat blows off, he does not blow up. He is also (2) *able to delay his response,* as contrasted with the impulsiveness of the young child. Another indication of maturity is in his (3) *handling of self-pity.* Instead of showing unrestrained self-pity he tries to feel no sorrier for himself than others would feel for him.

The most outstanding mark of emotional maturity, according to Cole (1944), is *ability to bear tension.* Other marks of emotional maturity are an indifference toward certain kinds of stimuli that affect the child or adolescent (such as some of the circumstances that make the child afraid), and an outgrowing of adolescent moodiness and sentimentality.

Both Hollingworth and Cole have ably described some characteristics which we expect, in our culture, to find in a mature person, but their criteria do not provide an adequate theoretical base for the study of emotional maturity. Emotional maturity should be defined in the light of all the resources and powers that come into a person's possession in the process of development. It should not simply emphasize the idea of *controlling* emotions or keeping a lid on them. It should emphasize the idea of using emotional resources in a healthy and spontaneous way. According to this concept, "mature" emotional behavior at any level of growth is that which reflects the fruits of normal development in all the interacting aspects of the child's personality.[1] On this theory, a person who is able to keep his emotions under control, who is able to brook delay and to suffer without self-pity, might still be emotionally stunted and childish.

An adequate theory of emotional maturity must take account of the full scope of the individual's powers and his ability to enjoy the use of his powers.[2]

Below are listed some of the trends and tendencies involved in the process of physical, motor, intellectual, social, and emotional development that have a bearing on emotional maturity:

A change from helplessness to a greatly increased capacity for self-help, with a consequent progressive freedom from the frustrations and fears that beset a helpless creature.

A shift from abject dependence on others to increasing balanced independence, with consequent opening of channels for enjoyment of self-help and an increasing degree of psychological as well as physical self-support.

A shift from capacity to appreciate and react only to the immediate present to increasing capacity to encompass the past and to anticipate the future, with resulting changes in anticipation of both good and ill.

Increasing intellectual capacity, including increased capacity for dealing with aspects of life on a symbolic level, increased ability to plan; increased "attention span," bringing increased ability to see beyond and to be immune to momentary or intermediate frustrations; increased intellectual perspective and an increased ability to take a panoramic view of things.

A change from a disposition to be physically very active to an increased capacity during adolescence and later to tolerate and to enjoy sedentary pursuits.

A shift from social life centered only on the parents to a social life that encompasses one's peers and which also includes a capacity not simply to tolerate but to appreciate persons who are considerably older and considerably younger than oneself.

A change from being a creature who at first receives much, gives little, to one who is capable of giving as well as of receiving, and capable of learning to get enjoyment from giving.

Development of capacity to identify oneself with a larger social group, and the ability to participate emotionally in the fortunes of the larger group.

Development from the status of being the child of the family to the status, ultimately, of being able to have children of one's own and, along with this develop-

1 The discussion here follows rather closely an account written subsequent to, but published prior to, this book (Jersild, 1951a).

2 This point of view is implicit in Morgan's (1934) account of emotional maturity, and it has been emphasized and elaborated by Saul (1947).

ment, a capacity to exercise the feelings and attitudes involved in being a parent psychologically, whether or not one is a parent biologically.

Progressive sexual development and the capacity after puberty for enjoying mature sex experiences.

An increased capacity for bearing the inevitable sufferings and pains connected with life and growth without feeling abused.

An increased capacity for sympathy and compassion as one assimilates the meaning for self and others of the joys and vicissitudes of life.

These are a few of the trends in development that seem to have a bearing on a maturing person's emotional life. We might add the view that if a person has progressed in a healthy manner he will not, at maturity, be involved in hostilities or campaigns of self-vindication that arose in connection with childhood struggles and frustrations or in anxieties pertaining to childhood dangers that no longer exist. [According to Saul (1947), the emotionally mature person's aggressiveness will serve constructive ends.] But this perhaps sets so high a standard of "maturity" that only a few adults could measure up to it. Probably a more realistic way of putting it is that the "mature" adult is not one who necessarily has resolved all conditions that aroused anxiety and hostility but is continuously in process of seeing himself in clearer perspective and continually involved in a struggle to gain a healthy integration of feeling, thinking, and action.

STUDIES OF VARIOUS EMOTIONAL STATES

The ensuing sections will draw upon studies which deal with topics such as anger and hostility, joy, love and affection, and fear and anxiety. Much of the systematic research has been formulated in terms of these topics. At first glance this might seem like a fractional or atomistic approach, for emotions do not, of course, come in separate bundles that can be examined in the abstract. However, when we deal with these emotional states or with the circumstances underlying them, we actually are not dealing with a segment of experience, for anger and hostility, fear and anxiety, joy and contentment and all other conditions we might name represent an orientation of the organism as a whole. To understand any of these emotional states we must continually take account of the fact that all are intimately linked with the economy of the personality as a whole.

FEAR AND ANXIETY

In this section we will consider apprehensions ranging from episodes of conscious fear in response to a clearly perceived external event to anxieties and phobias which stem from vague or unrecognized tendencies within the individual himself.[1]

The Roots of Fear

Fear is a form of withdrawal or actual or incipient flight from a situation for which the individual has no adequate response. Fear has also been defined, from a purposive point of view, as a form of self-protecting flight from any circumstance which threatens a person's well-being (or what he regards as his well-being). In defining fear we need to encompass more than actual injury or imminent danger, for, almost from the time of birth, fear is often shown in response to stimuli which signalize a *possibility* but not an actuality of danger.

The circumstances in which fear arises even at a very early age, are so diverse that one cannot account for them simply

[1] Some of the differences between "fear" and "anxiety," as these terms have been used in the literature, are noted at a later point.

by analyzing the properties of the external stimulus. It is difficult also to find a common psychological ground, or cluster of common subjective or internal factors, that account for the various cases of fear. In a search for factors underlying fear, Hebb (1946) lists three. There are fears which he calls *fears due to "conflict,"* such as those aroused by pain or loud noise which have a "primitive disrupting action, not psychologically analyzable nor dependent on any previous experience" (p. 271). A second class, according to Hebb, consists of *fears due to sensory deficit.* In this class he lists fear of darkness, loss of support, and solitude, all of which "have in common an absence of sensory stimulation" (p. 272). A third class contains *fears arising from constitutional disturbances and maturation.*

This classification by Hebb leaves many questions unanswered but it represents a much-needed effort to bring scientific precision to bear on a subject which has suffered from much loose and oversimplified discussion.

Although fear may be described as a form of flight, the overt response takes many forms other than cringing or fleeing. It may range from apparently quite nonchalant behavior to violent displays of rage.

Psychologists show considerable agreement concerning some fears that appear early in life.[1]

Noise and Loss of Support. As already noted, among the conditions that frequently produce fear during the first days and weeks of life, without prior conditioning, are noises and sudden displacement or loss of support. Fears in the latter category may occur not only when an infant is thrown off balance or actually falls but also as a response to any rapid movement through space, as when carried rapidly downstairs. These stimuli do not invariably produce fear, and there is need for more investigation, both from the point of view of the properties or characteristics of these stimuli and from the point of view of the larger context in which they occur, before we go further than to say that they are especially potent at an early age.

Other Sensory Stimuli. Apart from noise and displacement, any sudden, intense, abrupt stimulus such as the sudden motion of an object, or an unexpected cutaneous contact, may be a source of primary, unlearned fear.

Fear of the Unfamiliar. Among the primary fears are fears of what is novel, strange, and unfamiliar (strange, that is, from the point of view of the child's previous experience). Somewhere between the age of about 5 and 9 months, many infants show fear of unfamiliar persons (Dearborn, 1910; Shirley, 1933; Jersild and Holmes, 1935*a*). Fear of strange things and situations has also been observed (H. E. Jones and Jones, 1928; Ellesor, 1933; Valentine, 1930; Bühler, 1930).

Novelty or strangeness has also been observed as a factor in producing fear when combined with other events which separately did not produce fear (Valentine, 1930).

In addition to fears of unfamiliar persons, things, and situations, fears have also been noted as response to unusual or "uncanny" things, including some forms of mutilation such as the detached arm of a doll or the half-decapitated body of a favorite doll (Dearborn, 1910; Valentine, 1930).

Fear of the strange and "uncanny" has also been observed in animals (Köhler, 1925; Hebb, 1946). Chimpanzees, in a study by Hebb (1946), showed numerous instances of fear when confronted with strange or unusual objects, such as a skull

[1] Among the early studies of fear not here reviewed are the works of Calkins (1894-1896); Binet (1895); Mosso (1896); and Hall (1897).

with moving jaw, a plaster cast of a chimpanzee visage, a model of an imaginary white grub with long legs. In an earlier study, Hebb and Riesen (1943) had observed fear of strangers in infant chimpanzees. After eliminating, experimentally or otherwise, other variables that might account for this behavior, Hebb concludes that anthropoid fears of inert, mutilated, or dismembered bodies are spontaneous in the sense that avoidance of such objects is not built up by association with a more primitive cause of fear.

When fear of the unfamiliar thus appears as a "primary" fear, without prior conditioning, it does not mean necessarily that this occurs independent of any learning. Learning is involved in such fears to the extent that what is *familiar,* and from which the strange person or thing differs, has become familiar through experience. Whether there is anything corresponding to primitive strangeness, something which in the nature of things will be perceived as strange, apart from any learned kind of awareness, or criterion or standard of familiarity, against which or in contrast with which something is unfamiliar, would be hard to tell. Conceivably there might be experiences arising from organic causes that might be experienced as something intrinsically queer and fear-inspiring.

The foregoing also indicates that, in the course of a child's experience, there are fears that arise by virtue of *lack* of conditioning or lack of familiarization to events that are not intrinsically and universally fear-producing. Six-month-old Charles fears *Jim's* mother because she is strange to him, and 6-month-old Jim fears *Charles's* mother for the same reason. Both might fear their own mothers at 6 months if they had been interchanged at birth and now saw their mothers for the first time.

The unfamiliar confronts a person with something for which he has no prepared response. It represents something which he cannot, at the moment at least, assimilate or take in stride in terms of his accustomed habits of action and perception. It does not fit into his established world; it calls upon him, on a small or large scale, to amend or even to reorganize his "inner" world.

Studies which show the extent to which children outgrow or lay by their fears (see, e.g., Jersild and Holmes, 1935*a*; Slater *et al.,* 1939) indicate that the process of experience through which the unfamiliar and fearful become familiar and commonplace occurs on a vast scale in the course of development.

But it also is apparent from various studies, as well as from everyday observation, that there may be large gaps and many lags in the process. Many children (perhaps we should say all) reach adulthood with fear of many things *not because these things are intrinsically fearful* but because they have not learned to take them in stride. A genetic study probably would show that fear of the unfamiliar and untried which appears in early infancy has the same paternity, psychologically, as the fear a person shows when he shrinks from new theories in politics and is afraid to face the prospect of getting new or different ideas about himself.

Individual Differences in Scope and Degree of Familiarization. The concept of fear by virtue of lack of familiarity, like the concept of fear through conditioning, greatly enlarges the extent to which it is possible for children to differ in their fears even when they do not have a different inherent tendency to be afraid.

Fear of Animals. Fear of animals usually does not appear as early as many other fears, but once susceptibility to such fears has been established, fear of animals remains prominent during childhood (Hagman, 1932; Jersild and Holmes, 1935*a*;

Pratt, 1945). As noted in an earlier reference to a study by H. E. Jones and Jones (1928) of fear of snakes, susceptibility to fear of animals changes as a child matures. More children at the age of 2 and at the age of 3 showed fear in response to a dog which was included as one of a number of experimental fear stimuli in a study by Holmes (1935) than to any other situation.

The question whether fear of animals is inherent or acquired has been raised from time to time in the literature. Valentine (1930) is one of the more recent writers who suggests that high susceptibility to fear of animals which he observed in his study suggests that this fear may be innate. On the other hand, Yerkes and Yerkes (1936), in a study of chimpanzees, tentatively conclude that their evidence does not demonstrate a specific fear response prior to or apart from individual experience. In view of findings regarding fears in response to strange things and to sudden, abrupt, or unexpected movements, and to noise, it seems probable, in the judgment of the writer, that fear of animals might occur as an unconditioned fear whether or not fear of the "animalness" of animals as such is innate.

Fear of Darkness. Observers have differed considerably with regard to the inception of fear of the dark. Freud (1936) speaks of being in the dark, being left alone, and finding a strange person in place of the mother as three of the primary anxiety situations in infancy. He believes that all three are "reducible to a single situation, that of feeling the loss of the loved [longed-for] person" (p. 99). Fear of the dark, then, is a feature of "the most basic anxiety of all," which arises in connection with separation from the mother (p. 100).

The evidence from direct observation of children raises doubts concerning this statement with regard to fear of the dark. The earliest record of fear of the dark in any of the five children observed by Valentine (1930) occurred when one of them was 2 years and 1 month old. J. B. Watson (1924) studied the response of three babies to darkness at about the age of half a year and found no fear, but one child cried when held by a stranger in a dimly lighted room. Dearborn (1910) observed at 176 days what might appear like fear of the dark. Stern (1930) did not record any appearance of fear of the dark in a child he observed until the youngster was 4 years, 2½ months old (p. 514).

The slow appearance of fear of the dark has also been noted by the writer in informal observations of his own as well as in a study in which mothers cooperated (Jersild and Holmes, 1935*a*). None of the mothers of 8 children who were observed in the age range from birth to a year reported fear of the dark or being alone in the dark (in contrast with many reports of fear of noises, falling, strange situations, etc.). Only 4 instances of fear of the dark, of being alone in the dark, were reported from observations of 23 children aged 12 to 23 months.

According to many observers, then, fear of the dark is rather infrequent during the first year or two as revealed by crying and other signs which the same observers often noted as signs of fear in many other situations during this same period. And, in some of the instances recorded, it was not darkness alone but noise, or a novel circumstance combined with darkness, that seemed to be responsible.[1]

However, as children grow older, darkness is a contributing factor, if not the

[1] On the theory that the flood of new sensory stimuli to which the newborn child is exposed is frightening, one should expect the child at first to be more frightened by any form of illumination than by darkness, and more afraid during the day than during the night, for night time usually brings not only darkness but also less noise.

main cause, in a great many fears. The fact that darkness actually separates a child from others in a psychological sense (as suggested by Freud) by making him and others invisible to one another is an important contributing factor. A state of darkness is often equivalent to a state of being alone. Regardless of the presence or absence of others, darkness makes a person more vulnerable, less able to cope with things. Apart from dangers a person's imagination might conjure up, darkness enhances some actual dangers.

Fear of Solitude and Separation. Freud regarded anxiety with respect to separation from the mother as a basic anxiety. Probably all children sooner or later become susceptible to fear of such loss. It also appears, however, that it takes something more severe and momentous than the ordinary comings and goings of a parent to elicit a fear of being alone or of being abandoned by the parent. In the study cited above (Jersild and Holmes, 1935*a*), no parents of children under 1 year of age observed fear of being left alone or abandoned during the period of observation. Fear of this sort was reported in 13 per cent of the children at the age level from 12 through 23 months. Perhaps all or nearly all the children might have shown the fear if they had been subjected to separation from their mothers in a drastic manner.

The fact that such separation can be very disturbing is brought out in observations by Edelston (1943) of hospitalized children. He reports a series of 44 cases showing neurotic disturbances of varying degrees. After ruling out physical or physiological interpretations, he concludes that separation-anxiety was the cause of the disturbances. He also points out that such anxiety as a response to hospitalization is not universal, for many children spend time in hospitals without any apparent ill effects. It appears that separation-anxiety, when it occurs, is part of a larger clinical picture.

Disturbing effects of being separated from the home were noted also in studies of children who were evacuated from cities in England during World War II (Isaacs *et al.*, 1941). As interpreted by Isaacs this separation-anxiety is something more sophisticated than a primitive fear. Isaacs states that it is complicated by conflicts involving secret guilt and shame as a result of the child's earlier hate, anger, and defiance toward his parent.

The foregoing observations emphasize that separation from the parent may involve children in intense apprehension, but we need more light on the total context associated with fear-inducing separation before we can conclude that fear of separation as such is one of the earliest spontaneous and practically universal fear reactions.

As far as fear of strangers is concerned, we would conclude, in the light of our earlier discussion, that this cannot be regarded as representing only a fear of separation. Fear of the novel, unhabitual, and strange relate not only to people, as we have seen, but also to situations and things, and it may appear even when a loved person is at hand (as when a child shrinks in apparent fear from a mutilated toy offered to him by his parent).

Later Trends in Children's Fears

Fears in response to events such as those noted above in the infancy period continue to occur quite frequently during preschool years. During the preschool years there is an increase in the everyday display of fear of animals. Fears pertaining to being alone or abandoned also occur, as noted. Many children exhibit fear of dangers associated with imaginary creatures and with darkness. Many of the fears of children of this age also pertain to possible injury through

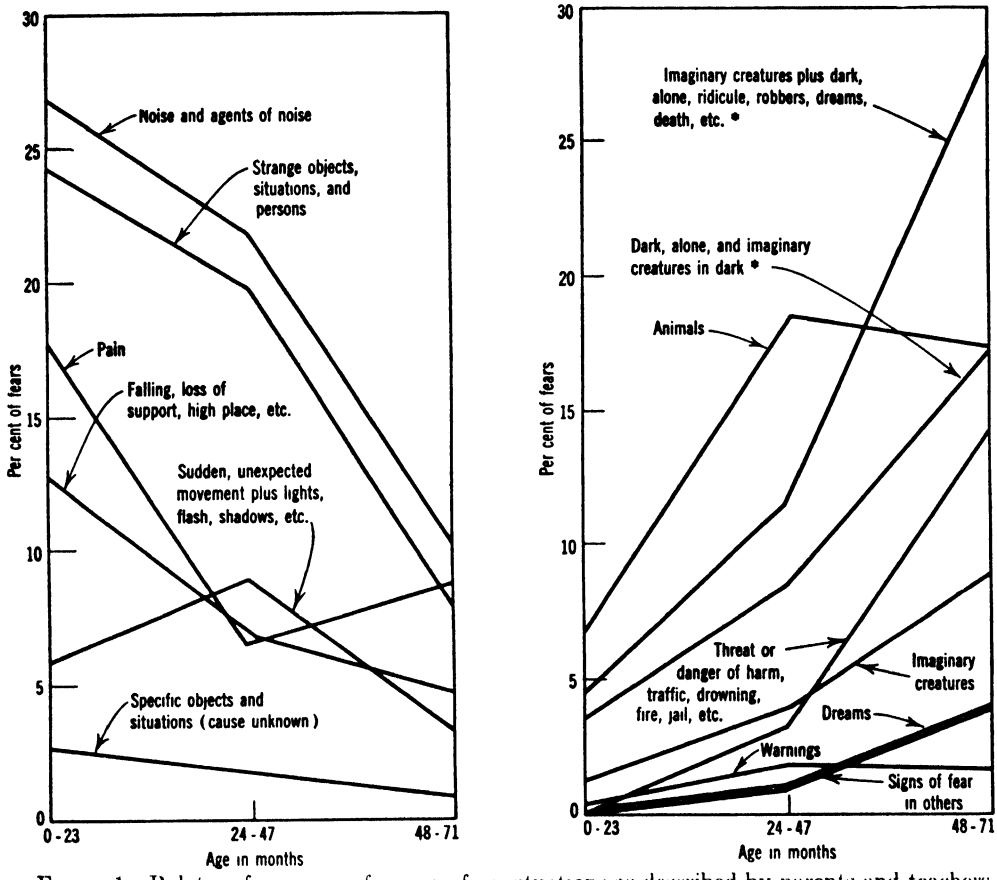

FIGURE 1. Relative frequency of various fear situations as described by parents and teachers, including 146 records of observation of children for periods of 21 days (31, 91, and 24 at the respective age levels), combined with occasional records of 117 additional children (27, 67, and 23 at the respective age levels). (Adapted from "Children's Fears," by A. T. Jersild and F. B. Holmes. *Child Development Monographs*, 1935, No. 20, 54. By permission of the publisher.) Entries followed by an asterisk include a combination of categories some of which are also shown separately.

drowning, fire, traffic accidents, and other physical accidents. Such fears also are relatively frequent during later years.

There are parallels between fears and other features of development during the preschool period [1] and into the elementary period and the period of adolescence. As children grow older they shrink from seeming different or peculiar. At the adolescent period, fears and anxieties relating to physical inadequacies and asymmetries, intellectual inadequacies, and sexual functions may arise (Bonar, 1942; Marsh, 1942).

Figure 1 shows trends in the frequency of various fear situations that were reported

[1] In a study by Dorkey and Amen (1947; see also Temple and Amen, 1944), evidence of "anxiety" in connection with personal relationships between nursery school children was obtained by means of a projective technique which gave the children a chance to use a happy face or a sad face in completing incomplete pictures of children in various situations.

in a study by Jersild and Holmes (1935*a*) in which parents made a record of fears manifested by their children during 21-day periods.

As the child grows older and is increasingly able to take account of the past and to anticipate the future, his fears are formulated increasingly in terms of remote or imaginary dangers or in terms of misfortunes that do not immediately threaten him but might befall him at a future time when he describes them in words. However, many fears of a concrete character also persist (England, 1946).

Discrepancy between Conceptual Fears and External Danger

By the time children reach school age, and in the years that follow, there is much disparity between the frequency of fear of certain dangers as described by children and the actual incidence of these dangers. In one study in which children were asked to tell about their fears and also, in another part of the same interview, to describe the "worst happenings" of their lives (Jersild, Markey, and Jersild, 1933) it was found, for example, that in the age range from 5 to 12 years 14 per cent of the children expressed fear of animals while only 2 per cent mentioned that they actually had been attacked by animals; 19 per cent expressed fear of ghosts, other supernatural agents, corpses, and the like, while none in actual life had suffered attack from these. In contrast, far fewer mentioned actual bodily injuries and accidents in describing fears than in describing "worst happenings." Interestingly enough, death or loss of relatives was mentioned slightly more often as an actual misfortune than as a recurring fear, and the same held true with respect to a category which included scolding, embarrassment, ridicule, and the like.

In another study, it was found that 53 per cent of 1124 children responded on a check list that they sometimes or often "worried" about "being left back in school" (not promoted), though actually the promotion policies in the schools were such that only about 1 per cent would be "left back" (Jersild, Goldman, and Loftus, 1941). In a situation such as this, the child's "fear" apparently gives an external reference to an internal or "intrapsychic" difficulty: even if there is every likelihood that he will "pass" according to the external standard imposed by the school, he still may regard himself as a failure according to internal standards for his performance falls short of what he thinks he should be able to do.

"Irrational Fears." As suggested above, many of the fears that beset children are "irrational" in the sense that they occur when there is no real external danger. Such "irrational" fears appear early in a child's life. Many of the strange persons, objects, happenings, and situations that he fears are quite harmless. Among a hundred frightening noises or other happenings that arouse fear only one may be a signal of real danger. Probably if we studied other creatures we would find the same: the rabbit is alerted again and again when actually things are safe; the hen runs to cover when the hawk overhead is heading somewhere else; and so on. A great many circumstances which elicit fear are, in effect, signals that danger *might* be afoot. The response anticipates the *possibility* of danger. If we regard such fears as irrational we must go the next step and say that it is natural and normal for children to have irrational fears.

Such irrational fear cannot be regarded, *per se*, as a sign of neurotic tendencies or intrapsychic conflict. But, having recognized this, we still face a question concerning what distinguishes morbid from healthy fears.

"Healthy" and "Morbid" Fears. It would be useful, indeed, if we had a ready way of distinguishing between healthy and morbid fears, between fears that serve a useful function in the normal course of development and fears that persist because something has gone wrong.

To solve this problem we need far more data than now are available from *direct, systematic study* of the personal lives of children over a long span of years. Probably we would need longitudinal studies not in one culture but in several, for cultural conditions influence the fears that arise and they must also be taken into account in judging whether a fear may reasonably be regarded as a response to real danger. In illustrating this point, Horney (1937) points out that a person in a group that has taboos against the eating of meat would, according to his indoctrination, have real cause for fright if he chanced to eat meat, whereas such fright would be unwarranted in someone living under a different set of taboos.

Although the developmental data are inadequate, we may proceed to review some of the efforts that have been made, and theories that have been advanced, in solving the problems raised above.

Anxiety

The concept of anxiety is very important for understanding the emotional life of the child even though there is much diversity, at present, in the definition of anxiety, its origin, and rôle. According to one dictionary definition, anxiety is a painful uneasiness of mind respecting an impending or anticipated ill. Various criteria have been used to distinguish between anxiety and ordinary fear. Generally speaking, it is assumed that the danger or disaster which is involved in anxiety is subjective or internal in nature—it resides within the personality of the anxious person—there are conflicting tendencies and impulses, unfulfilled needs, strivings, obligations, "oughts" and "shoulds" within him that underlie the disturbance known as anxiety.

One difference between ordinary fear and anxiety (as here distinguished) is in clarity and definition, as seen from the point of view of the person who is affected or from an objective standpoint. In fear there is usually a relatively clear *perception of the threatening circumstance* (whether this be external, such as a charging bull, or internal in the form of a sharp pain which makes a person apprehensive about his health). In a state of anxiety, on the other hand, the individual may be unable clearly to define to himself what it is that makes him anxious. "Something" makes him feel uneasy, "sets him off," but this "something" is difficult to recognize.

Also, in a state of ordinary fear the *feeling* is more or less clearly defined. The affected person is frightened and recognizes (if free to give thought to the matter) his feelings as feelings of fright. In anxiety, on the other hand, the feeling states may be quite diffuse, vague, and varied. They may or may not involve an experience of fear. They may involve experiences of being depressed, or tense, or keyed-up, or irritable, or "uneasy," or "under pressure."

There is a difference also in the clarity of the *impulse* that comes into play. The frightened person seeks to avoid or escape, even when he resorts to quite aggressive means of freeing himself from the danger which threatens (as when a frightened child, in desperation, attacks a big bully). But in anxiety the direction of the impulse is usually not so clear. The source or direction from which the danger comes may be perceived so dimly that the anxious person does not know in which direction to flee. So his reaction may appear to be quite indiscriminate and unsuitable.

Moreover, since the source of anxiety consists, by definition, in whole or in part, in a condition within the individual himself, there actually is no clear line of retreat, for a person cannot run away from himself.

Actually, the impulses shown by the anxious person may bear little or no resemblance to an impulse to flee. The anxious person may even seek out rather than shun an external circumstance which symbolizes, in part, his internal conflict (as when a person who is afraid of sex actually seeks out situations which will activate his fears). Again, the impulses connected with anxiety may take compulsive or obsessive forms. Anxiety may be expressed by a compulsion to be good and conforming and at all costs to avoid opposition to others, or a driven tendency to be perfectly neat, punctual, industrious. In older persons, anxiety may express itself by an insatiable drive for prestige, power, or possessions. These are only a few of the means, as described in the literature, by which an anxious person tries to protect and bolster himself.[1]

An illuminating account of manifestations of anxiety in everyday life has been given by Sullivan (1948). He maintains that "man in the process of becoming a person always develops a great variety of processes directly related to the undergoing of anxiety" (p. 3). The situations which arouse anxiety are "almost infinitely varied" but they are generally obscure. The expressions of anxiety that come into play whenever anything goes counter to a person's pride, or prestige, or his conviction that he is worthwhile and respected, or threatens the "self-system" involved in his accustomed way of life, take many forms that bear no resemblance to fear.

The concept of anxiety is useful, according to Sullivan, in explaining "a great many instances of irritation, anger, and unpleasant misunderstanding; all more or less enduring hateful relationships; the welter of belittling, disparaging performances which seem to be almost a national . . . characteristic; . . . the time-destroying more or less obsessional preoccupations which so frequently characterize the gifted; the sad way of the pathologically alcoholic; and a startlingly great proportion of the so-called sexual problems of our times" (p. 11). Sullivan states that resentment often, if not always, includes anxiety in its composition. He sees anxiety also as an element in the condition of many people who are chronically tired. He also regards "feverish overactivity" in work or play (shown by people who, as we say, "work themselves to death") as an expression of anxiety about becoming anxious, or about being discovered to be anxious, or as a means of avoiding awareness of an anxiety-provoking condition.

The inner tendencies and unresolved conflicts which underlie anxiety are quite commonly described as *unconscious* either in the sense that the individual has always been completely blind to them, or in the sense that he has lost sight of happenings within himself.

Other distinctions have also been made between fear and anxiety. The reaction in anxiety tends to be more disproportionate than the ordinary fear response: for example, we may expect a person who is crossing a canyon on an unstable half-rotten plank to be afraid, but it would be much less appropriate for a person to tremble with fear when walking across a well-built bridge.

Another distinction that sometimes is drawn is that anxiety anticipates danger

[1] For accounts of anxiety, see Freud (1936), Sullivan (1948), Horney (1937, 1945, 1950), May (1950), and Hoch and Zubin (1950). A classical treatment of anxiety which combines a religious orientation with many penetrating psychological insights can be found in Søren Kierkegaard's *The Sickness unto Death* (1951).

and thus serves, in a sense, as a protection against fear.

It has also been observed that the anxiety reaction may be conspicuously indiscriminate and undiscriminating. A person who is frightened by his hostile impulses, may, for example, not only feel panic at the thought of making only a mild criticism but he may go to great lengths later to placate someone whom he actually did not offend (except in his own imagination).

There is disagreement between writers with respect to what they encompass under the term "anxiety." Because of such disagreement, we cannot take findings about anxiety that A has reported and integrate them with the findings of B. For example, anxiety is sometimes treated as a state which fits into a continuum or gradation of fear. Mira (1940) lists phases of fear which begin with prudence and range through precaution, alarm, anxiety, panic, and terror. Goldstein (1947), on the other hand, draws a distinction between anxiety and fear and states that infants in whom the abstract attitude is still in process of developing are much more harassed by anxiety than by fear. Freud and his followers apply the term anxiety (*Angst*) to the earliest infantile levels in a manner that suggests that it should be regarded as a normal feature of development. On the other hand, anxiety is sometimes discussed in terms that have little resemblance to fear but which suggest, rather, a kind of weakness or disturbance in the personality which may express itself through a variety of emotional states.

Concerning the causes of anxiety, as we will note more particularly at a later point, there also is a large difference of opinion.

Phobias. Anxiety may be expressed in the form of phobia. A phobia has variously been defined as an irrational, persistent, and recurrent fear of an object or particular class of objects or situations which in objective reality represent no danger; as a "morbid fear"; as a fear whose origins have been forgotten.[1] According to Freud's (1933) account, a phobia represents a transformation of an internal danger into an external one: a "neurotic anxiety" is turned into an apparent "objective anxiety" (pp. 117–118).

A classical example of the Freudian conception that a phobia may serve as a transformation of anxiety is given in Freud's (1936) account of little Hans, which we discuss elsewhere in this chapter.

In her account of children's phobias, Isaacs (1933) develops the theme that anxiety is largely allayed by projecting troublesome aggressive wishes on to an external object and so being afraid of it. According to Isaacs, the fear of this phobic object is bad enough but it is not as overwhelming as the internal anxiety and guilt it replaces (p. 308).

As defined above, the fear involved in phobia might be called an *anxious fear* in that it involves hidden and subjective elements.

"Phobias" or "Fears"? The foregoing statements about phobias, like the earlier statements about *anxiety*, raise questions concerning the interpretation of the common varieties of "fear" which children display in their everyday lives, and they also raise a question as to terminology. English and Pearson (1945), in calling attention to findings obtained in studies of children's fears by the writer and his associates (Jersild, Markey, and Jersild, 1933; Jersild and Holmes, 1935*a*), comment on the "unreality" of a great number of these fears. They express the view that frequently children's expressed "fears" pertaining to wild animals, bad people, conditions associated with darkness, and the like, represent *phobias* rather than simple fears: the con-

1 Crider (1949) has reviewed numerous writings dealing with the definition and origin of phobias.

scious feeling tone of fear is ascribed to phobic objects which represent a projection of unsolved emotional conflict.

Leaving aside the question as to the nature of the emotional conflict underlying phobias (on which there is considerable disagreement), the writer is of the opinion that this position is partially correct: many of the "fears" that appear in the literature on child psychology are phobias in the sense that they represent something more than a rational fear of an objective danger. We may, however, question the view that all seemingly irrational fears of the sort mentioned above should be regarded as phobias. There probably are many seemingly "unreal" fears that need not be explained as a form of fear due primarily to something else. When a child for a long time is afraid of dogs after actually having been injured and terrorized by a dog, we do not need to assume that this fear represents, say, a displacement of a fear of his father arising out of ambivalent feelings. We face here a problem that is partly a question of the use of words, but largely a problem that can be solved only by more intensive genetic study of normal children.

Factors Contributing to Susceptibility to Fear

In many cases the cause-and-effect relationships in children's fears are relatively clear. The simplest response occurs when a child is frightened by a certain event and fears it when he meets it again. A more complex yet fairly clear sequence occurs when the child fears not only the event that scared him but also events that happen to be directly associated with it. Sometimes the chain of association is more devious and indirect and yet traceable. For example, a child who was frightened when struck by an automobile on the street later not only showed fear of crossing the street but he also had nightmares involving traffic accidents following which, for the first time, he showed fear of being alone in a dark room (Jersild and Holmes, 1935*a*). Many fears are not so easily traceable; and, even when fears are traceable, the conditions that render one child more susceptible to fright, and to after-effects of fright, are not easily determined.

Factors that contribute to a child's tendency to be afraid overlap and interact, but for convenience they may roughly be grouped under a few general headings.

Circumstances Involved in Parent-Child Relationships. We have noted earlier that many children, sooner or later, experience fear of being separated from their parents. There are many happenings short of actual abandonment that contribute to a child's apprehensiveness.

One such factor is severe *punishment* or *threats of punishment.* Such punishment may be corporal or it may be psychological in nature, such as punishment by way of being compared unfavorably with others, or by ridicule or by lurid stories. Punishment of a damaging sort may be meted out through a thinly disguised proxy, such as holding over the child the threat that the police will get him, or that he might become sick or paralyzed if he is not good, or that he is headed for hell. When children tell about their fears many of them will specifically describe various forms of threats and intimidation, including various forms of verbal *rejection* (see, e.g., Jersild, Markey, and Jersild, 1933).

Punishment and threats of punishment from the parent or a proxy affect the child in at least three ways which, in turn, may influence his tendency to be anxious. First, punishment may represent a form of rejection or abandonment. Secondly, it may instill the idea that the child is especially *bad* and thereby foster the idea that he is guilty and deserves to come to grief.

Thirdly, the punishment is likely also to arouse hostility toward the person who does the punishing and the child may, in turn, become afraid of his hostile impulses. Anxiety engendered by hostility has been described by Freud and his followers and by Horney.

According to some writers, a child early in life reacts to any form of denial of his wishes by the parents as a form of punishment which might predispose him to anxiety.

Apart from the effects of punishment administered by his elders, a child's tendency to be afraid may be aggravated by circumstances that *threaten to deprive* him of his parents. The coming of a new baby may be construed by the child as such a threat, with resulting apprehensiveness. An example of this appears in one of Holmes's studies of overcoming fear (1936). Here, again, according to psychoanalytical interpretation, the child may become anxious not simply because of the direct threat of loss but indirectly as a reaction against the hostility he feels by virtue of the threat of deprivation. Klein (1932) describes a 4-year-old's fear of being left alone as arising from the child's desire to injure her mother who was pregnant.

A child's disposition to be frightened may also be influenced by the *example of fear shown by his parents*. In a study conducted by the interview method, Hagman (1932) found many similarities between the fears of mothers and the fears of children of preschool age. During World War II, John (1941) found that a young child's fears and the persistence of after-effects following an alarming event, such as an air raid, are likely to be influenced to a marked degree by the extent to which his elders are calm or display terror. When a parent shows fear he tells the child, in effect, that there is danger afoot, and the fact that the parent is afraid perhaps also has the effect of lowering the child's confidence in the parent's ability to protect him from this danger.

Physical Weakness or Handicap. A child's disposition to be apprehensive may be affected by anything that physically weakens him or lowers his capacity, such as *illness* or a *physical handicap*. Stratton (1929) reports that college students who had a history of many illnesses during childhood are likely to exhibit more fear reactions than persons who have been free from serious illness. Not only is illness debilitating in itself but also it may have many psychological consequences by way of overprotection, interference with normal development of independence and self-help, effects on the growing child's ideas about himself and his worth, which indirectly can have a bearing on his anxieties and fears. In a study by Pintner and Brunschwig (1937) *deaf* children of school age reported more fears than children with normal hearing. In a study of *blind* people in the age range from 10 to 21 years, Boutonier and Henri (1946) found that the fears of the blind were aggravated by their difficulty in visually imagining and identifying noises. Their fear of loud noises was aggravated by the fact that such noises mask feebler sounds on which they depend for spatial orientation. They were also subject to shock when suddenly touching something without visual forewarning such as a normal person would have.[1]

Stresses in the Process of Development. Various *hurdles in the process of development* may also involve the child in circumstances that influence his fears. We have already pointed to examples of these.

Conditions contributing to anxiety may occur in connection with the child's *sexual development*. In connection with the prac-

[1] A survey of studies dealing with adjustment to physical handicap and illness has been prepared by Barker, Wright, and Gonick (1946).

tice of masturbation, children are frequently subjected to treatment that arouses shame and guilt and fear concerning their present integrity and future well-being. In a study published in 1937, Pullias found that about 7 out of 10 first-year college boys in his group had received information sometime during childhood or adolescence that the practice of masturbation would lead to serious mental damage, and about the same number had been informed that it would lead to serious physical damage. At the time of the study, over 80 per cent of the college boys stated that they believed that masturbation would produce some form of serious harm either mental or physical or both.

In a survey of the sex practices of boys, Ramsey (1943) found that about 73 per cent reported that they had had experience with masturbation by the age of 12, and about a third reported that they had attempted heterosexual intercourse before adolescence. Many of the boys (exact details are not given) reported that they were worried and afraid by reason of their sex interests. The physical changes that occur in sexual development, notably with the onset of puberty, may also arouse fear. In a study by Landis, Landis, and Bolles (1940) it was found that many women reported that they were emotionally disturbed by their first menstruation, but others were untroubled by this development, or proud of it.

With the onset of puberty some children also are worried by aspects of their physical development that influence their appearance (Stone and Barker, 1939).

According to Freudian theory, there are many other hurdles in the development of sexuality that expose a child to emotional stress. Some psychoanalysts maintain that children are subject to feelings of anxiety or hostility (or both) when they discover the genital differences betwen the two sexes (see, e.g., Levy, 1940). Findings by Conn (1940) did not reveal that such reactions are typical in normal children.

After-Effects of Severe Fright. After an especially harrowing and frightening event a child (like an adult) may for a time show a heightened tendency to be afraid of the thing that scared him and of other things, besides (John, 1941).

The after-effects of a particular frightening experience probably will be more severe in a child who has a past history of being anxious and emotionally disturbed than in a child who hitherto has been quite stable. In line with this, it was observed in England during the second world war that children who already suffered from anxieties in connection with their everyday home life were more likely to be anxious about being evacuated from home than children who had a happy home life (see, e.g., Burbury, 1941; Davidson and Slade, 1940; Isaacs, Brown, and Thouless, 1941; John, 1941).

Stresses Which Threaten Self-Esteem or Self-Acceptance. Anything that lowers a child's confidence in himself, anything that threatens his self-regard or threatens to disturb the rôle he wishes or pretends to play or threatens to block goals which he regards as important, may increase his tendency to be anxious or afraid.

Blows to Self-Esteem at School. Many of the circumstances that affect a child's self-esteem arise in connection with his life at school. At school, children are exposed to failure, or the threat of failure, on a colossal scale. Even when customary competitive trappings are eliminated, such as public marks and ratings, being labeled as a "slow learner," being "kept back" to repeat a grade, and the like, the academic and the social setting is such that the children become involved in many competitive situations of their own making. School is the situation in which children try themselves out in countless ways, realize their

strengths, and discover many of their weaknesses and limitations.

Some schools have standards and policies that foredoom many children to repeated failure. Sandin (1944) has described the emotional impact on children of being officially stamped as failures at school when told that they will not be promoted to the next grade.

Apart from failure in this stark form, the school may function as a proving ground in which the child is plagued by weaknesses and disorders which have arisen in connection with his life at home. In a study by Hattwick and Stowell (1936) it was observed that children who were "pushed" or "babied" by their parents had more social and academic difficulties at school than children who were not subject to such treatment. An especially acute disorder involving fear directed toward the school has been described by several writers as a "school phobia" (Johnson *et al.*, 1941; Van Houten, 1947–1948; Jacobsen, 1947–1948). This phobia has been regarded as a result of emotional conflict which does not originate in experiences in school but is precipitated by something that happens in school. Several writers, in reporting factors associated with this phobia, have mentioned, among other matters, disturbances in the relationships between the children and their mothers, including inconsistency and frustration on the mothers' part, complicated by other happenings in their lives, and, on the children's part, aggressive impulses toward a parent on whom they are very dependent, and a tendency to make demands and to dominate. In a discussion of conditions underlying children's reluctance to go to school, E. Klein (1945) maintains that "all of a child's worries, fears, anxieties, self-consciousness, feelings of inadequacy, his relations to his parents, to his siblings, and to himself tend to gain reflection in the school situation" (p. 263).

The possibility of failure in meeting the demands of the school is mentioned by a large proportion of children when they report what they "worry" about (Zeligs, 1939; Hicks and Hayes, 1938; Pintner and Lev, 1940; Jersild, Goldman, and Loftus, 1941; Pressey and Robinson, 1944).

Conflicting Tendencies and Impulses. Apart from the effects of external threats or reminders of failure and other circumstances that might endanger his self-regard, a child's tendency to be anxious or afraid may be greatly influenced by conflicting tendencies and impulses within himself. In drawing attention to such conflicts and inner defenses, Freud has made a profound contribution to the understanding of human emotions which has wide application whether or not we accept all his theories concerning the nature and cause of conflict.

Theories of Anxiety

The foregoing statements concerning conditions that predispose or contribute to fear or anxiety touch on circumstances which have been emphasized in current prominent theories of the origin of anxiety. But to single out some of the theories for further discussion might help to crystallize certain research issues for developmental psychology. In this area there is great need for direct longitudinal study of children. Much of the theoretical structure underlying present-day concepts of anxiety has been built upon findings gained from work with people in the process of undergoing psychological treatment or from laboratory studies which may or may not duplicate the realities of life as faced by the growing child.

We have already alluded to some features of Freud's (1936) accounts of anxiety. He expresses the opinion that a certain predisposition to anxiety is undoubtedly present in the infant. It is not at its maximum

immediately after birth but "first makes its appearance later on with the progress of psychic development" (p. 98). Among "instances of the expression of anxiety in infancy" are those arising in response to the three situations of being left alone, being in the dark, and finding a strange person in place of the one in whom the child has confidence (the mother). And these, according to Freud, are all reducible to a single situation, that of feeling the loss of the loved (longed-for) person (p. 99). He conjectures that the most basic anxiety of all, the "primal anxiety" of birth, arises in connection with separation from the mother (p. 100). He says further in line with this that the situation that the infant appraises as danger and against which it desires reassurance is one of not being gratified. It involves a situation of deprivation. Along the same line he says that "object loss" is the precondition of anxiety, and such a loss appears not only in the early anxiety arising from the loss (separation from the mother) but also in the "next transformation of anxiety," the castration anxiety, which involves a danger of separation from the genital which is "tantamount to a second separation from the mother" (p. 103) for the reason that possession of the genital organ contains a guarantee of reunion with the mother (or a mother substitute) in the act of coitus. And the loss of the organ would mean the loss of this guarantee.

Freud states that in the normal process of development children outgrow their susceptibility to anxiety-producing situations such as a morbid fear of being alone, or of being in the dark, or of strangers. Many phobias of animals likewise are outgrown, according to Freud. But many people continue as adults to remain infantile in their response to danger, continuing to react with anxiety to situations which should have long ceased to arouse it, and "it is exactly such persons whom we call neurotics" (p. 120).

We have earlier referred to Freud's (1936) classic case of little Hans who had a phobia of horses. He feared that he might be bitten by a horse. Underlying this fear in little Hans was an anxiety stemming from an ambivalent attitude toward his father. He had an Oedipus conflict: he was jealous and hostile toward his father, but he also loved him. He felt hostile, but he also had reason to fear retaliation. His father might punish, might mutilate (castrate) him, and it was "because of castration anxiety that little Hans renounces aggression against his father" (p. 48). His phobia of the horse was an attempt to deal with this conflict. He hit upon a horse as the object of his phobia partly by reason of having once actually seen a horse fall down and he had also seen a playmate fall and hurt himself while playing "horsie." Hans displaced or "detoured" his hostility from the father to the horse. His repressed "instinctual" hostile impulse toward his father was represented in a wish on his part that his father should fall down and hurt himself as had the horse and his playmate. The hidden force behind the repression of hostility toward the father was castration anxiety, and the manifest content of the anxiety, being bitten by a horse, was a "distortion of and substitute for another content, that of being castrated by the father" (p. 49).

Elsewhere Freud says, in more general terms, "anxiety is the reaction to a situation of danger," and the symptoms of anxiety are created in order to avoid the danger situation of which anxiety sounds the alarm (p. 82).

In the foregoing review of Freud's statements, there is the view that anxiety may arise by reason of loss of or threatened separation from the loved object (mother), and also the idea that anxiety may arise

because of conflict between incompatible impulses and tendencies (Hans's "instinctual" hostility toward his father clashed with fear of his father). To subsume both of these under one theory, on the ground that the latter, by involving "castration anxiety," also has the meaning of threatened separation from the mother, involves rather complicated speculation.[1] If the two are to be combined it might be better, in this writer's opinion, on the theory that both the separation anxiety and the anxiety arising from hostility toward the father represent conditions which threaten to remove, destroy, or disturb a relationship between the child and someone who is very important to his survival and his development.[2]

We have earlier referred to theories of anxiety set forth by Horney and Sullivan. Although these have not been documented by systematic longitudinal studies of young children, each has the great merit of interpreting anxiety in the context of a systematic theory of personality development and each involves a concept of developmental continuity even though many developmental details need to be filled in or inferred, especially at the early childhood level.

Horney (1939) advances a concept of basic anxiety consisting of a feeling of helplessness toward a potentially hostile world. Anxiety of this kind leads to the development of neurotic defenses and is, in this respect, different from the kind of anxiety which may be aroused by dangers to life and limb, through illness and overwhelming forces of nature. Anxiety develops in an environment which is unreliable, unjust, and cruel, which thwarts the child's free use of his energies and undermines his self-esteem and self-reliance. This is something more comprehensive than Freud's concept, as stated above. According to Horney's concept, the child does not simply fear punishment or desertion because of forbidden drives; rather, a harsh environment as a whole is dreaded as something which is a menace to his development. Such an environment threatens not simply an instinctual desire but the child's individuality, his whole way of life, for his security and his opportunity to develop and to make free use of his resources and to draw upon his potentialities for growth depend upon the adults who have him in their care.[3]

Since it would be dangerous for the child directly to give vent to hostility which is aroused by restrictive treatment, he resorts, according to Horney's account, to certain defenses and strategies in an effort to cope with the world. Depending on a combination of many factors, he may adopt a strategy of trying to assume control over others, a strategy supported by aggressive, expansive, and competitive behavior traits

1 The concept that a boy fears that his father might castrate him represents, it seems to this writer, something even more recondite than the concept of anxiety.

2 Mowrer (No. 3 in Part I in Hoch and Zubin's *Anxiety*, 1950) has presented a theory of anxiety which takes its lead from Freud's work, but instead of regarding anxiety as arising out of "repressed id" he sees anxiety as representing "repressed superego." Anxiety does not come by reason of repressed instinctual impulses, according to his view. It is "simply the conscious manifestation of unconscious, repressed, repudiated guilt" (p. 28).

3 The position that frustrations and discrepancies represent the primary source of disturbance in early personality development (as distinguished from early instinctual aggression) has also been set forth by Lauretta Bender (No. 7 in Part IV in Hoch and Zubin's *Anxiety*, 1950). Bender regards anxiety which occurs "as a response to early instinctual aggression" as a matter of secondary importance. She reports that a "serious deformity in personality may occur in a child when there is a critical change in parent relationships before the latter part of the first half-year of life" (p. 121). She regards this as the period when children "first identify their parents and show a definite and individual relationship to people around them" (p. 121). But personality distortion may also be produced, according to her observations, by a very critical break in total family identification during the second, third, and fourth years.

that serve his struggle to vie with others, to go against them, to outdo or rise above. Or he may adopt a strategy of withdrawing within himself, with a predominant tendency to remain aloof and detached. Or he may adopt a self-effacing, compliant, conforming type of behavior. But such strategies (which may appear in mixed forms) provide an expedient and not a solution. To the extent that they are stratagems rather than an authentic expression of the child's nature, they represent something devious and ulterior—a pose, an assumed rôle, rather than the real person. When the individual becomes committed to such an assumed rôle he is, in effect, showing alienation from himself.

In the process of living up to the assumed rôle, defending it and protecting it from being exposed and destroyed, the individual continues and aggravates the process of alienation from self. This condition is burdensome because the realities of life continually threaten the pose that the person has taken.

As the child develops, he will, according to Horney (1939, 1950), acquire a large variety of inhibitions, subsidiary techniques, assumed values, and acquired sensitivities in the service of the strategies he uses in his relationships with other people. The person with a trend toward aggressiveness and competitiveness reacts to others as though they were against him but from an early age he may conceal this tendency under a front of politeness and good fellowship.

The person whose pose is to show a compliant trend has a need to be accepted, liked, wanted, and appreciated, but the "genuine portion" of the urge for affection and approval is "heavily overshadowed by his insatiable urge to feel safe" (p. 51).

The person who takes the way of withdrawal and detachment in interpersonal relationships does not show simply a desire to be alone at times but a form of estrangement from people, a compulsion to put an emotional distance between himself and others, even though he may succeed in putting on an act of getting along very well with others. The detached person eventually develops many forms of behavior in the service of an indiscriminate need not to be influenced, coerced, obligated, or tied to someone else.

These disturbances in *interpersonal* relationships, according to Horney's theory, produce disorders in the *"intrapsychic"* sphere—in the child's own subjective view of himself and relation to himself. In the process of developing artifices and stratagems in coping with others he becomes estranged from himself. In coping with others he is forced to override his genuine feelings, wishes, and thoughts. He is not, as Horney puts it, the driver but the driven. He is divided in the sense that he cannot freely enjoy and freely express his own feelings and thoughts but must subdue them in the interest of safety. He cannot freely be himself. In assuming a front in his relations with others he also adopts a front within himself. Having subordinated his own thoughts and feelings in his defense against others, he has in a sense surrendered the stuff out of which his growing self might develop and evolve.

What emerges is a distorted self different from what might be called the real self. What Horney has called an idealized self comes into being. This represents a kind of pseudo-identity through which the child achieves a false kind of integration and inner rationale for the stratagems and techniques, the "solutions" which he has been driven to adopt in his dealings with others. He needs something that will give him a hold, a feeling of identity, something that would make him meaningful to himself and give him a feeling of significance. Whereas the real or potential self represents all the individual's resources for growth and ful-

fillment, the idealized self represents what a person is according to an irrational image of what he is or should be. If he feels driven to comply indiscriminately or to be aggressive or detached he does not see these artifices in their true light. He may, for example, see his aggressiveness as a form of strength, as something heroic, marking him with qualities of leadership.

Moreover, according to Horney, the person may even succeed in reconciling (to himself) the contradictory tendencies that occur when trends clash (as would occur when a predominantly compliant person has the impulse to assert himself), and he sees these contradictory tendencies as features of a rich personality—he has the resources not only for being meek and humble but also for being strong.

The idealized image, according to Horney's position, is not a matter of convenience that suddenly comes into being. It develops through time. It serves as a precipitate of the individual's mode of dealing with himself and with others. As one writer has put it, it "consolidates" the individual's defenses, it concretizes them into an integrated whole, "it becomes the epitomy of the defense system" (Gershman, 1950).

Anxiety occurs when this system of defense is tampered with or threatened. Anxiety which originally occurred in the individual's relationship with others now arises by reason of incompatible tendencies within himself. Anxiety is aroused when the neurotic "solution" is threatened. As Gershman (1950) puts it, "the total anxiety of a person is a measure of the discrepancy between the idealized image and the real self."

Some features of this account are easier to verify than others. A child is ignored or harshly punished; he suffers, cringes, feels abused, but is afraid to strike back. So far the process is fairly clear. He adopts a strategy to protect himself from abuse by being, say, very "good" (compliant), and we can see how he can adopt such a strategy without necessarily being very deliberate or conscious of it. But when we move to the next step, as in Horney's account, and bring in the concept of alienation from self, the concept of an idealized image which involves an internal integration of the stratagem or solution the child has adopted to fend for himself in his relations with others, we move from what can be observed and verified to a process which cannot so readily be traced step by step through a series of observable developments. But this difficulty appears, it seems to the writer, in connection with all theories, psychoanalytic or otherwise, which in one way or another attach importance to subjective processes that occur before the child can perceive or formulate in words matters of importance that are happening to him.

This does not negate the truth of a theory, but it does make it more complicated. One trouble about theories of anxiety is that the theories themselves are somewhat anxiety-provoking to those who have to try to express them in their own words. Perhaps this is one reason why so many psychologists for so many years were so easily seduced into following the simplified version of emotional development proposed some decades ago by John B. Watson.

Sullivan's (1947) theory of anxiety likewise is tied to a concept of the developing self and the dependence of the child upon others. According to him, a person comes into being in an interpersonal field. The development of the self in the little child is intimately and intricately tied to the child's relationship with others, especially those nearest to him, the "significant" person or persons in his early life. The self, while it is a highly individual

phenomenon, has social origins. The attitudes of the person or persons in whose close care the child lives from hour to hour and from day to day constitute the emotional climate, the psychological environment, in which the process of self-discovery and self-development takes place.

According to Sullivan, the infant feels the approving and disapproving attitudes of significant people in his environment before he is able clearly to perceive what is going on. There is what he calls interpersonal induction of anxiety. Anxiety is induced by the disapproval of people who are significant within the child's interpersonal world. In due time the child is able to perceive approval and disapproval and to recognize the actions or circumstances which bring approval or disapproval, and he becomes alert to signs of approval or disapproval in others. The self-dynamism is built out of experiences of approbation and disapproval, reward and punishment. According to Sullivan, approval brings comfort and satisfaction whereas disapproval brings discomfort, and such discomfort, at a stage of development at which the child is incapable of a clear perception of what is happening to him, may be the origin of a condition of anxiety. The "good mother" is associated with relaxation; the "evil mother," with the undergoing of anxiety (1948, p. 10).

According to Sullivan, the attitudes of significant persons toward the young child have a crucial bearing upon his developing attitudes toward himself. The self is made up of "reflected appraisals." "The child's earliest self-appraisal is in terms of what others think and feel about him. If these appraisals are chiefly derogatory (as they will be for a child with parents who impose unbearable demands on him or otherwise reject him or ignore him), the growing child's attitude toward himself will be chiefly derogatory. The kind of interpersonal relationships that induce anxiety are also the source of intrapersonal anxiety. In the older person, anxiety is aroused by anything that threatens the "self-system." Anxiety intervenes to ward off experiences which might keep a person from living in his accustomed way. Anxiety helps to ward off awareness of tendencies in the individual's personality which have not been integrated with the self the individual conceives and approves. Anxiety, thus conceived, has the effect of safeguarding the morbid condition of the self which arose as a defense against earlier anxiety-producing circumstances, which continue to render a person subject to anxiety. It serves as a defense against the danger of self-discovery.

OVERCOMING FEAR

Numerous methods of dealing with fear have been applied in everyday dealings with children, and many of them have also been tried out under experimental conditions. In a review of such methods, English and Pearson (1945) maintain that they touch only upon the *conscious* aspect of the situation. According to English and Pearson, these measures are only supplemental to the aid the child should have in dealing with the real causes of his phobias.

Probably all would agree that it is important in dealing with fear to try to dispose of both the conscious and the unconscious elements that may be involved. But we need more clarification of how operations on a conscious level might also have an influence on the unconscious level.

In connection with his own studies of fear, the writer has the impression that when a child is helped to overcome a "fear" which a psychiatrist might label as a "phobia" there is also a possibility that the child can gain relief from (or greater strength in dealing with) the condition that underlies the fear or phobia. A child who

has with help "overcome" an intense fear of dogs actually may have undergone an experience that extends beyond the mere removal of a symptom. He has faced up against what to him was an objective danger. In the process he may have gained a changed conception of himself and more confidence in his ability to deal with his problems. Any such gain in self-reliance might involve a significant change in the total subjective environment, the self-system. At least, there is this possibility. We can accept this as a possibility in some circumstances and still recognize that in many other situations the steps taken to cope with the conscious or objective aspect of a phobia may have little or no influence on the underlying anxiety.

In an experimental study of methods of eliminating fear, M. C. Jones (1924*b*) used a number of procedures described as the methods of disuse, verbal appeal, negative adaptation, repression, distraction, direct conditioning, and social imitation. Only the methods of direct conditioning and social imitation proved to be very successful. Hagman (1932) found that when mothers used the method of explanation alone it was unfruitful in a large number of cases, but it was superior to no treatment at all. Explanation was more effective when combined with exposure to the situation. Conn (1941) has described the use of a play-interview technique for helping children to understand and to cope with their fears.

Findings in an investigation by Jersild and Holmes (1935*c*) by means of interviews with parents and reports by other observers, and results in a later experimental study by Holmes (1935), confirm some of the findings mentioned above and emphasize other procedures.

Greatest success was reported for procedures that helped the child to gain increased competence and skill, aided him in finding practical methods of his own for dealing with the feared situation, and helped him by degrees to have active experience with, or successful direct participation in, the feared situation. Probably, as suggested above, this procedure was effective in some instances because it helped the child to acquire a changed conception of his ability to cope with his weakness and this might entail a changed attitude toward himself.

In an experimental study in which efforts were made to foster active experience with feared situations and skill in handling them, Holmes (1936) worked with 13 children who were afraid to enter a dark room. After 3 to 7 exposures each child in the experiment entered the room alone, without hesitation or requests for company, felt his way through the darkness, turned on the light, and retrieved the ball. Although, as Holmes points out, the results do not indicate whether the gains made by the children would transfer to other situations, the findings, as far as they go, have practical implications.

In another experiment, Holmes worked with 2 children who showed fear of walking across a plank at a height of 4 feet. After 8 exposures, one of the children (aged 39 months) walked the length of the board alone at a height of 6 feet. She also walked happily at the same altitude after 1 exposure to a modified apparatus that was set up in a different situation. The other child also made progress at first, but then reverted to earlier forms of behavior. His problem, as shown by his response to the experiment and by other information, was obviously more complicated than a simple fear of walking on an elevation.

This case emphasizes that direct dealings with a fear which apparently represents an underlying anxiety may fail to have much effect.

Children themselves often are eager to come to grips with fears that impede their

everyday activities, and they will sometimes devise quite ingenious ways of their own to gain mastery over a feared situation (Jersild and Holmes, 1935*a*, 1935*c*).

A study by Shaffer (1947) of fear and courage during aerial combat confirms and supplements findings from children regarding factors that aggravate and that help to relieve fears. Information was gained from over 4000 fliers after return from combat, practically all of whom reported that they were afraid on every mission. From this study it appears that forewarning about a known danger with ensuing anticipation of it aggravated fear: more showed fear when a mission was known well in advance than when it was announced suddenly. Among the conditions that reduced fear in combat were: confidence and morale (confidence in equipment, crew, etc.) and effective activity (keeping busy, concentrating on the job, on making a good hit, or on other constructive activities). On the other hand, fear increased by helplessness and hopelessness, including inability to fight back, having to be idle while in danger, and being insecure about the future. The finding that helplessness aggravates fear and that ability to control or cope with an anticipated painful event reduces fear also has emerged from experimental work with rats (Mowrer and Viek, 1948).

Overcoming Anxiety through Psychotherapy and Psychoanalysis. We will not in this chapter attempt to review the vast clinical literature dealing with psychotherapy as applied to anxiety or to personality disorders in general. In this area, as in others, there are differences of theory and practical approach, but we will touch briefly on only a few points that are of more or less general interest.

One significant observation, in the writer's opinion, is that concepts which are prominent in current theories in psychotherapy and psychoanalysis are becoming more and more illuminating when applied to the psychology of everyday life. Many concepts which owe their origin directly or indirectly to the genius of Freud are taking on an added meaning. Theories pertaining to the self (as set forth by writers such as Horney; Rogers, 1942; and Sullivan), concepts pertaining to self-acceptance, self-rejection, the developmental continuity of the self-system, the concept of defenses of the ego (or self), and the concept of alienation from self are as important in understanding children and our everyday adult associates as in understanding the character of a patient.

A great impetus to the understanding of the mature individual also is offered by the concept (explicit in our developmental literature and emphasized also more and more in many psychoanalytic writings) that the *developmental continuity* that links the "mature" personality to early childhood occurs in the form of pervasive trends or tendencies in the total personality structure and not simply by way of an isolated episode or a limited and hidden "traumatic event" or a failure to scale a particular hypothetical hurdle, such as the "oral phase" of "pregenital" development.

The concept of *interpersonal relationships* helps in understanding the great range and variety of factors involved in the social origins of the child's ideas concerning himself (and of self-acceptance and alienation from self).

The concept of *resistance,* long recognized especially in psychoanalytic work, has important implications in connection with the emotional behavior of the "normal" child and the resistance to learning that takes place in the child's life at school and in his relationships with his peers and parents. Lecky (1945) has offered an interesting discussion of this matter. A person seeks to protect and preserve his pic-

ture of himself; he strives for self-consistency, and he will resist or try to avoid or reject experiences that threaten to modify or require a re-examination of a cherished view of the self. This concept of resistance helps to throw light on much of the behavior a child shows at home, and it certainly throws light on the vast amount of evasive shadow-boxing in school that goes on under the name of "not being interested" or under the label of "free discussion" at the elementary, high school, college, and post-college levels, and even under the label of "research." This concept also carries with it, the writer believes, the principle that the process of learning involved in revising a concept and attitudes pertaining to the self is likely to be painful. Learning that actually involves an inner revision is likely to hurt, whether the education producing it is offered in the office of a clinical psychologist, or on a psychoanalytic couch, or in the classroom of an ordinary school.

The concept of *transference*, which also has held an important place in psychoanalytic theory, likewise has important ramifications in everyday life. The feelings of hostility, affection, grievance, and the like, which a client or patient projects on to the person who is treating him, may, at moments, be more intense but they are not different in kind from the feelings which a person brings with him into his relationships with people at large.

ANGER, HOSTILITY, AND AGGRESSIVENESS

Anger, like fear, is a response to a threatening circumstance, but in anger the impulse is to move against rather than to move away from the source of the disturbance.

Anger is a response to thwarting under circumstances in which the individual is not completely at a loss or momentarily overwhelmed as in terror.[1] The circumstances that give rise to anger range from those in which a person is restrained from bodily movement to circumstances in which he perceives or believes that his desires, expectations, ideas, or his pride and self-esteem are or might be under attack.

The term *anger*, like the term *fear*, denotes a vast variety and gradation of responses including momentary outbursts of rage, temper tantrums involving a great amount of undirected activity, and more prolonged and recurring states such as those involving chronic feelings of hostility or milder forms of annoyance, sulkiness, and peevishness.[2]

Developmental Changes. The occasions that elicit anger parallel the course of development. A child's susceptibility to anger at any given maturity level is influenced by the *limitations* and by the *urges, strivings,* and *activity tendencies* that are characteristic of that level. As examples, we may note the anger of a young child who wants to put an object in his mouth but lacks the proper motor coordination; the anger of a child who lacks physical strength to dislodge his wagon when it is stuck; the anger of a child who is eagerly "learning" to walk but is hindered; the anger of a school-age child who, as a feature of his social development, has a strong desire to "belong" to a certain group but is blocked by a dominant member; the anger of an adolescent whose urge to make a favorable impression on the opposite sex is thwarted, or who is reminded of his child-

1 A somewhat more specialized characterization of anger has been offered by Lazell (1929), who maintains that anger afflicts only those who refuse to permit themselves to become conscious of their inferiorities or failures.

2 Logre and Fouquet (1940–1941) have drawn a distinction between "exasperation" and other emotions such as anger and hysteria. Exasperation, they say, is the "anger of the weak."

ish characteristics when he especially wants to appear mature and independent.

The most systematic evidence concerning anger in young children is provided in a study by Goodenough (1931*b*) in which parents cooperated in observing and recording anger episodes. In the case of the children who were less than 1 year old, one-fourth of all outbursts arose in connection with routine care such as dressing or bathing. Minor physical discomforts were reported as responsible for about one-fourth of the outbursts. Direct restriction of bodily movements accounted for slightly over 6 per cent of the outbrusts.

At 2 years, a large percentage of anger outbursts arose in connection with the establishment of routine physical habits, and second in frequency were conflicts with authority over matters not directly concerned with habit training. Problems of social relationship represented a third important source of difficulty. Provocations arising in connection with matters of self-help or minor physical discomfort or restriction of bodily movement were less prominent.

At the 2-to-3-year level, the three outstanding sources of provocation were conflicts with authority, difficulties connected with the establishment of routine physical habits, and social difficulties with playmates. Between the ages of 3 and 4 years, provocations arising in connection with social difficulties and disagreement with playmates reached their maximum, and conflicts with authority accounted for about one-third of the outbursts that were noted. At 4 years and upward, difficulties arising in connection with social relations continued to represent the most frequent sources of provocation. Next in order came difficulties arising over physical habits and conflicts with authority over matters not connected with physical habits or self-help.

Unfortunately, there are no studies at the school age and adolescent levels similar to the study Goodenough made of younger children. Moreover, the Goodenough study, rich as it is in facts about the young child, offers only a limited amount of information concerning the interplay of anger-provoking situations or episodes (as described above) and the basic or pervasive attitudes of the parent toward his child. Goodenough's observations suggest that situations leading to anger in the child are more likely to occur in his home if parents are inclined to be anxious. From everyday observation one can get the impression that the more a parent is troubled and torn by conflicts the more occasions there will be for the child to be troubled. But even in the most serene home there are bound to be frictions and thwartings leading to anger. It would be helpful if we had a clearer conception of the phenomenon of anger as a frank and inevitable reaction to the robust realities of life as distinguished from the play of irascibility and peevishness which springs from hidden anxieties.

As a child grows older and as his relations with people outside the home become increasingly important to him, there is an increase in frequency of annoyances pertaining to people other than his relatives (Jersild and Tasch, 1949), just as nonrelatives play an increasing rôle in his everyday joys and satisfactions.

In a study of 250 junior high school pupils, aged 11 to 16 years, by means of interviews and other methods, Hicks and Hayes (1938) found that the following circumstances, in order of frequency, most often made the children angry: being teased; people being unfair to them; a sibling taking their property or imposing on them; people lying to them; things not going right; people being sarcastic; and people being bossy (p. 233). Most

of these conditions, it can be seen, relate to people and characteristics of people that infringe on the child's comfort, his pride, or his conception of what others have the right to do to him or expect of him. One item on the list indicates that friction between siblings is still an important source of annoyance to children in their early teens.

In a study including both junior and senior high school pupils and dealing specifically with conflicts between children and their mothers, Block (1937) found that 71 per cent of the young people checked an item to the effect that they were disturbed by having their mothers hold brothers or sisters up to them as models of behavior. Many other items pertaining to desires for independence, nagging of various kinds, restrictions of various sorts, were also checked with high frequency. Many children (half of the boys and over four-fifths of the girls) also reported that they had been disturbed because the mother insisted that they must take a brother or sister with them wherever they went.

Findings such as these indicate that the child's need to protect his pride, his independence, and his self-respect represents the most important basis for anger.[1]

At the adolescent level, many children are annoyed not only by specific parental practices but also by parental traits and habits (Stott, 1940).

At the college level, Gates (1926) likewise found that people more often caused anger than things. Meltzer (1933) also found that conditions arising in connection with social relationships were a frequent cause of anger at the college level. Another frequent cause was failure in activities that had been undertaken.

The fact that there are many conditions in everyday life which continue to be annoying to people over a wide age range has been brought out in a study by Alexander (1946), who questioned people in the age range from 10 to 50 concerning their antipathies, and in a study by Conrad and Jones (1942), who obtained information concerning the annoyance encountered by a sampling of about 300 children yearly for a period of about 5 years beginning in the sixth grade.

FACTORS CONTRIBUTING TO SUSCEPTIBILITY TO ANGER

Among the circumstances in the environment that made children more susceptible to anger in Goodenough's study were the following: the presence of many adults or many older siblings in the family group; visitors; a tendency on the part of a child's elders to be critical or overanxious or uncertain, or inclined to nag about small matters; a concern about the moral goodness or badness of the child's behavior rather than its appropriateness from a developmental or situational point of view; inconsistency in discipline; past experience in gaining objectives by a show of anger.

Among the organic factors noted by Goodenough (1931*b*) as contributing to increased irascibility were the child's state of health as indicated by colds, bed-wetting, constipation, etc.; delays in feeding; the presence of fatigue and previous sleeplessness. The influence of factors such as fatigue and hunger on emotional susceptibility has been noted also by Gates (1926) and Young (1937) in studies of college students. Stratton (1929) found that adults who had a history of illness during early childhood tended to be somewhat more subject to anger than persons who had no history of serious illness.

Another factor that directly or indirectly disposes a child to anger is the assignment of tasks that are very difficult or impos-

[1] Hostility associated with sibling rivalry is treated in a separate section below.

sible for him to perform (Dembo, 1931; Keister and Updegraff, 1937); restrictions in space, both psychological and physical, or having to stay within rigid confines may increase tension that leads to aggressive feelings (Lewin, Lippitt, and White, 1939).

Varieties of Expression of Anger and Hostility

The infant's first expressions of anger involve much diffuse, poorly coordinated behavior. The most frequent single expression of anger in early childhood is crying, but this diminishes with age. Goodenough (1931*b*) observed that before the age of a year the child's outbursts of anger are rather explosive in nature, not well designed to remove a thwarting obstacle or to fight off an offender. As the child grows older his behavior when angry becomes less random and more directly aimed at something or someone. At the age of 4, about half the expressions of anger were found to be aimed at the object of the children's wrath. With this change toward calculated and directed behavior there also was an increase in retaliative behavior of a sort which denoted a desire to get revenge. Goodenough found that threats began to appear between the ages of 2 and 3 and increased in frequency thereafter.

No sooner has a child acquired the ability to direct his anger at the object of his wrath than he comes under pressure to inhibit his expression of anger. For a child to give vent to his anger is uncomfortable and annoying to others and it may even be dangerous to others or to the child himself. The child is not only only under strong and sometimes violent pressure from others to inhibit outward show of anger but he also discovers that if he attacks he is likely to provoke a counterattack. So in the process of development human beings learn a great variety of ways of giving vent to anger and hostility other than in open and direct attack.

Verbal Aggression. At an early age children express their resentment verbally rather than by physical violence. A shift with age toward more bickering and quarreling and less fighting appears notably in connection with children's quarrels at the preschool level. The means of verbal attack which a child is able to learn by the time he reaches maturity are practically endless. They include direct methods, such as calling the other person bad. They include, from an early age, *verbal denial of affection*, which may be expressed directly ("I don't like you"), or indirectly by calling attention to the lovable qualities of someone else.

Verbal aggression may also take the form of assertions of superiority by the aggressor ("I can lick you"; "I've got ten thousand marbles") or by assertions aimed to belittle the offender.

It is largely by verbal means, also, that a large variety of indirect forms of attack are carried out, ranging from simple forms of tattling to gossip and slander designed to injure another person's name.

Teasing. Teasing is a frequent way of expressing hostility, especially in relations between children. Teasing can be developed into such a fine art that the blame is placed on the one who is teased when at last he loses his temper and continues with his fists a fight which his adversary started with words.

Swearing. The function of swearing in relieving the tension associated with aggressive feelings has been examined by Montagu (1942), who notes that social taboos have restricted women from swearing, and when not allowed to swear, women substitute the more infantile reaction of weeping. With increasing social emancipation, according to this line of thought, we may perhaps ex-

pect women more and more to renounce weeping in favor of swearing.

There has been no developmental study of swearing, as far as the writer knows. It is a common expectation in our culture that children, like women, will not swear (or, at least, not swear as much as men). Many boys who are destined to do a great deal of swearing do not begin in earnest until they are of adolescent age. It is interesting to note that while swearing is in many respects an infantile form of response, it usually does not appear habitually until the child has "matured" well beyond the infantile level.

Expressions of Hostility in Fantasy and Play. From an early age aggressive impulses occur prominently in children's fantasy and overt make-believe play. Hostile feelings may occur in connection with an imaginary plot or counterattack which includes imaginary scenes in which the individual is superior to the offender, or scores a triumph of wit, or calls him names, or witnesses him actually coming to grief through tripping, stumbling, or some other accident or misfortune. Imaginings of this sort are especially prevalent in connection with anger experiences in adults (Richardson, 1918), and they probably appear, in one form or another, as soon as children are able to pursue an imaginary theme in their own thoughts.

The fact that a child in his play may reveal feelings of hostility (as well as other feelings, such as anxiety and desires for recognition and approval) has made the use of play situations a very productive technique in connection both with research and with therapy with children. When provided with a suitable play setting it has been observed that a large proportion of children will show aggressive behavior of one sort or another. In a study by Baruch (1941) which used dolls representing children's families, 32 of 46 preschool children within a period of 15 minutes showed aggression in ways such as: separating a single member of the family from others, spanking, burying a member, and calling names.

Although it is an easy matter to provide a play setting in which children will show aggressive behavior, it is not a simple matter to tell what such behavior means. There may be a clear discrepancy between the kind of aggressive behavior a child shows in play and the kind of treatment he receives from his parents. One child who is not spanked by his parents may freely spank the doll he plays with; another who is often spanked may not allow himself to spank the baby doll. There may be a discrepancy also between what the child does in a make-believe setting and what he does in actuality (on the playground with other children, or with his family at home), and what he *says* he does or would do (Fite, 1940).

In a study by Korner (1947), play materials, incomplete stories, and frustrating situations were used with children aged 4 to 6. Expressions of hostility which children revealed included direct expression of hostility; retaliation in kind, such as spanking if the parents spank; open spite; verbal rejection; ridicule. Other, less direct, expressions of hostility included destructiveness; hostility carried out by an external agent, such as having another child in the doll family inflict punishment on the person who causes the frustration; hostility displaced, on to others, such as having the child hit other children rather than the offending father or mother; hostile acts rationalized through identification with the parents, such as having the little boy throw the child who has fought with him out explaining, "My mother throws people out who fight."

Although the children in Korner's study responded rather vigorously to vicarious frustrations imposed in a story-telling sit-

uation and to the direct frustration of being kept from using a preferred toy, it was found that there was only a low correlation (.29) between the sum total of hostility tallies in the two experiments. There was also a rather low correlation (.21) between the total of hostility tallies in the story-telling experiments (there were ten story-telling play-material situations) and hostility shown by the children in real-life situations as reported by the parents.

Displaced Hostility. When blocked or inhibited in his impulse to express his anger directly against an offender, a child, like an adult, will frequently center his anger against objects, as when he smashes a toy when angered by his mother whom he hesitates to attack openly. He may direct his anger against animals, as when he hurts the family cat. He may vent his anger upon other persons, as when he "takes it out" on a younger sibling, or turns wrathfully against the milder of his parents when he has been angered by a parent who is stern and whom he fears. He may turn wrath that has been generated at school against his parents. Sometimes there may be a combination of direct or primary anger and projected anger, as when a child is spiteful toward a sibling who has directly annoyed him and who also serves as a scapegoat for anger induced by other frustrations.

Cruelty. The expression of hostile feelings may take the form of recurrent cruelty, as when a child hatches schemes to hurt another innocent person, or sets fire to ant hills, or goes out of his way to kill frogs, toads, and other creatures. The subject of cruelty in children is in need of study from a developmental point of view, for "cruel" behavior may represent varying combinations of hostility, thoughtlessness, and exploratory interest at different developmental levels. The development of marked reactions against cruelty, in the form of irrational solicitude for animals and childish forms of antivivisectionism, also offers a significant field for study. In cases of extreme solicitude for animals it is difficult to tell to what extent it represents pity and sympathy, or an expression of the child's anxieties, or a form of denying or reacting against his own hostile feelings.

Prejudice. Prejudice serves as a means of projecting one's anger on someone else, although this is not its only motivation. While children may incorporate as their own, without feeling very deeply about it, the prejudices held by their elders, the phenomenon of prejudice as a form of displaced hostility sometimes appears at a relatively early age. First graders, for example, sometimes are aggressive toward innocent "foreigners" (the "foreigner" may be a member of a different race or religion, or a different socio-economic level, or simply a stranger or outsider to some or all of the children when he first arrives). In a study of older children, Frenkel-Brunswik (1948) found that those who were notably prejudiced tended, among other matters, to be more punitive in their attitudes than children who were relatively unprejudiced.

Bullying. The aggressive motive behind bullying is usually quite obvious. If a child expresses his hostility primarily or solely by bullying, one may suspect that he not only is hostile but also is subject to anxiety or feelings of inferiority. Bullying as a form of displaced revenge may prevail for a time in children who are abused or persecuted when they first join a new group. In a study of camp children, Osborne (1937) describes a sequence in which a child is first the butt of bullying and teasing, and who then, as he learns to hold his own in the group, for a time bullies others, and then, as he makes further gains in poise and self-confidence within the group, discontinues his bullying.

Antisocial Acts and Ideals. Aggressive impulses may be expressed through various forms of resistance or rebellion against prevailing standards. The most violent forms of expression in this category occur in the form of acts of delinquency and crime. Truancy may also be a gesture of hostility and defiance. Sexual promiscuity apparently also sometimes serves as an expression of resentment or rebellion.

A subtler form of hostile, antisocial behavior occurs when a child harbors ideas or feelings that go markedly counter to the needs or aspirations of the group. In an informal study of children's heroes and ideals by the writer and some of his students it was observed that a few notably rebellious children expressed their aggressive feelings by naming, as their ideals, celebrated criminals. Examples of the manner in which children may show overt sympathy with the enemy during wartime as a way of expressing their hostility toward persons in their environment are described by Escalona (1946).

Self-Inflicted Punishment. From an early age, children occasionally "take out" their anger on themselves. The violent head banging which some children display during temper tantrums is a notable example. Head banging has also been observed as an expression of rage in chimpanzees (Hebb, 1945). As time passes, many additional forms of self-punishment appear, such as when the child unduly blames himself or deliberately courts troubles or accidents that might injure him. This phenomenon of self-inflicted pain, and motives behind it, has been discussed more fully from the point of view of its meaning in adult life than it has been investigated from a developmental point of view.

Psychosomatic Mechanisms. In children, as in adults, the effects of anxiety, hostility, and other disturbing emotional states may appear as physical symptoms. Also, as we have noted elsewhere, a physical weakness or ailment will influence a person's irritability and emotional susceptibility. Both these conditions represent a form of psychosomatic interaction. Emotions may have secondary somatic effects, and a somatic condition may have a pronounced influence on emotion.

Many studies have added to knowledge concerning the interplay of mind and body as revealed in well-known phenomena such as physical disabilities occurring in connection with emotional conflict, as in conversion hysteria; the influence of drugs and toxins on moods and emotions; the occurrence of nausea, voiding of the bowels, and other involuntary physical reactions during times of acute stress.[1]

Sulzberger and Zaidens (1948) have described how emotions may directly involve skin reactions, such as blushing, and gooseflesh, and may also indirectly precipitate skin disorders. Numerous writers have explored the theory that illness may serve as an escape from frustration. The interplay between psychological and biochemical factors in connection with asthma and other allergic reactions has likewise received considerable attention. Among other troubles, arthritis and other rheumatic diseases frequently appear to have a psychogenic origin and represent, according to one theory, a reaction to suppressed hostility.

Probably in instances where such reactions occur there is a physical reason why this particular symptom, and not some other form of somatic reaction, should appear. It is difficult to determine, as one writer puts it, which comes first, the "rheumatic chicken or the emotional egg" (*Time*, June 13, 1949). But, whatever the answer

[1] Readers are referred to the journal *Psychosomatic Medicine* and to various books and articles such as Cannon (1929, 1939); Young (1937); Dunbar (1946); Saul (1947).

to that may be, it is clear that in studying the emotional behavior of children it is important to recognize that a great variety of physical disorders may be symptoms of emotional disorder. This observation includes also physical injuries which may arise, as pointed out in another section, when an emotionally disturbed child deliberately or unwittingly exposes himself to physical accidents as a form of taking revenge upon others or as a means of punishing himself.

Externalization. In many of the expressions of hostility noted above, the hostile person is, in effect, disavowing his anger or avoiding a direct display of it. Such disavowal involves much actual or attempted self-deception.

Anger and hostility are so sharply deplored in most strata of our society that children from a rather early age develop stratagems to conceal their anger from themselves and others and techniques for evading responsibility for their rage. One mechanism is to externalize hostility. The child who has externalized his hostility toward his teacher does not see himself but the teacher as a hostile person, and by this stroke he justifies his grievances against her and is freed from the painful thought that the seat of the difficulty is in him and not in her.

Grievances and Feeling Abused. A common manifestation of externalized hostility appears in the child or adult who is full of grievances.[1] The concept of grievance helps greatly to illuminate many childish arguments, quarrels, complaints, and antipathies, and it is also a great help in understanding much of the recrimination and argumentation that goes on in the name of various "causes" espoused by adults. The person who has managed to develop what to him is a grievance, a "real" reason for feeling abused, possesses a fine device for placing full blame on others and for removing all blame or responsibility from himself. It is the others who are mean, dishonest, unfair. "They" are against him. "They" are the ones who will seize every opportunity to do him about. At the adult level, there are many symbols and whipping boys representing grievances. We need a "New Deal" because we have been abused by the Old Deal. But to those who feel abused by the New Deal, it is a Raw Deal, so we need a Square Deal, and so on.

An appeal to grievances, an effort (in a political campaign, for example) to play upon the resentments of persons who feel abused, is an especially powerful device because it is directed at something that probably is latent to some extent in all people from early childhood on. It touches upon feelings that have a basis in reality (it is likely that all children actually have experienced mean and unfair treatment from someone and to that extent have a grievance founded in reality). And it touches even more effectively on the irrational attitudes such as those that come into play when an aggrieved person feels hostile toward others and then externalizes hostility, as described above.

While a person's feeling of being abused is directed against others, it may be tied to a person's unrecognized attitudes of contempt and hostility toward himself. On this theory, the person who to a substantial degree predicates his behavior on irrational feelings of being abused lacks integrity in his dealings with himself, and if he plays on these irrational attitudes as a means of manipulating others he lacks integrity also in his dealings with others.

Weakness of "Inner Controls." In an absorbing account of "children who hate," Redl and Wineman (1951) have described difficulties which beset children who have been exposed to severe rejection and abuse. Such children may show a conspicuous lack

1 For a discussion of the feeling of being abused, see Horney (1951).

of the "inner controls" which we expect to find in children who in the course of their character development have had the benefit of friendly relationships with others and have been able to count on others for sympathy, example, and moral support. Among the characteristics observed in such children by Redl and Wineman (1951, pp. 74–140) were: low frustration tolerance; unconstructive stratagems for coping with insecurity, anxiety, and fear; low resistance to temptation; a tendency to become excited and to show "group psychological intoxication" (as revealed, for example, by impulsivity and primitive forms of sublimation); "sublimation deafness"; irresponsibility with regard to property and possessions; a tendency toward panic when confronted with something new; a loss of control over the "traumatic onrush from the past"; disorganization in the face of guilt; lack of insight into self-contributed causal links in a sequence of happenings; lack of a realistic attitude toward time, including lack of a realistic concept of "future consequences" or of "themselves in the future"; considerable blindness to social realities; loss of potentials for learning from experience; greater than normal difficulty in reacting rationally to failure, mistakes, and success; difficulty in reacting constructively to the challenge of competition.

Variations in Culturally Sanctioned Channels of Aggression. The fact that cultural sanctions regarding the expression of aggression operate in varying ways was noted above in a brief comment about swearing, and it has also been emphasized in other observations. In the Saulteaux Indian Society, according to Hallowell (1940), members of the group are under social constraint to cultivate patience, self-restraint, cooperation, and harmony in their dealings with each other and to avoid overt aggression, but closer study shows that strongly hostile feelings still prevail and are expressed through the culturally sanctioned channels of gossip and resort to sorcery and magic. This study suggests that observed differences in aggressiveness between various primitive groups may be more apparent than real, and it also suggests the possibility that a concerted study of many different cultural groups might reveal not only that the problem of aggressiveness prevails in all but also that some groups have solved this problem more constructively than others.

Interplay of Anger and Fear

We have already noted that there is a close relationship between anger and fear. Sometimes a person vacillates between the two. Some circumstances produce both. By virtue of a change in the child, a circumstance which once produced fear (such as a threat by another child) may produce anger (if the threatened child now is older or more confident of his strength). The occurrence of one of the emotions may stimulate the arousal of the other, as when a person is frightened by the violence of his anger, or is angry at himself by reason of the restriction of freedom which his fears impose upon him.

Various studies have shown that there is a correlation between susceptibility to anger and fear. In a study of a group of especially "aggressive" children, Kepler (1933–1934) found that about half of them also showed anxiety in their behavior. In studies of college students, Stratton (1927) and Anastasi, Cohen, and Spatz (1948) found a positive correlation between the frequency of reported experiences of anger and fear. The frequency of reporting both anger and fear might be influenced by the faithfulness and by the perceptiveness of the person who is keeping the record, but it seems reasonable to assume that these emotions would be associated. A person

who shows a high incidence of one of them quite likely is vulnerable or irritable or frustrated or harassed to a degree and in a manner that might readily lead to a high incidence of the other.

At the 3-to-5-year level, Felder (1932) found that anger outbursts were far more frequent than displays of fear. It appears that in a well-protected environment it is easier to shield a child from specific events that are likely to frighten him than to eliminate thwartings of the kind that lead to anger. In some instances, however, the higher incidence of anger than of fear may be more apparent than real, since there are children who express their anger quite overtly but conceal their fears or find means of avoiding direct contact with the situations that they dread.

Although passing displays of temper may be more frequent than manifestations of fear, the latter are regarded quite often as constituting a "problem" in behavior of young children (Foster and Anderson, 1930).

Non-Aggressive Responses to Frustration

The subject of frustration overlaps but does not fully coincide with the subject of conditions that give rise to anger and hostility. The term "frustration" as used in current writings has a meaning somewhat broader than the thwarting that elicits anger. In their classic study of frustration, Dollard, Doob, Miller, Mowrer, Sears, *et al.* (1939) speak of frustration as "an interference with the occurrence of an instigated goal-response at its proper time in the behavior sequence" (p. 7). Other definitions have variously identified frustration as the blocking of or interference with the satisfaction of an aroused need through some barrier or obstruction (Symonds, 1946, p. 51); as a situation in which accustomed reactions do not satisfy an aroused motive (Shaffer, 1936, p. 117); as a state of high tension incident to the blockage of a path to a goal (G. Murphy, 1947, p. 145).

Many methods have been used in experiments with frustration, including difficult or insolvable problems or tasks, being denied a favorite toy, having a lure such as chocolate bar suspended just beyond reach, substituting something that has no appeal for something that has much appeal.[1]

Experimentally induced abnormal behavior in animals through the use of frustration techniques has been studied by Maier (1939, see also review of studies, 1948) and others. In Maier's study, rats were placed in a card-discrimination problem situation in which reward and punishment were applied in random order, confronting the animals with an insolvable problem; besides, a jet of air was directed at the rat to force it to react.

Among the responses which frustration may arouse are the following: aggression, regression to a more childish level of behavior, resistance, withdrawal, apathy, expressions of guilt or remorse or shame or embarrassment, nagging, threatening, efforts to evade the issue, efforts to rationalize or explain away the issue. In response to long-continued frustration, the individual may build up mechanisms of self-deception, or he may respond with rigid ritual-like forms of behavior.[2]

As in response to thwartings of a sort that normally produce anger, the response to frustrating situations will depend not only on the source or nature of the frustra-

[1] See, e.g., Fajans, 1933; Barker, Dembo, and Lewin, 1937; Britt and Janus, 1940; Burton, 1942; Frederickson, 1942; Seashore and Bavelas, 1942; Sherman and Jost, 1942; Korner, 1947; Miller and Bugelski, 1948.

[2] A comprehensive account of various forms of frustration arising both from internal and from external circumstances, and of varying types of response, has been given by Rosenzweig, 1933–1939. Rosenzweig also develops the concept of "frustration tolerance."

tion but also upon habitual tendencies in the child. If he generally tends to be assertive and aggressive, he may respond aggressively; if he is insecure or anxious, he may withdraw or respond with behavior rituals that do not solve the problem. By reason of the fact that response to frustration shows variations of this sort, the particular behavior which the frustrated individual shows may give little or no indication of his needs.

LOVE AND AFFECTION

We have noted earlier that during the first year of life children begin to show affection for others. It would be difficult to determine to what extent the young child's affectionate behavior represents a primary drive or an acquired motive. But we can say, at any rate, that a child's display of affection for others seems to appear spontaneously, and, as Dennis (1938) has shown, it will arise with a minimum of social stimulation from others. The factor of learning will, of course, influence the particular persons and objects to which the child's affections become attached.

Developmental Changes

Most of the written material on affection deals with the child's need for love. It pictures him as one who receives affection without much mention of the fact that he also gives affection. If we could study this matter we probably would find that at a relatively early age the ability to accept and the ability to bestow affection are closely interrelated.

There is very little systematic information concerning the development of affection, concerning the way in which the child's capacity for loving, and the range or scope of his affections, wax and change in the process of development. We know from everyday observation that as time passes the child's affections expand in scope. He shows affection for his parents, immediate members of his family, and, as time passes, for other persons in his environment. Eventually he become capable of a wide range of loyalties that contain an element of affection.

Likewise, from an early age, the child begins to acquire affection for pets and things and places, his doll, his favorite toy, an old blanket, the family cat, the house and grounds wherein he lives, and so on.

With the passing of time there are changes also in the quality of his affection. As he develops, he increasingly gains in ability to appreciate the feelings of others, to sympathize, to feel compassion, to respond to loved persons with thoughtfulness and tenderness, to give to others out of love.

We can also observe in everyday life manifestations of infatuation and romanticized love which some persons show in adolescence but which many exhibit long before adolescence, and others continue to exhibit long after.

We can also observe the manifestations of parental love which may involve a degree of solicitude and tenderness and a degree of self-forgetfulness that mark it off from any other experience in life.[1] This love appears in its fullest form when parenthood is attained, but even this form of love often appears at an early age when a child "mothers" another child, shows a loving, motherly attitude toward a doll, or shows an affectionate, motherly or fatherly attitude toward a parent.

There are findings dealing with one aspect or another of these manifestations, but we

[1] Deutsch (1944–1945) has drawn an interesting distinction between psychological and biological motherhood. A woman can function psychologically as a mother without having borne a child, and the fact that a woman actually has offspring will not necessarily give assurance that she is a motherly person.

have nothing approaching a systematic developmental record of the actual and potential range and scope of a child's affections or of changes in form and quality, or of the dynamic relationship which the development of his own affectional life bears to his personality as a whole. Findings on the last point are limited, for most observers, as we have said, have stressed the child's need of being loved without dwelling on the degree to which it is essential, for his own full development, not only to be loved but to love others. The intimate relationship between love for others and love of self has been discussed by Fromm (1947). The Golden Rule also touches rather trenchantly on this relationship. The relationship between love for self and love for others, acceptance of self and acceptance of others, self-rejection and rejection of others, self-hate and hatred for others is emphasized explicitly or by implication in the writings of Horney (1937 *et seq.*), Rogers (1942), Sullivan (1947), and Sheerer (1949). Love of others and love of self can best be understood when viewed as constituting an intimate and essential interrelationship and not simply a kind of bargaining arrangement.

Impact of Affection on Development

As a matter of common sense, we know that if a child is to thrive he needs to be reared in an atmosphere of affection and that he is under a tragic handicap if he lives in an environment devoid of love. The reason is not simply that love is something nice to have, an added vitamin in the diet, so to speak. The reason goes far deeper and is more pervasive. Love is not just an extra touch—it is something that enters into the quality of the total environment. Where it prevails it affects the nature of all the child's relationships with the people on whom as a helpless person he is at first abjectly dependent; it is a feature of everything that is involved in the child's nurture.

When a parent genuinely is fond of his child and spontaneously enjoys him as a companion there will be more give and take, more mutual participation in activities through which the child can discover his resources and limitations, less unresolved friction (but not necessarily less friction), less need for evasion and concealment in facing life's problems.

In their relations with their child the loving mother and father communicate affection through all their ways of dealing with him. Love is not offered simply by way of coos and caresses, fond pats and affectionate squeezes (although these are nice at all levels from infancy to old age) but in countless rather prosaic and practical ways. A basic and all-pervasive feature of parental love for a child is that the child is liked for his own sake; he is viewed as something valuable *per se;* he is respected as a personality in his own right. His selfhood is accepted. An outstanding feature of parental love for a child is that it is *unconditional:* the child is worthy as he is; the child is not loved on the condition that he or she is blonde or brunette, or male or female, a "good" baby, a pretty baby, a baby likely to add to the glory of the family name.

Such love for a child has a telling influence on the child's development. The greatest impact is on the development of the self. This position has been advanced most forcefully by Sullivan (1947). Approval and acceptance by others are necessary for the development of self-approval and self-acceptance. The self, according to Sullivan, is made up of "reflected appraisals." As noted earlier, according to this theory, if the appraisals are chiefly derogatory the child's attitudes toward himself will become chiefly derogatory, but if he

is accepted and approved by significant people this will influence him in the direction of self-approval and appreciation of his own worth.

There is something emotionally satisfying about being loved, and there also is something very practical about it. The child who is loved for himself is free to be himself. He is free from an early age to manipulate, to explore, to try himself out, to discover his resources and limitations, to test his environment (including the limits of his mother's and father's patience). He has freedom to do the things that lead to learning: to try and err, to make mistakes, to do childish and foolish things, to experiment. Not the least of the factors that help him in learning to realize himself is that the loving parent also has a certain kind of freedom which the unloving parent is not so likely to possess, namely, freedom to be himself in his rôle as a parent; he will not feel a need to put a false face on his own feelings, to act as though he always were chipper and cheerful, full of sweetness and light, with a boundless amount of patience and an inexhaustible capacity for controlling his temper. He does not need to distort his personality by trying to live up to the impossible ideal of being a perfect parent. He will not feel a guilty need to grant the child's every whim or to indulge his every desire for fear that to do otherwise would threaten a precarious relationship between him and his youngster.

A study by Skeels, Updegraff, Wellman, and Williams (1938), earlier referred to, shows impressively how young children, reared in an orphanage without the personal attention which children usually receive at home, may be adversely affected in various aspects of their development, including their capacity for friendly relationships with other people. Goldfarb (1943) found that institutionalized children, as compared with children in foster homes, showed, among other things, a lower capacity for personal ties and relationships and various symptoms of emotional unresponsiveness. An interesting paper by McCarthy (1953) traces the relationship that might exist between lack of mothering in the mother-son relationship and the frequently observed backwardness of boys as compared with girls in certain aspects of language development.

Zucker (1943) used a story-completion technique and a questionnaire to test the hypothesis that lack of a close emotional tie between children and parents may result in only a superficial assimilation by children of the parents' values and ideas.[1]

The fact that there may be a relationship between an adult's attitudes toward authority, existing institutions, and political and economic issues and his emotional relationships with his parents as a child has been indicated in several studies. Lasswell (1930) reports that attitudes in favor of revolt against established institutional practices were associated in the persons he studied with repressed aggression against the father. Findings obtained by Krout and Stagner (1939) tended to confirm that avowed radicals showed more frequent findings of rejection by their parents and in general more unhappiness in childhood than a control group. In a later study, Stagner

1 The huge amount of literature dealing with the bearing of parent-child relationships on problem disorders and emotional maladjustment will not be reviewed here except through a brief reference below to parental "rejection" and "overprotection." Among matters associated with maladjustment are the emotional complications involved in living in "broken" families. It is impressive to note that in 1940 it is reported that of the 40,286,770 children under 18 years of age in the United States, 4,518,000 lived in broken homes (Anon., 1944). In 1947 Madow and Hardy (1947) estimated that from available statistics approximately from 11 to 15 per cent of children have broken families before the age of 16. In addition to the homes that are physically "broken" there are uncalculated numbers of homes that are psychologically torn and broken even though they are physically intact.

(1944) found that in a male college population active radicals reported less satisfactory relationships with parents than a control group.

Response to Evacuation. The evacuation of large numbers of children from their homes during wartime has offered opportunities for studying the meaning of normal parent-child relationships in the home. Some observers have expressed the opinion that the immediate effects of evacuation when it involved separation from parents are worse than the immediate effects of air raids, and that it is a greater shock to a child to be separated from his parents than to experience bombardment; other observers voice a contrary opinion (see, e.g., Burbury, 1941; Burt, 1941; Coromina, 1943; A. Freud and Burlingham, 1943; Isaacs, Brown, and Thouless, 1941; John, 1941; Mons, 1941).

Parental Rejection and Overprotection

The term "rejection" and the label "rejected child" have been used to denote the condition of a child who is not loved by his parents (or parent-substitute). The term "overprotection" has been used to designate a parental attitude involving excessive contact and mothering. The term rejection is commonly used to denote the antithesis of a relationship in which there is wholehearted acceptance of the child. However, overprotection and rejection cannot be regarded as opposites, for, as usually construed, overprotection is colored by anxiety and, besides, overprotecting behavior may be one symptom or means of rejecting the child.

Signs or criteria of rejection and overprotection have been discussed by Levy (1943), Symonds (1938, 1939), and Fitz-Simons (1935). Circumstances which might lead a mother to overprotect her child have been discussed by Levy (1943).

One response to maternal rejection is aggressiveness on the part of the child, according to Knight (1933–1934). According to Symonds (1946), the child who is denied love by his parents is thrown back upon himself for love. The fact that rejection by one parent or the other cannot alone account for subsequent behavior is suggested in a study of delinquent children who had received treatment (Glueck and Glueck, 1940). When studied several years after treatment, the same percentage of young persons were reported to have the affection of their fathers in the group that was unreformed as in the group that was reformed.

The concept of rejection is a valuable one for understanding child behavior although it touches on an area of human relationship in which there is need for further research.

A full understanding of the effects of rejection would have to take account of the total social and psychological setting in which practices and attitudes of an apparently rejecting sort operate. Rejection cannot be studied simply by noting the acts, attitudes, and apparent intentions of the person whose affection the child desires. The child who is subject to consistent, strict discipline of an apparently "rejecting" sort may feel less cast off than a child who is subject to inconsistent and unpredictable discipline of a milder sort. Behavior which in itself is not rejecting might have the effect of rejection in a setting in which there is favoritism for one child. The practices that prevail in a given culture or even within a given community will have a bearing on the extent to which parental behavior becomes psychologically equivalent to rejection. A very important factor in determining whether the attitude of a parent or parent-substitute is regarded as rejecting is the attitude already established in a child. A child who feels abused (see

an earlier section) probably will interpret the behavior of a parent or teacher as a form of rejection far more readily than would another child. It is likely that a child will have the experience of feeling rejected in many situations which the parent does not regard as rejecting in character. For example, the child who is constantly being pressed to live up to standards that are beyond his reach is being rejected. He will have constant reminders of his imperfection—he is not as clean, or is not as obedient, as quiet, or quick at learning as he should be, and so on.

Whenever a child is measured against a preconceived standard and found wanting (or feels that he is found wanting) it is likely that his experience may be much like that of an openly rejected child.

Emotional Acceptance and Rejection of Children by Persons Outside the Home

Many features of the parent-child relationship in the home are likely to be reestablished in the child's relationship with adults outside the home who serve, to some degree, as substitute parents (the teacher, camp counselor, nurse, and the like). Usually, however, the emotional relationship involved will be far less affectionate and intimate than that which prevails in a good home. In a study by del Solar (1949) in which children were appraised by their parents and also by their teachers (in a school with an avowedly humane philosophy of education) it was found that emphasis on companionship and mutual affection was frequent in the reports of parents but almost completely lacking in the reports by teachers. Teachers also mentioned fewer satisfying qualities in the children than did the parents. This is not at all surprising, but in emphasizing the vast disparity between the emotional ties a child can establish in the home and those he can expect to establish with adults outside the home, these findings underscore the importance of the former.

In his relations with adults outside the home the child not only is likely to meet aloofness but may even encounter severe rejection. In commenting on psychiatric work with evacuated children in England during World War II, Alcock (1948) states that there often exists in many adults an impulse of hostility, often deeply unconscious, toward children who are not actually or emotionally their own. How widely this statement applies would be difficult to tell. Certainly one can conclude from everyday observation that adults cannot be counted on to be more charitable toward other children by virtue of having children of their own. For this reason, among others, the father or mother of many children may be a poorer guardian of the welfare of children at large than a childless teacher. Indeed, it is only by assuming that Alcock's statement holds true, rather widely in some communities, that we can account for the fury of the attacks that sometimes are made when educators, welfare workers, and others make modest proposals for improving the lot of children.

Actually, in contacts with institutions outside the home, children encounter a vast amount of treatment which, in effect, might well be construed as a kind of rejection. At school large numbers of children who do not happen to possess the kind of intelligence that is necessary for doing average or above average academic work are frequently reminded that they are not much good. The school dispenses failure on a colossal scale, and this sort of failure can readily strike a young person as a kind of repudiation. Moreover, much of this failure is due to questionable standards which require that all children go through certain academic exercises that have little if any meaning to them. It is perhaps only on the assump-

tion that there is a large amount of hostility toward children in our society (as suggested by Alcock's study) that we can explain the fact that our society tolerates the kind of self-derogating treatment to which so many children are constantly being subjected in the name of education.

Emotional Rewards and Penalties of Parenthood

Anything that contributes to the emotional rewards of being a parent and anything that adds to the emotional burden is bound in one way or another to influence the parent-child relationship.

When parents themselves are questioned concerning the emotional rewards of parenthood they place great emphasis upon the friendliness their children show toward them, the companionship they derive from them, the interests they share with them, and other features that represent a loving relationship. In a study in which 554 parents were questioned (Jersild, Woodyard, and del Solar, 1949), items under this general heading of companionship and affectional relationships were mentioned by 72 per cent of the parents. A large proportion of the parents also mentioned satisfaction and pride in their rôle as parents (64 per cent), and an even larger proportion mentioned the pleasure they derived from witnessing the development and manifestations of their children's personalities (82 per cent). A great number of other expressions of appreciation pertained to the relationship existing between the child and the other parent or with relatives (54 per cent). There were many expressions of appreciation also of various features in the child's progress, his development, his relations with people in the community, and the like.

An important factor which influences the composure of parents and which, in turn, may affect the emotions that come into play in dealings with their children is the factor of physical discomfort and fatigue. Problems and irritations due to crowding and congestion, lack of room space, lack of play space, and the like, were mentioned by large numbers of urban parents in the study cited above. City parents of low economic status especially felt the pinch of congested city life, cramped quarters, and other matters that added to the physical burden of caring for children, and their problem on this score was aggravated by the fact that they not only had less space as a family but also, on the average, had more children to occupy this space. The poorer parents were relatively far more preoccupied with the physical aspects of child care than with the psychological characteristics or psychological needs of their children. Financial poverty, it might be thought, could entail a certain impoverishment of affection, for poor parents would have less time and leisure and perhaps less psychological energy and freedom to enjoy their children. But, as it happened, the poorest group of parents in the study above, in spite of all their complaints about physical hardships, mentioned the companionship of their children as a source of satisfaction just as much as did members of other groups.

SIBLING RIVALRY AND JEALOUSY

One frequent source of thwarting which leads to hostility (and which may also produce grief and anxiety) arises in rivalry between siblings.

Feelings and Impulses Associated with Jealousy. Jealousy has not usually been described as a primary emotion but has been treated as a hybrid. Ribot (1903) notes that the gradations of jealousy range from "mild cases up to madness and homicide" and cites Descartes' definition of jealousy as "a kind of fear related to the desire we

have for keeping some possession" (p. 268). Components of jealousy, as described by Ribot, include a pleasurable element related to something desired or possessed, an element of depressing vexation arising through the idea of dispossession or privation, and destructive tendencies, such as hatred and anger directed toward the real or imagined cause of this dispossession or privation. Among the feelings mentioned as components of jealousy by adult subjects in an investigation by Gesell (1906) were anger (which was most frequent, and was sometimes combined with feelings of hatred and with vengeful thoughts), self-pity, grief, sadness and dejection, mortification, fear, and anxiety. The most frequent combinations were anger, self-pity, and grief. These descriptions by adults seem to conform to symptoms exhibited by jealous children, but just what are the feelings of a jealous child would be difficult to appraise, since children are not very articulate about such matters.

Overt Expressions of Jealousy. Prominent among the overt symptoms of jealousy as described by S. Foster (1927) and others are expressions of anger, ranging from open hostility to substitute forms of attack. These may be directed toward the person whom the child looks upon as a rival for affection and attentions which he desires for himself, or they may be directed against the person whose affection is desired. The latter may also be subjected to reproaches and appeals, designed to arouse sympathy. The child who is jealous of a younger sibling may revert to infantile habits, such as demands to be fed and dressed when actually he is able to take care of himself (Sewall, 1930). As a bid for attention he may also exhibit fears that previously did not exist, show relapses in bladder and bowel control, and idiosyncrasies with regard to food. Various expressions of hostility have been described by Levy (1937*b*) in a study which utilized dolls to represent a mother, a baby, and an older brother or sister.

Among other expressions may appear an unwonted display of affection or helpfulness, or a tendency to lie and tattle, or varying forms of competitiveness. The child may also be very subdued in his behavior, as though he were grieving, or he may resort to vindictive make-believe and fantasies of self-glorification. Children who are afflicted sometimes will show quite contrasting behavior at different times and in different situations, and their reactions to the same person at different times may range from attack to attempts to curry favor. The repertoire of the jealous child is likely to be that of a troubled person who tries many different techniques in meeting a problem.

The label "jealous child" commonly refers to children who exhibit marked symptoms, or whose elders are unusually alert to any symptoms that appear. A systematic study of normal children would no doubt show that all of them exhibit symptoms of jealousy to a greater or lesser degree.

It should be noted that many of the forms of behavior described above may also be exhibited by a child who is not directly competing with a sibling but who is uncertain or troubled about his relations with his parents or teachers or other associates, and many of the struggles of a jealous child resemble those of a person who is uncertain concerning his own worth and seeks to vindicate or prove himself even though he has no visible rival.

Causal Factors. Studies of children who are conspicuously jealous (S. Foster, 1927; Sewall, 1930; Smalley, 1930; Ross, 1931) and of children who show rivalry (Macfarlane, 1938) do not reveal any other single, outstanding factor that distinguishes them from others. Differences in intelligence and age between two siblings may have an in-

fluence in individual cases, but more important are the complex factors involved in the relationship between parents and their children, between the father and the mother, and disturbing influences such as friction in the home, favoritism, and rejection of one child.

There probably will be an exceedingly great provocation to jealousy if one of the rivals in the family is used as a foil or scapegoat in a hostile struggle between the father and mother. If, because of the resemblance in appearance or temperament or for some other reason, a child is made the object of a father's or a mother's resentment toward the spouse, the child obviously is in a tough spot, and being barred, as a child, from directing his hostility against the offending parent, he will be under all the more pressure to project his anger and anxiety upon the sibling who is favored by that parent.

Ramifications of Childhood Jealousy. Many writers have maintained that the emotional drama involved in a child's relationships with members of the family, including relationships with his siblings, may have a marked influence on attitudes toward people and toward the world as long as he lives. Many of the disorders that arise between persons and between people in the adult society have their prototype in the family scene when the adults were small.

Benedict (1940) has pointed out that extreme hostility that is engendered within the family is not merely a function of high civilization as such or of the mechanization of industries of the institution of capitalism. It is a condition which may arise within a simple society or a complex one if certain social institutions prevail. Benedict makes this observation in commenting on a study by Henry (1940) which describes the hostility and quarrelsomeness of Pilaga Indian children who experience a great amount of affection and attention during their early months of life and then later are more and more ignored, until, with the coming of a new child, they are left to their own resources. Within this relatively simple culture the customs are such that the child, after having received much attention, is virtually rejected, and, according to Henry, as a consequence he becomes a "poor, hostile, little flounderer for many years" (p. 119).

By reason of the complexity of the factors involved in rivalry and jealousy, minor expedients for allaying jealousy such as simply announcing to a child that a new baby is coming or a policy of providing "two of everything" to eliminate friction over possessions seem to be of little avail (Sewall, 1930; Macfarlane, 1938).

JOY

Studies dealing with the pleasures and joys of life are very skimpy compared with works that deal with frustration, anger, fear and anxiety, and other forms of unpleasantness. If judged by the preponderance of attention given to painful emotions, psychologists must be regarded as a gloomy lot, and some psychiatrists look even a shade gloomier.

Signs and occasions of joy in infancy were noted in earlier references to Bühler (1930) and Bridges (1932). Available data do not provide the basis for a precise classification of behavior that might be described as joy or pleasure. Even more tenuous are the nuances of feeling, mood, and expression involved in later forms of behavior that are described by such terms as pride, positive self-feeling, pleasant anticipation, interest, contentment, and happiness.

A consideration of the ramifications of the feeling of satisfaction or joy would carry us into the field of children's interests, play activities, and also into the larger field of personality development. In

a study based upon compositions written by children in the elementary school grades, Stryker (1898) found that outstanding specific occasions for joy named by the children included gifts, expeditions and excursions, parties and games, and experiences with new places and things.

When children describe what makes them especially joyful, some types of happenings appear quite frequently over a wide age range, whereas others show a decline or an increase with age. Table 1 is a summary, in terms of broad categories, of circumstances named by children at different age-

TABLE 1 *

FREQUENCY OF RESPONSES IN VARIOUS CATEGORIES WHEN CHILDREN DESCRIBED "ONE OF THE HAPPIEST DAYS OF MY LIFE"

(The values represent percentage of children giving one or more responses in each category.)

	Grades 1–3 Ages 6–9		*Grades 4–6 Ages 9–12*		*Grades 7–9 Ages 12–15*		*Grades 10–12 Ages 15–18*	
	Boys	*Girls*	*Boys*	*Girls*	*Boys*	*Girls*	*Boys*	*Girls*
Number	*363*	*331*	*309*	*343*	*282*	*290*	*159*	*171*
Receiving or having or otherwise enjoying material things, gifts, toys, money, living quarters	8.7	8.1	10.4	7.2	10.1	4.5	5.6	3.1
Holidays, festive occasions, birthdays, Christmas, etc.	39.1	40.5	32.4	38.9	6.3	10.1	0.6	6.5
Sports, games, hiking, hunting, bicycling, etc.	10.2	6.4	9.1	5.5	12.4	5.8	13.0	7.3
Going to miscellaneous places of recreation, going to camps, traveling, going to resorts, to parks	9.6	9.0	10.1	11.4	9.7	13.9	30.2	6.9
Self-improvement, success in school, educational opportunity, evidence of vocational competence, getting a job	2.4	2.3	2.9	1.9	4.8	4.1	13.6	15.9
Happenings connected with school, including last day, end of school, going to a certain school	3.6	3.4	5.4	4.3	14.0	11.1	7.0	5.4
Relationship with people (explicitly described), companionship, being with certain friend, return home of relatives, etc.	7.7	15.9	8.0	15.8	10.5	22.0	8.7	19.9
Residing in, moving to, a certain city or community	1.3	1.0	0.8	2.9	0.9	2.9	1.4	5.0
Benefits befalling others, or mankind in general, including end of war	0.6	0.8	3.2	2.8	2.2	2.6	7.9	9.7

* Reproduced, by permission, from Jersild and Tasch (1949). The table omits several categories including hobbies, movies and radio programs, art activities, etc., mentioned by only small percentages of children.

grade levels when they described what they regarded as "One of the happiest days" of their lives.

Young children decidedly more often report a holiday or birthday or other occasion when they receive special attention and tokens of affection by way of gifts as a "happiest day" than do the older children. Older children oftener report as especially joyful occasions on which they are made aware of their own qualities and achievements. The older children place more emphasis than the younger ones on pleasures connected with self-discovery and self-realization. They mention successes and opportunities which involve evidence of or an opportunity for self-improvement or vocational preparation or placement, or experience of greater independence, more often than younger children. Older children also mention more often benefits befalling others. Experiences involving visits with friends, being able to enjoy the companionship of a certain person, and happenings which affect their relationship with members of their families are mentioned by a rather large number of children at all ages. Girls mention joyful events involving relationships with *people* considerably more than do the boys.

The findings here reviewed give only a limited picture of the day-to-day joys of growing children. There is need in this area, as in several others, for more systematic and comprehensive research.

Throughout life, satisfactions will arise from unimpeded activity, successful achievement, and ventures into new activities which give a person a broadened conception of himself. Children will themselves often seek hurdles, including mild forms of danger, for the satisfaction of overcoming them (Valentine, 1930; T. D. Jones, 1939; Gutteridge, 1939).

Prominent among the gratifications of everyday life are, of course, the numerous pleasures derived from ministering to bodily needs and the satisfying of physical appetites, pleasures associated with food and drink, fragrant odors, the comforts of rest and relaxation. To the extent that overt signs may be trusted, it would appear that pleasant, or at least neutral, tones predominate greatly over unpleasant states in normal children, as seems also to be true of normal adults (see, for example, Wohlgemuth, 1922–1923; Flügel, 1925; G. Watson, 1930; Hersey, 1931; Jersild, 1931; Hartmann, 1934–1935; W. B. Johnson, 1937).

LAUGHTER AND HUMOR

Although laughter does not represent any distinct emotion it deserves consideration as an outstanding expressive reaction. References have been made in an earlier section to the accounts by Bridges (1932) and Bühler (1930) of the appearance of laughter during the early months of life. Washburn (1928) noted laughter at 12 weeks in response to a "chirruping" sound as the experimenter bent over the child. The most effective laughter stimulus (at 16 weeks) was the "threatening head."

There have been many theories of laughter and humor which we will not here review in detail, including the theory that it represents the sudden transformation of expectation into nothing, that it represents a sudden release from anxiety or repression, that it represents a form of derision, that it represents relief from aggressive and libidinous tendencies, that it is a response to incongruity, that it represents a happy overflow of animal spirits. Actually, when we observe the variety of conditions that produce laughter, and the fact that different people laugh at different things, we probably have to accept all these hypotheses and more besides to account for all occasions. We probably would also find, on

close study, that one theory might fit one person and not another, for, at one extreme, there may be a sour child who laughs only in derision of others and, at the other extreme, one whose laughter is a bubbling expression of friendly mirth.

Several studies at the preschool age have shown that laughter is most likely to appear in association with bodily activity, especially in connection with social play (M. C. Jones, 1925; Enders, 1927; Kenderdine, 1931; Ding and Jersild, 1932; Brackett, 1934). Kenderdine (1931) found that at 2 years laughter in response to motions made by the child himself or others was highest in frequency, and next in order came laughter in response to socially unacceptable situations. At 3 years the latter situations led the former. She also noted laughter in response to circumstances such as grimaces and pleasure in accomplishment and word play. In a study of preschool children, Ding and Jersild (1932) found little evidence for the theory that laughter commonly denotes feelings of derision or superiority. Kenderdine (1931), however, noted some instances of laughter in response to inferiority in others.

Justin (1932), in a study of children aged 3 to 6 years, used a number of situations to represent the following conditions: (1) surprise or defeat expectation; (2) superiority and degradation; (3) incongruity and contrast situations; (4) social smile as a stimulus; (5) relief from strain; (6) play situation. Some children at all age levels laughed or smiled in response to all the experimental situations. Incongruity and superiority and the play situations became somewhat more laughter-provoking as age increased, but the main change noted in relation to age was increased tendency to laugh at more of the specific situations that were used to represent each of the large classes of laughter-provoking stimuli.

Children of high intelligence in the group studied by Kenderdine tended to laugh more than children of average or somewhat above average IQ. Justin also found a positive correlation between IQ and tendency to laugh, especially in response to incongruity. It seems plausible that bright children might be more responsive than less intelligent children to laughter-provoking subtleties; in a study of older children, Brumbaugh (1939) found, for example, that brighter children were better able to recognize absurdities. Other factors in a child's social and emotional adjustment, however, are likely to have a more important bearing upon his disposition to laugh than the factor of intelligence alone.

In a study of children aged 7 to 18 years, Laing (1939) concluded from data obtained through questioning, essays, and reports by the subjects concerning their best jokes that the development of a sense of humor parallels the child's intellectual and emotional development. At 7 to 10 years, the major sources of humor are described as deviation from the normal; and at 11 to 13 years, important sources were the discomfiture of others and deviation from the normal. In the range from 7 to 13 years, situations regarded as humorous were mostly visual, but at 14 to 18 there was an increased appreciation of verbal humor. Herzfeld and Prager (1930) likewise describe changes in children's understanding of the comic as related to intellectual development. They note, for example, that when the child has acquired a grasp of size relationships he finds amusement in inanimate objects that show gross disproportions in size or colors, and at later ages other forms of distortion and incongruity, including human frailties, become effective. Piret (1940) also found that appreciation of humor parallels intellectual development. Brumbaugh (1939), in a study of children in grades 3 to 6, found that

incongruity was the most frequent stimulus to laughter and that the children often showed a liking for comedy of the sort that was disapproved by many of their elders.

The fact that one prominent form of children's humor involves play with forbidden ideas appears from a study of the favorite "jokes" of children. In an informal study, the writer found many "off color" items among the favorite jokes written down by several hundred children aged 12–13. A fairly typical item was the following: *Question:* Why did the ram fall over the cliff? *Answer:* He didn't see the U-turn.

SYMPATHY

Sympathy denotes suffering with another, and therefore an account of sympathetic behavior should emphasize feelings that are involved. In young children, such feelings can only be inferred from the child's language and actions.

In a study by Boeck (1909) based upon parental reminiscences and questionnaire returns, the largest number of reported sympathetic responses was directed toward people (358, of which 285 were directed toward the father, mother, sisters, or brothers); 207 responses were directed toward animals; and 65 responses were directed toward other objects.[1]

Bern° (1930), in a study that utilized rating scales, found evidence of a slight increase in sympathy at the four-year level as compared with the three-year level.

In a study by L. B. Murphy (1937) of preschool children, sympathetic responses were classified under headings such as helping, comforting, punishing, or removing the causes of distress, protecting, defending, warning, suggesting a solution, anxious or disorganized responses (such as showing an anxious expression, evidences of worry, and crying). Murphy utilized a number of experimental situations that provided an opportunity for the display of sympathy, and also observed children during their free play.

Murphy noted that children 2 and 3 years old did not generally respond sympathetically to black-and-blue wounds, swellings, and other minor distortions of flesh which to an adult would suggest discomfort or illness, or to Red Riding Hood's being eaten up by the Wolf, pictures of accidents, funerals, being crippled, and the like. Three-year-olds responded generally, although not universally, to such evidences of distress as bandages, blindness, injuries colored with iodine, red swellings, and the like; also to crying, accidental falls, attacks by another person, deprivation of toys, of food, or of mother; interferences, such as being caught in a pen or having to stay in bed.

Records obtained during 188 hours of observation of the behavior of one group of children disclosed 318 sympathetic responses and 195 responses that were classified as unsympathetic. In another nursery school group, 398 sympathetic and 60 unsympathetic responses were observed during 234 hours of observation. These frequencies of sympathetic behavior are considerably lower than the frequencies of resistant or combative behavior exhibited by children of this age. Such frequencies are not directly comparable, however, since the number of times sympathy occurs will depend, among other things, upon the occasions that arise for a display of sympathy.

Older children not only responded to a wider range of distress situations but also exhibited more active responses to comfort and defense as distinguished from passive staring or inquiries concerning another's misfortunes. Factors in the personality of the individual children were, however, more im-

1 These statements concerning Boeck's findings are taken from a review by L. B. Murphy (1937).

portant than the factor of age. Murphy describes many such factors. For example, a child who is sympathetic when he himself is disturbed or uncertain of his status in the group may become less sympathetic as he gains in confidence, whereas another child may show the reverse tendency. Again, a child may shift from sympathetic to unsympathetic behavior if his own self-interest is involved. Macfarlane (1938) likewise found that a child was less likely to sympathize with another's distress if the child himself was the cause of the distress.

Compassion

By origin and usage, "sympathy" and "compassion" are similar in meaning, but "compassion" might well be reserved to designate a higher order of emotional maturity. Compassion may be defined as a kind of fellowship of feeling which involves a capacity for kinship with the totality of another's emotional state. As such it involves an appreciation of some of the struggle, the striving, hope, or despair that lies beneath surface manifestations of anger, gaiety, grief, pride, or fear. To be compassionate a person must be able to draw fully upon his own capacities for feeling, for unless he is at home with his own feelings he cannot recognize the feelings of another, nor will he have the incentive to understand the roots from which they spring.

The one who is capable of compassion, so defined, is aware of the self-distrust that lies behind another's overeagerness to please. The compassionate parent recognizes the fear behind the bold front his child assumes when he faces up against a bully, and he senses his child's grim courage as he goes jauntily off to school to face a harsh teacher. But he realizes also that the bully is unhappy and that the harsh teacher suffers too, for otherwise they would not want to inflict pain. The compassionate teacher recognizes the anxiety that is concealed under the insolence of his most troublesome pupil. To be compassionate means to have an ability to mourn with one who mourns but also subtly to console him, for one who is compassionate will probably surmise that the person who grieves is richer than he who has nothing worth grieving about, and it is better to feel sorrow than to feel nothing.

In keeping with this concept, to be compassionate a person must be able to face his own emotions, and that is why compassion here is designated as something "mature." To perceive the anguish behind another's anger, instead of recoiling or striking back, a person must be strong enough to acknowledge some implications of his own hostility. To be able to react sympathetically to anxiety in others as it appears in the form of arrogance or false pride or a show of power or in the countless obsequious contrivances of everyday life he must have the strength to see some of his own anxiety in naked form. And to feel compassion for those who struggle against despair he must have had the courage to perceive the dreadful threat of despair in his own life. While compassion, as here described, involves feeling for others it requires a mature form of self-realization, since compassion for others is possible only if a person is capable of compassion for himself.

In the writer's opinion, it is necessary in our research to explore more adequately than we have in the past the implications of such a concept of the intimate relationship between feelings toward self and feelings toward others if we are to arrive at a mature formulation of emotional development and of what constitutes emotional "maturity."

EMOTIONAL IMPACT OF SEXUAL DEVELOPMENT

A few points should be added to round out the numerous references made in earlier sections to the subject of sex.

Infantile Sexuality. Freud's theory (see, e.g., Freud, 1930) that sex is not something that is visited upon the child at about the time of puberty but is a development which goes back to early infancy can be confirmed by everyday observation, and it has also been underscored by numerous research investigations.

There is sensitivity in the genital areas in early infancy, and many children (probably all, to some degree) in infancy and early childhood manipulate their genitals or use some other form of self-stimulation, apparently to achieve pleasure or relief. Halverson (1940), in observations of 9 male infants aged 3 to 20 weeks, found that tumescence occurred at least once daily in most of the children. Mothers interviewed in a study by Levy (1928) reported that by the age of 3 years 26 of 49 boys involved in the questioning had applied direct manual stimulation, such as holding, stroking, or pressing the genital organ. Manual stimulation was reported also in the case of 4 of 26 girls, but this, as Levy points out, does not take account of the possible occurrence of other forms of stimulation that are difficult to detect, such as thigh-rubbing. Koch (1935), in systematic observations of children of nursery school age, also found a higher incidence of masturbatory activities in boys than in girls. Isaacs (1933), on the basis of direct observation, has presented an impressive collection of anecdotes showing ways in which children of preschool age express an interest in genital functions.[1]

[1] For reviews, or reports of original findings, see Willoughby (1937); Sears (1943); Landis, Landis, Bolles, *et al.* (1940); Ramsey (1943); and Kinsey, Pomeroy, and Martin (1948).

The advantage of systematic, direct observation, such as was employed in some of the studies mentioned above, cannot be exploited with older children. The findings at later levels indicate that there is a wide, and perhaps almost universal, prevalence of varying degrees of interest and curiosity concerning sex in the prepubertal years and a large proportion of children during this period engage in experimentation, manipulation, and sex play. Sex apparently does not take a holiday, such as Freud assumed in his concept of the latency period.

As one would expect, there is an accentuation of such interests and activities at puberty. By the time adulthood is reached, findings in various studies indicate that 90 per cent or more of males and a smaller proportion of females have engaged in masturbation at one time or another with varying duration. Likewise, varying but quite substantial percentages report other forms of sex experimentation ranging from mild petting to intercourse, crushes, love affairs, exposure to mild or major forms of sex aggression, and the like. The study by Kinsey, Pomeroy, and Martin (1948) shows that a large proportion of males have had premarital intercourse. Such endeavors are probably accompanied by varying degrees of placidity and enjoyment, and varying degrees of fear and guilt. The Kinsey Report centers attention primarily on sexual outlet, and does not explore the question as to how often a sexual outlet leads to shame and guilt or pride and joy.

For a large number of young persons there is a long period of sexual unemployment between the time of pubescence and the time when the young people marry. Though findings by Kinsey and his associates, and by others, show that a large proportion of persons rebel against the social codes, many of those who rebel still conform to a great extent, for many of

them violate the code only once or twice or a few times—in other words, less frequently than they would if they habitually followed only their own urges. Findings in this area open a vast field for further study. They have shown that many of our laws and attitudes relating to sex are unrealistic, but they have not shown how these problems might be solved.[1] Moreover, a survey of sex practices may show what is "normal" from a statistical point of view without answering questions about the psychological meaning of this norm. Sex behavior may, in one instance, be a part of a spontaneous, self-fulfilling process and, in another instance, a kind of compulsion or an expression of anxiety.

Probably because of the many problems that sex raises, we find that discussions of sex emphasize mostly frustrations such as those named above without dwelling on the fact that sex is a source of satisfaction, enjoyment, and self-fulfillment.

One outstanding development in the psychology of sex is that sex is being viewed less from a segmental, parochial point of view and more from the point of view of its place in the total picture of personality. This view recognizes that sex is a motivational force that has an urgency in its own right, but it recognizes also that much behavior that has an erotic character and which seems to have a sexual motivation may actually be ancillary to a larger motivational pattern. In other words, sexual disorders may be an expression of a more general disorder. Sex behavior, according to this view, cannot be understood when studied solely by itself but must be examined also in the light of the larger entirety of the life pattern of which it is a part.

Sex may be the medium, the vehicle through which other tendencies or forces in the personality express themselves. It may serve, as it were, as the avenue through which attitudes which have an important bearing on self-development are communicated to a child, and it may serve also as the idiom through which the self communicates with others. When parents deal with their child's sex development as something repugnant they may, in effect, communicate to the child that he is a repugnant person.

In a climate of disapproval which leads to self-disapproval, the child may fix upon the sexual aspect of his nature as a convenient symbol and confirmation of his unworthiness. If he has been subject to disparagement of a kind that would make him feel guilty, the sexual part of his nature provides a convenient fixation point for his feelings of guilt.[2]

According to this viewpoint, the sex behavior of the adolescent and older person may express a wide range of symptoms of self-distrust or alienation. The young person who feels emotionally out of touch with people may seek sexual contact as the only means of closeness and emotional intimacy he knows.

If he feels the need for self-vindication and assurance of his own worth, he may resort to sexual conquest as a means of proving himself.

His sexual behavior may be a feature, central or peripheral, of a larger, more inclusive competitive attitude toward people.

If he has hostile and vindictive attitudes toward himself and others he may use sex behavior as a means of inflicting hurt and gaining revenge.

Sex may be the theatre of operations, so to speak, in which a person expresses his contempt for himself or others, or tests himself, strives to achieve a feeling of re-

1 See studies already named and also Pullias (1937) and Hattendorf (1932).

2 Ways in which sex may be a symbol or vehicle for personality tendencies have been discussed by Weiss (1950).

latedness to others, or seeks to find confirmation of his worth. According to this same view, frigidity and impotence in various forms and degrees may be secondary, as it were, to attitudes of contempt toward self (see, e.g., Pinsky, 1950*a*, 1950*b*). And a set of inconsistent attitudes toward the opposite sex which enable the adolescent to look upon some girls as fair game while others (close to his family and social circle) are exempt and put on a pedestal of virtue may, according to this view, represent a kind of neurotic duplicity, a lack of integrity within the self even though the person, according to his own lights, views his attitudes as a rational "solution."

AMOROUS BEHAVIOR

A large proportion of children become infatuated or are romantically attracted to a member of the opposite sex before puberty, and the average person, during the course of development, falls in love not once but several times. It is difficult to review the literature in this area, for usually the meanings authors attach to terms such as "love," "love attachment," "falling in love," "being in love," and "love affair" are not entirely clear.

One of the problems is the relation or distinction, if any, between amorous behavior and erotic behavior. A review of studies in this area has been offered by Grant (1948). Writers report distinctions between what has variously been known as amorous enchantment, amorous attachment, erotic attraction, infatuation, "venereal voluptuousness," or feelings of "love" and longings that definitely include a desire to copulate. Reik (1945) notes the difference between the relatively undiscriminating quality of venereal desire and the highly personalized and selective character of amorous attachment, and regards these as representing different categories of experience.

In a population of adults studied by Hamilton (1929), the first experience of falling in love was placed somewhere between the ages of 6 and 11 inclusive by 38 per cent of the women and 40 per cent of the men. Many reported that when they were in love at this early age they did not have conscious sex feelings or desires. S. Bell (1902) earlier compiled numerous records of the presence of the "love emotion" in children between 3 and 8 years of age as shown by behavior such as embracing, sitting close together, grief at separation, giving of gifts, jealousy, and making sacrifices. The pleasure involved in the early stages, according to Bell, is not specifically sexual except in some cases: there may be "love making" in the form of hugging and kissing without physical sensation of being sexually excited and aroused.

In a study of college girls, Ellis (1949) found that the median girl said that she had become infatuated with a male at the age of 12 but had not fallen in love until the age of 17. Ellis found that in adolescence the girls became infatuated and also fell in love more often than prior to adolescence. The median girl reported she had only one infatuation before the age of 12, and that she was infatuated five different times between the ages of 12 and 18. From these and other findings Ellis concludes that the college girls in question had tended to become infatuated considerably earlier than they fell in love; had had more prepubertal infatuations than loves; had more adolescent infatuations than loves; had fewer single but more plural infatuations than loves from the eighteenth year onward.

The emotional characteristics of "being in love" have received some attention from psychologists, but far less than the subject deserves.

According to Reik (1945), when a person falls in love it means that he has become emotionally attached to a person who rep-

resents the idealized image of himself. Loving means exchanging the ego ideal, which the person vainly seeks to reach, for an external object. The unconscious process by means of which this is done is in the nature of a projection. Reik's readable account no doubt describes what often happens when people fall in love. But, as far as this writer can discern, Reik is describing a neurotic condition; a person thus in love is in a false position in relation to another person and is in a state of duplicity in relation to himself. The idealized image may be compounded of a variety of unrealistic and irrational elements. Reik himself speaks of it as something impossible of attainment.

A different interpretation of the experience of love as it might strike the healthy young adolescent has been offered by Macmurray (1937), who regards falling in love as a kind of mutual self-discovery. The person in love and the loved person each is appreciated for his own sake. Wenkart (1949) describes how adolescents are prepared for love by a longing to have someone to acknowledge, accept, and appreciate them for themselves, and when members of the opposite sex give each other such assurance they are confronted with a wealth of feeling which they never knew they had and which gives the first love experience an element of revelation. Healthy love, according to Wenkart, involves mutuality, enjoyment of expressing and offering love, and delight in what is reciprocated. It presupposes awareness of self and a desire to grow. It involves self-fulfillment rather than an escape into an idealized image. The healthy adolescent, according to this position, grows in self-realization through his love and does not depend upon the love of another as an external substitute or consolation for his own lack of self-esteem.

It is apparent that being in love means different things to different people. Also, as can be seen from everyday observation, it involves a variety of emotional components. There is erotic attraction. There are feelings of tenderness. There is a desire to be with, to give. to share. These elements may appear in various mixtures and gradations. There may be strong feelings of apprehension somewhere along the way. The person in love may experience strong feelings of resentment at one stage or another in his relationship with the beloved person. He may feel threatened. If he is troubled with guilt and feelings of inferiority, these may be reactivated. If he has many grievances associated with a hostile attitude toward people, he may be in conflict, uncertain as to whether he is capable of a genuine feeling of affection. If he has lived as a withdrawn sort of person, or if he harbors a vindictive attitude toward the opposite sex, stemming from earlier years, the experiences associated with one phase or another of being in love may produce anxiety, for he cannot fall in love and still retain the emotional isolation and aloofness or vengefulness which hitherto has characterized his relationships with other human beings.

There is much else in the situation that might make him uneasy. The beloved person may be wonderful but (unlike Reik's choice) she (or he) may in many ways fall short of the ideal the person had set for himself. So, if he commits himself nonetheless, he must renounce some of his claims, not only upon the loved one but also upon himself. If he can succeed in doing this realistically he probably is ready for the next chapter in his life. But if his illusions remain intact and he is swept along on a romantic wave of self-deception he probably will go through the process again as he turns (in actuality or in his imagination) from one infatuation or from one spouse to another in a futile endeavor to

find through another a release from an unhealthy condition within himself.

CHAPTER 15

BEHAVIOR AND DEVELOPMENT AS A FUNCTION OF THE TOTAL SITUATION

THE LATE KURT LEWIN

If one wishes to use the facts concerning development, personality, social relations, cognition, and motivation which are discussed in the various chapters of this book for the purpose of understanding, guiding, or predicting the behavior of the child, these data will have to be linked in such a way that they become applicable to a particular child at a particular time. This chapter discusses procedures and concepts which have been found to be instrumental for this purpose. Some of the relevant methodological questions are considered and certain problems of cognition, motivation, and development are treated as examples. Frequently, reference is made to data which are discussed in more detail in other chapters; but no attempt to achieve completeness could be made within the limitations of this chapter.

ANALYSIS, CONCEPTS, AND THEORY IN CHILD PSYCHOLOGY

The Psychological Field

STIMULUS AND SITUATION: THE BASIC FORMULA FOR BEHAVIOR

Scientific procedure is analytical in that it tries to determine or to "isolate" the effect of the various factors. It studies, for instance, the effect on the child of different intensities of light, of different degrees of hunger (Irwin, 1930; Pratt, 1933), of failure or praise. It is widely agreed, however, that the effect of a given stimulus depends upon the stimulus constellation and upon the state of the particular person at that time. The perceived form, size, and color of a visual object corresponding to the same retinal stimulus vary widely according to the visual background and the nature of the rest of the visual field (Gelb, 1938). The toys and other objects in a room may lead to very different reactions of the year-old child when the mother is present and when she is not (MacDonald, 1940). In general terms, behavior (B) is a function (F) of the person (P) and of his environment (E), $B = F(P, E)$. This statement is correct for emotional outbreaks as well as for "purposive" directed activities; for dreaming, wishing, and thinking, as well as for talking and acting.

PERSON AND PSYCHOLOGICAL ENVIRONMENT

In this formula for behavior, the state of the person (P) and that of his environment (E) are not independent of each other. How a child sees a given physical setting—for instance, whether the frozen pond looks dangerous to him or not—depends upon the developmental state and the character of that child (Murray, 1938) and upon his ideology (Mead, 1928). The worlds in which the newborn, the one-year-old child, and the ten-year-old child live are different even in identical physical or social surroundings. This holds also for the

same child when it is hungry or satiated, full of energy or fatigued. In other words, $E = F(P)$. The reverse is also true: The state of the person depends upon his environment, $P = F(E)$. The state of the person after encouragement is different from that after discouragement (Fajans, 1933), that in an area of sympathy or security from that in an area of tension (Murphy, 1937), that in a democratic group atmosphere from that in an autocratic atmosphere (Lewin, Lippitt, and White, 1939). The momentary intellectual ability of a child as measured by an intelligence test (MA) is different in an atmosphere of good rapport with the examiner from what it is in one of poor rapport. In regard to the effect of the environment upon development there is a consensus that environment may change intelligence, although opinion differs in regard to how much intelligence can be changed by environment (Terman, 1919; Wellman, 1932–1933; Stoddard and Wellman, 1934; Burks, 1940; Goodenough, 1940). Certainly the ideology, values, and attitudes of the growing individual depend greatly upon the culture in which he is reared (Mead, 1937; L. K. Frank, 1938) and upon his belonging to a privileged or underprivileged group (Dollard, 1937; Lewin, 1940*b*).

In summary, one can say that behavior and development[1] depend upon the state of the person and his environment, $B = F(P, E)$. In this equation the person P and his environment E have to be viewed as variables which are mutually dependent upon each other. In other words, to understand or to predict behavior, the person and his environment have to be considered as *one* constellation of interdependent factors. We call the totality of these factors the life space (LSp) of that individual, and write $B = F(P, E) = F(LSp)$. The life space, therefore, includes both the person and his psychological environment. The task of explaining behavior then becomes identical with (1) finding a scientific representation of the life space (LSp) and (2) determining the function (F) which links the behavior to the life space. This function F is what one usually calls a *law*.

[1] The possibility of treating the factors determining development formally in the same way as the factors determining behavior simplifies psychological theory considerably. I owe this idea to Donald K. Adams.

General characteristics of a psychological field

The novelist who tells the story behind the behavior and development of an individual gives us detailed data about his parents, his siblings, his character, his intelligence, his occupation, his friends, his status. He gives us these data in their specific interrelation, that is, as part of a total situation. Psychology has to fulfill the same task with scientific instead of poetic means. The method should be analytical in that the different factors which influence behavior have to be specifically distinguished. In science, these data have also to be represented in their particular setting within the specific situation. A totality of coexisting facts which are conceived of as mutually interdependent is called a *field* (Einstein, 1933). Psychology has to view the life space, including the person and his environment, as one field.

What means are most appropriate for analyzing and representing scientifically a psychological field have to be judged on the basis of their fruitfulness for explaining behavior. In this respect, the following general points should be remembered:

(1) A prerequisite for properly guiding a child or for the theoretical understanding of his behavior is the distinction between that situation which the teacher, the parents, or the experimenter sees and that situation which exists for the child as his life

space. *Objectivity* in psychology demands representing the field correctly as it exists for the individual in question at that particular time. For this field the child's friendships, conscious and "unconscious" goals, dreams, ideals, and fears are at least as essential as any physical setting. Since this field is different for every age and for every individual, the situation as characterized by physics or sociology, which is the same for everybody, cannot be substituted for it. It is important, however, to know the physical and social conditions because they limit the variety of possible life spaces—probably as *boundary conditions* (Lewin, 1936*a*) of the psychological field.

(2) The social aspect of the psychological situation is at least as important as the physical. This holds even for the very young child.

(3) To characterize properly the psychological field, one has to take into account such *specific* items as particular goals, stimuli, needs, social relations, as well as such more *general* characteristics of the field as the *atmosphere* (for instance, the friendly, tense, or hostile atmosphere) or the amount of freedom. These characteristics of the *field as a whole* are as important in psychology as, for instance, the field of gravity for the explanation of events in classical physics. Psychological atmospheres are empirical realities and are scientifically describable facts (Lewin, Lippitt, and White, 1939).

(4) The concept of the psychological field as a determinant of behavior implies that everything which affects behavior at a given time should be represented in the field existing at that time, and that only those facts can affect behavior which are part of the present field (Lewin, 1936*a*).

(5) To avoid unnecessary assumptions, one can represent the psychological field scientifically by the interrelation of its parts in mathematical terms without asking what the "essence behind" this field is.[1] Such a mathematical representation of the psychological field and the equations expressing the psychological laws are all that have to be known for predicting behavior.

Theories and Constructs: Law and the Individual Case

Theories are unavoidable

Without theories it is impossible in psychology, as in any other science, to proceed beyond the mere collection and description of facts which have no predictive value. It is impossible to handle problems of conditions or effects without characterizing the *dynamic* properties behind the surface of the directly observable *phenotypical* properties.

The terms *need, association, conditioned reflex, excitatory tendency, gestalt, libido,* and *super-ego* are examples of theoretical constructs with which various psychological schools have attempted to characterize certain underlying dynamical or genotypical facts. It is important to distinguish those facts which are essential for prediction and explanation from their various symptoms. For instance, an emotional state such as anger can lead to a variety of very different symptoms (noisiness, as well as extreme politeness [Dembo, 1931]); tension can lead to aggressiveness as well as apathy (Lewin, Lippitt, and White, 1939). The same personality may manifest itself in practically opposite actions. In other words, a given state of a person corresponds to a variety of behavior and can, therefore, be inferred only from a combined determination of overt behavior and the situation. This is only another way of saying that behavior (B) is deter-

[1] What here is called *life space* is more or less identical with or closely related to the concept of brain field (Köhler, 1920) or regnancy (Murray, 1938).

mined by the person and the environment $[B = F(P, E)]$ and not by the person or the environment alone.

Psychology has never avoided, nor can it avoid, theory (Reichenbach, 1928; Hull, 1930; Tolman, 1935; J. F. Brown, 1936; Lewin, 1938), but it can try to eliminate those speculative theories which are frequently introduced without clear intent or in a hidden way, and try instead to make use of openly stated empirical theories. The main desiderata for an efficient empirical theory are: (1) constructs which (*a*) are linked to observable facts (symptoms) by a so-called operational definition or by a number of operational definitions corresponding to the possibilities of observation under different circumstances; and constructs which (*b*) have clearly defined conceptual properties. These properties are coordinated to certain mathematical (logical) concepts. Such a coordination is a prerequisite for logically strict derivations (Hull, 1930; J. F. Brown, 1936; Lewin, 1938). (2) The laws (that is, the relation between behavior, on the one hand, and the field characterized by certain constructs, on the other, or between various factors determining the field) should be verified by experiment. A law should be accepted as valid only if it is not contradicted by data in any branch of psychology. In this sense, a law should always be general.

General laws and individual differences

The problems of general laws and of individual differences frequently appear to be unrelated questions which follow somewhat opposite lines. Any prediction, however, presupposes a consideration of both types of questions.

To give just one example of the linkage between the study of general laws and of individual differences: The velocity with which an activity is satiated increases, according to Karsten (1928) (see p. 825), with the degree to which the activity is psychologically central (as against peripheral). This proposition has the nature of a general law. If correct, it would explain why both agreeable and disagreeable activities are more quickly satiated than relatively neutral ones, and why fashions in women's clothes change faster than in men's clothes. By means of this law one can account for variations in the speed of satiation exhibited by the same person in different states. Certain activities, for example, are more central during menstruum than during intermenstruum and, in accordance with the general law, these activities are satiated more quickly during menstruum. When applied to age differences the law would explain why the velocity of satiation of certain activities is slower in older than in younger children. Finally, it would explain why certain types of problem children who are oversensitive reach the satiation point more quickly than the average child of that age.

This example may show that problems of individual differences, of age levels, of personality, of specific situations, and of general laws are closely interwoven. A law is expressed in an equation which relates certain variables. Individual differences have to be conceived of as various specific values which these variables have in a particular case. In other words, general laws and individual differences are merely two aspects of one problem; they are mutually dependent on each other and the study of the one cannot proceed without the study of the other. This implies that the data about the various age levels provided by child psychology have practical value for the understanding and guiding of individual children only if these data are linked with the concrete situation which is dominating the behavior of a given child at a given time.

Linking the various parts of psychology

This example concerning psychological satiation illustrates also that laws should, and usually can, be applied to all parts of psychology. One of the main functions of theories and constructs is to bind together all the various fields of psychology which otherwise would tend to fall apart into a number of unconnected disciplines. Child psychology, which necessarily has to deal with such apparently divergent questions as nutrition, growth, emotions, perceptions, culture, personalities, social relations, actions, and thought (L. K. Frank, 1938), demands the synthetic ties offered by theories and constructs probably more than any other branch of psychology and is a particularly good testing ground for their validity.

Microscopic and Macroscopic Units in Psychology

A problem where prejudices have greatly hampered progress of research is the treatment of units of different sizes. In child psychology we want to know the development of, and conditions for, the movement of the various fingers in the action of grasping (Halverson, 1931) or the movement of the tongue (Gesell *et al.*, 1940), as well as the effect of the home background upon the school work of a child, or the effect of his childhood relations with his parents on his behavior as an adult. Child psychology is concerned with questions regarding time units of a fraction of a second ("reaction of the eyelid, eye movements in the act of reading") and with time units of many years (problems of life history, Dollard, 1935; Allport, 1937; Bühler, 1939).

For instance, the investigation of stuttering involves the study of the position of a sound or syllable in a word (S. F. Brown, 1938*a*), of a word in a sentence (S. F. Brown, 1936–1937; 1938*b*); it involves the study of the importance of the sentence in the text of the paragraph (Johnson and Knott, 1937); the relation of this verbal expression to the immediate social situation—speaking alone or to a small or large audience (Porter, 1939; Barber, 1939); the effect of the family's classification of the child as a stutterer (Gray, 1940); the individual's position in his family—for instance, his position in the rank order of siblings (Rotter, 1939); his position within the population at large (Travis, Johnson, and Shover, 1937); and the general atmosphere of his life space. In other words, it is necessary to investigate units of action of widely different sizes and situations of widely different scope, such as the "immediate situation" and the "situation at large."

Dealing with units of different sizes is common in every science. Physics, for instance, deals with the ion, the atom, the molecule, and the so-called macroscopic physical objects up to units of the size of the stars. Each size of unit has to be approached technically in a somewhat different way and has some characteristics of its own. However, there is no logical reason to call one type of unit—for instance, the smaller one—more real than the other.

In psychology, too, it is possible to obtain objective and reliable observations in regard to units of any size if one uses methods fitted to the various types (Ronald Lippitt, 1940; Barker, Dembo, and Lewin, 1941). The attempt to determine reliably large macroscopic units by observing microscopic units, however, is bound to fail (Thomas, 1932) in psychology as in other sciences. It is technically impossible to describe the movement of the sun by describing the movement of every ion contained in it.

Laws usually are concerned with the relations between various parts of a situation and are independent of the absolute size to a high degree. Without this dependence of laws upon structure rather than upon size, experimentation would be infinitely more difficult.

Constructs Basic for Representing the Psychological Field

It seems to be possible to represent the essential properties of the life space with the help of relatively few (perhaps a dozen) related constructs. To some degree it is a matter of convenience which of a group of interrelated constructs are to be considered the basic ones (Reichenbach, 1928). For the purpose of this representation we shall use mainly the following constructs: psychological force, psychological position, and potency of a situation.

(1) The concept of force in psychology refers to phenomena which have been called *drive, excitatory tendency,* or by any other name expressing "tendency to act in a certain direction." The term *force* intends to express this directed element, attributing to it, in addition, a magnitude (strength of force) and a point of application, without assuming any additional implications (Lewin, 1938).

(2) The position of the person within the total psychological field and the position of the other parts of the field in relation to one another are of prime importance. This holds for the relative position of various areas of activities the child might enter, the relative position of social groups to which the child belongs, or would like to belong, and of areas of security and insecurity. Although it is not possible today to measure psychological distance or direction quantitatively, it is possible to treat some problems of position by means of the qualitative geometry called topology.

(3) Potency refers to the weight which a certain area of the life space has for a child relative to other areas. This concept is particularly valuable in case of "overlapping situations," that is, when the belongingness to two groups or the involvement in two or more activities at the same time is pertinent.

THE BEHAVIOR IN A GIVEN PSYCHOLOGICAL FIELD

Cognitive Structure of the Life Space

THE LIFE SPACE AS A WHOLE DURING DEVELOPMENT

Differentiation of the Various Dimensions of the Life Space. An outstanding characteristic of the change of the life space during development is an increasing differentiation. The importance of this factor has been shown in regard to the development of language (Gesell and Thompson, 1934), knowledge (Tolman, 1932), social interrelations (Murphy, 1937), emotions (Jersild, 1936), and actions (Fajans, 1933).

The life space of the newborn child may be described as a field which has relatively few and only vaguely distinguishable areas (Koffka, 1928). The situation probably corresponds to a general state of greater or less comfort. No definite objects or persons seem to be distinguished. No area called "my own body" exists. Future events or expectations do not exist; the child is ruled by the situation immediately at hand.

Some of the first areas which get a definite character seem to be connected with food and elimination. As early as three to six days the child reacts to being prepared for nursing (Marquis, 1931). A similar increase in size and differentiation of the life space occurs in other respects. The child studies his own body (Bühler, 1939)

and his immediate physical surroundings. Within the first few months, certain social relations develop.

The increase of the life space in regard to the psychological time dimension continues into adulthood. Plans extend farther into the future, and activities of increasingly longer duration are organized as one unit. For instance, between two and six years of age the duration of play units increases (Barker, Dembo, and Lewin, 1941).

The differentiation of the life space also increases in the dimension of reality-irreality. The different degrees of irreality correspond to different degrees of fantasy. They include both the positive wishes and the fears. Dynamically, the level of irreality corresponds to a more fluid medium (J. F. Brown, 1933; Erikson, 1940) and is more closely related to the central layers of the person. This fact is particularly important for the psychology of dreams (Freud, 1916; T. French, 1939). Play can be understood as an action on the level of reality closely related to the irreal level (Sliosberg, 1934). The play technique (Homburger, 1937), in the study of personality, makes use of the fact that the irreal level is closely related to the central layers of the person.

The level of irreality in the psychological future corresponds to the wishes or fears for the future; the level of reality, to what is expected. The discrepancy between the structure of the life space on the levels of irreality and of reality is important for planning and for the productivity of the child (Barker, Dembo, and Lewin, 1941). Hope corresponds to a sufficient similarity between reality and irreality somewhere in the psychological future; guilt to a certain discrepancy between reality and irreality in the psychological past. In the young child, truth and lying, perception and imagination are less clearly distinguished than in an older child (Piaget, 1932; Sliosberg, 1934; L. K. Frank, 1935). This is partly due to the fact that the younger child has not yet developed that degree of differentiation of the life space into levels of reality and irreality which is characteristic of the adult.

The speed with which the life space increases in scope and degree of differentiation during development varies greatly. A close relation seems to exist between intelligence or, more specifically, between mental age and the degree of differentiation of the person and the psychological environment (Lewin, 1935; Kounin, 1939). If this is correct, differences in IQ should be considered as different rates of increasing differentiation of the life space. Similar considerations apply to motor development (McGraw, 1935) and to social development.

The growth of the life space has a different rate at different times. Such differences are particularly important for the so-called developmental crises, as in adolescence (Dimock, 1937; Lewin, 1939).

Figure 1*a* and *b* represents schematically the scope and degree of differentiation of the life space as a whole at two developmental stages. The differentiation concerns the psychological environment as well as the person. The increasing differentiation of needs, for instance, can be represented as an increase in the differentiation of certain intrapersonal regions. The main differences between these developmental stages are: (1) an increase in the *scope* of the life space in regard to (*a*) what is part of the psychological present; (*b*) the time perspective in the direction of the psychological past and the psychological future; (*c*) the reality-irreality dimension; (2) an increasing *differentiation* of every level of the life space into a mul-

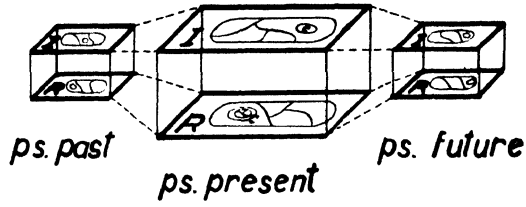
titude of social relations and areas of activities; (3) an increasing *organization;* (4) a change in the general *fluidity* or *rigidity* of the life space.

Not all the areas of this life space are accessible to the child. He sees older children engaged in certain activities, which he would like to do himself, but into which he finds he cannot enter because he is not strong or clever enough. Additional limitations of his space of free movements are established by the prohibitions of the adult or by other social taboos.

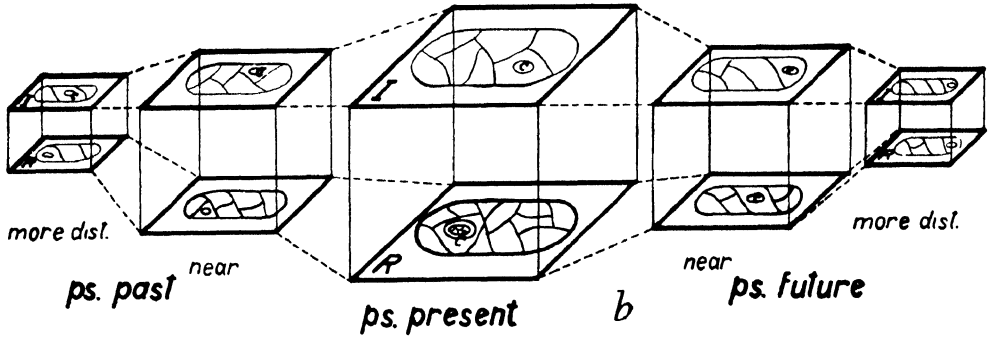
The relation between accessible and inaccessible regions in the life space, the size of the space of free movement, and the precision of boundary between accessible and inaccessible areas are of great importance for behavior and development of the normal and abnormal child (Lewin, 1936*a*).

Regression. A change of the life space as a whole in the direction opposite to that characteristic of development may be called *regression.* Regression may include a decrease in time perspective, dedifferentiation or disorganization, leading to behavior more or less typical for children on a younger age level.

Regression may be either permanent or temporary. It is a common phenomenon and may be due, for instance, to sickness (Jersild, 1936), frustration (Barker, Dembo, and Lewin, 1941), insecurity (Murphy, 1937), or emotional tension (Dembo, 1931; Jersild, 1936). Regression, in the sense of a narrowing-down of the psychologically



a



b

FIGURE 1. The life space at two developmental stages.

Figure 1*a* represents the life space of a younger child. Figure 1*b* represents the higher degree of differentiation of the life space of the older child in regard to the present situation, the reality-irreality dimension, and the time perspective. *C,* child; *R,* level of reality; *I,* level of irreality; *Ps Past,* psychological past; *Ps Present,* psychological present; *Ps Future,* psychological future.

present area, may result from emotional tension, for instance, if the child is too eager to overcome an obstacle (Köhler, 1925).

Regression may occur not only as a result of such frustration in the immediate situation but also as the result of a back-

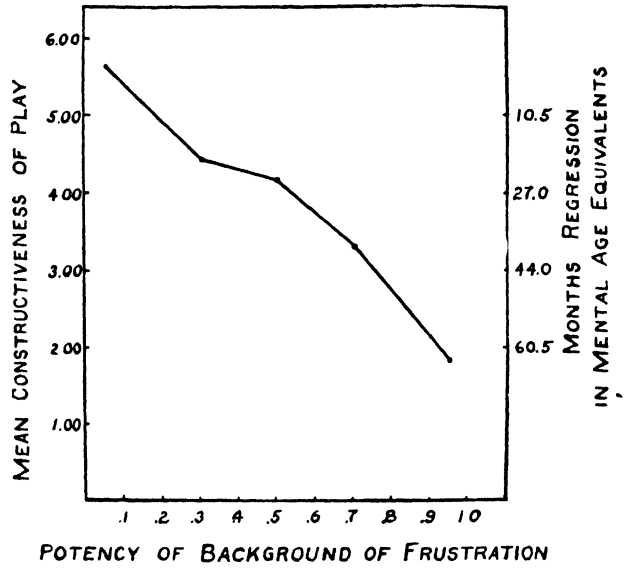


FIGURE 2. Decrease in constructiveness with a background of various degrees of frustration. (From "Studies in Topological and Vector Psychology: II. Frustration and Regression," by R. Barker, T. Dembo, and K. Lewin. *University of Iowa Studies in Child Welfare*, 1941, **18**, 166. By permission of the publisher.)

ground of frustration. Barker, Dembo, and Lewin (1941) have shown that the constructiveness of play of a five-and-one-half-year-old child may regress to the level of a three-and-one-half-year-old child as a result of a background of frustration. This is due to the fact that constructiveness of play is closely related to time perspective, the degree of differentiation within an organized unit of play, and the functional relation between irreality and reality. The amount of regression increases with the potency of the background of frustration (Figure 2).

THE POSITION OF THE PERSON. BEING INSIDE AND OUTSIDE A REGION

Position, Neighboringness, and Locomotion. The determination of the position of the person within the life space is the first prerequisite for understanding behavior. His social position within or outside of various groups should be known; his position in regard to various activities, in regard to his goal regions, and in regard to physical areas should be determined. This is fundamental because the region in which the person is located determines (1) the quality of his immediate surroundings, (2) what kinds of regions are adjacent to the present region—that is, what possibilities the individual has for his next step—and (3) what step has the meaning of an action toward his goal and what step corresponds to an action away from his goal.

Most behavior can be conceived of as a

change of position—in other words, as a locomotion of the person. (The other cases of behavior are changes of structure.) In turn, every behavior changes the situation. We shall mention only a few examples of the effect of the region in which the person is located.

"Adaptation" to a Situation. A common phenomenon is what is usually called adaptation in the sense of "getting tuned to the present atmosphere." H. Anderson (1939) found that children of preschool age reacted to an aggressive approach with aggression, to a friendly approach in a friendly manner. Ronald Lippitt's (1940) study on democratic and autocratic atmospheres found similar adaptation of the children to the cultural atmosphere produced by the leader. J. R. P. French, Jr. (1944) found adaptation to group atmospheres in experiments with college freshmen. There are many indications from case studies that the tenseness of the mother easily affects the emotional state of the young child. There are indications that this occurs even during the first few months of life. It is a common observation that children who are learning bladder control may resume bed-wetting if exposed to the sound of running water. .

The adaptation to the present region is frequently employed to make a child do something "against his will." A child of a few weeks may be induced to drink at the breast when he does not like to by keeping his head pressed to the breast in the position of feeding. Waring, Dwyer, and Junkin (1939) describe how the child and the adult both commonly use this technique for their own purposes when they differ about the desirability of eating a certain food. The child tries to avoid the pressure of the adult by leaving the eating-situation (for instance, by going to the toilet) or by making the adult leave the eating-situation psychologically (for instance, by starting conversations about noneating topics). On the other hand, the adult frequently uses one of two methods of coercion. He may lower the potency of the eating-situation (see later), and thus the resistance of the child, by "distracting his attention" from the eating (that is, by making the child enter a psychologically different region) and then slip in the food. Or he may heighten the potency of the eating-situation and of his own pressure, and in this way induce the child to eat. In the latter case he frequently uses the "step-by-step method": having the child sit at the table, then putting the food on the spoon, and so on.

J. D. Frank (1944) has found, in an experiment with college students, that the step-by-step method is more efficient in ccercing the person to eat than the attempt to make him go the whole way at one step. The effectiveness of the step-by-step method seems to be based on the gradual acceptance of the situation in which the person finds himself so that he resists less the making of the next step. A similar method is frequently used in domestic and international politics. People who are ready to fight against being pushed into a situation may accept the *fait accompli.*

Group Belongingness. Most social goals can be characterized as a wish to belong or not to belong to a certain group. This group may be a group of friends, an athletic organization, or a favorite subgroup within a larger group. It may be a group of only two persons, as with the friendship between mother and child. Belonging or not belonging to the group is equivalent to having a position inside or outside this group. This position determines the rights and duties of the individual and is decisive for the ideology of the individual.

The feeling of belonging to certain groups is a crucial factor for the feeling

of security in children of minorities (Dollard, 1937; Lewin, 1940*b*). MacDonald (1940) found that the security of the child is greatly increased by the presence of the mother. The tendency to enter a certain group and to keep certain children in and feeling of group belongingness (as expressed, for instance, by the use of the term "we" instead of "I") is stronger in democratic than in autocratic clubs. In the autocratic atmosphere the larger group is actually composed of a number of sub-

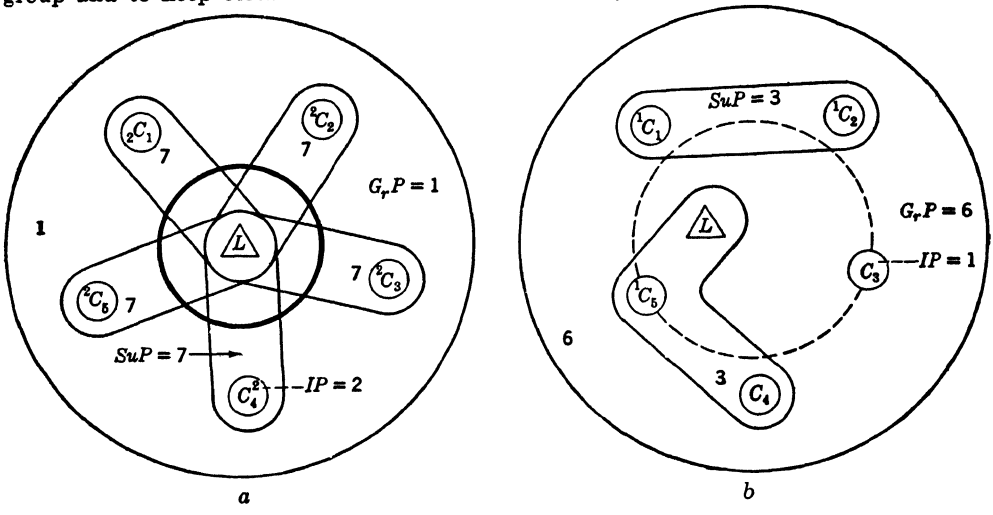

FIGURE 3. Subgrouping and potency of the group as a whole in (*a*) an autocratic and (*b*) a democratic setting. (Derived from "Studies in Topological and Vector Psychology: I. An Experimental Study of the Effect of Democratic and Authoritarian Group Atmospheres," by Ronald Lippitt. *University of Iowa Studies in Child Welfare*, 1940, **16**, 133–135. By permission of the publisher.)

In the autocratic situation two distinct social strata exist, a higher one containing the leader (*L*) and a lower containing the children (*C*). (The social distance between these strata is indicated by the heavy black circle.) In democracy the status differences are less marked (dotted line). In the autocratic setting distinct subgroups of two exist containing one child and the leader. Therefore, if the leader is taken away, no strong bond between the members remains. In democracy the subgrouping is varying and less rigid. The potency of the group as a whole (*GrP*) is higher there than in the autocratic setting where the potency of the individual goal (*IP*) and of the subgroup (*SuP*) is relatively higher.

other children out of that group plays a great rôle in the behavior of the nursery school child (Murphy, 1937; Rosemary Lippitt, 1940). This tendency is important for the children's gang (Shaw, 1933). Juveniles in the reformatory who have not fully accepted their belonging to the criminals have a tendency to name as their best friends persons outside the reformatory (Kephart, 1937).

Ronald Lippitt (1940) found that the groups containing the leader and one child each, whereas in the democratic group the group as a whole has a greater potency (Figure 3*a* and *b*). This is one of the reasons why children in these autocracies are more likely to be aggressive against their fellows although submissive to the leader. M. E. Wright (1940) found that friendship between two children increases in certain situations of frustration partly because these situations favor a group structure in

which the children see themselves opposed to the adult.

Bavelas (1942*a*) found that the degree of cooperation between children in a day camp increased after their adult leaders were retrained from autocratic to democratic leadership techniques.

Moreno (1934) has developed a technique which permits an easy determination of group structure and group belongingness under certain circumstances. Other techniques have been developed, for instance, by Bogardus (1933) and by Ronald Lippitt (1940).

The difference between being inside and outside a region is basic not only for social groups but for all goal-seeking activities, and for the problem of frustration. Seeking a certain goal is equivalent to a tendency to enter a region outside of which one is located. We shall take up this question when discussing psychological forces.

Change in cognitive structure

The structure of the life space is the positional relations of its parts. Structure may be expressed by the topology of the life space. Locomotion of the person, that is, the change of his position from one region to another region, can be viewed as one type of change in structure. Other examples are those changes which occur during "insight" or learning. The infinite variety of changes in structure may be classified roughly into (1) an increase in differentiation of a region, that is, an increase in the number of subregions; (2) a combination of separated regions into one differentiated region; (3) a decrease in differentiation, that is, a decrease in the number of subregions within a region; (4) a breaking-up of a whole, that is, previously connected subparts of a region are separated into relatively independent regions; and (5) a restructuring, that is, a change in pattern without increase or decrease of differentiation.

Detour. Insight. Restructuring of certain areas of the life space can be readily

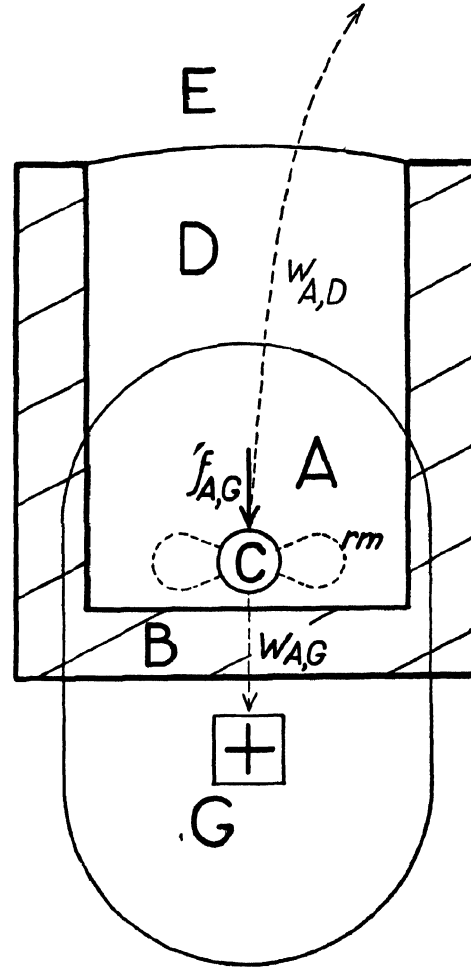

Figure 4. A simple detour problem as seen by the young child.

observed in the solution of detour problems. The basic questions can be illustrated by a simple example: A goal *G* (Figure 4) lies behind a U-shaped physical barrier *B*. The child *C*, of a mental age of one year (this may be a chronologically young child,

or an older feeble-minded child) is likely to try to reach the goal by an action toward the barrier along the path $w_{A,G}$.[1] A child of five years, under the same circumstances, will have no difficulty. It will

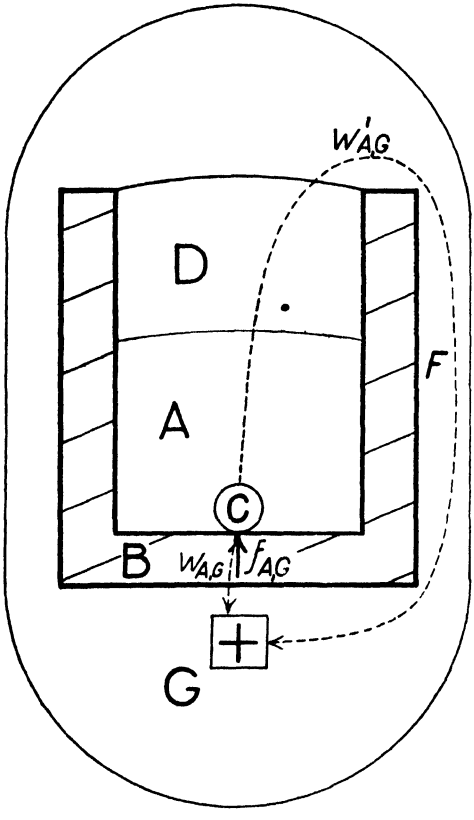

FIGURE 5. The detour problem represented in Figure 4 as seen by the older child.

reach the goal by way of a roundabout route along the path $w'_{A,G}$ (Figure 5). What are the difficulties of the younger child? Both children have the tendency to locomote from their present situation A toward the goal G. (As we shall see later, we can say there exists a psychological force $f_{A,G}$ acting on the child in the direction from A toward G.)

We can understand the difference in difficulties if we consider what "direction toward G" means for both children. For the young child the direction from A to G, $d_{A,G}$, is equal to the direction toward the barrier B, $(d_{A,G} = d_{A,B})$. A movement from A to D along the path $w_{A,D}$ would have, for this child, the meaning of going away from G. In other words, the direction toward D, $d_{A,D}$, is opposite to the direction toward G, $d_{A,G}$ $(d_{A,D} = \overline{d_{A,G}})$. For the older child (Figure 5) the direction toward D, $d_{A,D}$, has not the character of being opposite to the direction but of being equal to the direction to G $(d_{A,D} = d_{A,G})$, because the step from A to D is seen by this child as a part of the roundabout route $w'_{A,G}$ toward G. The difference in the meaning of the direction $d_{A,G}$ toward G is due mainly to two facts:

(1) For the younger child the immediate situation is less extended than for the older one (this is but one result of the fact that the life space of the younger child is smaller in many aspects than that of the older child). It includes only the regions A, B, and G (Figure 4). For the older child, a wider area is psychologically present, including, for instance, the areas D and F. As an effect of this difference in scope of the present situation the younger child sees the areas A and G separated by the impassable barrier B. For the older child, regions A and G are connected by way of passable regions D and F.

Directions in the psychological life space are defined by certain paths as a whole. The older child sees the step from A to D as a part of the path A, D, F, G toward G. The young child sees the step A, D as a part of the path A, E, that is, away from G. The difference in the cognitive structure of the situation for the young and

[1] A fuller discussion of the problems of direction and path in psychology may be found in Lewin (1938).

older child leads, therefore, to a different meaning of the direction toward G and, accordingly, to a different locomotion resulting from the same tendencies of both children to reach G.

(2) For the young child, the path $w'_{A,G}$ simply does not exist psychologically. For the older child two paths toward G exist psychologically, namely, the roundabout route $w'_{A,G}$ and the blocked "direct" path $w_{A,G}$. The "direct" direction toward G can be interpreted, in this case, as the direction of looking toward G; the less "direct" direction as that of walking toward G. For the young child, "direction toward G" has not yet been differentiated into these two directions. (This is an example of the lesser degree of differentiation of the life space of the younger child.)

A two-year-old child placed in the same situation may at first have a cognitive structure corresponding to that of the younger child (Figure 4). After a few attempts the structure of the situation may change to that of the older child (Figure 5). These changes frequently occur as a sudden shift. They are an example of what has been called *insight* (Köhler, 1925).

Insight can always be viewed as a change in the cognitive structure of the situation. It frequently includes differentiation and restructuring in the sense of separating certain regions which have been connected and connecting regions which have been separated. For instance, to use a branch of a tree as a stick (Köhler, 1925) for reaching a goal behind a fence (Figure 6) it is necessary to see the branch *br* as a relatively separate unit instead of a part within the larger unit of the tree *Tr*. In addition, it is necessary to connect this branch *br* with the goal G behind the fence.

From the theory of insight in detour problems certain conclusions in regard to factors facilitating insight can be derived. Becoming emotional leads frequently to a narrowing-down of the psychologically existing area. A state of strong emotionality should, therefore, be detrimental to finding intellectual solutions (see p. 815). A distance sufficient to permit a survey of the larger situation helps in the solution of intellectual problems. Katona (1940) discusses the effect of various settings upon the change of the cognitive structure and the ability to find new solutions.

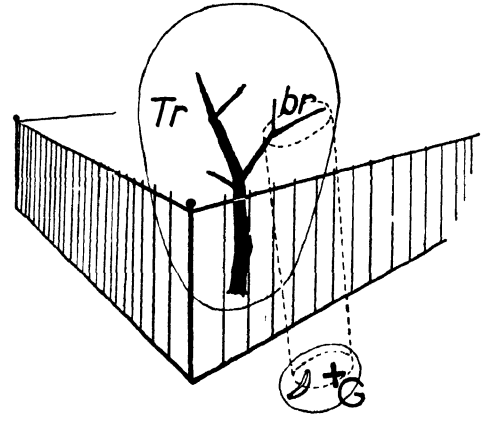

FIGURE 6. Problem solving. A case of change in cognitive structure.

The principles of change in cognitive structure discussed here are as applicable to social and mathematical problems as to physical problems.

Learning. Orientation. Learning is a popular term referring to such different processes as learning to like spinach, learning to walk, and learning French vocabularies, that is, problems of changes of goals or needs, changes of posture and muscular coordination, and changes in knowledge. Therefore, no one theory of learning is possible. Problems of change in goals will be discussed later. Insight is an example of learning in the sense of change of cognitive structure. Learning, in this sense, usually involves several of those types of structural changes which we have men-

tioned previously, combined with a change in the degree of organization.

A change in the direction of greater differentiation takes place, for instance, when a child gets oriented in a new surrounding. Being in an unknown surrounding is equivalent to being in a region which is unstructured in the double sense that neither the quality nor the subparts of the present region, nor the immediately neighboring regions, are determined. Orientation means the structurization of the unstructured region. In this way, direction within the life space becomes determined (Lewin, 1938). Orientation is a process which, on a smaller scale, shows significant parallels to the development of the life space of the young child.

An unstructured region usually has the same effect as an impassable obstacle. Being in unstructured surroundings leads to uncertainty of behavior because it is not clear whether a certain action will lead to or away from the goal. It is undetermined whether the neighboring regions are dangerous or friendly. Waring, Dwyer, and Junkin (1939) found that children during the meals of the first nursery school day were more ready to acquiesce to the advice of the adult than later on when they felt themselves to be on better-known ground for resisting.

The problem of learning is treated in detail in another chapter (Chapter 8). We shall add, therefore, but one remark about the relation between repetition and learning. Repetition of a certain activity may lead to differentiation of a previously undifferentiated region of the life space, and to unification of previously separated activities. This is frequently the case in motor learning. However, if continued long enough, repetition may have the opposite effect, namely, a breaking-up of the larger units of actions, a dedifferentiation, unlearning, and disorganization similar to that of primitivation or degeneration. These processes are typical of psychological satiation and oversatiation.

Force and Force Field

Force and valence

Resultant Force, Locomotion, and Force Field. The structure of the life space determines what locomotions are possible at a given time. What change actually occurs depends on the constellation of psychological forces. The construct *force* characterizes, for a given point of the life space, the direction and strength of the tendency to change. This construct does not imply any additional assumptions as to the "cause" of this tendency. The combination of a number of forces acting at the same point at a given time is called the *resultant force.* The relation between force and behavior can then be summed up in the following way: Whenever a resultant force (different from zero) exists, there is either a locomotion in the direction of that force or a change in cognitive structure equivalent to this locomotion. The reverse also holds; namely, whenever a locomotion or change of structure exists, resultant forces exist in that direction.[1]

Psychological forces correspond to a relation between at least two regions of the life space. A simple example is the force $f_{A,G}$ acting on a child C in the direction toward a goal G (Figure 7). This force depends upon the state of the child C, particularly upon the state of his needs, and upon the nature of the region G. If the region G (which may represent an activity, a social position, an object, or any other possible goal) is attractive to the person,

1 We are not discussing here the complicated problems of the alien factors, that is, those physical and social factors which may be viewed as the boundary conditions of the life space (Lewin, 1936a; 1943; 1944). We keep within the realm of psychology.

it is said to have a positive valence ($Va(G) > 0$).

Such a valence corresponds to a field of forces which has the structure of a positive central field (Figure 7). If no other valences existed, the person located in any region *A, B, D, E* . . . would always try to move in the direction toward *G*. In other words, the valence *G* corresponds to a force $f_{A,G}$, $f_{B,G}$, $f_{D,G}$, etc. The observation of behavior permits not only the determination of conscious goals but also of "unconscious goals," as Freud uses the term.

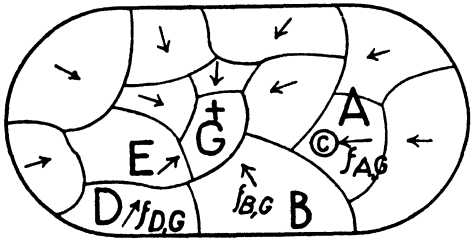

FIGURE 7. A positive central field of forces corresponding to a positive valence.

If the person is repulsed, we speak of a negative valence of *G* ($Va(G) > 0$), corresponding to a negative central field (Figure 8), which is composed of forces $f_{A,-G}$, $f_{B,-G}$, $f_{D,-G}$, etc., away from *G*.

The effect of forces may be observed from earliest infancy: Movements toward or away from the breast during feeding are noted in the first weeks of life. Looking toward an object (fixation) is another example of directed action. Later on, there is grasping. More elaborate directed actions presuppose a correspondingly higher differentiation of the life space. In a young child a force is more likely to affect directly every part of the child than it is at a later age. For instance, the child of six months reaching out for a toy may move both arms and legs in this direction (Figure 9). He may open his mouth and bend his head toward the goal. The older, more differentiated child is likely to react in a more "controlled" way with only a part of the body.

Strength of Force and Distance of Valence. We shall discuss later what factors determine a change of valence. First, let us ask what effect a given valence, or distribution of valences, has on behavior. The strength of the force toward or away from a valence depends upon the strength of

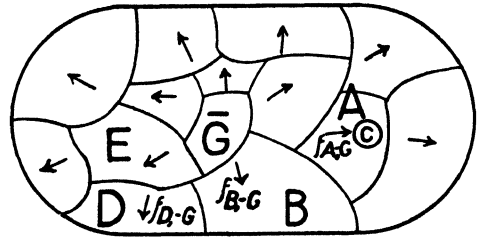

FIGURE 8. A negative central field of forces corresponding to a negative valence.

that valence and the psychological distance ($e_{A,G}$) between the person and the valence [$f_{A,G} = F(Va(G), e_{A,G})$].

Fajans (1933) found that the persistence of children (ages 1 to 6 years) trying to reach a goal from various physical distances (8 to 100 cm.) increases with decreasing distance. This may mean that, with increasing distance, either the force decreases or the child sees more quickly that the barrier is insurmountable. If the first factor is dominant, emotional tension should decrease with distance (see p. 815). Fajans found this to be true only for the infants. For the older children, the second factor seems to be dominant, probably because these children view the obstacle as dependent upon the will of the experimenter rather than as physical distance.

In some experiments with rats, the velocity of running toward a goal was found to increase with decreasing distance (Hull, 1932). H. F. Wright (1937) found no

consistent indication of such a speed gradient in experiments where nursery school children pulled the goal (a marble) toward themselves. This indicates that the relation between strength of force and bodily locomotion is rather complicated in psychology and that physical and psychological distance may be related quite differently under different circumstances.

FIGURE 9. Action in the direction of a positive valence. (From *Dynamic Theory of Personality*, by K. Lewin. New York: McGraw-Hill, 1935, 82. By permission of the publisher.)

As a particular example, the situation may be mentioned where the person "nearly" reaches a goal. In animals (Hull, 1932), as in children (H. F. Wright, 1937), a marked slowing-down has been observed at the last section before the goal is reached. If the force were related simply to the physical distance, there should be no sudden drop in velocity at this point. Obviously, after the individual is inside the goal region, the force $f_{A,G}$ can no longer have the direction "toward" the goal region but changes to a force $f_{G,G}$, which properly has to be interpreted as a tendency to resist being forced out of the goal region (for details see Lewin, 1938). Being in the goal region is frequently not equivalent to consumption of, or to bodily contact with, the goal, but it is equivalent to having the goal in one's power, to being sure of it. This is probably the reason for the slowing-down in the last section before the goal. This also explains the frequent "decrease of interest" after possession, illustrated by the following example. A nine-month-old child reaches out for two rattles lying before him. When he gets one he does not begin to play but is interested only in the rattle he does not have.

An example of a decrease of the strength of a force with the distance from the negative valence can be found in certain eating-situations (Lewin, 1938, p. 117). For a child who dislikes his spinach, the act of eating might consist of a series of relatively separate steps, such as putting the hand on the table, taking the spoon, putting food on the spoon, etc. (Figure 10*a*). The strength of the force away from eating the disagreeable food and, therefore, the resistance against making the next step increases with the nearness of the step to the actual eating (*Re*). After the child starts chewing, the structure of the situation in regard to this bite usually is fundamentally changed, as shown in Figure 10*b*. Instead of resisting, the child tries to finish the bite. This is an example of how the direction and strength of the forces acting on the person depend upon the region in which the person is located.

The change of the strength of the force with the distance to the valence is different for positive and for negative valences. The latter usually diminishes much faster (see later, Figure 15). The amount of decrease depends also upon the nature of the region which has a positive or negative valence. It is different, for example, in case of a dangerous animal which can move about, from the amount in case of an immovable unpleasant object.

The effect of temporal distance on the strength of the force seems to parallel that

of physical distance in some respects. E Katz (1938), in experiments with nursery school children, found that the frequency of resumption of interrupted tasks increases with the nearness of the interruption to the completion of the task, but that it drops for interruptions very close to the end. Institutionalized adolescents, like other prisoners, may attempt to escape shortly before they are eligible for release. Frequently they become rebellious (Farber, 1944). Their emotional tension is heightened by the temporal nearness of the goal.

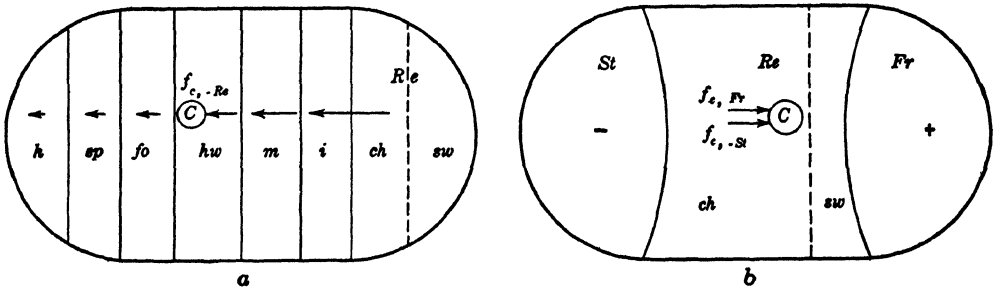

FIGURE 10. (*a*) Eating situation in case of disliked food. (*b*) Change of direction of forces after the child started real eating. (From "The Conceptual Representation and Measurement of Psychological Forces," by K. Lewin. *Contributions to Psychological Theory*, 1938, **1**, 117. By permission of the Duke University Press, publisher.)

(*a*) *C*, child; *Re*, real eating; *h*, putting hand on table; *sp*, taking spoon; *fo*, putting food on spoon; *hw*, bring spoon halfway to mouth; *m*, bringing spoon to mouth; *i*, taking food into mouth; *ch*, chewing; *sw*, swallowing. Eating has a negative valence; the force away from eating $f_{C,-Re}$ increases stepwise with the decrease of distance between *C* and *Re*.

(*b*) *C*, child; *Re*, real eating; *St*, struggle with adults; *Fr*, freedom; $f_{C,Fr}$, force in the direction of freedom; $f_{C,-St}$, force away from struggle.

TYPE OF FORCES

Driving and Restraining Forces. The forces toward a positive, or away from a negative, valence can be called *driving forces*. They lead to locomotion. These locomotions might be hindered by physical or social obstacles. Such barriers correspond to *restraining forces* (Lewin, 1938). Restraining forces, as such, do not lead to locomotion, but they do influence the effect of driving forces.

The restraining forces, just as the driving forces, are due to a relation between two regions of the life space, namely, the nature of the barrier region and the "ability" of the individual. The same social or physical obstacle corresponds, therefore, to different restraining forces for different individuals.

Induced Forces, Forces Corresponding to Own Needs and Impersonal Forces. Forces may correspond to a person's own needs. For instance, the child may wish to go to the movie or to eat certain food. Many psychological forces acting on a child do not, however, correspond to his own wishes but to the wish of another person, for instance, of the mother. These forces in the life space of the child can be called *induced forces*, and the corresponding positive or negative valence "induced valence." (A force acting on the child in the direction to the goal *G* induced by the mother *M* may be written $i^{M}f_{C,G}$.)

There are forces which psychologically correspond neither to the own wish of the child nor the wish of another person, but

have, for the child, the character of something "impersonal," a matter-of-fact demand. We call them *impersonal forces*. It is of great importance for the reaction of the child and for the atmosphere of the situation whether an impersonal request or the personal will of another individual is dominant.

Point of Application. Forces may act on any part of the life space. Frequently, the point of application is that region of the life space which corresponds to the own person. The child may, however, experience that the "doll wants to go to bed," or that "another child wants a certain toy." In these cases the points of application of the forces are regions in the life space of a child other than his own person. Such cases are most common and play an important part, for instance, in the problems of altruism.

Conflict situations

Definition of Conflict. A conflict situation can be defined as a situation where forces acting on the person are opposite in direction and about equal in strength. In regard to driving forces three cases are possible: The person may be located between two positive valences, between two negative valences, or a positive and negative valence may lie in the same direction. There may be, also, conflicts between driving and restraining forces. Finally, there may be conflicts between own forces and various combinations of induced and impersonal forces. The effect and the development of conflicts vary with these different constellations, although all conflicts have certain properties in common.

Conflicts between Driving Forces. What is usually called a *choice* means that a person is located between two positive or negative valences which are mutually exclusive. The child has to choose, for example, between going on a picnic (G^1, Figure 11*a*) and playing (G^2) with his comrades. (Figure 11 and some of the later figures represent situations where the physical directions and distances are sufficiently important psychologically to be used as frames of reference for the life space. One can speak in these cases of quasi-physical fields.) An example of a child standing between two negative valences is a situation in which punishment (G^1) is threatened if he does not do a certain disagreeable task (G^2, Figure 11*b*). Figure 11*a* and *b* represents the corresponding force fields. If the child is located at A and the strength of the valences are equal, he will be exposed to forces which are equal in strength but opposite in direction. In the first example, the opposing forces f_{A,G^1} and f_{A,G^2} are directed toward the picnic and play. In the second example, the opposing forces $f_{A,-G^1}$ and $f_{A,-G^2}$ are directed away from the task and the punishment.

From these force fields certain differences of behavior can be derived. In the case of two negative valences, there is a resultant force in the direction of "leaving the field" altogether. If the two negative valences are very great, the child may run away from home, or try to avoid the issue. To be effective, the threat of punishment has to include the creation of a set-up which prohibits this avoidance (Lewin, 1935), that is, the creation of a prisonlike situation, where barriers B prohibit leaving the situation in any other way than by facing the task T or the punishment P (Figure 12). If there is a choice between two positive valences, no force in the direction of leaving the field exists. Instead, the child will try to reach both goals if possible.

An example of a conflict due to the presence of a negative and a positive valence is the promise of reward for doing

a disagreeable task (Figure 13). Here a conflict is brought about by the opposition of the force $f_{A,R}$ toward the reward R and the force $f_{A,-T}$ away from the disagreeable activity T. The structure of the situation is similar to that characteristic of a detour problem. Indeed, the child frequently tries to reach the reward R along a roundabout route $w_{A,C,R}$ without passing through the disagreeable activity. The reward will be effective only if all other paths to R are blocked by an impassable barrier B which permits entrance to R only by way of T. The barriers in this case, as in the case of the threat of punishment (Figure 12), are usually social in nature: The child knows that the adult will prevent certain actions by social force.

The necessity for setting up a barrier around the reward indicates one of the differences between this method of making the child perform a disagreeable activity T and the methods which try to change the negative valence of T itself into a positive one. A "change of interest" in T may be brought about by imbedding the activity T (for instance, the disliked figuring) into a different setting (for instance, into playing store), so that the meaning, and consequently the valence, of T is changed for the child. Such a method makes the creation of a barrier unnecessary and secures spontaneous actions of the child toward the previously disliked activity as a result of the newly created positive central field.

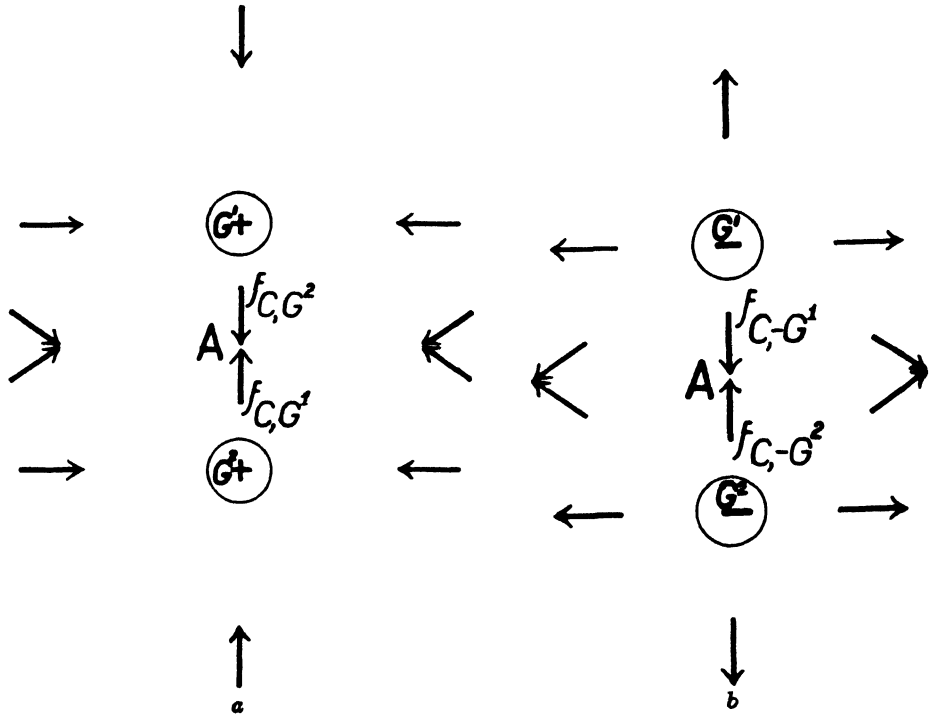

FIGURE 11. (a) Force field corresponding to two positive valences. (b) Force field corresponding to two negative valences.

Another example of a conflict between a positive and a negative valence can be observed in a setting where a child of three years is trying to seize a toy swan S from the waves W on the seashore (Figure 14). Following the forces $f_{C,S}$, the child will approach the swan. If, however, he comes too close to the waves W, the force away from the waves $f_{C,-W}$ may be greater than those toward the swan. In this case the child will retreat. The force corresponding to the negative valence of the waves decreases rather rapidly with the increasing distance because of the limited range of the effect of the waves (Figure 15). The forces corresponding to the positive valence of the swan diminish much more slowly with the distance. There exists, therefore, an equilibrium between the opposing forces at point E where their strengths are equal ($f_{E,S} = f_{E,-W}$). The children may be observed wavering around this point of equilibrium until one of these forces becomes dominant as a result of changes of circumstances or of a decision. In this example the force field corresponding to the swan is a positive central field; the forces corresponding to the waves have a direction perpendicular to the shore.

T, disagreeable task; *P*, threat of punishment; *C*, child; *B*, barrier preventing the child from leaving the situation through other regions than *T* or *P*.

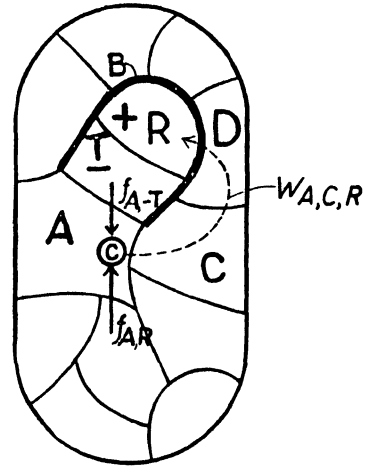

FIGURE 13. Offer of a reward.

Conflicts between Driving and Restraining Forces. A most common type of conflict arises when a child is prevented from reaching a goal G by a barrier B. Two basic cases may be distinguished: (1) the child is surrounded by a barrier with the goal outside (Figure 12); (2) the goal is surrounded by a barrier with the child outside (Figure 16). The first case is a prison-like situation which gives the child little space of free movement. In the second case, the child is free except in regard to the region G. Each of these cases leads to specific reactions (Lewin, 1935). We

shall now discuss in greater detail a sequence of behavior typical of the second case.

At first, a certain amount of change in structure usually occurs: The child tries to investigate the nature of the obstacle with the purpose of finding a sector *s* within the barrier which will permit passage. Such a change in cognitive structure is similar to that observed in detour problems. It is very common for a child to be in situations where an obstacle could be overcome with the help of an adult. In these situations the barrier is composed of at least two sectors, one corresponding to the physical obstacle (*ph*, Figure 16), the other to the social obstacle (*sl*). In the experiment of Fajans, mentioned above, practically all children conceived of the barrier at first as a physical obstacle (as too great a physical distance). For the children above two years, after some time the social aspect of the situation became clear and led to social approaches toward the goal (the children asked the adult for help).

The barrier acquires a negative valence

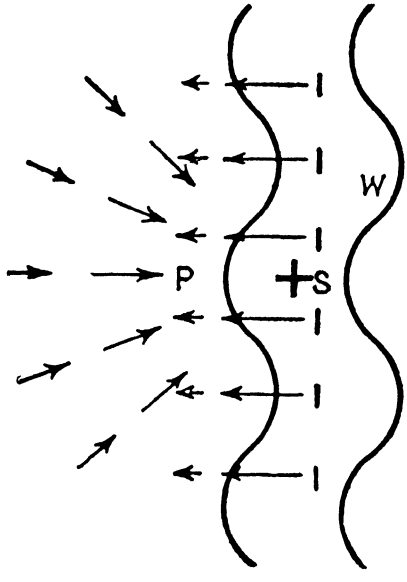

FIGURE 14. Force field in a conflict resulting from a positive and negative valence. (From *Dynamic Theory of Personality*, by K. Lewin. New York: McGraw-Hill, 1935, 92. By permission of the publisher.)

S, attractive toy; *W*, waves perceived as dangerous; *P*, point of equilibrium.

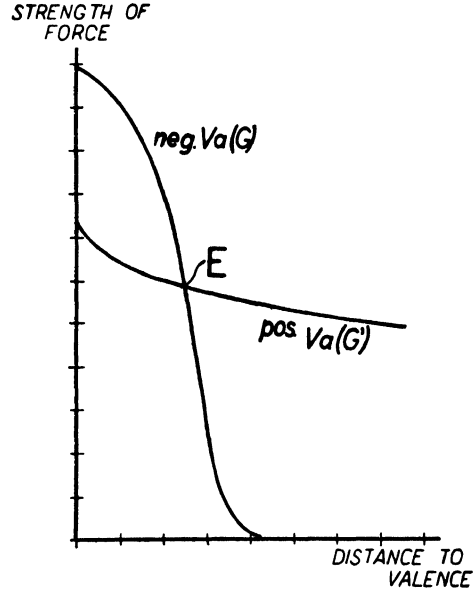

FIGURE 15. Schematic representation of the change of the strength of a force with the distance to a positive and a negative valence.

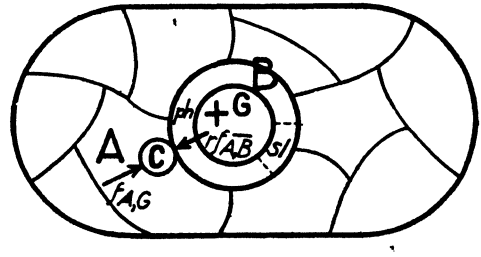

FIGURE 16. Conflict between driving and restraining forces in the case of a physical and social obstacle to a goal.

$f_{A,G}$, driving force; $rf_{\overline{A,B}}$, restraining force; *ph*, physical sector of the barrier (*B*); *sl*, social sector of the barrier.

for the child after a number of unsuccessful attempts to cross it. This change is equivalent to a change in the force field from the structure represented in Figure 17 to that of Figure 18. If the barrier is an obstacle but has no negative valence, the corresponding force field does not reach much beyond the barrier (Figure 17). The

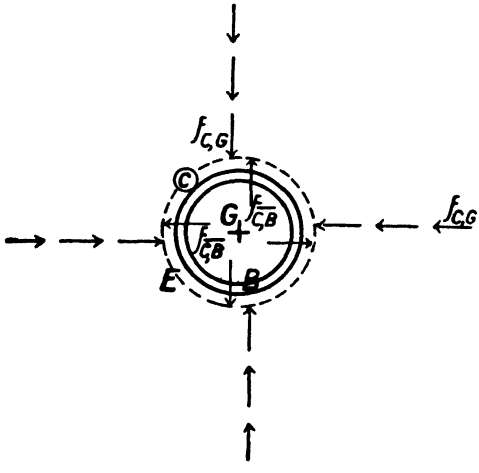

FIGURE 17. Line of equilibrium between driving and restraining forces in case of a circular barrier.

restraining forces $rf_{\overline{O,B}}$ merely hinder a locomotion in the direction of the force $f_{O,B}$ without driving the person away from B. The line of equilibrium E between driving and restraining forces lies, therefore, close to the barrier region. If, after failure, the barrier acquires a negative valence, the corresponding negative central force field will reach out farther (Figure 18) so that the line of equilibrium E between the force $f_{O,G}$ toward the goal and the force $f_{O,-B}$ away from the barrier is located at a greater distance.

With increasing failure, the negative valence tends to increase. This enlarges the distance between the line of equilibrium and the barrier until the child leaves the field altogether.

Fajans (1933) has given a detailed report about the form and sequence of events in such a situation. Usually the child leaves the field at first only temporarily. After some time, the forces toward the goal again become greater than the forces away from the barrier, and the child returns. If the new attempts are still unsuccessful,

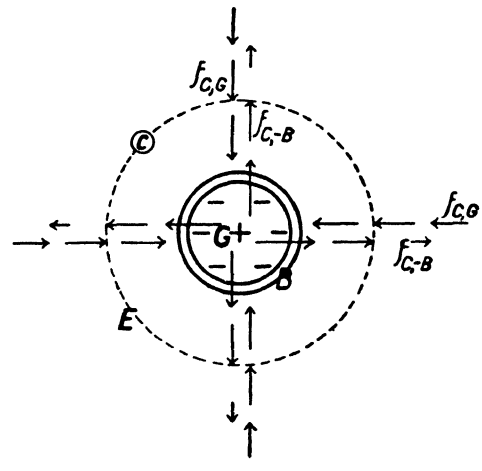

FIGURE 18. Line of equilibrium after the barrier has acquired a negative valence.

the negative valence increases again until the child leaves. On the average, these later attempts show less duration. Finally, the child leaves the field permanently; he gives up. Barker, Dembo, and Lewin (1941) report similar sequences of behavior in children between two and six years in a slightly different setting of frustration.

Active children, on the average, are more persistent than passive ones (Fajans, 1933). Some active children, however, are particularly quick to leave the situation, probably because they decide soon that the barrier is impassable. A state of equilibrium in such a conflict can lead to passive, gesturelike action toward the goal: The child stays below the goal with his arm erect but he makes no actual attempts to reach it. Children frequently leave the

field psychologically without leaving the room bodily. They may try to enter a different activity, may daydream, or start self-manipulation with their clothes or their body (Fajans, 1933; Sliosberg, 1934; MacDonald, 1940).

A conflict between driving and restraining forces may also occur if the child is prevented by an obstacle from leaving the field of a negative valence. Such a situation exists, for instance, if a child is oversatiated with an activity but prevented from leaving it, or in any other prison-like situation. The sequence of behavior is, in many respects, similar to that discussed above. Attempts to leave are followed by the giving-up of such attempts as the result of the relation between the strength of the force $f_{A,-A}$ away from the region A and the increasing negative valence of the barrier. Frequently a state of high emotional tension results.

Conflicts between Own and Induced Forces. Every one of the conflict situations discussed above might be due to the opposition of two forces corresponding to the child's own needs, to the opposition of two induced forces, or to the opposition between an own and an induced force. Many effects of conflict situations are independent of these differences. Certain effects, however, are typical of conflicts between own and induced forces.

A force induced by a person P on a child C can be viewed as the result of the power field of that person over the child (Figure 19). The person having power over the child is able to induce positive and negative valences by giving orders. By a restraining command, he can change the character of a region which would be passable according to the child's own ability into an impassable barrier. In other words, "the power of P over C" means that P is able to create induced driving or restraining forces ${}^{i^P}f_{C,G}$ which correspond to P's will.

A conflict between own and induced forces always permits at least one other solution in addition to those discussed above: The child may attempt to undermine the power of the other person, at least in the area of conflict. The tendency of a conflict between own and induced

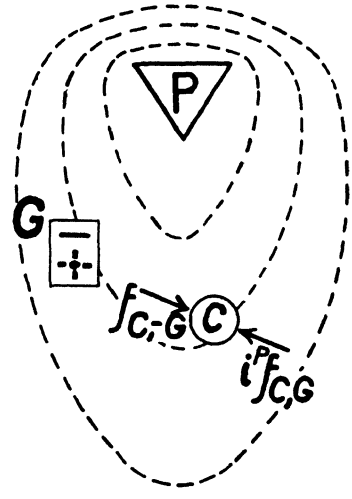

FIGURE 19. Power field.

P, stranger; C, child; G, activity having positive valence for the child and an induced negative valence; $f_{C,-G}$, own force away from G; ${}^{i^P}f_{C,G}$, force induced by P in the direction of G. ———, lines corresponding to equal strength of power field.

forces to lead to fights has been observed by Waring, Dwyer, and Junkin (1939) in nursery school children in an eating-situation. Dembo (1931) and J. D. Frank (1944) have observed similar tendencies in students. M. E. Wright (1940) found an increasing aggression against the experimenter in pairs of nursery school children in a setting of frustration induced by the experimenter. The children showed greater cooperation among themselves. This might be interpreted as due partly to the tendency to increase their own power relative to the power of the experimenter. Lewin, Lippitt, and White (1939) found a strong

tendency toward aggression in autocratic atmospheres which are dominated much more by induced forces than by forces corresponding to the own needs of the children. This aggressiveness, however, was usually not directed against the supreme powers of the leader but diverted toward their fellows or toward material objects. If the suppressive power of the leader is too great, even this aggression ceases.

Emotional tension and restlessness

Emotional Tension and Strength of Conflict. If two opposing forces, $f_{A,G}$ and $f_{A,D}$ (Figure 20*a* and *b*), are equal in strength the resultant force will be zero, independent of the absolute strength of the forces. As far as changes in position are concerned, therefore, no difference should exist in the effect of conflicts between weak and between strong forces. Actually, the state of the person is quite different in a weak and in a strong conflict. One of the main differences is the intensity of emotional tension (*et*), which seems to be a function of the strength of the opposing forces $[et = F(|f_{A,G}|)]$ (Sears and Sears, 1940). As mentioned above, greater emotionality is found in infants if the distance to an inaccessible goal is small than if it is larger. This is one of the reasons why increasing incentives favor the solution of detour and other intellectual problems only up to a certain intensity level. Above this level, however, increasing the forces to the goal makes the necessary restructurization more difficult, partly because the person has to move against stronger forces, partly because the resultant emotionality leads to primitivation (regression). Barker, Dembo, and Lewin (1941) found that the frequency of negative emotional behavior increased with the intensity of frustration. The same holds for the amount of regression as measured by the constructiveness of play (Figure 2).

The Form of Restless Movement. One of the simplest expressions of emotionality is restless movements, movements which are not directed to a certain goal but are merely an expression of tension. (Actually, all combinations of undirected expression, such as restlessness and purposeless behavior, occur [Dembo, 1931].) Irwin (1932) found that general activity as measured by the stabilimeter increases in infants with the time after the last feeding. This indicates that the amount of undirected activity is a good measurement for the state of tension accompanying hunger at that age level.

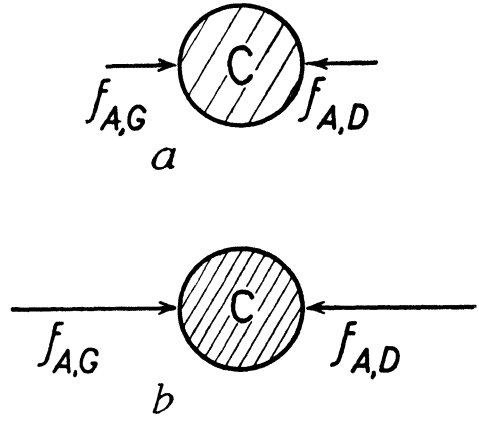

FIGURE 20. Emotional tension in case of (*a*) weak conflict and (*b*) strong conflict.

Restless movements are usually perpendicular to the direction of the force to the goal, or, more generally, they proceed as much as possible along the line of equilibrium. In the case of the six-month-old child reaching to the goal (Figure 9), restless movements of his arms and legs occur perpendicular to the direction of the goal. Behind a U-shaped barrier (Figure 4), the restless movements are parallel to the barrier along the line *rm*. In a constellation corresponding to Figure 17 or 18 the restless movements will follow the line *E*. This

is verified in a situation where a one-and-one-half-year-old child tries to reach a toy G behind a circular physical barrier B. The restless movements of the child take the form of circling around that barrier. (For details see Lewin, 1938.)

The restless movement can be understood as a tendency to move away from the present situation, that is, as a movement corresponding to a force $f_{A,-A}$.

Overlapping Situations

Overlapping situations defined. Relative potency

Frequently the person finds himself at the same time in more than one situation. The simplest example is that of divided attention: A child in the classroom listens to the teacher but also thinks about the ball game after school. The amount to which the child is involved in either of these two situations, S^1 and S^2, is called their relative potency, $Po(S^1)$ and $Po(S^2)$.

The effect a situation has on behavior depends upon the potency of that situation. In particular, the effect a force has on behavior is proportional to the potency of the related situation.

Overlapping activities

Barker, Dembo, and Lewin (1941) speak of secondary play, as distinguished from primary play, when the child does not give his full attention to play. The constructiveness of secondary play is decisively below that of primary play. In experiments about psychological satiation (Karsten, 1928; Kounin, 1939), a person who is supposed to do an activity over and over again tends to perform the repetition as a secondary activity on a peripheral level. Activities such as writing may be considered as an overlapping of two activities, namely, (1) conveying a certain meaning, (2) writing symbols. The first has the nature of a steadily progressing action, the second that of a repetition. The velocity of becoming satiated depends upon the relative potency of the repetitive aspect of the activity. Writing a letter, therefore, may lead more quickly to satiation in a child for whom writing is more difficult. Similarly, walking or other activities which usually have very low potency for the adult may soon lead to satiation in the child (see p. 825).

Decision

A situation of choice can be viewed as an overlapping situation. The person be-

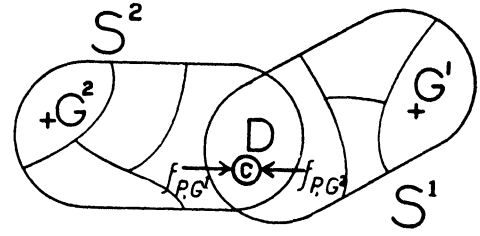

Figure 21. State of indecision.

S^1 and S^2, the two possibilities with the corresponding goals G^1 and G^2; D, a region of making a decision.

ing in the process of making a decision D (Figure 21) usually alternates between seeing himself in a future situation corresponding to the one and to the other possibility (S^1 and S^2). In other words, the potency of the various possibilities fluctuates. When a decision is reached, one of these situations acquires the dominant potency permanently. In a choice between activities of different degrees of difficulty, the decision is influenced by the probability of success or failure on each task. Escalona (1940) has shown that this probability is equivalent to the potency of the corresponding future situation.

The decision time increases also, the more the opposing forces are equal in

strength (Barker, 1942). B. A. Wright (1942*a*, 1942*b*) found, in a study of altruistic and egoistic choices, that eight-year-old children whose choices were all either altruistic or egoistic arrived at a decision more quickly than those who made sometimes the one type of choice and sometimes the other (Figure 22). Cartwright (1941), in experiments on discrimination of figures or of meaning, found the decision time to be longest if the forces in opposite directions were equal. Recently the theory has been elaborated and quantified by Cartwright and Festinger (1943).

Decision time also increases with the importance of the decision (the valence of the goals). Jucknat (1937), in a study of the level of aspiration with children, and Barker (1942), in a study of choices between more or less agreeable or disagreeable foods, found that the choice time increases with the intensity of the conflict. The decision time is longer in choices between two negative than between two positive valences (Barker, 1942). This latter fact derives from the different equilibria existing in the different constellations of forces (Lewin, 1938). Decision time shows great individual variations. Extreme decision-retardation is typical of certain types of depression (Escalona, 1940; Deri, 1943).

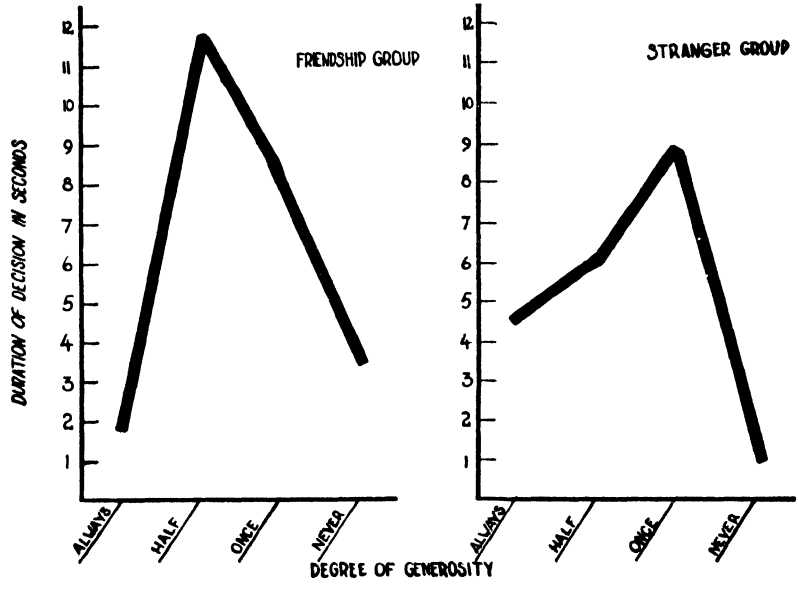

FIGURE 22. Time of decision in various degrees of conflict. (Derived from "Altruism in Children and the Perceived Conduct of Others," by B. A. Wright. *Journal of Abnormal and Social Psychology*, 1942, **37**, 218-233)

IMMEDIATE SITUATION AND BACKGROUND

The influence which the background of a situation has on behavior can be understood as an overlapping of an immediate situation and of the situation at large (Barker, Dembo, Lewin, 1941). A background of frustration decreases constructiveness of play even if the play itself is not hampered from the outside. The amount of regression increases with increasing potency of the background of frustration (Figure 2).

Sheffield (1937) and others report cases where school work was greatly changed by a change of the home background.

The effect of the group on the individual. The marginal child

The effect of group belongingness on the behavior of an individual can be viewed as the result of an overlapping situation: One situation corresponds to the child's own needs and goals; the other, to the goals, rules, and values which exist for him as a group member. Adaptation of an individual to the group depends upon the avoidance of too great a conflict between the two sets of forces (Lewin, 1938).

A child usually belongs to a great number of groups, such as his family, the school, the church, friends. Within the family he may belong to a subgroup containing him and his closest sibling. The effect of the various groups, particularly whether or not the child is ruled by the ideology and values of the one or the other, depends on the relative potency of these groups at that time. Schanck (1932) has found that the influence of public or private morale is different at home and in the church. In school children, the tendency to cheat changes with the social setting (Hartshorne and May, 1929).

Many conflicts in childhood are due to forces corresponding to the various groups to which the child belongs. Such conflicts are particularly important for children in marginal positions, that is, for children who are standing on the boundary between two groups. One example is the adolescent who no longer wants to belong to the children's group but who is not yet fully accepted by the adults. Uncertainty of the ground on which the child stands leads to an alternation between the values of the one and of the other group, to a state of emotional tension, and to a frequent fluctuation between overaggressiveness and overtimidity (Lewin, 1939). The degree to which such adolescent behavior is shown depends upon the degree to which children and adolescents are treated as separate groups in that culture (Benedict, 1934; Reuter, 1937).

A similar effect of marginality can be observed in regard to other types of groups. Emotional tension is high in inmates of reformatory schools as a result of the marginal position of these children between the criminal and the "honest citizen" (Kephart, 1937). Emotional tension diminishes when the child accepts his belongingness to a definite group. A decrease in emotionality was observed in those inmates who accepted their belonging to the criminal class. Marginality is an important problem for the crippled or the otherwise handicapped child (Bartõs, 1932; Dresdner, 1933). Shaw *et al.* (1929) have shown the influence of residing in marginal sections of a city on criminality of children. Marginality raises important problems for children belonging to minority groups, such as Negroes or Jews (Lewin, 1940*b*; Frazier, 1940). The effect, in many respects, is similar to that typical of the adolescent.

FACTORS DETERMINING THE FIELD AND ITS CHANGE

In the preceding section we have discussed the results of the cognitive structure and of certain constellations of forces on behavior. We shall now discuss factors which determine the constellation of forces. This second problem is equivalent to the question of how one part or aspect of the life space depends upon other parts or aspects. Of course, both problems are interrelated since any behavior resulting from a certain situation alters the situation to some degree. We shall here limit our discussion to problems related to needs. They refer to the relation between the state of

that region in the life space which represents the person and the psychological environment.

Need, Force Fields, and Cognitive Structure

Need and valence

During the development of the child, needs are constantly changing in intensity and degree of differentiation. The so-called crises of development are periods of particularly important or particularly quick changes in needs (Dimock, 1937; Bühler, 1939). In addition, there is a change of needs in briefer periods corresponding to the states of hunger, satiation, and oversatiation.

Needs have the character of "organizing" behavior. One can distinguish a hierarchy of needs (Allport, 1937; Murray, 1938; Barker, Dembo, Lewin, 1941). One need or a combination of several needs may set up derived needs (quasi-needs) equivalent to specific intentions.

Needs are closely related to valences. What valence a certain object or activity $[Va(G)]$ has depends partly upon the nature of that activity (G), and partly upon the state of the needs $[t(G)]$ of the person at that time $[Va(G) = F(G, t(G))]$. An increase in the intensity of need (for instance, the need for recreation) leads to an increase of the positive valence of certain activities (such as going to the movies or reading a book) and to an increase in the negative valence of certain other activities (such as doing hard work). Any statement regarding change of needs can be expressed by a statement about certain positive and negative valences.

As a result of the increase in positive valence which accompanies the state of hunger of a particular need, areas of activities which are negative or on a zero level when the need is satiated acquire a positive valence. The hungrier person is usually satisfied with poorer food (D. Katz, 1937).

The valence of an activity is related to its consummatory value for satisfying the need. Not all activities, however, which have positive valence also have satisfaction value in case of consumption; on the other hand, activities with no or even negative valence may have satisfaction value. Valence and satisfaction value should, therefore, be clearly distinguished. It is surprising how frequently valence and value actually go hand in hand. D. Katz (1937) reported an increase in the valence of foods which contain minerals for which deficiencies had been established in chickens. When the deficiency was removed the valence again decreased. Similar results have been claimed for children. Experience may change the valence as well as the meaning which an activity has for the child. The child has to make many important decisions (for instance, in regard to occupation) on the basis of the valence of an activity rather than on the basis of clear knowledge of its satisfaction value.

Need and cognitive structure

The cognitive structure of the life space is influenced by the state of the needs. Murray (1938) found that faces of other people appear more malicious to children in a state of fear than normally. Stern and MacDonald (1937) found that pictures without definite meanings will be seen according to the mood of the child.

The effect which a need has on the structure of the life space depends upon the *intensity of the need* and upon the fluidity of the related areas of the life space. Dembo (1931) found hallucination-like wish fulfillments in highly emotional situations. If the visual field is sufficiently fluid, its

structure may be considerably changed by intention (quasi-need) (Gottschaldt, 1926; Lewin, 1935). Levels of irreality, being more fluid than the level of reality, are, consequently, more easily influenced by both wishes and fears. This is the reason why dreams and daydreams mirror the needs of the child. This also explains why, in fantasy and dreams, needs may come into the open which are kept from "public life" by social taboos.

Sliosberg (1934) has shown that the meaning of objects and events is more fluid in *play* than in nonplay situations. The so-called play technique (Homburger, 1937; Erikson, 1940) and other projective methods (Murray, 1938) make use of this greater flexibility of play to study the deeper desires and suppressed wishes of children. (It should be mentioned, however, that play frequently mirrors the actual home situation rather than the wishes and fears of the child.)

Needs affect the cognitive structure not only of the psychological present but, even more, of the psychological future and past. This is particularly important for the level of aspiration (see p. 830). If the effect of the needs on the psychological future is particularly great, one speaks of an unrealistic person. One form of the influence of needs on the structure of the psychological past is called *rationalization;* other forms are *repression* and *lying*. The lying of the child in the first years of life seems frequently to have the nature of an actual change of the psychological past in line with the child's needs.

There are great individual differences (Davidson and Klopfer, 1938) in the way in which a child sees ink blots (Rorschach test). Unstable problem children are more likely to be carried away by wishes and fears than the average child as a result of their greater fluidity.

Satisfying a Need

A need may be satisfied either by reaching the desired goal or by reaching a substitute goal.

The effect of satisfied and unsatisfied needs. Satisfaction through reaching the original goal

The intention to carry out a certain action is equivalent to the creation of a quasi-need (Lewin, 1935). As long as that need is not satisfied, a force corresponding to the valence of the goal region should exist and lead to an action in the direction of that goal (Lewin, 1940*a*).

Ovsiankina (1928) studied the resumption of interrupted activities. She found a high tendency to resume the task (about 80 per cent) if the inner goal of the person was not reached. In some cases, after resumption, the person stopped as soon as a substitute satisfaction was reached. The frequency of resumption depends upon the nature of the task (it is high for tasks with a definite end as against continuous tasks) and upon the attitude (need) of the subject. Children between nine and eleven showed a percentage of resumption (86 per cent) similar to that of adults. Children who had the attitude of being examined and of strict obedience showed little resumption owing to the lack of involvement; they were governed mainly by induced forces (see p. 808). E. Katz (1938), in a study of resumption of interrupted activities on nursery school children, found practically the same frequency of resumption as Ovsiankina (88 per cent). Differences of intelligence, within the normal range, did not affect the resumption significantly.

The tendency to resume is not diminished if the unfinished work is out of sight (Ovsiankina, 1928). On the other hand, the presence of uncompleted work of an-

other person does not lead (or extremely seldom leads) to spontaneous completion in adults (Ovsiankina, 1928) or in children (Adler and Kounin, 1939). Both results indicate that the state of the need of the child is decisive for resumption. Such a need might be instigated if the child becomes sufficiently involved through watching another person doing the work. (The results of Rosenzweig [1933] with children of various ages differ somewhat from those of E. Katz and Adler and Kounin. These differences are probably due to factors peculiar to his situation.)

The forces in the direction of the goal which correspond to a need can be observed in thinking as well as in action. Zeigarnik (1927) studied the effect of quasi-needs on the tendency to recall. She found the quotient of the recollection of uncompleted to completed tasks to be 1.9 for adults and 2.5 for children between five and ten years old. This quotient, like the frequency of resumption, depends on the degree of involvement of the subject. The difference between children and adults is probably due to a greater involvement of the children in the particular type of activity and to a more immediate dependence of thinking upon the valences. Zeigarnik found that certain types of unintelligent children are particularly persistent in their tendency to come back to the unfinished tasks, whereas easily distractable children show a low quotient.

Marrow (1938) investigated the effect of praise and condemnation in a competitive situation on the Zeigarnik quotient. He found that in both cases it rises. This indicates that the strength of the force in the direction of spontaneous recollection is a function of the intensity of the need. When the subject was told that he would be interrupted as soon as the experimenter saw that he could complete the activity successfully, the quotient was slightly below one. The findings of Marrow and Zeigarnik show that the decisive factor for the release of the need tension is the reaching of the individual's goal rather than the finishing of the work as such. Experiments by Schlote (1930), Sandvoss (1933), and Pachauri (1935) generally substantiate Zeigarnik's findings.

Rosenzweig (1933) studied the Zeigarnik quotient under conditions where the interruption created a feeling of failure. Some children recollected more unfinished, others more finished, tasks. The latter children had a higher average rating on pride. In Rosenzweig's setting, the force in the direction of recalling a task, which is due to the need tension, is counteracted by a force away from this task, which is due to the negative valence of failure. For the children who show a high rating in pride, this negative valence should be higher, thus producing Rosenzweig's results.

Substitute satisfaction

The term *substitution* has been introduced into psychology by Freud (1916). Frequently one activity is called a substitute for another if they show similarity. However, as any two types of behavior show some kind of similarity, this terminology is misleading. Functionally, substitution can be linked either to the valence of an activity or to its satisfaction value.

Substitute Value, Similarity, and Degree of Difficulty. Lissner (1933) studied the value which one activity has for satisfying a need originally directed toward another activity by a technique of resumption. The substitute value is measured by the amount of decrease in resumption of the interrupted original activity after a substitute activity has been completed. The substitute value increases (1) with the degree of similarity between the original and the substitute activity and (2) with the degree of difficulty of the substitute ac-

tivity. The latter factor seemed to be related to the higher level of aspiration corresponding to a more difficult task.

Substitution on Fantasy Level. If reaching the original goal (for instance, that of attacking another person) is hindered, frequently a substitute action on the level of fantasy or talk can be observed (Doob and Sears, 1939). Freud views the dream in part as such a substitute activity. Have these substitute activities substitute value?

Mahler (1933), using as her subjects children six to ten years old, has studied the substitute value of finishing an interrupted activity by talking or thinking instead of acting. She, too, measured substitute value by the decrease of the frequency of resumption. On the average, the substitute value (2.3) for finishing by action was considerably higher than for finishing by talking (1.2). (Little difference was found between children and adults.) For some activities, such as figuring, however, finishing by talking had a high substitute value. According to Mahler, the same factor which determines the substitute value of actions is decisive for the substitute value of talking, namely, whether or not the individual's goal is reached. For *problem tasks* the intellectual solution is decisive; therefore, talking can have a very high substitute value. For *realization tasks* the building of a material object (such as making a box) is the goal; therefore, talking has practically no substitute value. Thinking through an activity had no measurable substitute value for realization or problem tasks. This finding indicates that frequently a condition for satisfaction value is the creation of a social fact (letting another person know). "Magic" solutions performed in a "make-believe" manner seemed to have a certain amount of substitute value, but only if the subject had accepted the magical nature of the situation. This was accepted more readily by children than by adults.

Substitute Value and Cognition. Adler (1939) studied the relation between certain cognitive processes and substitute value at three age levels (seven to ten years chronological age). After interruption of the original task, the child had to finish a second task which was physically identical to the interrupted one. For the younger children, building a house for Mary had no substitute value for building a like house for Johnny, although these children were able to see the similarity of the two activities. For older children, too, the substitute value was low in a situation which favored the "concrete attitude" (that is, viewing each house as specifically related to Mary or Johnny). If, however, a *categorical attitude* (that is, if house-building as such) was stressed, the two activities showed considerable substitute value in the older children. For the younger children, the substitute value was low even in the "categorical" situation.

Theoretically, the substitute value of one activity for another depends upon a communication between the two underlying need systems in such a way that satisfying the one also satisfies the other. The results of Lissner, Mahler, and Adler indicate that this communication depends partly on the cognitive similarity of the activities, and this in turn on the nature of the situation and the developmental state of the person. These results are in line with the findings that the more primitive person is more *concrete-minded* (Gelb and Goldstein's [1924] work on patients with brain lesions; H. Werner's [1940*a*, 1940*b*] findings concerning the increase of "objectivation and abstraction" during development; Weigl's [1941] experiments on children; common observations of feeble-minded). They support Vigotsky's (1934) theory that "situational" thinking precedes the "abstract,

conceptual" thinking in the development of the child. The relatively high age (ten years) at which the "categorical situation" became effective in Adler's experiment indicates, in addition, that the mere ability to see abstract similarities does not necessarily have sufficient weight to establish substitute value for needs.

SUBSTITUTE VALENCE IN PLAY AND NON-PLAY SITUATION

If reaching a goal, that is, satisfying a need in a particular way, is hindered, spontaneous substitute goals may arise. Students who were unsuccessful in their attempts to throw rings over a bottle were found to throw them over near-by hooks (Dembo, 1931). Such spontaneous substitute actions, according to Dembo, have frequently no permanent substitute value. Instead of satisfying, they seem only to heighten the emotional state. This indicates that activities which appeal as substitutes, that is, which have substitute valence, do not need to have satisfaction value. We have mentioned a similar discrepancy between valence and value in ordinary consumption.

Sliosberg (1934) studied substitute valence with children between three and six years in play and in a serious situation. In a serious situation, children would not accept make-believe candy (cardboard) for a piece of chocolate if the make-believe candy was offered after they had started to use real chocolate. If the make-believe candy was offered from the beginning, 17 per cent of three- and four-year-old children accepted it and treated it in a gesture-like way as real candy. Also, make-believe scissors were accepted (in 15 per cent of the cases) for real ones only if they were offered before the real ones.

In a play situation, the children accepted the make-believe chocolate or scissors in almost 100 per cent of the cases (some of them even started to chew the chocolate cardboard). If the make-believe object was introduced without relation to the particular play at hand, the percentage of acceptance decreased slightly to 75. The child was less ready to accept the substitute object if the related need was in a state of greater hunger.

Important for the acceptance or refusal of a substitute is the plasticity of the meaning of the object and of the situation. A toy animal has a more fixed meaning than a pebble or a piece of plasticene and is, therefore, less likely to be accepted as a substitute for something else. The acceptability of substitutes depends more on the plasticity of meaning of the substitute object than on that of the original object. That substitutes are more readily accepted in play is due to greater plasticity of play in respect to social rôles, to the child's own position and goals, and to the meaning of objects.

Changes of Needs and Goals

The emergence of a substitute valence can be viewed as one example of a change of needs or valences. How needs arise in the long-range history of a person and in momentary situations is one of the basic problems of child psychology. New needs, or, more correctly, a change in needs, may result from a great variety of circumstances (Murray, 1938). A child may find out that his friend thinks highly of certain actions and he then comes to value them himself. A change in a social setting, such as attending a children's party, may significantly change the needs of the child in regard to his table manners. Reaching a goal, as well as not reaching it, may change the valences in a momentary or permanent way. During development, new needs may arise by way of differentiation from the previous ones. Behavior in a specific

situation usually results from a combination of several needs; in this way, a "derived need" for this behavior may arise. Such a derived need may be kept dependent upon the *source needs* or may become functionally autonomous (Allport, 1937). Some needs seem to die gradually in various periods of the life history of the individual.

Generally speaking, needs may be changed by changes in any part of the psychological environment, by changes of the inner-personal regions, by changes on the reality level as well as on the irreality level (for instance, by a change in hope), and by changes in the cognitive structure of the psychological future and of the psychological past (Lewin, 1942). This is well in line with the fact that the total life space of a person has to be considered as one connected field. The problem of emergence of needs lies at the crossroad of cultural anthropology, developmental psychology, and the psychology of motivation. Its investigation has been hampered by premature speculative attempts to systematize needs into a few categories. In the following pages we shall discuss a few of the related questions.

Restraining forces affecting needs

Giving Up. Persistence. We have seen (p. 813) that a failure to reach a certain goal may increase the negative valence of the obstacle until the constellation of forces is changed in such a way that a person will withdraw temporarily or finally. This withdrawal is frequently accompanied by an open or concealed conflict which may show itself in aggressiveness. The withdrawal can, however, go hand in hand with a full acceptance of the inaccessibility of the goal. This is equivalent to an actual giving-up: The inaccessible region ceases to be an effective part of the life space. If the child reaches a state where the inaccessibility becomes a "matter of fact," he is no longer in a state of frustration or conflict.

What is usually called persistence is an expression of how quickly goals change when the individual encounters obstacles.

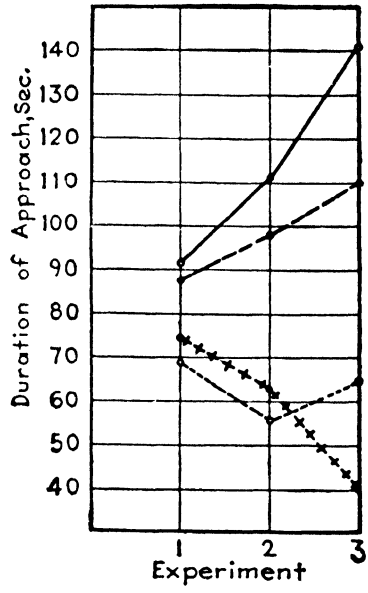

Figure 23. The effect of success, encouragement, substitution, and failure upon persistency. ———, success with concomitant encouragement; — — —, success; – – –, substitute success; ++++, failure. (From *Dynamic Theory of Personality,* by K. Lewin. New York: McGraw-Hill, 1935, 253. By permission of the publisher.)

Fajans (1933) found previous failure to decrease persistence in one- to six-year-old children when they were again confronted with the same type of difficulty. Success led to a relative increase in persistence (Figure 23). When the same task was repeated, a combination of success and praise increased persistence 48 per cent, a success alone 25 per cent; a substitute success led to a decrease of 6 per cent, failure to a decrease of 48 per cent. Similar effects of

praise and failure were found by Wolf (1938). We have seen that such a change in goals depends on the change in the cognitive structure and on individual differences (Wolf, 1938) which can be observed even in the infant (Fajans, 1933). These experiments indicate that the velocity with which these goals change depends, in addition, upon the psychological past and the social atmosphere. Jack (1934) and Keister (1936) found that it is possible to change the reaction of nursery school children to failure through proper training. The increase of persistence and the decrease of rationalization and of emotional and destructive reactions showed a certain amount of transfer to different areas of activity.

Difficulties Intensifying Needs. H. F. Wright (1937) has shown in experiments with adults and children that a difficulty may increase the need for an object behind a barrier. Children, like adults, will prefer a goal which is more difficult to reach, provided that the barrier is not too strong and that both goal objects are not fully identical. This preference is observed if the object itself has the nature of a goal, but not if it is merely a means. For instance, the child will prefer (everything else being equal) a toy which is slightly more difficult to reach. If, however, he has to choose between two tools with which to get the same object, he will prefer that tool which is easier to reach. Wright's investigations indicate that the so-called law of parsimony (using the easiest way) holds only for psychological means, but not for ends. This latter fact is closely related to the problem of the level of aspiration (see p. 830).

Psychological satiation

One can distinguish in regard to all or most needs a state of hunger, of satiation, and of oversatiation. These states correspond to a positive, a neutral, and a negative valence of the activity regions which are related to a particular need. Karsten (1928), in experiments with college students, has studied the effect of repeating over and over again such activities as reading a poem, writing letters, drawing, and turning a wheel. She found the main symptoms of satiation to be (1) small variations; (2) large variations; (3) the breaking-up of larger units of actions into smaller parts, loss of meaning; (4) mistakes, unlearning; (5) fatigue and similar "bodily" symptoms.

These results provide one more reason for revising the older theories which explain the genesis of larger units of actions in terms of associations between smaller units established through repetition. Repetition may lead to the combining of smaller units of action into larger ones, but sufficient repetition will break up larger units. This involves, in case of meaningful material such as poems or sentences, a destruction of the meaning. A similar disintegration may also occur for the situation as a whole.

Satiation occurs only if the activity has, psychologically, the character of an actual repetition, of marking time as opposed to making progress. If the character of making progress can be maintained, the usual symptoms of satiation will not appear.

Psychological satiation frequently leads to muscular fatigue or such bodily symptoms as hoarseness. It is frequently the main cause of "fatigue" in children. Like hysterical symptoms, these bodily symptoms cannot be eliminated by voluntary effort, although they are caused by psychological factors and may disappear with the transition to other activities even though the new activity makes use of the same muscles in practically the same way. Imbedding an activity in a different psychological whole so that its meaning is

changed has practically the same effect in satiation as shifting to a different activity. The superiority of the method of learning to read and write whole sentences or words rather than single letters is based partly on the fact that the former method is less likely to lead to satiation. The good primer is careful to repeat the same words in such a way that they are imbedded in somewhat different wholes, and that a "progress of meaning" rather than actual repetition occurs.

Repetition not only changes the needs related to the activity which is carried out, but usually also affects the needs related to psychologically similar activities, by way of cosatiation.

The velocity of satiation (that is, how quickly repetition leads to a change in needs) depends, according to Karsten, mainly upon (1) the nature of the activity (particularly the size of its units of action), (2) the degree of centrality, and (3) the individual character and state of the person. Pleasant as well as unpleasant activities are more quickly satiated than neutral activities which in other respects are equivalent. Giving more attention to an activity (without changing its meaning) seems merely to quicken satiation. Freund (1930) found that the velocity of satiation of minute tasks is greater during menstruum. All three results can be interpreted as indicating that the velocity of satiation increases with the centrality of the activity. Frequently a person tries to avoid satiation by doing the activity in a peripheral manner. Automatic activities such as breathing or walking do not become satiated if they are not carried out consciously as mere repetition. The effect of primary and secondary aspects of an activity can be handled with the concept of relative potency (see p. 816).

Children, in line with their lesser degree of differentiation, are likely to be involved in an activity with their whole person. The velocity of satiation should, therefore, vary inversely with mental age. Experimental results seem to confirm this expectation, although they are not univocal (Lewin, 1935; Wolf, 1938). The apparent divergence of findings is probably due to the fact that child psychology treats the problems of satiation under the title of persisting or perseverant behavior and that the term *persistence* is used to refer to dynamically rather different situations (for instance, persistence in overcoming an obstacle and persistence in carrying on an activity without an obstacle). Shacter (1933) found satiation time to be longer for a complex task than for a simpler one, without much age difference between three-, four-, and five-year-old children.

Wolf (1938) studied satiation in situations of praise, competition, and of no incentive with children of four and six years, making a careful analysis of the individual cases. She found the individual goal of the child to be of primary importance and this goal to depend upon the level of aspiration (see p. 830).

Kounin (1939) compared the satiation and cosatiation of normal 7-year-old children with 12- and 30- to 40-year-old feeble-minded persons of the same mental age. He found (Figure 24) that the velocity of satiation (drawings of different patterns) decreased with increasing age. The younger child shows greater cosatiation in spite of the small number of repetitions required for satiating an activity. In other words, the velocity of satiation and the degree of cosatiation decrease with chronological age even if mental age is kept constant. Kounin (1939) and Seashore and Bavelas (1942) found about the same symptoms of satiation in children which Karsten has described with adults.

The phenomena of satiation indicate (1) that there is a close relation between activities and needs, and (2) that an activity can be viewed as a consumption which changes the underlying need and, therefore, the positive valence of the activity into a negative one. As a result of this consumption the valence of "similar activities" also becomes negative, whereas certain different types of activities acquire an increasingly positive valence.

A satiated or oversatiated need, after a

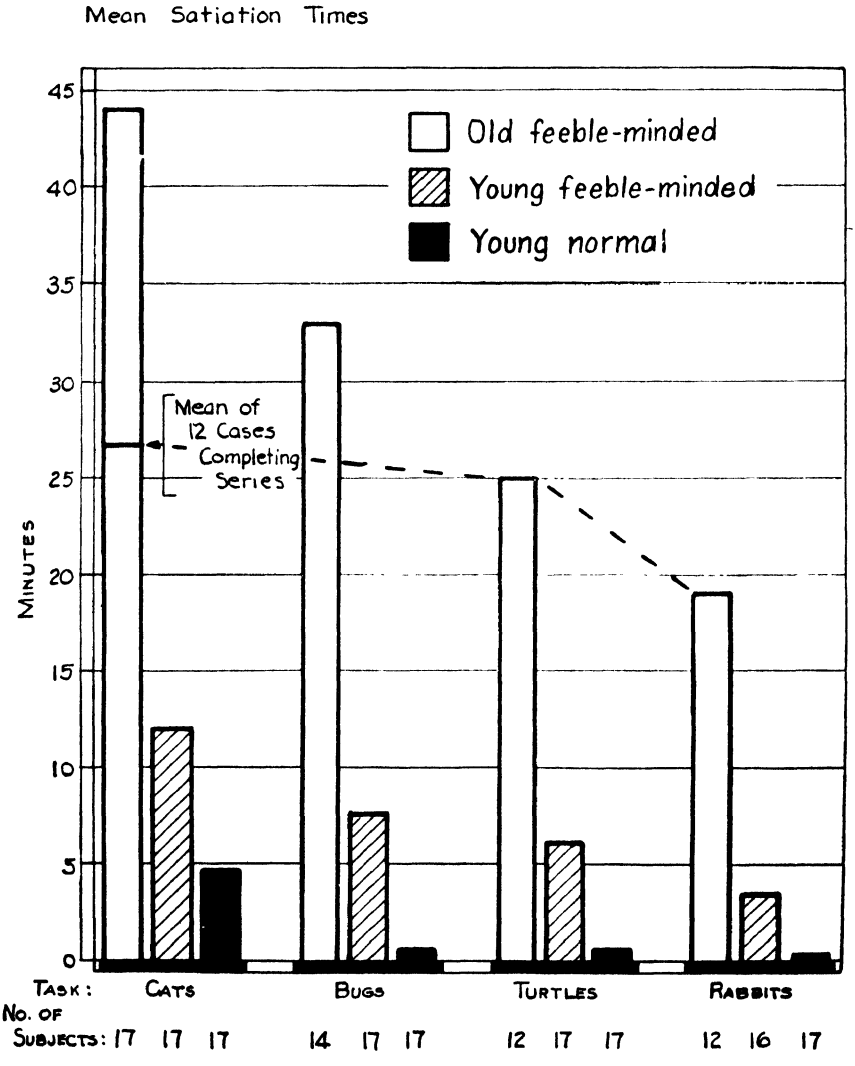

FIGURE 24. Velocity of satiation and cosatiation with individuals of different chronological age and the same mental age. (From *Experimental Studies of Rigidity as a Function of Age and Feeblemindedness*, by J. S. Kounin. Unpublished Ph.D. Dissertation, University of Iowa, 1939.)

lapse of time, frequently changes back into a state of hunger. The conditions of these changes need investigation.

Intention

The effect of an intention can be viewed as the setting-up of a quasi-need (Lewin, 1935). A quasi-need is dynamically equivalent to other needs in that it tends to create actions in the direction of satisfying the need with or without the presence of a corresponding goal object. Intentions are made, as a result of a given time perspective, to secure a certain behavior in the future which is expected to bring nearer the fulfillment of one or of several needs. The newly established quasi-need usually remains dependent on these source needs.

Experiments of Birenbaum (1930) show that the tension level of such a quasi-need depends upon the tension level of the more inclusive set of needs of which this quasi-need is a part. An intention will be "forgotten," that is, not carried out, if these source needs have been satisfied in the meantime, or if the state of the person as a whole has become one of high general satisfaction.

Needs as part of more inclusive needs. Goal structure

It has been stated that goals or other valences are closely related to needs. Changes of goals depend largely upon the interdependence of needs. Needs may be interdependent in different ways. (*a*) Two or more needs can be in communication so that their need tensions vary concomitantly. As we have seen, such relation is important for the problem of substitution. (*b*) The interdependence between needs can be one of ruling and being ruled. For instance, quasi-needs which correspond to intentions are induced by ruling needs. In both cases of interdependence, the need becomes a part of a more inclusive need system.

We have discussed the effect of completion and noncompletion in regard to satisfying or not satisfying the need behind an action. We shall discuss now the effect of those actions on the setting-up of new goals.

Maturity of Aspiration. To a child of six months, lying on his stomach and trying to reach a rattle, it seems to make no difference whether he finally reaches the rattle as the result of his own effort or whether the rattle is brought within his reach by someone else. The child will be satisfied both ways. A child of three, trying to jump down from the third step, may refuse help. He will not be content unless he has reached certain results by his own effort. The very young child seems to know only satisfaction and dissatisfaction but not success and failure. In other words, he has needs and goals but not yet a level of aspiration.

We speak of *aspiration* in regard to an action if the result of this action is seen as an achievement reflecting one's own ability; if, in addition, different degrees of difficulty can be distinguished, we speak of a *level of aspiration.* The level of aspiration is of basic importance for the conduct of human beings and influences most of their goal-seeking. In this connection we have the paradox that the individual may prefer something more difficult to something more easy.

Fales (C. Anderson, 1940) has studied the development, over a period of six months, of aspiration in two- to three-year-old children. She observed such activities as putting on and removing snow suits. Refusing help is probably the best behavioral symptom for the existence of an aspiration in regard to an activity. Such insistence on independence indicates that one's own action has become a part

of the goal. Observing manipulations of various degrees of difficulty (such as opening the zipper, getting an arm out of the coat, hanging the cap on the hook), she found that children at this age have an aspiration only in regard to particular activities. One of the determining factors is the ability of the child; he will not refuse help for activities definitely beyond his reach. As he becomes older or is better trained (Figure 25) an aspiration develops in regard to the more difficult actions. Fales also found that social situations or praise (Figure 25) facilitate the rise of an aspiration. This indicates that a social component is important for aspiration from its earliest development.

It is possible to distinguish different degrees of "maturity of aspiration," corresponding to different types of goals and procedures in attaining them at various age levels. C. Anderson (1940) developed a scale of maturity of aspiration for children between two and eight years, using activities such as throwing a series of rings over a stick and knocking down tenpins with a ball. A child of eight will consider the series of five throws as one unit and will not, therefore, rethrow single rings which miss the stick before counting his score. Children of the youngest group (three years old) always pick up the single rings after missing the stick and rethrow them or place them directly on the stick (Figure 26). The youngest children do not hold to the rule of standing behind a

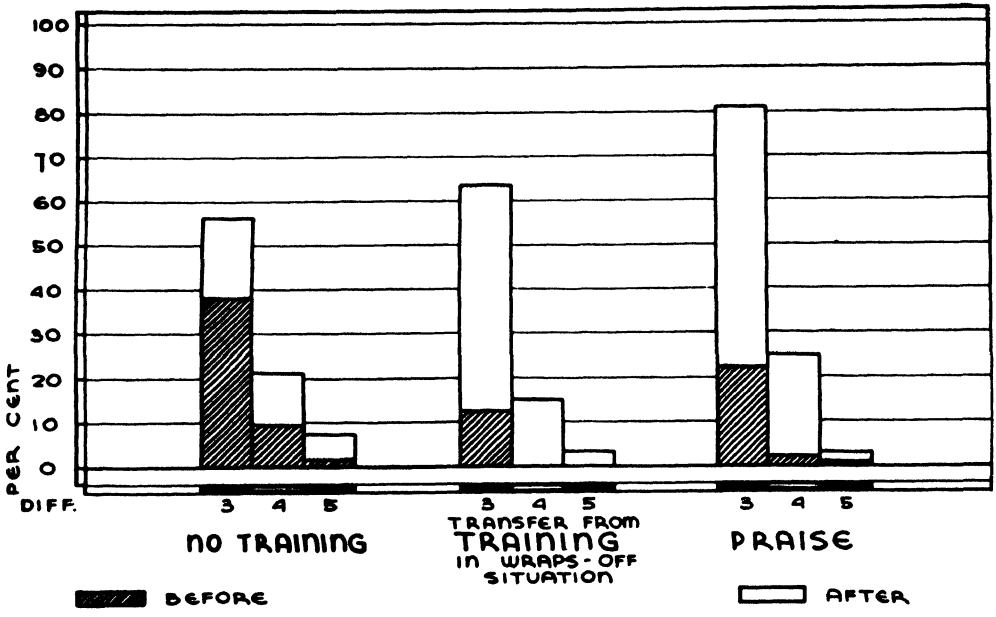

FIGURE 25. Development of aspiration as a function of difficulty of task, training, and praise. (From an incomplete study by Fales, quoted in *The Development of a Level of Aspiration in Young Children,* by C. Anderson. Unpublished Ph.D. Dissertation, University of Iowa, 1940.)

Ordinate refers to per cent of refusal of help. Numbers on abscissa refer to degrees of difficulty of task.

given place. These and other symptoms indicate that the development of a level of aspiration, the choosing of a goal of a particular degree of difficulty, presupposes (1) that a number of goals are seen as subgoals within a larger goal structure, (2) that the action itself is conceived as a part of the goal, and (3) that the child understands the meaning of rules and is ready to keep them.

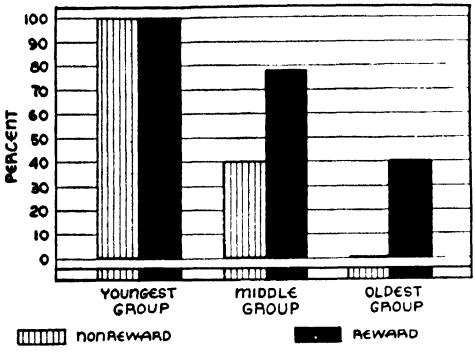

FIGURE 26. Maturity of aspiration at three age levels and amount of regression in case of social pressure (reward situation). (From *The Development of a Level of Aspiration in Young Children*, by C. Anderson. Unpublished Ph.D. Dissertation, University of Iowa, 1940.)

The frequency with which the child places the missed ring on a stick or rethrows the single ring instead of finishing the series of rings is indicated.

If pressure is brought to bear on a child by offering a reward, the level of aspiration (that is, the degree of difficulty chosen) will decrease. If a lowering of the level of aspiration is made impossible, the maturity of aspiration may regress (Figure 26); that is, a procedure is used which is characteristic of a younger age level. Regression of the maturity of aspiration can be observed in adults in emotional situations.

Level of Aspiration. Level of aspiration has been defined (Hoppe, 1930) as the degree of difficulty of that task chosen as a goal for the next action. One may distinguish two main problems: (1) under what condition the individual experiences success or failure and (2) what factors influence the level of aspiration.

Conditions for the experience of success or failure. The experience of success or failure depends on the level of performance within a frame of reference (Lewin, Dembo, Festinger, and Sears, 1944). This frame of reference can be the level of aspiration (that is, the goal which has been set for that action), the past performance, or the standards of a group. A feeling of success will prevail if a certain level, related to the dominant frame of reference, is reached. What frame of reference will be dominant depends upon a number of factors, one of which is the tendency to avoid the feeling of failure.

It has been shown (Gould, 1939; P. Sears, 1940; Festinger, 1942) that to avoid the feeling of failure after a poor performance the frame of reference is frequently shifted. Other ways to avoid failure are various forms of rationalization (Hoppe, 1930; Gould, 1939), such as blaming a poor instrument for the shortcomings of the performance. In this way the link between performance and one's own ability is cut, which is, as we have seen, one of the conditions for the phenomenon of aspiration.

Jucknat (1937) distinguishes different intensities of the feeling of success and failure. They are to be related to the amount of discrepancy between goal and performance. This holds, however, only within the range of difficulties which is close to the boundary level of ability. "Too easy" and "too difficult" tasks do not lead to feelings of success and failure. This may be the reason why rivalry among siblings is less frequent when there are relatively great differences of age among them (Sewall, 1930).

The relation between the feeling of success and failure, on the one hand, and the boundary of ability, on the other, is operative only if other frames of reference, such as certain group standards, do not become dominant. The mentally retarded child might have permanently the feeling of failure in a group of children of high ability even though the tasks were actually far beyond the limit of his own ability.

Case studies (Kanner, 1935) and experimental data (Fajans, 1933) show that change in group status (for instance, gaining recognition or love or being rejected by an individual or a larger group) is, in many respects, equivalent to success or failure.

Factors determining the level of aspiration. After the experience of success or failure the person may either quit or continue with a higher, equal, or lower level of aspiration. The difference between the level of aspiration for the new action and the level of past performance is called the "discrepancy" between level of aspiration and performance. (For details see Lewin, Dembo, Festinger, and Sears, 1944.)

The factors determining a change in the level of aspiration are manifold. Jucknat (1937) found that with children from nine to fifteen and with adults the direction and the amount of the change in the level of aspiration depend upon the degree of success and failure (Figure 27). In addition, within a given series of tasks, the discrepancy is smaller for the same amount of success and greater for the same amount of failure the closer the previous level of performance comes to the extreme of the series of difficulties.

The level of aspiration is much influenced by social factors. In a situation of competition it might be increased (J. D. Frank, 1935). The knowledge of group standards may affect the level of aspiration (Festinger, 1942). For instance, the discrepancy between aspiration and performance increases toward a higher level of aspiration if the person learns that his performance is below the standard of his own group or of a group which he considers to be lower. The discrepancy decreases if the opposite conditions obtain. The level of aspiration is affected also by the degree of realistic judgment about one's own ability (J. D. Frank, 1935). P. Sears (1940) found the average positive discrep-

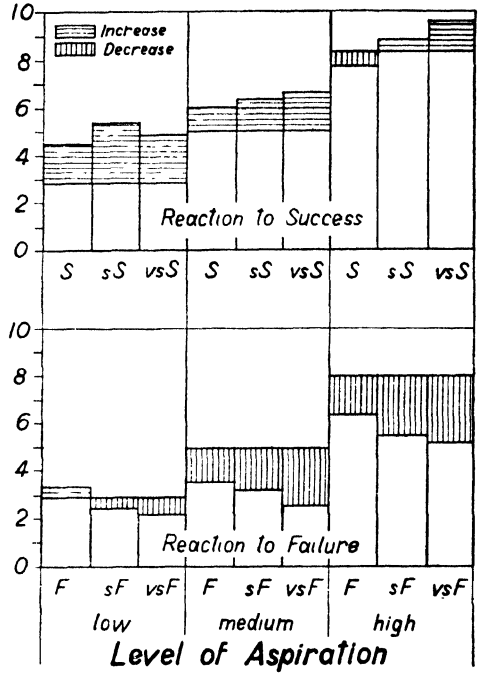

FIGURE 27. Change in the level of aspiration as a function of (*a*) strength of the feeling of success and failure; (*b*) the relative difficulty of the previous level of performance. (From "Performance, Level of Aspiration and Self-consciousness," by M. Jucknat. *Psychologische Forschung*, 1937, **22**, 102. By permission of the publisher.)

S, success; *sS*, strong success; *vsS*, very strong success; *F*, failure; *sF*, strong failure; *vsF*, very strong failure. Ordinate refers to degrees of difficulty of task.

ancy (that is, the amount by which the level of aspiration exceeds past performance) to be greater in children after failure than after success, indicating a greater degree of realism after success than after failure.

For the same individual, the direction and amount of discrepancy seem to be constant to a certain degree for a number of activities (J. D. Frank, 1935; P. Sears, 1940; Gardner, 1939). P. Sears (1940) and Jucknat (1937) found the discrepancy to be greater in children of poor standing than in children of good standing in school. The degree to which the level of aspiration in one activity affects the level of aspiration in another activity depends upon their similarity and upon how well previous experience has stabilized the level of aspiration in these activities (Jucknat, 1937). The influence of success in one activity on the level of aspiration in another is slight if the child has clearly found out his ability in the latter.

The level of aspiration is closely related to the time perspective with respect to both the psychological past and the psychological future. According to Escalona (1940), the level of aspiration at a given time depends upon the strength of the valence of success and failure and upon the probability of success at that time. By representing this probability as the potency of the future success or failure situation, the basic facts concerning the level of aspiration can be understood (see Lewin, Dembo, Festinger, and Sears, 1944).

Induced needs. Group goals and individual goals

The needs of the individual are, to a very high degree, determined by social factors. The needs of the growing child are changed and new needs induced as a result of the many small and large social groups to which he belongs. His needs are much affected, also, by the ideology and conduct of those groups to which he would like to belong or from which he would like to be set apart. The effects of the advice of the mother, of the demand of a fellow child, or of what the psychoanalyst calls *super-ego*, all are closely interwoven with socially induced needs. We have seen that the level of aspiration is related to social facts. We may state more generally that the culture in which a child grows affects practically every need and all his behavior and that the problem of acculturation is one of the foremost in child psychology.

One can distinguish three types of cases where needs pertain to social relations: (1) the action of the individual may be performed for the benefit of someone else (in the manner of an altruistic act); (2) needs may be induced by the power field of another person or group (as a weaker person's obedience of a more powerful one); (3) needs may be created by belonging to a group and adhering to its goals. Actually, these three types are closely interwoven.

Sources of Ideology. The frequency with which children named the teacher as a source for praise or scolding of behavior in school remained relatively constant from the fourth to the eighth grade in certain schools (Bavelas, 1942*b*). An individual classmate (as distinguished from the concept "children") was frequently named as source for evaluation of behavior at the fourth grade (Figure 28); this frequency declined to zero at the eighth grade. The school superintendent was practically never named as source at the fourth grade (Figure 28); he was named with increasing frequency later on, mainly as a source for scolding.

Kalhorn (1944) compared positive and negative values (Figure 29*a*) and sources of values (Figure 29*b*) in Mennonite and

non-Mennonite children in rural areas. She found differences in the emphasis on such values as individual achievement and religion. In both groups the parents are indicated by the children to have the most dominant influence as a source of values.

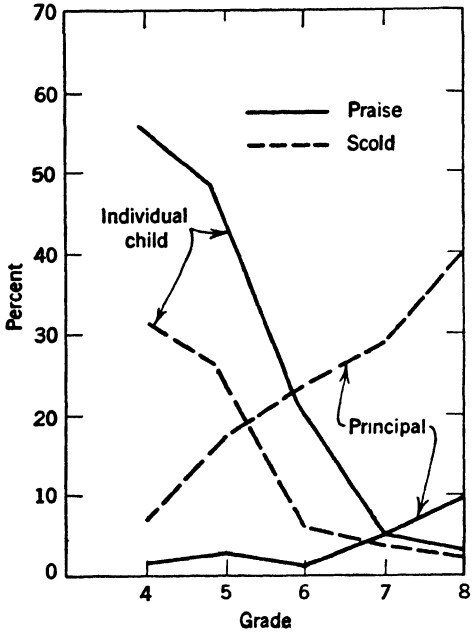

FIG. 28. Frequency with which an individual child and the school principal are given as source for praise or scolding of school conduct at different grades. (From "A Method for Investigating Individual and Group Ideology," by A. Bavelas. *Sociometry*, 1942, **5**, 376. By permission of the publisher.)

The same conduct may have different psychological meaning in different cultures. For instance, going to church is linked with God as the source of approval by the Mennonite children, with everyone by the non-Mennonite children. This indicates that church-going is primarily a religious affair with the former, a social affair with the latter.

Egoism and Altruism. In an experiment by Moore (1931), children between the ages of two and three were asked to share orange juice with a companion who was seated beside the subject. Her results show wide individual differences and no correlation with the degree to which the child respects the rights of others as determined by other methods. Hartshorne and May (1929) studied test situations in which service (altruism, cooperation) of the children could be observed. They claim that the tendency to serve is "specific" rather than "general" in children between ten and fourteen years (for a discussion of the problem of generality of traits see Allport, 1937). McGrath (1923), using a questionnaire technique, reports that an altruistic response to a hypothetical situation increases with age. Piaget (1932) orders his findings on the moral development of children in terms of two psychologically different moralities which are an outgrowth of two types of social relations: up to seven or eight years, there exists a social relation of unilateral respect in which the child is subjected to adult authority. Gradually a relationship of mutual respect is set up in which each member has a more equal part of the control.

B. Wright (1941, 1942*a*, 1942*b*) studied children in a situation where they had a choice of keeping a preferred toy or giving it to someone else. The other child (who was not present) was either someone unknown or a best friend. The five-year-old child was practically always egoistic; the eight-year-old child showed considerable altruism, and more so toward the stranger (58 per cent generous choices) than to the friend (23 per cent generous choices). When acting as an umpire between a friend and a strange child in distributing the toys, the five-year-old child favored the friend more frequently than the stranger. The eight-year-old favored the stranger more frequently than the friend.

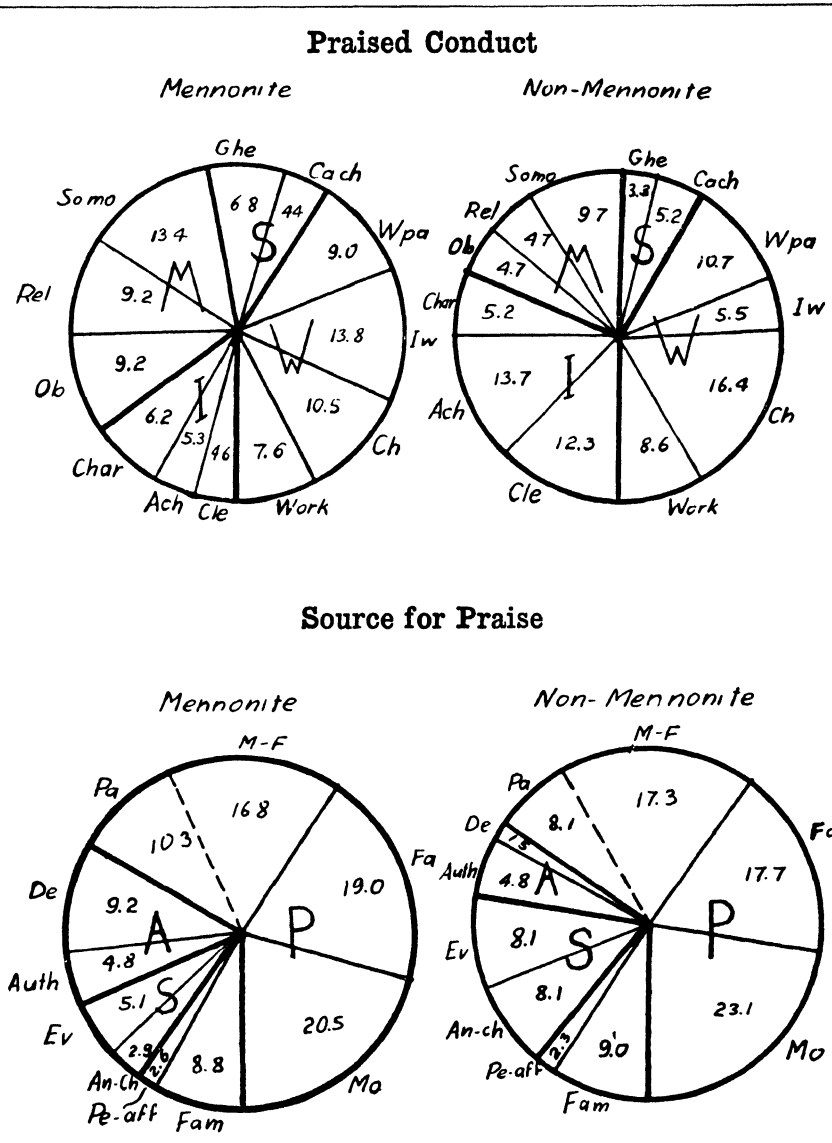

FIGURE 29. (*a*) Praised conduct. (*b*) Source for praise. (From "Studies in Topological and Vector Psychology: III. Values and Sources of Authority among Rural Children," by J. Kalhorn. *University of Iowa Studies in Child Welfare*, 1945, **20**. By permission of the publisher.)

(*a*) *W*, work area (work; *Ch*, chore; *Iw*, intensive work; *Wpa*, work for parents); *S*, social area (*Ca ch*, care of other children; *Ghe*, generalized help); *M*, morality area (*So mo*, social morality; *Rel*, religion and virtues; *Ob*, obedience); *I*, individual area (*Char*, character; *Ach*, individual achievement; *Cle*, cleanliness).

(*b*) *P*, parents (*Mo*, mother; *Fa*, father; *M-F*, mother and father; *Pa*, parents); *A*, authority (*De*, deity; *Auth*, authority); *S*, society (*Ev*, everybody; *An-ch*, another child; *Pe-aff*, person affected; *Fam*, family).

Theoretically, the altruistic or the egoistic choice can be viewed as the result of the relative strength of forces acting on different regions of the life space and of the potency of various situations. In the life space of child *C* (Figure 30), a force $f_{C,G}$ acts on his own person in the direction to a goal *G*. In addition, a force $f^{C}_{Ot,G}$ exists in his life space, acting on the other child, *Ot*, in the direction of the same goal. (The situation permits only one person to obtain the goal.) This second force, $f^{C}_{Ot,G}$, corresponds to the need of the other child as perceived by the child whose life space is represented and the readiness of the child *C* to back the goal of the child *Ot*. Formalistically speaking, the altruistic or egoistic choice depends on the relative strength of these two forces. According to Wright, the need of the other child is not perceived by the very young child. This may be the reason for the absence of cooperative play in the young child. With increasing age, the potency of the perceived need of the other child increases. Similarly, the potency of the outgroup increases relative to the potency of the ingroup (friend).

The greater altruism toward the stranger than toward the friend seems to be due partly to the fact that the child sees himself in the position of a host toward the stranger, but not toward the friend, and that his ideology requires that he be hospitable. The children judged other people to be altruistic or egoistic to the same degree as they themselves were. A preliminary study seems to indicate that adults in a similar setting are more egoistic than the eight-year-old child.

Obedience and Social Pressure. In discussing problems of conflicts we have seen that the force acting on a person in the direction of a goal might be counteracted by induced forces corresponding to the will of another person. In view of the relation between psychological forces and psychological needs we can also speak of *induced needs*. The relation between two persons might be that of friends or that of enemies; the need of each would depend greatly on the power field of the other.

Wiehe (Lewin, 1935) observed children between two and four years of age when a stranger entered the child's room. He found the strength of the power field of

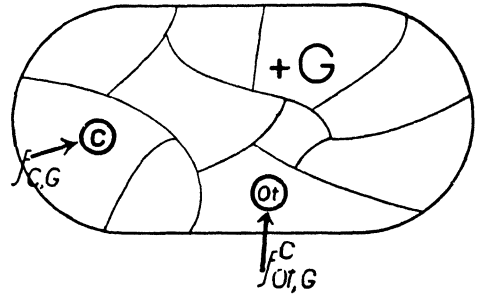

FIGURE 30. The situation of altruism. (Derived from *The Development of the Ideology of Altruism and Fairness in Children*, by B. A. Wright. Unpublished Ph.D. Dissertation, University of Iowa, 1942.)

the stranger at a given moment to be influenced by the physical position of both persons. The effect of the power field on the child increases with decreasing distance (see Figure 19). It is very high if the child is placed on the adult's lap. The power field is weaker back of the stranger, or where the child cannot be seen, than in front of the stranger. In other words, the strength of the power field of one person on another differs for different areas. J. D. Frank (1944), in experiments with students, and Waring, Dwyer, and Junkin (1939) in experiments with nursery school children at the dinner table, also found the effectiveness of the power field for creating induced forces to be greater if the distance between the persons is smaller.

Lippitt and White (1943), in experi-

ments with ten-year-old children, tested the effect of induced needs during the presence and the absence of the inducing power field. They found that the amount of work output in an autocratic group atmosphere dropped very decisively within a few minutes when the leader left the room. This was in contrast to a democratic group

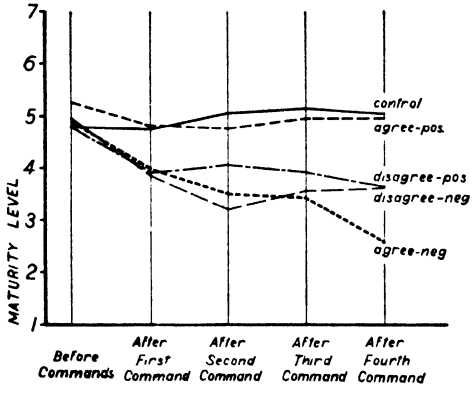

FIGURE 31. The effect of conflicting authorities on constructiveness. (From "Studies in Topological and Vector Psychology: III. The Effect of Conflicting Authority on the Child," by C. E. Meyers. *University of Iowa Studies in Child Welfare,* 1944. By permission of the publisher.)

atmosphere, where the work had been chosen and planned by the group itself, and where the work output was unchanged when the leader left. C. E. Meyers (1944) studied the effect of conflicting adult authority on children of nursery school age. He found that the opposing orders lower the children's constructiveness of play very considerably (from 4½ to 2½ on his constructiveness scale) (Figure 31). The child may stop action altogether (aside from self-manipulation similar to that described by MacDonald, 1940) if he does not find a way to follow the orders of both authorities. Even if the orders of both adults agree, too frequent interference with the child's play lowers his constructiveness somewhat. Negative commands were more damaging than positive commands, and vague commands more damaging than specific ones.

Induced needs which are opposite to own needs may lead to a permanent state of conflict which is more or less concealed. If such a conflict cannot be resolved by breaking the dominant power field (see p. 814), the child may become aggressive toward less powerful persons. Lewin, Lippitt, and White (1939) found that, on several occasions, one of the children was attacked as a scapegoat in the autocratic group (Figure 32).

Taking Over Foreign Goals. An induced need may slowly change its character in the direction of an own need. In other words, the person not only will follow orders but also "accept" them (in the meaning of taking them over). Waring, Dwyer, and Junkin (1939) have observed changes in this direction with nursery school children.

Duncker (1938) studied changes in food preferences of children from two to five years of age, as affected by a story in which the hero abhorred one and enthusiastically relished the other of two kinds of food. After the story, the children preferred the hero's favorite food, although previously it had been unattractive to them. This effect decreased with time, but could still be detected after six days. Thompson (1940) studied the effect of prejudicial leadership on ten-year-old children. The leader set up an underprivileged minority within a group of children who originally had equal status. After a number of club meetings the children of the privileged majority continued to treat the rest of the children as underprivileged even when the leader left the room. This discrimination, however, was not so strong as in the presence of the leader. This shows both that the presence of the power

field of the leader has some influence and that the induced goals have been taken over in some measure.

Lippitt and White (1943), in a study of autocratic, democratic, and laissez-faire groups, have found that the readiness of an individual to accept autocracy in the club depends partly upon the home background. A combination of a firm and warm home atmosphere seems to be most favorable to that end; that is, an atmosphere of relative autocracy which, nevertheless, by its warmness, prohibits the child from becoming independent of the family. These children are likely to adhere to "adult values" rather than "boy values." Children who follow boy values are more sociable among themselves but less obedient at school.

Horowitz (1936) found no prejudices against Negroes in white children under three years. The prejudices increased between four and six years. This increase was as great in New York as in the South. It was independent of the degree of acquaintance of the children with Negro children, and of the actual status of the Negro child in the class which the white child attended. The prejudices are, however, related to the attitude of the parents of the white child. This indicates that the prejudices against the Negroes are due to an

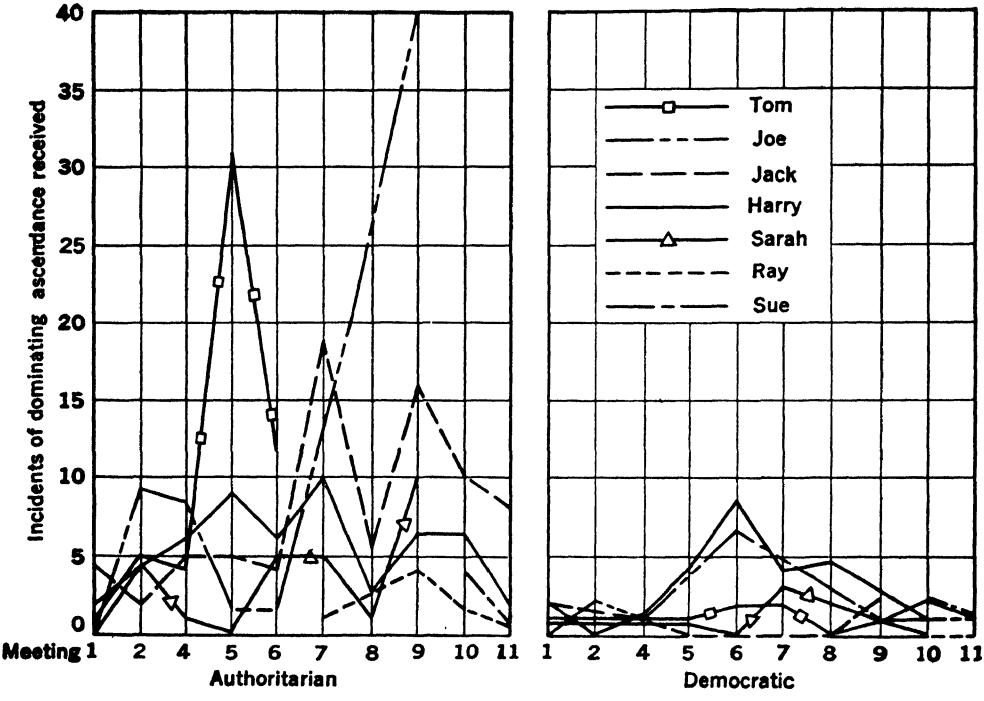

FIGURE 32. The emergence of scapegoats. (From "Studies in Topological and Vector Psychology: I. An Experimental Study of the Effect of Democratic and Authoritarian Group Atmospheres," by Ronald Lippitt. *University of Iowa Studies in Child Welfare*, 1940, **16**, 165. By permission of the publisher.)

The curves indicate that the amount of dominating behavior directed against the various individuals was much greater in autocracy than in democracy. In autocracy two individuals (Tom and Joe) were treated as scapegoats (at the fifth and ninth meetings, respectively).

induction and gradual taking-over of the culture of the parents by the child.

A phenomenon which is probably partly due to the acceptance of originally induced needs and partly to the problems of group belongingness (see p. 800) is the hatred against one's own group in persons belonging to an underprivileged group. This hatred against the own group is frequent among the bodily handicapped and among socially underprivileged groups (Davis and Dollard, 1940; Lewin, 1940*b*). It means that the values and prejudices of the privileged group have been taken over by the members of the socially lower group even if they are directed against their own group. This hatred of one's own group may lead to self-hatred. It is augmented by the need of the individual to raise his status and, therefore, to separate himself from the underprivileged group.

Whether or not an induced need has changed its character and has become an own need is frequently difficult to decide. Lippitt and White (1943) distinguished two types of reaction to an autocratic atmosphere: one called *aggressive autocracy*, and the other *apathetic autocracy*. In the latter case the children seem to work willingly. Signs of discontent or obstruction may be entirely absent. Particularly strict obedience may have the appearance of a voluntary action. This holds also for the behavior of children in institutions. Nevertheless, the effect of the removal of the leader in the experiment shows how great the actual difference in both situations is for the child.

Needs of a Child as a Group Member. As mentioned above, the children in the democratic group studied by Lippitt and White did not decrease the intensity of their work if the leader left. The plan for this work had been decided upon by majority vote after consideration. This shows that under these conditions a need corresponding to a group goal is more like an own need than an induced need. This problem is closely related to the difference between "we"-feeling and "I"-feeling. Lewin, Lippitt, and White (1939) found "we"-feeling, as measured by the verbal expression and the attitude toward the work, to be greater in the democratic group than in the autocratic group where an egocentric attitude prevailed.

One can consider two factors to be basic for the kind and degree of influence which group goals have for the goals of the individual: (1) the degree of dependence of the person on the group; (2) the character of enmity or friendship of this dependence. According to Ronald Lippitt (1940), the power fields of enemies weaken each other in areas where they overlap, whereas the power fields of friends strengthen each other. In addition, friendship as distinguished from enmity includes the readiness to accept and to back up the intention of the other person. According to M. E. Wright (1940), both characteristics can be expressed by the degree of accessibility of one's own power field to the power field of the other person.

Individual Differences

We have seen that it is not possible to determine the specific characteristics of individuals by classifying them according to their overt behavior. Instead, one has to look for factors which can be inserted as constant values into the variables of the equations which represent psychological laws. In this way also the variability of behavior, that is, the difference in behavior of the same individual in different situations, becomes susceptible to treatment. This variability does not mean merely that the absolute frequency or intensity of a certain type of behavior depends upon the situation. Actually, the rank-order of in-

dividuals in regard to a certain trait may also be different in different situations. For instance, Lewin, Lippitt, and White (1939) found in clubs of ten-year-old boys that, in regard to some "traits," such as "demanding attention from other club members" and "out-of-field conversation," the rank-order of the individual in different atmospheres remains rather constant (r = .85 and r = .78). In other traits, such as "dependence upon leader," there is scarcely any consistency of rank-order (r = .02). There are more extreme changes in the rank-order in "work-mindedness" than in "aggressiveness." The changes seem to be linked to the differences of meaning of the particular atmospheres to the particular children.

The attempts to link positively problems of individual differences and of general laws are relatively new in psychology. We shall mention but one example, which is related to differences in age, intelligence, and rigidity of the person. Lewin (1935) has outlined a theory according to which differences in mental age are closely related to the degree of differentiation of the person. The variety of states which an organism can assume, and the corresponding variety of patterns of behavior, must logically be conceived of (Barker, Dembo, and Lewin, 1941) as a function of the degree of the differentiation of that organism. Therefore, with increasing mental age, the individual should show an increasing flexibility, in the sense of richness, of behavior. This is in line with empirical observations of individuals of different mental age and with the peculiar pedantry and stubbornness of the young child.

The increase of flexibility with increasing mental age is somewhat counteracted by a decrease in plasticity which seems to go hand in hand with chronological age and which seems to be important for senility. A certain type of feeble-mindedness is characterized by the fact that these individuals show at the same level of differentiation (the same mental age) less plasticity (Lewin, 1935). If this theory is correct, one should expect less cosatiation in feeble-minded persons than in normal persons of the same mental age. Kounin (1939) demonstrated this with individuals whose chronological ages were 7, 12, or 30, all having a mental age of 7 (see p. 826). One can derive from the same set of premises that feeble-minded individuals should be less able to tolerate overlapping situations. One should expect, therefore, that the feeble-minded person would make fewer mistakes in case of change of habits under certain conditions, that he would show greater difference in speed of performance between overlapping and nonoverlapping situations, and that he would be less able to change the cognitive structure in a test requiring several classifications of the same group of objects. Kounin's experiments substantiate all these derivations. The results of Koepke (Lewin, 1935) and of Gottschaldt (1926) indicate that the readiness of the feeble-minded person to accept or to refuse a substitute is either very small or very great, according to the specific situation. This is in line with what should be expected from a relatively rigid individual.

The coordination of certain individual differences with differences in the degree of differentiation and rigidity of the person makes it possible to link behavior in quite a variety of fields, such as cognition, stubbornness, substitution, and satiation, and to understand apparent contradictions of behavior. A greater rigidity of the feeble-minded person also explains why his development is slower than that of the normal child (that is, the relative constancy of the IQ) and why he reaches his peak of development earlier.

It can be expected that all problems of

individual differences will be linked more and more with the general psychological laws of behavior and development and that in this way a deeper understanding of both the individual differences and the general laws will be possible.

THE INFLUENCE OF TOPOLOGICAL AND VECTOR PSYCHOLOGY UPON CURRENT RESEARCH IN CHILD DEVELOPMENT: AN ADDENDUM

SIBYLLE ESCALONA

Behavior and development as a function of the total situation is more than a summary of interrelated research studies; it is the expression of a point of view in psychology which is applicable to perception, thought, or personality as it is to child development. It was Kurt Lewin's expectation that topological and vector psychological concepts would help to break down the barriers between various branches of psychology and help to create a unified theory which would permit integrated treatment of all manner of psychological functions. In a sense Lewin's child psychology aimed at the destruction of child psychology as an independent specialty.

A comparison of representative work in 1953 with that of 1945 reflects a clear trend in the direction of unification. The content of the present volume is witness to the fact that there has been interpenetration and cross-fertilization among all facets of psychological endeavor to the degree that studies of motor learning (Gesell, 1946; Gesell and Amatruda, 1945, 1947) or of language development (McCarthy, 1949) usually imply a theoretical commitment to one among several models of personality theory. Child development, by the very nature of its subject matter, invites convergence of different disciplines from physical growth to cultural anthropology. A survey of the present volume will suggest to the reader the degree to which psychologists have succeeded in comprehending the "child as a whole." The writer believes that the dominant trend toward multidiscipline research has succeeded in all but abolishing the isolated study of narrow sections of the developmental process, but that a true integration of concepts and methods has yet to occur. In topological terms child psychology has become a more fluid and more highly differentiated field, but a consistent hierarchical structure to serve as organizing agent has not yet been developed. It is the task of this addendum to summarize the rôle which topological and vector psychology has played in psychological research within the field of child development.

Almost [1] no purely topological and vector psychological studies of children have been conducted since the Iowa work on frustration and aggression (Barker, Dembo, and Lewin, 1941) referred to in the above chapter. Instead, concepts and methods from this source have found their way into research with children which may be characterized as primarily clinical or primarily within the frame of reference of social psychology. It would be more accurate to say that psychologists who were and are identified with topological and vector psychology have since focused their interest on clinical or social psychology (as it applies to child

[1] An exception which came to our attention is a master's thesis by William A. Koppe (1944). Experiments with a kindergarten population demonstrated that the "laws" governing the level of aspiration as formulated by others (Escalona, 1948; Frank, 1935; Hoppe, 1930; Jucknat, 1937) are substantially applicable to children at this age level. His results also indicated that level of aspiration is partly determined by a variable not usually controlled, namely, the absolute level of attainment.

development) and have found Lewin's systematic position valuable in setting and solving their problems. Below we shall refer to three major studies of this type. The intent is to illustrate the type of inquiry which has remained closest to topological and vector psychological studies.

A second and perhaps more important observation is that many of the principles brilliantly summarized in Lewin's article included in this volume are no longer identifiable as belonging to one school of thought within psychology, so general is their acceptance. For instance, the great majority of child psychologists stress the importance of seeing each behavior episode in context, and, consequently, simple frequency statistics are being replaced by more sophisticated measurements which give expression to the multiple determination of behavior. Similarly, few child psychologists now need to be reminded that the physical "objective" environment is not identical with the child's psychological environment, and that knowledge of the latter is required for an understanding of his actions. The concepts of differentiation and organization as central ones in the description of any developmental process have found universal acceptance. More specific Lewinian formulations of aspects of child behavior have also found application in psychological research which may be remote from topological and vector psychology in general orientation. Among these one might name "detour" problems (as related to intelligence and learning), time perspective as a dimension of psychological functioning which changes with growth, "substitution," and "satiation." These remarks are included here in order to suggest to the reader that the scarcity of narrowly topological research in child psychology may indicate not that this approach has proved unproductive in later years but rather that child psychology as a whole is changing and that topological and vector psychology has played a significant rôle in determining the nature of this change.

Experiments and Field Studies of Contagion.[1] In a group situation children influence the behavior of one another in two important ways, among others. The more familiar variety of social influence comprises situations where one child communicates his *intention* of changing the behavior of others ("let's play football"). The other variety of social influence has been discussed by Fritz Redl (1949) and others under the heading *behavioral contagion.* In the group treatment of delinquent children Redl noted occasions when the behavior of one child suddenly spread to other group members. Yet it was highly questionable whether the "initiator" had any intention of influencing the others; if so he certainly did not communicate this in an observable manner. As long as it remained unpredictable and somewhat inexplicable, contagious behavior created practical problems in the management of groups.

The effect of various group atmospheres (autocratic, laissez-faire, democratic) upon behavior was studied by Lippitt (1939) and Lewin, Lippitt, and White (1939). These studies resulted in the first of a series of formulations which treat of groups as dynamic wholes with identifiable properties. Both methodologically and theoretically this work found its continuation in action research with adult populations. The study of contagion reported here, which was directed jointly by Ronald Lippitt and Fritz Redl, is the exception in that it concerns child behavior.

1 This project was supported in part by a grant from the National Institute of Mental Health, U.S.P.H.S. Principal investigators: Fritz Redl, Wayne University, and Ronald Lippitt, Michigan University.

A field staff systematically observed 16 children's groups in the setting of summer camps for emotionally disturbed children. Contagion was here defined as a situation where the behavior of one child (the initiator) brought in its wake behavioral changes in other members of the group in the same direction (i.e., the behavior of those susceptible to contagion became similar to that of the initiator), and where the initiator had not overtly indicated an intention to influence the behavior of others. This was distinguished from "direct attempts to influence" in order to see what similarities or differences might be found in the determinants of the two kinds of influence. The most important data consisted of: (*a*) The recording of instances of contagion and instances of direct attempt to influence throughout the camp season for all groups. (*b*) Serial assessment of each child's position within the group, and the network of relationships constituting the group, by means of sociometric techniques. (*c*) Repeated ratings provided by camp counselors for each child assessing relevant variables in terms of the child's behavior and his rôle in the group. It was found that whether or not a child is likely to succeed in initiating contagion does not greatly depend on his more permanent personality characteristics but depends instead upon his perception of his status in the group, and on the group's perception of his position within it. Both these conditions had to be present; the data showed that a child who regarded his position in the group as secure and high in status value but whose actual position was low seldom succeeded in releasing contagious behavior. Conversely, even if highly esteemed by the group, a child was not likely to become an initiator if he was unaware of his "power." Contagion was the more likely to occur the greater the similarity between the goals (and underlying need structure) of the group and the individual initiator (Polanski, Lippitt, and Redl, 1950).

In the planning of therapeutic groups and more generally it has often been assumed that a child's behavior in a group can largely be predicted from an understanding of his personality. These findings, however, seem to show that children's behavior in a group can be predicted, to a surprising degree, solely in terms of functioning group positions. While a diagnostic appraisal of personality is a necessary supplement to prediction of group behavior, it is the more useful the more diagnosis is geared to "group relevant" dimensions of personality. Among these, "social sensitivity" to group atmospheres and standards was found especially important.

From a methodological point of view it is interesting to note that the field study yielded more precisely formulated hypotheses, some of which were then checked in a series of experiments. It had originally been thought plausible that contagion might depend upon the characteristic impulse-balance of the child, i.e., that children whose control of impulses is especially weak would be especially likely to set off or succumb to contagion. The field study showed that generally this is not the case, but in one specifically structured situation impulsivity did predict initiators of contagious behavior more significantly than did group status, namely, if the entire group was in a state of need frustration, but the children were restrained from expressing their reactions to frustration. Using this clue, experiments were designed in which need frustration was induced and restraints against the expression of frustrated needs were also induced, and it was possible to measure susceptibility to contagion under various conditions. It was in this latter phase of the study that topological concepts were used to clarify the psychological proc-

esses which allow behavioral contagion to occur (Grosser, Polansky, and Lippitt, 1951).

We shall refer to only those aspects of the experimental procedure which are necessary for an understanding of the theoretical statement. Children were studied in "groups" of two, and, unbeknown to the experimental subject, the second "group member" was in fact a collaborator [1] whose behavior was directed by prearranged signals from the experimenter. The desired conflict between a goal and opposing psychological forces was created in the classical manner. The subject, or as he believed the group of two, was introduced to a highly pleasurable activity (dart throwing), which was interrupted at a high point of motivation. He was then put to the performance of a boring task (filling sheets with figures 8). He was made to feel that unpleasant consequences might ensue were he to neglect the assigned task and return to the dart throwing. The experimenter then left the room, observing through a one-way vision screen and directing the behavior of the child collaborator by means of inconspicuous sounds. In the control situation for each experimental variation the collaborator simply obeyed instructions, i.e., did not initiate behavior which might prove contagious. In the experimental condition he engaged in a graded series of behaviors which corresponded to the frustrated need, from "wriggling fingers," and thus evading the task, to resuming dart play. The design was such as to allow for an analysis of variance. For each condition the behavior of subjects who were exposed to "temptation" was compared with the behavior of subjects whose partner did not violate the rules. Variations included different degrees of friendliness between the children (induced by the collaborator), different degrees of activity on the part of the collaborator, and a situation in which a variety of pleasurable distractions from the task were available.

It was conclusively demonstrated that the initiating behavior of the collaborating child so changed the experimental child's perception of the situation as to cause him to express the frustrated need in overt behavior, as he did not in the control situations. Neither the degree of friendliness between the group members nor any of the other variables studied exerted an appreciable influence upon susceptibility to contagion. The experimental situation was conceptualized as a conflict between the desire to resume dart throwing (own goal, OG), the induced intention to perform the assigned task (induced goal, IG), the fear of unpleasant consequences of disobedience (restraining force of barrier surrounding task region, $rf_{P,\,TS}$), and the desire to get out of the increasingly unpleasant task situation (force away from task situation, $f_{P,\,-TS}$). In the control situation (Figure 1) it could be said that: $f_{P,\,IG} + rf_{P,\,TS} > f_{P,\,-TS} + f_{P,\,OG}$. An integrated treatment of the statistical data in terms of the topological concepts permitted the derivation that the initiator's actions changed the situation for the experimental child chiefly in two ways, one structural and one dynamic. Seeing the group member fritter away time without working created a new region (F = fidgeting), which was attractive because it offered a way of leaving the field without being an outright violation of the induced rules. Also, in the child's experience the behavior of the initiator led to a decrease in the strength of the barrier surrounding the task region. In situations where the collaborator actually engaged in the "forbidden pleasure," only the second condition was met. As shown

[1] As far as we know this is the first time that children (12 to 14 years of age) have by design and with foreknowledge collaborated in an experimental procedure.

in Figure 2, the task was now partially surrounded by a barrier but a path was open to a region of activities outside of the assigned task not in a direction contrary to the induced forces.

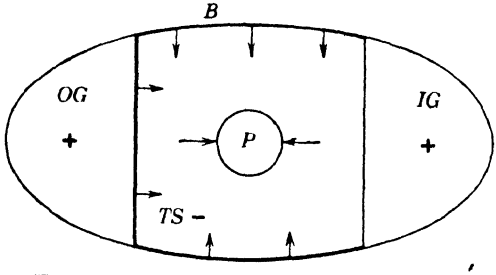

FIGURE 1. Experimentally produced conflict, control situation. OG = own goal; IG = induced goal; TS = task situation; P = person; B = barrier.

In view of the fact that under the sway of contagion children overtly expressed the frustrated needs it may be said that $f_{P,IG} + rf_{P,TS} < f_{P,OG} + f_{P,-TS}$. This state of affairs led, among other things, to locomotion in the direction of region F (fidgeting), which was unequal in direction to both OG and IG but was in the direction of $f_{P,-TS}$. This direction of the child's behavior was hence due to a change in the strength of the restraining force emanating from the experimenter's instructions.

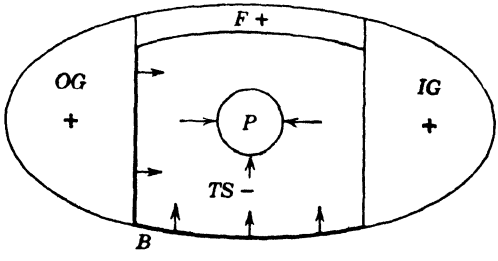

FIGURE 2. Experimental conflict, collaborator has altered child's perception of situation. OG = own goal; IG = induced goal; B = barrier; F = fidgeting; TS = task situation; P = person.

This study illustrates an integrated approach to one facet of child behavior. The interest in the dynamics of group life is combined with a clinical therapeutic interest in the treatment of behavior disorders by means of group therapy. The underlying problems concerning behavior as a function of the (group) situation and concerning the dynamics of groups-as-a-whole were conceptualized largely in terms of topological and vector psychology.

Earliest Phases of Personality Development: A Non-normative Study of Infant Behavior.[1] Among the early attempts to substantiate (in part) the general theory of development in topological terms was Fajans's (1933) study of goal-directed behavior in infants. A more complex and precise formulation was later presented by Barker, Dembo, and Lewin (1941). Although the second study was based on experimental work with preschool-age children the theory encompasses the total span from infancy to maturity. Both studies were concerned with the general laws of the developmental process; in so far as prediction was used it referred to group differences in the behavior of different age groups under comparable situational conditions.

In more recent years the direct observation and experimental study of infant behavior has come into its own as an important component of child psychology.[2] Unlike the study referred to below, most

1 This project was supported (in part) by a grant from the National Institute of Mental Health, U.S.P.H.S. Principal investigators: Mary E. Leitch and Sibylle Escalona, both of the Menninger Foundation, Topeka, Kansas.

2 This statement is based more on the existence of numerous large-scale research projects now under way than on published results. Among others we may mention the Fels Institute at Antioch College, the Denver Child Research Council of the University of Colorado Medical School, and the Child Study Center of Yale University. Each of these groups is currently conducting intensive studies of infant behavior and development.

of these researches have fallen into one of two categories: (*a*) the relationship between one environmental variable (or a constellation of such) present in infancy has been related to subsequent personality development (Spitz, 1945, 1946*a* and *b*, 1949); (*b*) empirical-descriptive data concerning the behavior of young children was systematized in terms of the presence or absence of specific intrapersonal variables which were seen as constitutionally given co-determiners of behavior and development (Fries, 1938, 1944, 1945, 1946; Spitz and Wolf, 1946).

Leitch and Escalona, and their associates, conducted an observational study of the variability of behavior among healthy infants ranging from 4 to 32 weeks in age. Their primary concern was to describe the great variety of behavior adaptations that occur among normal infants and to define some determinants of this variability. The method was substantially that of a field study, but supplemented by some methodological refinements ordinarily employed in experimental research.[1] In brief, the behavior of each of the 128 infants (16 at each lunar month level) was recorded continuously by three trained observers for a period of approximately 4 hours in a natural situation. That is, the infant and his mother were observed as the mother took care of the baby, feeding him, putting him to sleep, dressing him, etc. The detailed behavior observations and extensive interviews with mothers were supplemented by further observations in the babies' homes, by cinema photography, by psychological testing (of the infants), and by various ratings and simple growth measurements.

The observations made in the course of this study support those made by others (Bayley, 1949; Escalona and Leitch, 1949; Escalona, 1950; Fries, 1938; Gesell and Ames, 1937; and Gesell, 1946) to the effect that the behavior of an infant cannot be understood solely in relation to his environmental experience. Not only do different babies behave quite differently in comparable situations, but it has also been found impossible to explain all differences or communalities in infant behavior in terms of the past experience of these children. Although on the one hand it can often be demonstrated that at each moment the infant is responding to the momentary situation *as he perceives it*, it cannot be plausibly demonstrated that he acquired the characteristics which determine his subjective perception in the course of previous experience. To illustrate, some babies characteristically respond to stimulation by marked bodily activity, others characteristically show much less motility and may respond to stimulation by a decrease in activity (stiffening their bodies or "going limp") These differences appear to be manifest soon after birth and to remain stable during the first few years of life, at any rate (Escalona, 1950). Although the relative amount of bodily activity which an infant characteristically displays can undoubtedly be heightened or lowered by environmental influences, the observed activity differences under a wide range of environmental circumstances leave little doubt that a spontaneous tendency toward relatively greater or lesser bodily activity is an inherent property of the organism

The theoretical framework which determined initial hypotheses as well as the analysis of data in this study consisted of an attempt at integration between the

1 It seems notable that all three studies reported here have gone to the field for their data but have brought to the field studies the methods and statistical procedures usually characteristic of laboratory research. All these field studies are explicitly designed to yield hypotheses of such a form that confirmation by the experimental method will ultimately be possible.

content of psychodynamic personality theory and the systematic position of Lewin. In his chapter Lewin indicated the importance of individual differences for the application of general laws of behavior to specific predictions. "It can be expected that all problems of individual differences will be linked more and more with the general psychological laws of behavior and development and that in this way a deeper understanding (of both) will be possible." The familiar formula $B = f(P, E)$, like any general law, is applicable only if certain values can be inserted to specify the nature of P(erson) and E(nvironment) for the fraction of time for which a derivative statement is to be made. This study was, in part, an attempt to delineate the dimensions of P (structure and dynamic state of person) which could be distinguished during the first half year of life. With the systematic inclusion of the physical and social environment it became an attempt to approximate a description of the lifespace (or 128 lifespaces) for the early infancy period. Since personality development may be thought of as a behavior continuum through the life cycle, the above formula should hold for the more stable characteristics called "personality" quite as much as for each momentary behavior episode, $PD^{t_1 \cdots t_n} = f(P, E)^{t_1 \cdots t_n}$ (personality development through time is a function of the person and the environment through time). Written thus, the formula appears to express a circular relationship. However, a dynamic view of personality growth implies interdependence among the three elements of the equation though the geometrical analogy would be a spiral rather than a circle.

Leitch and Escalona applied the lifespace concept to their material by postulating that the psychological environment which determines behavior and development is a function of the relevant nonpsychological factors (biological, physical, and social environment) as modified by, or filtered through, certain possibly constitutional properties of the person. These organismic characteristics may include among others: (*a*) Perceptual sensitivity and differential distribution of sensitivity over various sensory modalities. For example, infants differ in absolute threshold for sensory stimuli so that some startle or otherwise respond strongly to light, sound, touch, temperature, or other stimuli (low threshold), whereas from other infants the same stimuli elicit mere attentiveness or other minor behavioral responses (high threshold). Similarly, the same baby is thought to be differentially sensitive in various modalities, so that one baby may for instance respond relatively most acutely in the auditory sphere and less so in the visual, whereas the reverse may be true of another. (*b*) Strength of movement impulse or activity level; this has been referred to above. (*c*) Tension tolerance, which refers to the degree of tension (or disequilibrium) which the organism can maintain without resulting primitivization of behavior. The investigators saw individual differences in infant behavior, and especially differences in response to similar or identical environmental circumstances, as partly a function of the fact that the world impinges in a different fashion upon differently constituted infants; i.e., the same stimuli are not perceived identically by different babies.[1] It was hypothesized that certain behavior syndromes can be discerned among infants which reflect various styles of infantile adaptation, and which

[1] It goes without saying that organismic characteristics are hypothesized to be only one among several factors influencing the state of the person which in turn influences subjective perception. The kind and intensity of existing needs and other conditions which arose owing to past or present circumstances play a large rôle.

may be found to occur among a wide range of environmental constellations.[1]

As a by-product of this investigation the effects of overstimulation upon infant behavior were explored by the same research group (Escalona and Bergmann, 1949). The behavioral consequences of heightened tension states were investigated by Dembo (1931) and by Barker, Dembo, and Lewin (1941). When changes in infant behavior under perceptual overstimulation were observed it was found that these behavior changes conformed to the coordinating definitions for a "system in a state of tension." In this instance "tension" could not be said to result from psychic conflict (there being no demonstrable conflict between simultaneous goals when infants are stimulated through prolonged exposure to sights, sounds, touch, and social contacts), but there occurred: (*a*) increased communication between intrapersonal regions; (*b*) a decrease in the capacity for coordinated behavior (decrease in hierarchical organization), and, finally, in many instances (*c*) de-differentiation or primitivization of behavior. An experimental situation was filmed [2] in which a heightened tension state was created in infants 4½ to 6 months of age by means of perceptual overstimulation. Primitivization of behavior was assessed through a comparison of the behavior of the same children in response to standard situations adapted from developmental tests before and after exposure to prolonged stimulation.

The Midwest Field Study of Children's Behavior. In one sense the Midwest study of children's behavior parallels the study of infant behavior described above. If the formula $B = f(P, E)$ is the point of departure one might say that in the infant study emphasis was placed on exploration of specific variable properties of P, whereas in the Midwest study emphasis was focused upon a determination of the distribution of variables which go to make up E, at least in one specific sociocultural group. In both investigations interest centered on the *mediation* process by means of which nonpsychological factors are transformed into the "psychological world" of the individual child.

The complex interrelationships between psychological experience and the nonpsychological milieu were formulated by Lewin (1944) and by Heider (1927, 1944). Climatic and geographical conditions, economic and social factors, the actual physical properties of the world about, all enter and determine the lifespace. This is as true for the neonate crying from cold as for the octogenarian smoking his pipe. Yet the same object, or the same bodily sensation, may have different meanings to different persons, or to the same person at different times. Lewin (1944) used the term "psychological ecology" to designate the realm of inquiry which deals with the laws governing the mediation between the nonpsychological environment and the psychological field.

The Midwest project was a large-scale study in psychological ecology (Barker and Wright, 1950; Wright and Barker, 1950*a*). Under the direction of Roger Barker and Herbert Wright a field staff (most of whom resided in Midwest [3]) developed a complex research design for the precise recording of spontaneous child behavior in a community. The aim was to describe the conditions of life and the behavior of all the children in a small American town (named "Midwest"). Trained observers

1 At the time of this writing some such behavior syndromes have tentatively been suggested, chiefly as a guide to analysis of data. The analysis may or may not succeed in demonstrating their existence.

3 "Midwest" is a fictitious name assigned to the actual community where this study was conducted.

accumulated what is probably the largest amount of behavior data ever collected by a single research group. Sampling techniques were used in order to determine the amount of material descriptive of child behavior which was needed in different settings (school, playground, home, church, club meeting, etc.), for different age groups, and the like. In addition, a sizable number of "day records" (Barker and Wright, 1951) were made; these were continuous observations of a single child's day from the moment he arose to the moment he went to bed at night (observers spelling each other off at half-hour intervals).

At the time of this writing results have not appeared in print. A major research contribution, and one that stems directly from a topological analysis of the problem, has been made, however, in terms of a theoretical framework and elaborate methodology (of data analysis) by means of which the overwhelming mass of data can be made comprehensible (Wright and Barker, 1950*a*). The authors conceptualized the field in which behavior takes place as the *psychological habitat*.[1] This "primary homeland of behavior" envelops the child wherever he goes; it is the things and conditions that make up his world in terms of their subjective *meaning*. The attempt was to reconstruct, by inference, the psychological habitat for each child at each moment under observation by simultaneous recording of the child's surroundings and of his overt behavior. The mediating process between outer and inner world, which determines the aspects of his environment which the child will perceive as goals, as barriers, as tools, as negative or positive regions, etc., was conceptualized in terms of *behavior settings* and *behavior objects* (see Figure 3[2]). A behavior setting was defined as a part of the nonpsychological milieu which is perceived by the community as appropriate for a certain range of behaviors. (A drugstore, a church, a back alley, and a river bank are all behavior settings.) Behavior objects were defined as parts of the nonpsychological environment which are perceived by the community as appropriate for a certain range

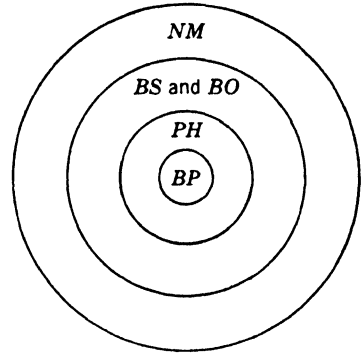

FIGURE 3. Mediation between nonpsychological milieu and psychological habitat. BP = behaving person; PH = psychological habitat; BS = behavior settings; BO = behavior objects; NM = nonpsychological milieu.

of actions. (A baseball bat, a Sunday school teacher, an ice cream cone, and a fountain pen are all behavior objects.) Topologically speaking, a behavior setting is an activity region (Lewin, 1936, 1938); a behavior object is a point region within an activity region. Although it is true that almost anything may happen almost anywhere, the Midwest data furnished impressive evidence to show the coerciveness of behavior settings and behavior objects. All behavior observed in the same setting (over a period of years) showed a striking similarity; behavior in different settings or with different objects showed strikingly

1 The definition is equivalent to those for "psychological environment" or "momentary lifespace" as these appear elsewhere in the literature.

2 Figure 3 is *not* a topological representation but a diagram intended to save the space which would be required for a full written statement.

consistent disparity. In conjunction with parallel behavior observations the systematized assessment of the child's changing surroundings permitted interesting types of analysis. For instance, a given child on a certain day of his life in Midwest entered 27 different behavior settings and used over 500 different behavior objects in a manner sufficiently overt to enter the descriptive records. Figures such as these could be compared for children belonging to different socio-economic groups, different age levels, etc.

Quantifying on-going behavior without violating its psychological meaning is more complex than doing the same for its outer context. It is at this point that topology, and more especially the coordinating definitions constructing the hodological space (Lewin, 1938), proved important.[1] The analysis of behavior units, which formed the core of this research, is too complex to be fully described here. The following will give some notion of the empirical and theoretical potentialities of this approach to child research.

The largest meaningful unit in the division of a behavior continuum was defined as an *episode*, which encompasses an action from the first step in the direction toward a goal to the last step which is still a part of the same action directed toward the same specific end. Since most behavior is structured in such a way that several subgoals are attained on the road toward the main goal, the unit corresponding to a subgoal which is dynamically dependent upon the major goal and hence in the same direction is designated as a *phase*. By definition, a phase cannot be further subdivided on the level of molar (psychologically meaningful) behavior. (The rule of thumb by which to distinguish molar from molecular behavior has been to say that those actions which are meaningfully performed by a person are molar, those that are performed by a leg, a set of glands, a finger, etc., are molecular: A *person* walks or reads, a *foot* is lowered to the ground in taking a step, the *eyes* move laterally while the *person* is reading. Therefore, the same set of motions may constitute an action, molar behavior, at one moment, and an actone, molecular behavior, the next. For instance, a deliberate wink may be an action performed by a person; a second later blinking may occur unnoticed.) The phase was further defined by the criterion that its potency must be less than that of the episode of which it is a part.

Each complete episode falls into two *stages*, the translocation and the consummatory stage respectively. This is to distinguish that part of an action which consists of moving toward a goal (translocation) from those activities which ensue once the goal has been reached (consummatory). If the episode is, for instance, the purchase of an ice cream cone, the child's actions up to the point the nickel has been paid and the cone has been grasped fall into the translocation stage, the manner in which he eats the cone falls into the consummatory stage. Behavior is organized not only in terms of a single major goal and a series of subgoals on the way; for instance, the episode "going to school" may be so structured that "crossing Main Street" may be subgoal, yet reaching Main Street may be experienced as falling into several smaller units such as "passing the bakery" and "turning the corner." These and similar subdivisions were taken into account in this behavior analysis, but it will not be necessary to burden the reader with the cumbersome corresponding terminology. Fig-

1 We thought it interesting to read (Wright and Barker, 1950*a*) that the investigators experimented with numerous conceptualizations to guide their behavior analyses. After more than a year's work they "rediscovered" Lewin's (1938) formulations and found them appropriate to their needs.

ure 4 is a schematic representation of this mode of analysis.

It is comparatively rare for a person to be engaged in only one situation, or one meaningful action, at a time. More frequently, both episodes and/or phases may overlap (as when children converse while walking to school). Episodes or phases may be interrupted by episodes of quite a different meaning (i.e., direction); subsituation were experienced as restricting, coercing, helping, increasing, or decreasing the scope of free movement, etc. Other variables concerned the clarity with which the child perceived the situation, the degree of efficiency and creativity he attained, and the like.

The results of these behavior analyses were entered on Hollerith cards, which permits nearly infinite patterning of results.

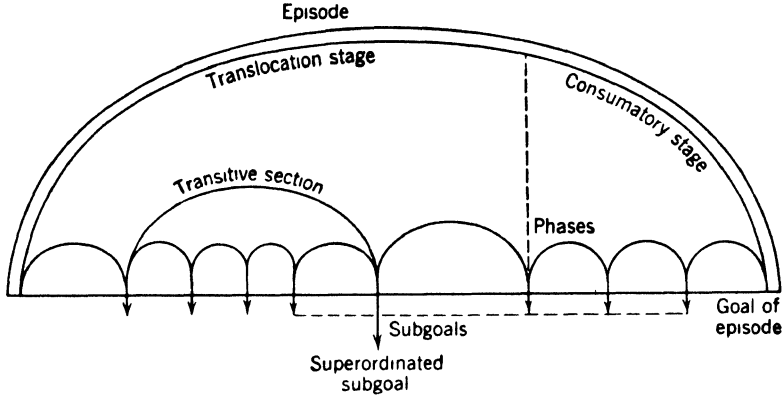

FIGURE 4. Units of analysis for single behavior episode.

sequently they may be resumed, or may remain unfinished (for instance, playing ball on the way to school may temporarily give rise to behavior directed toward goals that have nothing whatever to do with school). It may also happen that what would ordinarily be a step in the direction of a goal may come to be so absorbing in its own right as to be no longer experienced as related to the main goal (this was designated as a "dependent episode").

Comparably complex modes of analysis have been worked out in order to allow for inferences about the quality of each experience and the fate of each episode. On the basis of specified behavior clues, ratings were made concerning such things as how great the child's involvement was, the degree of satisfaction or frustration he experienced, whether other persons in the

For the child population of the community called Midwest it is possible to know what proportion of their actions was successful, and which kinds of actions in what settings, with what objects and in which social situations, tended to be successful most often. In case of failure it is possible to know in what proportion of actions the adult prevented the child from reaching his goal, and where and how this occurred, as well as the proportion of instances where the child's goals were impracticable because of the reality of the outer situation, because of his misjudgment of his own capacities, or for other reasons. For Midwest we may expect to learn in which settings children experienced the least and the most coercion and at whose hands. We can learn about those settings and objects in relation to which children displayed the greatest and

the least emotional intensity, and the nature of the emotions they expressed. We may learn the degree to which some children were restricted in terms of settings they were allowed to enter, objects they were allowed to use, etc. Or we may ask for a curve depicting the increasing complexity of goal structure in the behavior of children as a function of increasing age, and so on, ad infinitum.

If the three studies referred to in this section are representative of current research conducted within the general framework of topological and vector psychology, the following may be said in summary: Those adopting Lewin's systematic position tend to think of all psychological phenomena as a continuum, and they tend to search for formulations of lawfulness applicable to all behavior. In conformity with a trend conspicuous in all the social sciences, they therefore work towards an integration of the various subdisciplines (from sociology and social psychology to psychoanalysis and physiology). Their interest has shifted somewhat from the validation of general laws by experimental procedures in laboratory situations to the discovery of constellations of variables as they occur in life situations, by means of controlled observations under field conditions. Furthermore, a marked research interest has developed in the processes of mediation, which is but another way of saying that topologists have broadened their realm by concerning themselves not only with the nature of the psychological situation but also with its genesis and its development through time.

Chapter 16

GIFTED CHILDREN

Catharine Cox Miles

Foreword

Study of gifted children was largely descriptive and anecdotal until Terman and Hollingworth identified and then analyzed the backgrounds and characteristics of boys and girls of high IQ. Other investigators, among them Witty, Hildreth, and Sumption, confirmed the earlier findings of Terman and Hollingworth and their associates. A number of valuable contributions came from investigators throughout the United States and abroad.

The major study of the gifted, Terman's 50-year project, reached its halfway mark at midcentury. The "composite picture" which emerged from study over a 25-year period of some 1500 gifted children by Terman and his associates stands as a monument to intelligent planning and the devotion of an investigator to an important psychological and educational problem.

In the following pages the study of the gifted is traced from its notable origins. The major scientific findings are presented chronologically down to the middle 1940's. A concluding section is devoted to developments in the period following the second world war in which Terman's 25-year report (1947) was a major event. A summary is attempted of Terman's principal results and other gifted studies of the period are also briefly reviewed. The status of gifted study evaluated in the light of contemporary genetic and biosocial research efforts and results affords a promising starting point for new research design. Continuing study of Terman's gifted subjects and their children may answer further questions regarding origins and influences in superior adult achievement.

Introduction to the Historical Review

When intelligence tests of the Binet type were first applied to the general population the purpose of measurement was the differentiation of the dull from the average. But the earliest surveys showed quite another possibility, for these tests, found to be singularly effective as indicators of mental power, at once set off a small group of superior individuals whose test scores were as far above the generality as those of the feeble-minded were below it. The rarity of individuals scoring 130 or 140 IQ and higher, and their extraordinary facility in performance, naturally aroused a feeling of wonder and surprise. In the first 1000 children tested, only 1 per cent rated as high as 130, and the 4 or 5 whose IQ's passed the 140 mark seemed indeed phenomenal. It was natural to think of these unusually brilliant test performers as the probable leaders of the future, those among whom the most distinguished personalities, including geniuses of all kinds, were most likely to appear. Furthermore, by assuming an appropriate critical point they could be arbitrarily defined as geniuses or near-geniuses in Galton's special sense of possessing unusually superior mental ability, if

this were defined as mental test ability. What the significance of their high competence might be for future attainment could only be surmised.

Research has now shown that children of high IQ maintain their score level relatively well. The superior school achievement of groups rating high in intelligence tests has also been sustained. These results confirm the validity of the IQ test-construction procedures. It should be noted, however, that while predictable results like these have been verified new ambiguities in interpretation have emerged and old problems have appeared in new guise. Conditions for the deviations of individuals and subgroups from total group trends are frequently unclear.

The turning of the research spotlight on the children of high IQ has illuminated more than one dark area. A change in terminology may be mentioned: the terms *genius* and *near genius* have been gradually abandoned in favor of the more acceptable designation *gifted*.

Consideration of the numbers of gifted children in the community indicates their absolute frequency as well as their relative rarity (Table 1). In the public school population of the United States, numbering some 28,000,000, there are probably not less than 110,000 to 140,000 of the very highly gifted children, and somewhere near twice this number who rate as high as 130 IQ. An average American town of 10,000 with a school population of roughly 2000 may be expected to have 20 children with IQ's of 130 or higher, of whom 10 or so rate as high as 140. Certain regions of the United States have relatively more, others relatively less, than the average approximations. Communities and cities vary within themselves in the density of the gifted population. Schools also differ, high schools generally attracting more of the superior intellects than elementary schools, and colleges more than either. Private schools also differ among themselves, some of them having as high populations of gifted children as the average or even the superior college.

Gifted children have many traits in common. It may be difficult to distinguish some 130 IQ's from the 140's, but the gifted group as a whole differs unmistakably from average children of the same age and schooling. Future investigators face the problem of designing research to reveal differences between gifted children and their less high scoring siblings or other associates whose origins and experience appear to have been similar. As other variables besides intelligence become more satisfactorily measurable their significance in these comparisons may be shown in as well-planned studies as those earlier designed to compare the gifted with samples from the general average.

The problem of creative genius has scarcely been touched in the studies of the gifted. However, it now seems more than probable that historical geniuses would, if tested in childhood, have scored high on the IQ scale.

Study of the most superior specimens of a species is of importance for pure and applied science. It is essential for pure science to determine the upper limits of superiority, the nature of the characteristics of the upper deviates, the ways in which they differ from the average, the individual differences among them, and their similarities. It is not to be expected in any biological series that they will prove to be a type, yet there will be certain traits in which they tend to resemble one another more than they resemble, for example, the average of their species or the average of those less superior whose backgrounds and opportunities have apparently resembled their own.

TABLE 1

PERCENTAGE OF GIFTED CHILDREN IN SCHOOL POPULATIONS AS REPORTED BY VARIOUS INVESTIGATORS

(IQ 140 Plus and Upper Centile)

	Stanford-Binet Intelligence Test					
Population	Revised 2904	Old Form 874	905	112	149	100
Investigator	Merrill	Macmeeken	Terman	Terman	Terman	Malherbe
Date	1938	1939	1916	1919	1919	1921
School status	Grades 1–8	Single age	Grades 1–8	Kindergarten	Grade 1	Grades 1–8
Percentage of group rating 140+	1.33	1.03		2.7	1.30	13.0
Percentage of group rating 136+			.55			
Upper 1 per cent	143 IQ+		130 IQ+

Date	1931	1923	1934	1935	1930	1928	1940	
School status	Grades 1–8	Grades 11–12	H. S.	Senior H. S.	Grades 1–8	Grades 1–8	Grades 1–8	Grades 7–8
Percentage of group rating 140+	1.20	.12	.34	3.34	6.3	6.4	3.9	7.4
Percentage of group rating 136+							6.5	11.2
Median IQ of group	96	100	104		119	115	116	117

It is of importance to applied science to know under what circumstances these superior deviates appear. If it should be found that the function of intelligence can be measurably increased through training methods, through environmental influences, and the like, then the hope would be justified that the effective number of the gifted may be considerably enlarged. If, on the other hand, biological elements are chiefly involved, it is not likely, under existing conditions, that the present percentage can be appreciably augmented. The attention of psychologists, which has been directed toward the study of background as well as foreground, is now being turned especially to a consideration of the environmental conditions favorable for the development of gifted children, that is, toward the discovery of opportunities and influences which can stimulate their talents to strong, healthy, optimal growth.

History

Philosophers and other teachers who have tried to work out systematic methods of producing a good human society have given thought to the selection and education of superior children. Plato spoke of the importance of discovering and suitably educating the most able youths for leadership in the state. He suggested that tests of native ability should be the basis of the selection. From his day until the introduction of modern universal school systems, education was, however, generally the prerogative of the children of the well-born and the able, plus a few outstanding minds from the lower economic or social groups. State administrators, teachers, and priests tried to recruit pupils of superior natural gifts who might be trained to carry on community institutions and maintain or extend the group culture. Under the apprentice system skilled specialists tried to attract gifted youngsters apt in learning and capable of superior accomplishment. Practical rather than scientific methods of finding and training gifted children are still in general use today. Ostwald in 1909 formulated his scheme for the selection of gifted university students for advanced research. Present-day personnel methods involve essentially similar problems and procedures. With or without the use of special technical aids, education and industry seek the gifted and train those who are expected to qualify for later leadership (E. L. Thorndike, 1939).

Prescientific Observation of Gifted Children. Parents in all times have been alert to recognize superior competence in their offspring, and it has often been they who discovered and brought to wider attention children with special mental ability. When the parents were themselves teachers they not infrequently attributed the unusual competence of the children to their own superior methods of instruction. Superior children have frequently been reported singly and in interesting collections. One of the more famous prodigies was Christian Heinrich Heineken, who showed remarkable powers of observation and speech at the age of 10 months. Before the age of one year he could recite stories and verses. Under a tutor's instruction he soon learned arithmetic fundamentals, anatomical systems, ahd world history. At the age of 4 years he could read printed and written German, relate stories in French, and recite 1400 sentences from good Latin authors; he knew all the important places on the map. His knowledge was said to be more than mere memory, for he could discuss what he knew with intelligence. His fame spread through Europe and he was invited to visit the Danish king, who was delighted and amazed by his conversation. Unfortunately, his health failed and he died at the age of 4 years and 4

months. Like Christian Heinrich, some others cited down to our own time (Braun, 1920; Bridgman, 1938) died at an early age and before their unusual promise could show complete fulfillment.

In happy contrast, the life story of Karl Witte gives the sequel to a gifted childhood in terms of superior, highly esteemed adult achievement. Considered to be quite unprepossessing as an infant, he was so carefully trained that at 6 his thinking was logical and his information accurate. He learned foreign languages readily and by the age of 9 was proficient in several. Science, art, and history he acquired by a natural project method devised by his father. Entering the university at 9 he completed a distinguished course in all his subjects and at 14 received the Ph.D. degree. When, at 16, he was appointed university instructor his youthful appearance caused objection and it was suggested by a royal patron that he devote some years to travel. During a residence abroad he was led to the literary study in which he became distinguished while continuing his chosen career in jurisprudence. At 21 he became a university teacher, at 23 a full professor. His long and active life was happy in domestic as well as in wider social relationships. He was devoted to community, professional, and scholarly activities in which, before his death at the age of 83, he had won high honor and distinction.

From many accounts we may conclude that, as in Witte's case, rapid mental development in superior healthy children can further unfold at a high level of adult distinction. On the other hand, precocity due to overtraining may regress to a mean of mediocrity. The one-sided advancement of the emotionally unstable may later deteriorate or end in mental illness. A typical early collection of case studies of historical precocious children is that of Buckley (1853). A more recent report of seven American prodigies illustrates the late pretest point of view (Dolbear, 1912).

Beginning of Scientific Psychological Observation. Early scientific method was injected into the study of the gifted and a new phase of interest aroused in their investigation by the genetic and statistical researches of Galton (1869) and his contemporaries. These constituted the first quantitative psychological studies of human endowment. DeCandolle (1885) and, subsequently, Ward (1906) introduced scientific method into the classification of the social influences favorable to the appearance of the gifted, contending that these are at least as important as the constitutional endowment in determining achievement. J. McK. Cattell (1915, 1917) combined the two points of view and methods in his studies of *American Men of Science.*

Yoder (1894) included childhood traits in his statistical study of the natural history of fifty eminent men, and Ellis (1904) devoted special attention to interrelationships of precocity and health in the childhood of eminent Britons.

Three studies already referred to, by Terman, belong to the intermediate period in which the methods of psychology as of all natural science were gradually evolving. A study of leadership, suggestibility, and other traits in school children (Terman, 1904) was followed by a summary of contemporary opinion regarding precocity, prematuration, and the new concepts of mental hygiene (Terman, 1905). By laboratory study employing a large variety of early intelligence test items, the abilities of bright and dull boys were compared (Terman, 1906). In the title of this study, "Genius and Stupidity," Galton's concept of genius as superior mental ability was introduced.

In 1905 Binet's mental test scale was published, Goddard's translation appeared in 1911, and Terman's revision in 1916.

Case studies of gifted children soon showed the possibilities of the new methods to discover superior mentality. The first of these utilized mental ratings based on early versions of Binet's scale preceding the Stanford standardization. The author of the earliest report was incredulous (Bush, 1914); the second (Langenbeck, 1915) found in the Binet data gratifying proof of obvious precocity.

Modern Period of Quantitative Study. The small group of children with exceptionally high IQ's revealed by the revised Binet method proved to be neither peculiar nor one-sidedly intellectual as had been suggested in some earlier studies of precocious children. They were found rather to be essentially normal, well-adjusted children (Terman, 1915). Brief reports of four whose IQ's reached 140 or above were included as the highest in a series covering the IQ range and illustrating the measurement of intelligence (Terman, 1916). The definition of 130 IQ as the scoring point exceeded by the highest centile of mental ability was enunciated in the same volume.

The following year Garrison, Burke, and Hollingworth (1917) published the first account of an IQ in the 180's. Rusk (1917) described the test performance of an English child whose repeated Binet scores gave IQ's near 200, and Terman (1917), from biographical data, appraised Galton's childhood IQ as near 200. Other cases described in the first decade of measurement included an IQ of 167 (Coy, 1918); a phenomenally precocious reader (Terman, 1918), later found to have an IQ of 140 (Terman and Chase, 1920); and some 35 individuals in the IQ range from 140 to 184 (Terman, 1919). Besides affording case reports, these 35 gifted children with 14 other top centile individuals were the subjects of the first group study of the intellectual, educational, and social characteristics of gifted public school children. Gillingham (1920) reported seven IQ's of 140 and higher in a study of superior private school children with personality handicaps. Whipple (1919) outlined and illustrated methods of selection and instruction for superior, including technically gifted, children, reporting experimental results and norms and appending a bibliography. Clearly the new method of measurement had provided a means for differentiating intellectually able individuals in childhood, and psychologists soon became aware of the possibilities for the further study of individuals and groups thus differentiated.

The period from Henry's "Classroom Problems in the Education of Gifted Children," in the 1920 *Yearbook of the National Society for the Study of Education*, to Whipple's "Education of Gifted Children," in the 1924 *Yearbook* (Part I) of the Society, shows gradually developing systematization in method and presentation. The two volumes mentioned give cross-sections of contemporary interest and knowledge. Their bibliographies are extensive and valuable. Detailed studies of the educational status and progress of superior children in special classes published in this period include Coy (1923), in which the use of the term gifted was first specifically limited to the top centile; Cobb and Taylor (1924); and Stedman (1924). Goddard's monograph in this succession appeared in 1928. Root's (1921) descriptive study of superior children gave an experimental-psychological analysis of the mental processes of 53 cases, 23 of them of IQ 140+. A. M. Jones (1925) reported a detailed classification from clinical and educational data of material confirming for 120 children in Pennsylvania conclusions drawn by Terman for his first group of 59 upper centile Californians. Investigators at this time characteristically grouped their results and summarized the trends indicated

by ranges and central tendencies. Their studies of superior children included school or clinic children variously restricted, in terms of IQ level, some extending consideration to include children within the average intelligence range. The researches dealing chiefly with groups of IQ 130+ or 140+ or presenting individual case studies at this level form the material basis for the present review. Other supportive works concerning above-average groups are occasionally referred to briefly.

Yates's account, in 1922, of 25 superior high school students marked the first use of group tests for the selection of notably high intelligence. The assumption that the reported scores corresponded to individual IQ's of 140 or higher is open to question. The upper centile criterion may, however, have been approximately fulfilled in this early work.

Whipple's *Yearbook* in 1924 contained the first statistically developed results from studies of the traits and achievements of large populations of the gifted. In this volume Terman outlined the Stanford study of more than 1000 gifted children with IQ's of 140 or higher. The methods of sifting the population by group and individual tests were described, and results obtained in the first cross-sectional research were briefly enumerated (Terman, 1924*b*). Terman and DeVoss (1924) also presented a preliminary summary of the educational test achievements later reported in detail. Waddle's (1924) case studies included a number of exceptionally high IQ's and reported remarkable achievements. The *Yearbook* researches describing upper centile intelligences and reporting many cases with IQ's 140 and higher include the studies by Hollingworth and Taylor (1924) of physical size and strength, Cobb and Taylor (1924) of achievement test scores, and Patrick (1924) of school achievement and personality traits. Standard educational tests with the devices of educational ages and quotients had added considerably to the effectiveness of statistical techniques for gifted child study.

In the next six years, 1925 to 1930 inclusive, the essential descriptive and statistical picture of the gifted child as we recognize it today was drawn. The researches of Terman and his associates, frequently referred to in this article as the California or Stanford studies, and Hollingworth's monograph were primarily responsible. Other investigators made valuable additions, generally by way of supporting evidence. Terman's researches were published in 1925 and 1930 as Volumes I and III of his *Genetic Studies of Genius*. These compendia afford the most complete available store of factual data about large groups of gifted boys and girls in childhood and adolescence. The first volume devoted 19 chapters to the history, methods, and results of the Stanford study of 1000 gifted preschool and elementary school children and 300 gifted high school pupils. A brief report of a follow-up study after 2 years and an important review of conclusions and problems completed the work (Terman *et al.*, 1925). In Volume III were reported methods and results in a cross-section follow-up after 7 years, 13 chapters; 86 cases illustrating individual differences and personality problems, 9 chapters; personal histories and achievements of seven gifted juvenile writers, 5 chapters; and a summary of retrospect and prospect in a critical, evaluative presentation, 1 chapter (Burks, Jensen, and Terman, 1930). The work presented in these two volumes is invaluable (1) because of the large number of subjects, representing about nine-tenths of the highest IQ's in a population of 250,000 public school children of their age, (2) because of the combination of longitudinal and cross-sectional study, (3) because statistical

treatment is supported by case illustrations, and (4) because the basic data are made available for direct study and comparison.

Hollingworth, in 1926, published her monograph, *Gifted Children,* a general summary presentation of the background and foreground of the field of study. A series of researches by the same author and her associates on special problems concerning gifted children included further, before 1931, a study of the regression of the IQ's of the siblings of the gifted (Cobb and Hollingworth, 1925), measurements of motor functions (Hollingworth and Monahan, 1926), measurements of special musical abilities (Hollingworth, 1926*a*), a follow-up account 10 years after the first study of an unusually gifted boy, IQ 187 (Hollingworth, 1927), the important evidence of the superiority in school achievement of the more gifted over the less gifted (Hollingworth and Cobb, 1928), and a study of the growth in stature of the gifted (Hollingworth, 1930*a*).

In the same period Lamson (1930) reported on gifted children studied in the senior high school 7 years after their identification in the lower grades; Gray (1930) contributed a study of young college students; Lehman and Witty (1927) examined the play behavior of gifted school children; and Witty (1930) reported his first research on 100 gifted children with a follow-up after 6 years. The Witty studies covered many of the points studied also by Terman, and their similar findings gave direct support to the larger researches. Baumgarten in 1930 reviewed the studies of precocious children and described, psychologically, children with special artistic gifts.

In the year following the publication of Volume I of the *Genetic Studies of Genius,* Volume II of the series appeared: a study of the early mental traits of historical geniuses (Cox, 1926). This work belongs in the succession, from Galton through Yoder, Ellis, and Cattell, of quantitative evaluations of historically recorded biographical data concerning persons of eminent achievement. It differs from the older studies in the introduction of the new concept of intelligence measurement. The appraisal of the IQ's of historical persons in childhood as proposed and illustrated by Terman (1917) was here applied to a large number of the most eminent men of the past, including many of the world's greatest geniuses. Previsaged by Terman, this work reported by Cox, from data gathered by her and her associates, approached the problem of the gifted by making available for comparison the IQ ratings, personality trait evaluations, and environmental appraisals from available childhood data for 300 of the most distinguished figures in the history of American and European progress.

In the 1930's and the early 1940's individual and group studies of gifted children contributed many additional details to form the gradually emerging outline picture as it appears in later sections of this chapter. Three reviews and summaries gave the findings and conclusions to date (Terman, 1931; Terman and Burks, 1933; Hollingworth, 1940). Hollingworth's (1942) final volume directed attention to the rare individuals whose childhood IQ's reached 180 or higher. Case studies of 12 such unusual children were here prefaced by a detailed historical section with résumés of the previously published accounts of 19 other children with similarly high IQ's. The book contains also a summary (five chapters), with critical comments and amplifications, of the author's findings and conclusions hitherto available only in scattered periodical form.

Significant contributions of research in these years include (1) the increasing

evidence of the persistence in the gifted as they grow older of high intellectual ability and achievement as demonstrated by test performances and academic standing (Hollingworth and Kaunitz, 1934; Lorge and Hollingworth, 1936; Hildreth, 1939; Hollingworth, 1940; Terman and Oden, 1940*a*; Witty, 1940*a*; Hollingworth, 1942; Witty and Theman, 1943) and (2) the beginnings of differential study of subgroups of the gifted as in Lewis's (1941) comparison of the traits of gifted children of superior and inferior educational achievement and in Terman and Oden's (1940*b*) comparison of the most and the least successful of the California gifted group who had reached adulthood.

The more extensive bibliographies for the twenty-five-year period of research include those of Terman and Chase (1920), Henry (1920), Coy (1923), Whipple (1924), Hollingworth (1926*b*), Terman and Burks (1933), Blair (1938), Hollingworth, Terman, and Oden (1940), and Hollingworth (1942). Bibliographies on the education of the gifted in the 1940's were prepared by Newland (1941) and Hildreth and Ingram (1942).

Emerging Search for Further Defining Traits. A series of essentially duplicate studies tends to follow the elaboration of a new scientific technique. This occurred when the Binet method appeared. Many psychologists sought to discover or verify the presence of high IQ children in populations available for testing. To this primarily scientific interest a practical educational one was joined. Recognition of the desirability of segregating gifted children for educational economy and effectiveness made demands for adequate methods of selection. The mental tests provided a practical and objective basis that was found to be increasingly useful, especially when applied in conjunction with other methods of appraisal.

When the high IQ groups had been segregated, further progress depended on accurate measurement of behavior capacities and personalities. Again two interests converged. The need for scientific knowledge about the accomplishments, abilities, and traits other than the intellectual of the high IQ's was a compelling incentive to research; and the needs of teachers faced with the problems of instructing children 40 to 100 per cent accelerated intellectually gave the problem immediate practical urgency. The results have exceeded early anticipations in their extent and concurrence, and they have raised many new problems demanding further investigation.

With the preliminary publication of the 16-year follow-up of Terman's gifted thousand (Terman and Oden, 1940*a*, 1940*b*), research concerning gifted children entered a new phase. Personal characteristics, hereditary factors, school progress, and achievement were here for the first time compared for gifted children, apparently intellectually indistinguishable in childhood, who later became (1) successes or (2) failures in terms of professional, occupational, and economic achievement. The ground was thus cleared for the next step: the identification of those within the gifted groups who are likely to become in terms of total personality the most competent adults. A basis for a more restricted definition of the term gifted may result, or a new classificatory term may be found for the high IQ children of greatest potentiality, the gifted in childhood who in exceptional accomplishment in their maturity realize the rare promise of their youth.

Children who have not only the superior intellects to which the term gifted now attaches, but also the other traits and characteristics in which later superior achievement is rooted, are intrinsically gifted in a broad psychosocial meaning of the word. Whether there are others not so highly

gifted in intelligence as the 130 or 140+ IQ's discovered in childhood, nor so precocious in the unfolding of their mental powers, who later display equal or superior success in their mature work, only further research can prove. The indications now available seem to show that it is the integrated totality of personality, with its varying physical, emotional, intellectual, and social components forming more rather than less effective patterns, in which success in contrast to failure is conditioned under appropriate environmental stimulations. Tracing forward the life progress of large groups of gifted children and upper centile children and tracing backward the developmental course of equally successful adult individuals who were not labeled as gifted in childhood must eventually solve the puzzle.

Characteristics of Gifted Children

The understanding, care, and training of gifted children and the theory of their origin and psychological constitution depend on knowledge of their background, their emotional and social traits, and their physical characteristics and on adequate measures of their intellectual endowment. Detailed observation and extensive quantification must precede analysis, and hypotheses are not to be accepted as conclusions. Parents, teachers, even psychologists, may cling to certain prejudices regarding the problems of the gifted which only many facts can ultimately dispel. Some of these are now available and from them parts of the picture of the gifted children can be distinctly discerned; others are still fragmentary and unclear, with contradictory elements. In the following pages the present knowledge is briefly reviewed.

Racial Origin. Gifted children in the United States have been more frequently found in the racial groups in which in the past century economic, social, educational, and professional leadership has been generally centered. Yet exceptions have also appeared, indicating that superiority may occur in any of the races or ethnic groups that have contributed to the American population. In Terman's main group 51 per cent are of British descent; 17 per cent, German and Austrian; 6 per cent, French; 4 per cent, Scandinavian; and 10.5 per cent, of combined Jewish stock. Old American families from New England and the Middle West have contributed substantially more than their quota to the California group, whereas foreign-born parents are numerically less well represented. Whatever groups are in the general population are also represented in the gifted group; Negroes, Mexicans, and Orientals are included in the California studies. In the Middle West (Witty, 1930, 1940*a*), in Ohio (Cleveland, 1921), and in Pennsylvania (A. M. Jones, 1925), the gifted groups have drawn heavily on the hereditary stocks constituting the more favored and enterprising elements of the population. In New York City, Jewish children are especially in excess in the public school gifted groups (Hollingworth, 1926*b*).

The racial contributions to the gifted populations in the various studies correspond roughly to the rank order of IQ means of the same stocks in the public schools. They are also in general agreement with the draft army results of 1918. Yet conclusions as to the superiority of parent stocks or future groups of gifted children should not be drawn from results limited geographically, economically, and in terms of migration. Certain elements have never been adequately surveyed, as, for example, children of Irish descent in parochial schools. Indians and Negroes have been insufficiently represented in the public school groups surveyed. When

looked for in city Negro communities many high IQ Negro children can be found (Jenkins, 1943; Witty and Theman, 1943), and the degree of giftedness is uncorrelated with the extent of white ancestry (Jenkins, 1936). A Negro girl of 200 IQ has been reported (Witty and Jenkins, 1936). Studies of IQ distributions in England and Scotland show that roughly the same IQ level marks the upper centile in those countries as in the United States (Duff and Thomson, 1923; Macmeeken, 1939). We may say in summary that, although it is true that under existing social conditions certain racial or ethnic groups produce relatively more gifted children than others, no final conclusions about the relation of giftedness and race should be drawn until wider regions are sampled and conditions for the study of social inheritance are more fully understood (Hollingworth, 1940).

Sex Ratio. An excess of boys over girls has been found in the higher IQ brackets in the majority of groups of gifted children so far described. Among elementary school children Terman *et al.* (1925) found a ratio of 121 boys to 100 girls in 643 preschool and elementary school children; A. M. Jones (1925), 135 boys to 100 girls in 120 cases. In contrast, Witty's (1930) 100 numbered 51 boys and 49 girls, and Jenkins's (1936) Negroes showed excess in favor of the girls. In none of these researches, however, was the sex ratio a primary problem, and representative selection had not been attempted. The method of nomination used by Terman and the admission of volunteered subjects are both known to increase the numbers of higher scoring boys, as has been shown, among others, in the Scottish study of 1000 "representative" single age 11-year-olds (Scottish Council, 1933). In proof, the only completely objective sample, a rigid single age group in which all the Scottish children born on certain days were tested, was found to contain 4 boys and 5 girls of IQ 140+ (Macmeeken, 1939). Lewis's (1940) study also shows more girls than boys in the higher IQ categories. His ratio is 46 to 40 for IQ 140+.

Terman's high school group (Terman *et al.*, 1925) of 200 gifted boys and 109 gifted girls selected by nomination and group intelligence test offered an even larger numerical sex contrast than his younger populations, and other comparisons of the sexes with respect to numbers at the highest group test score levels seemed at one time to confirm a disproportion largely increasing with age (Terman and Burks, 1933). However, many of the reported results were drawn from groups unequally selected or were based on tests of unequal difficulty for boys and girls. Data reported for large high school and college populations derived from fairly homogeneous distributions with equal mean scores for the sexes show generally smaller contrasts than the earlier studies. In illustration (Table 2), Witty's (1934) group test results for IQ's 140+ in high school populations are compared with high school seniors' scores reported by Henmon and Holt (1931) and the Thurstones' (1937, 1938) statistics for college freshmen. The ratios show the boys generally but not always outnumbering the girls at the highest levels, but no regular age-sex trend appears consistently.

Causes for lack of agreement in the given results probably include lack of homogeneity in the population samples compared and inadequacy of the tests as measures equally fair to both sexes at the upper extremes even when the means are satisfactorily equated. Essential for fair comparison of superior deviates are sufficiently high "ceilings" in different sections of the tests, equality in population samples, and statistical adequacy of sample size at the gifted level. Appropriate consideration should also be given to the pos-

TABLE 2

SEX RATIO IN TOP RANGE OF GROUP-TEST DISTRIBUTIONS IN HIGH SCHOOLS AND COLLEGES

Investigator and Tests Used	Population Tested	Numbers Tested			Ratio *

sible involvement of differences beside the intellectual, such as social motivation, physical endurance, and fatigability in learning situations and examinations, and amount of practice and experience with different kinds of subject matter. Such factors may complicate the measurement of intelligence more at the extremes than at the means. The existence of a sex difference or its amount can be indicated certainly only when the secondary factors are eliminated and the comparisons are made with group or individual test techniques equally fair to both sexes at the part of the scoring range involved.

Heredity and Home Background. Gifted children may come from humble or from superior homes. In Terman's group 31 per cent of the fathers were professional; 50 per cent, semi-professional or in business; 12 per cent, skilled laborers; and less than 7 per cent, semi-skilled or unskilled. In Witty's group 64 per cent were in business, 34 per cent were professional. In terms of proportional representation in the general population the professional class has ten times its quota of gifted children; the commercial and public service groups exceed their quota by 50 per cent, whereas the industrial group contributes less than half its share. Even so, the large non-professional general population is so great that its numerical contribution to the gifted group is more than twice that of the professions. Groups of superior, but not gifted, children show relatively similar distributions in occupational and professional homes (Blair, 1938). Rated on the Barr Occupational Scale, the fathers of Terman's children show a much higher average index than the theoretical norm for the general population. And the fathers of two gifted children rate higher than the fathers of one. Witty has pointed out that the average Barr rating for the fathers of high school children, average IQ 111, is approximately halfway between the index of the fathers of gifted children and the estimated theoretical index for the general population.

The good stock producing the gifted is further indicated by the statistics for education and various measures of social value in the parents. The education of the fathers and mothers in the California study averages 12 years; the grandparents had less schooling than this, but more than the average in their day. Witty's Kansas and Missouri mothers also average 12 years of education; his fathers, 13 years. Among the parents of Jones's group, which seems to have been drawn from a university clinic, 55 per cent of the fathers and 24 per cent of the mothers were college graduates. These figures are higher than are generally found for the parents of typical gifted pupils in public schools. In the California group one or both parents of a fourth of all the children held a college degree. In Witty's group 50 per cent of the parents had 2 years or more of college training.

It is characteristic for gifted children to be born in families where positions of honor, trust, and responsibility are the rule rather than the exception. Terman found among the members of 528 families of gifted children more than twice that number of political, religious or fraternal, professional, financial, or executive positions. Witty reports similar results. Eminent relatives are also numerous in the families of the gifted in Terman's group, including 14 members of the Hall of Fame, 25 men and women listed in *Who's Who,* and 57 relatives in the *American Encyclopedia of Biography,* or an equivalent source. The fathers and mothers of the gifted children report a large and varied interest in hobbies (Witty, 1930). Teachers regard gifted homes as probably favorable in 85 per cent of Terman's cases, unfavorable in 9 per

cent; in a control group the corresponding figures are 62 and 24 per cent. Further statistics indicate energy and stability in the families of the gifted. The average family containing a gifted child has 3.35 children when completed, showing a relatively small decline from the 3.67 children in the completed families of the parents. The correlation coefficient between the schooling of the parents and the size of the family is $-.21 \pm .07$; between IQ and size of family, $-.27 \pm .06$. Seven per cent of the parents of the gifted have been divorced or separated as compared with an estimated rate in the general population of 8 to 9 per cent. Infant mortality and morbidity rates are low in the families of the gifted; only 8 per cent of the fathers and 12 per cent of the mothers report as much as one or more, often minor, chronic illnesses. In agreement with Cattell's findings for men of science, where there are two or more children in the family, the gifted is likely to be the first-born.

Physical Traits and Health History. Baldwin's study of the California gifted group finds them superior to the age norms in thirty-four anthropometric measurements, including height, weight, general physical development, and muscular energy (Burks, Jensen, and Terman, 1930). Age for age, they exceed the developmental norms for average children. In height and weight they resemble private school children and other select groups drawn from superior population samples and enjoying more adequate physical care than average children (Table 3). At each reported age the gifted boys considerably exceed Shuttleworth's (1939) superior socioeconomic group; they are slightly taller and heavier than Baldwin and Wood's (1923) norms; and they almost equal Gray and Jacomb's (1921) norms derived from exclusively healthy, private school children. Witty's (1930) results also show better than average bodily development.

Hollingworth and Taylor's (1924) data for 45 gifted Jewish children in New York City are in agreement with the other results with respect to height, and show, in a comparison of their results with norms for average and feeble-minded children, that a positive intelligence-height relationship is present. These children were also especially well nourished, as indicated by height-weight coefficients, and their strength, measured by dynamometer test, was supe-

rior to that of average and vastly superior to that of dull children of the same age. The height of these children measured year by year for a 6-year period continued on the average about 5 per cent above the norms (Hollingworth, 1926*b*). Monahan and Hollingworth (1927) found gifted children appreciably superior in neuromuscular capacity as measured in strength of grip, in jumping, and in tapping speed. The early studies of Cleveland (1921), Yates (1922), and A. M. Jones (1925) are in agreement with the more recent and more detailed results in indicating superior physical development and energy with infrequent physical defects. Hildreth's (1939) 50 upper centile elementary school children of Jewish race were superior to a matched control group in energy, physique, activity, and resistance to fatigue. In this connection the exploratory psychogalvanic research of Collmann (1931) is of interest. He found that superior children (average IQ 138) are less disturbed emotionally by an experimentally stimulating situation than average children.

Health histories were secured in Terman's and Witty's studies. The general conclusion from both researches is that gifted children are generally above the average in physical health and strength. The parents of the gifted are in the prime of life when the children are born, the fathers in the early thirties, the mothers in the late twenties, in agreement with Cattell's figures for the parents of 865 men of science. In the California group only 4.4 per cent of the children were born prematurely. The mother's health during pregnancy was rated as poor or very poor in but 7.8 per cent of the cases. The mean birth weight for both the California and Middle Western infants was approximately 12 ounces above the norm as given by Faber and Holt. Of the California gifted children, 57 per cent were breast-fed 8 months or longer as compared with 39 per cent reported by Woodbury in a norm group. In three successive health reports of Witty's gifted, superiority was maintained by upwards of 84 per cent; 90 per cent were reported to have good or excellent health during the first year. Sixty-eight per cent reached or exceeded a control group in health index in Witty's first study. Witty's children cut the first tooth at 6.8 months, Terman's at 7 months, in comparison with the norm range from 6 to 9 months. Terman's group talked at 11.3 months; the boys at 11.74 and the girls at 11.01. The average age for taking the first step was 13.05 months; for the boys, 13.10 and for the girls, 12.87. These results were compared by Terman *et al.* (1925) with Mead's norms: walking, 13.88; talking, 15.3 months. Talking appears in Witty's and Terman's gifted children to be slightly more precocious than the other activities reported from this early age. Comparison of the California elementary school gifted children with a control school group shows relatively fewer gifted children with defective hearing, mouth breathing, stuttering, headaches, or other symptoms of nervousness. The hours of sleep for the gifted are, age for age, more than those for the control group. Increasing from year 7 the difference amounts to about three-quarters of an hour at 12 and 13 years.

Pubescence was reached somewhat earlier by the gifted than by control children. Thus 100 per cent of Terman's 14-year-old boys were postpubescent as compared to 53 per cent of the control boys; and 48 per cent of 13-year-old girls had reached menarche in contrast to 25 per cent of control girls.

In the California study detailed medical examinations were given by two pediatricians to 783 gifted children. The careful individual appraisals by the physicians led

to an expressed impression that major and minor defects are much less common among the gifted than among unselected children, and that "other things being equal there is a direct correlation between physical health and mentality in children when studied in groups." The home care, cleanliness, and health habits of the majority of the children indicated by their diet, hours of sleep, etc., were evidence of the superior intelligence of the parents. The conclusion was reached that, physically, the gifted child ranks above the average child of the community.

School Progress. Early attendance, relatively rapid grade advancement, and more than average interest in the more theoretical subjects characterize gifted children in school. Of the California gifted group in the early 1920's, 3 out of 5 attended kindergarten before entering the elementary grades at the average age of 6 years, 3 months. One out of 5 skipped half the first grade, and 1 out of 10 was immediately entered in the second grade on beginning school. Acceleration tended gradually to increase so that by the time the elementary school course was completed one entire grade had commonly been skipped. Of Terman's children 85 per cent skipped one or more half grades. After skipping, and so missing a segment of the curriculum content, the gifted children were, in the teacher's opinion, entitled to still further advancement, 8 out of 10 deserving additional promotion. Although 4 per cent had actually repeated a half grade, no elementary school child in the California group was retarded in terms of age-grade standards. In terms of mental age and of tested educational accomplishment, however, the group was far below the appropriate placement, a characteristic condition of gifted children in school. The mean progress quotient (grade age divided by chronological age) was 114 for the California group, 116 for Witty's group. If the average gifted child were promoted in terms of mental age, he would be at least 2.8 years advanced at age 7, and at age 11 he would be entitled theoretically to placement in the tenth grade or higher by reason of his 5 or more years of acceleration. It is not, however, suggested that promotion in the regular school should be made in these terms, although the frequently serious misplacement of the gifted is clearly indicated by these figures.

The school work of the gifted is rated subjectively by their teachers as superior to that of their classmates in debating, history, composition, literature, grammar, general science, geography, civics, reading, and arithmetic. The contrast in the quality of the work is most conspicuous in subjects requiring verbal comprehension, usage, and formulation; least so in activity subjects little correlated with intelligence, such as physical training, sewing, drawing, clay modeling, penmanship, manual training, painting, and shopwork. In five elements of musical sensitivity measured by the Seashore tests, Hollingworth (1926*a*) found 49 gifted children (IQ 135+) undistinguished from a control group of the same age. In speed and quality of penmanship Hollingworth and Cobb (1928) found the performance of the gifted children very close to the norms for their age. Because of their more frequent superiority, the average excellence of the gifted in 29 subjects combined is one step higher on a 7-point scale than that of control children (Terman *et al.*, 1925). Witty's results are in agreement in showing excellence, whether qualitatively or quantitatively measured (Witty, 1940*a*).

The weaknesses of the gifted appear most often in subjects requiring manual coordination or dexterity; those of the control children, in work requiring abstract thought. For the gifted, 68 per cent of

the weaknesses are in writing, art, and handwork, as against 16 per cent for the control. Conversely, 17 per cent of the gifted are reported weak in such subjects as arithmetic, English, and history, whereas 61 per cent of the control children are weak in these subjects (Terman *et al.*, 1925).

Gifted children's school subject preferences correlate with the teachers' estimates of the quality of their work in the different subjects to the extent of .41 (Terman *et al.*, 1925). Witty found the same trends of preference, especially toward the verbal subjects (Witty, 1930). The boys are more alike in their preferences than the girls, and the gifted girls resemble the gifted boys in their choices more than they do the control girls. Subjects rated as easy by the gifted more often than by the control are again the more abstract and verbal: literature, debating, history, and grammar; and the preference and ease ratings correlate to the extent of .59. The normality of the gifted is indicated by their resemblance to control children in giving a high preference rating to games and sports as a school subject (Terman *et al.*, 1925).

Gifted children are regular in school attendance, very infrequently dislike school, and in more than half the cases—54 per cent for the boys and 70 per cent for the girls—have a "very strong liking for school." In the grades they devote on the average two hours of homework per week to school lessons (Terman *et al.*, 1925).

School Achievement. Educational achievement quotients from the Stanford Achievement Tests of gifted groups indicate without exception performance notably above the average, yet these scores age for age are little correlated in gifted children with years of grade school attendance. Intelligence, not formal schooling, largely determines their level (Terman *et al.*, 1925). For the brightest children in regular public school classes they are generally relatively lower than for the moderately superior children (Cohler, 1941; Johnson, 1942). The highest quotients so far reported are those from two New York City groups: (1) two opportunity classes where half the regular school time was devoted to the prescribed grade school curriculum, the other half to an enrichment program; (2) a mixed group of individual pupils in regular classes where no special enrichment had been attempted (Gray and Hollingworth, 1931). The unusually high scores in both groups suggest that exceptional motivation had been elicited through some technique of test administration. Relative to their IQ's, the two groups are closely equated in achievement, thus demonstrating neither advantage nor disadvantage in regular school accomplishment from (1) segregation, (2) shortened time for prescribed subjects, or (3) enrichment in the addition of special subjects. However, the fact that the opportunity class children achieved thus well after spending only half as much time on the subjects should not be lost sight of. Terman's large groups reported in 1925, Witty's 1930 group, and Terman's 11-year-olds from the 1925 group reported in 1930 also show high standing in terms of achievement quotients. But children, especially girls, selected in California for their high IQ's in 1922 and tested in achievement as 11-year-olds 5 to 7 years later show considerable regression in score from the means of those whose achievement was measured near the time of their qualification for the gifted group. Other score series may be compared with these (see Table 4): Patrick's (1924) upper centile opportunity group, Cobb and Taylor's (1924) gifted opportunity groups, Hildreth's (1938*b*) three IQ levels from regular classes in the Lincoln School, and

• Medians reported. † Means reported. ‡ Approximate based on group tests.

Woods's (1929) private school children with superior group IQ scores.

The differences in the various series of data raise many questions. To the extent that they are in agreement they show marked superiority in the average scores for the gifted; persistent excellence as compared with superior, but not exclusively gifted, private school pupils. In general, differing IQ levels are seen to maintain their relative status in achievement test scores. Differences in teaching emphasis may be involved in the contrasts and perhaps, as mentioned above, test motivation also. These factors, together with regression, here produce diverse score patterns under varying conditions of age, grade, and school curriculum.

Hollingworth and Cobb (1928), comparing a series of achievement test scores of two gifted groups of 20 children each as they progressed in a special public school opportunity class during a two-year period, found a brighter group, clustering around 165 IQ, maintaining its superior status over a less bright group (145 IQ), although educational opportunity had been the same for both. Results showed the excess for the higher IQ group to be most marked in tests measuring the more complex abilities. The higher IQ group was more than a year in advance of the lower group in all the reading comprehension tests, in spelling, in nature study and science information, and in difficult mathematical processes including fractions and long division. Later Hildreth (1938*b*), comparing three IQ levels from grade to grade in the same private school classes, also found no tendency for IQ differences to become ineffective under conditions of similar class instruction plus special coaching for the lower IQ's.

Studies of achievement scores have been reviewed by Gray and Hollingworth (1931) and by Terman and Burks (1933). The reported researches are in agreement with

those cited here in showing (1) superior school achievement scores of the gifted as compared to their age norms, (2) relative inferiority in most groups of educational age scores as compared to mental age scores, (3) equivocal evidence with respect to the advantages and disadvantages, as measured in available test scores, of special opportunities and programs.

DeVoss (Terman, 1925) made a careful study of the specialization of ability in achievement test terms, which he illustrated with case studies. He concluded that the achievement profiles of the gifted are like those of average children in pattern, but they rate at a much higher level. The score disparities in the various school subjects are similar and the gifted are no more one-sided than average children. Typical good readers tend to be relatively deficient in arithmetical computation, good calculators excel in science information, but are somewhat less capable in the language functions. Good spellers are relatively more successful with exact scientific work, including arithmetic, and less successful in verbal interpretation. In both gifted and control profiles the range from the best to the poorest single performance level is relatively narrow. The unevenness of scores, in younger children especially, can hardly be accounted for by differences in training and is believed to show the influence of innate factors. When measured in terms of standard scores with the intelligence level at 100 per cent, the high achievement level of the gifted is only 62 per cent above the chronological age norm. Measured in terms of educational quotient, the corresponding percentage is 80. Abilities in the various school subjects correlate more closely with general intelligence ratings than with any special ability for which measures were available in the gifted study.

As a corollary to the study of the evenness of achievement, the evenness of mental ability was rated by the teachers for the gifted and a control group with results favorable to the gifted. The question, as stated to the teacher, "Is child's mental ability very even, ordinarily even, rather uneven or very uneven?" may be interpreted in terms of day-to-day stability of performance or in terms of capacity for various types of work.

Extracurricular Pursuits and Interests. Somewhat more than half Terman's gifted group study music, drawing, painting, dancing, language, etc., outside the regular school curriculum. An average of 6½ hours a week is devoted to these studies by those who pursue them. The parents report noting superior ability in special subjects and in general intelligence as indicated in Table 5. It is of interest that 8 per cent of the parents report that they have never observed indications of superior intelligence in their children; 6 per cent more give no response to this item. Those who report recognition of intellectual superiority state that it was first noted just before 3½ years of age in the girls and a little later in the boys. Musical ability is noted on the average at 5 and the other special abilities at 6. The parents enumerate quick understanding, great curiosity, retentive memory, early speech, unusual vocabulary, and extensive information as the most frequent early indicators of superior intelligence.

Approximately 70 per cent of the parents state that they allowed the child to go his own pace in school, 19 per cent encouraged rapid progress, and 9 per cent held the child back. Most of the parents attempted to encourage progress by answering questions and by taking interest in the child's interests; few parents carried out systematic plans of home training.

Approximately half the California gifted children learned to read before starting to school. In Witty's group 38 per cent

learned to read before the age of 5; and of Terman's children 20 per cent learned at this age, 6 per cent before 4, and nearly 2 per cent before 3. This precocious activity among gifted children is stated to have occurred generally with little or no formal instruction. Learning to read at an unusually early age appears to be a correlate of high IQ in childhood.

Reading is the favorite pastime of the gifted children as well as their best-liked and easiest school subject. Teachers report that 9 out of 10 in a group of 400 read more than the average, and that nearly 60 per cent read very much, in contrast with about 12 per cent of a control group who do so. Parents estimate that their gifted children devote each week 6 hours at age 7 up to 12 hours at age 13 to their favorite pursuit.

A record of two months' reading shows that the gifted read more than twice as many books as control children of the same age. From the age of 9 the gifted exceed the average children of all ages up to 14 in number of books read (Terman *et al.*, 1925). That superiority in this respect is not necessarily a favorable sign of later achievement is shown by the comparison of the reading records of Terman's adult success and failure groups. The members of the failure group had reported in childhood a greater number of books read than had the success group (Terman and Oden, 1940*b*). Excess in this respect may admit of two interpretations beside the apparently favorable one: overstatement may be characteristic of some gifted children, and social withdrawal or flight from reality may be present in some children who read excessively.

Gifted, like control, children prefer, if they are boys, first of all stories of adventure or mystery; if girls, stories of home and school life; but gifted children name also many more works of genuine literary excellence, including two to ten times as many books of poetry and drama, science, history, biography and travel, and definitely less popular, emotional fiction. Another investigation concurs with these results of Terman's in reporting superior quality in a larger proportion (49 per cent) of high IQ than of control (9 per cent) children (Cleveland, 1921). The Californians' best-liked book was a favorite for both gifted and control children; but boys and girls had only 5 of 20 favorites in common.

Gifted children express slightly stronger interest than do unselected children in the various activities that occupy their out-of-school hours. Sex differences rather than intellectual differences largely determine the trend of activity choices, yet a real contrast is shown between the gifted and unselected children in the number of collections made at all ages from 6 to 13. The gifted make about twice as many collections as the control, and the number of these having scientific interest and value is twice as large (Terman *et al.*, 1925).

The vocational ambitions of the gifted as compared to those of control children rate one and a half to two and a half points higher on the Barr Scale, a significant difference for the group as a whole. In the gifted group the preferred occupation rates nearer to the occupational status of the fathers than in the control group. The ambitions of the unselected tend, in terms of their abilities, to be more wishful than realistic, whereas the gifted may in most cases fortunately combine these two trends. Among the gifted, a small fraction chooses in childhood, and subsequently enters, occupations generally followed by people of average intellect and opportunity. Culture and custom limit the choices and the careers of the girls, as in some cases temperament or the lack of social or educational advantages does those of the boys (Terman *et al.*, 1925).

Results from Wyman's (Terman *et al.*, 1925) association test of (1) intellectual, (2) social, and (3) activity interests show characteristic contrasts between gifted and control groups in these interests, at each of four ages from 10 to 13. The largest differences are in the intellectual interests, but the social interest contrasts are also significant statistically. The differences in the activity interests are significant only at ages 10 and 11 for the boys and at 10 for the girls. Measurement by correlation of the relative effect of intelligence and intellectual interests upon school achievement shows that when the factor of intellectual interests is rendered constant intelligence and achievement correlate .76; with intelligence constant, intellectual interests and achievement correlate .49. Intellectual interest, although not so potent as intelligence, is thus found to be a possibly significant factor in school accomplishment. It is significant for all the school subjects except spelling and is greatest in the case of arithmetical reasoning. By a similar method, social interest and activity interest prove to be uncorrelated with school achievement scores.

Play Activities. The play interests, knowledge, and practice of 554 gifted children have been compared with those of 474 control children from the same elementary school grades (Terman *et al.*, 1925). In play knowledge the quotient of the gifted is found to be 136; that is, a 10-year-old intellectually superior child has as much play information as an average 13-year-old child. The boys of both groups somewhat exceed the girls in play information. The gifted express as much liking for games and fondness for playing with others as average boys and girls. The gifted are inclined to prefer playmates who are older than themselves and they show less sex preference in the choice of playmates than do average children of the same age. The average amount of play with other children, 2¾ hours a day for the boys and 2¼ hours a day for the girls, is somewhat less than the time so spent by the average child. Yet the normality of the gifted is indicated by their devotion of more time to play than to reading and study combined (Terman *et al.*, 1925; Coy, 1930). The play interests of gifted and average children are generally similar rather than contrasting. The slight differences appear to be associated with the somewhat greater mental maturity of the gifted. They tend to prefer games played typically by older children, and interest in the childish games wanes with them at an earlier age than in the average. These results derive from ratings on a play maturity scale (Terman *et al.*, 1925).

Lehman and Witty (1927) report 50 gifted and 50 matched control children interested in the same diversity of plays and games. The gifted girls engage in a somewhat larger number of play activities than the average girls; the gifted boys in

a slightly smaller number of play activities. The averages of the sexes combined prove to be identical. The gifted less frequently take part in certain kinds of vigorous physical play exercises and more often in games and pursuits in which reading is an element. Aside from reading itself, the best-liked activities are similar for the gifted and the control groups. The like sex intercorrelations of the preference ratings for 90 plays, games, and amusements, based on the children's own expression of attitude and participation, are above .80. This demonstrates that the games enjoyed most and played oftenest by gifted and average children are generally the same active social games, although gifted children prefer thinking games and those that are mildly social and quiet. Boys, whether gifted or average, prefer boys' games, and similarly girls, whatever their mental endowment, generally prefer typical girls' activities.

Personal and Social Character Traits. The traits of gifted children have been appraised by means of various tests and by ratings on elements of behavior defined for the purpose. The results, although lacking the statistical reliability and objectivity of the intellectual and educational measurements, seem to indicate through cumulative agreement that gifted children as a group tend to differ characteristically and favorably from unselected children. A wide range of tests and ratings has been reported by Terman and his associates (1925) for more than 500 gifted children and an equally large unselected control group. Witty's (1930) results for 100 gifted children are corroborative. In a number of other studies top centile or other superior children have been reported whose traits tend to resemble the strictly gifted groups.

When compared with control children in scores on tests of personal and social standards and ideals (Raubenheimer-Cady Series), the gifted children show far more favorable social preferences and social attitudes, more desirable preferences, less boastful exaggeration, less cheating, and considerably greater trustworthiness under stress. Sixty to 80 per cent of the gifted exceed the median scores on the separate tests of the battery (Terman, 1925).

On a total score, combining results for the entire series of tests, the average excess for the gifted children was 85 per cent, and the typical gifted nine-year-olds equaled or exceeded control children through age 14. Although both groups showed wide individual differences with interesting age-sex trends, the characteristic contrasts were maintained between gifted and control children. Witty's 100 gifted children were also superior on three of the same tests.

Freedom from psychopathic trends, as measured by Cady's version for children of the Woodworth Personality Inventory, showed a further superiority of the gifted children, with 67 per cent of the boys and 75 per cent of the girls equaling or exceeding the control median. Emotional stability measured by this test rates for the gifted more than 0.5 SD above the control children's average, a position maintained or slightly increased after four or five years, as demonstrated by retest (Burks, Jensen, and Terman, 1930). The individual consistency in earlier and later test scores (.42) is sufficient to indicate at least some degree of predictability of the characteristics thus measured.

The developmental-maturity quotients of some 50 top centile opportunity class pupils aged 9 to 12 were found by R. L. Thorndike (1940*b*) to indicate an acceleration approximately equal to that of their school progress. On the Furfey Developmental Scale the boys rated an average quotient of 114; on its adaptation by Sullivan the girls' quotient was 118. Wide

item variation was characteristic, with high maturity shown in the choice of books to read, things to think about, and future vocations. Interest and attitude scores on the Pressey Test were reported for a similar group (R. L. Thorndike, 1939). The total test scores of interests and attitudes corresponded more closely to the mental than to the chronological ages of these children. The boys rated as definitely more mature than the girls. Both sexes scored highest in the traits which they admire in others and in their freedom from fears and worries. Judgments of wrong and interests rated as less mature, although above average for both sexes. Individuals showed wide variability in item and subtest scores.

Character trait ratings made by teachers and parents on more than 1000 gifted and control children indicate that the gifted as a group appear normal or better in the estimation of the adults most closely associated with them (Terman *et al.*, 1925). Compared to a control group, their ratings are equal or higher on 25 traits including intellectual, volitional, emotional, moral, physical, social, and special ability traits. Parents and teachers are agreed ($r = +.70$) in ranking the order of superiority from marked excess in the case of the intellectual and volitional traits (difference more than 1 SD) to approximate equality in the physical and social traits. The ratings are found to be discriminative, and the "certainty of judgment" is fairly high. Single traits showing the largest excess for the gifted include common sense, originality, desire to know and to excel, self-confidence, sense of humor, truthfulness, prudence and forethought, conscientiousness, and leadership. In each of these traits 70 per cent or more of the gifted exceed the rated mean of the control children. In fondness for large groups, in freedom from vanity, and in cheerfulness the gifted differ least from average boys and girls. Although distinguished for leadership, in popularity they are close to the general mean. In ratings made five years later, the gifted still showed excess in the same traits when compared to a control group (Table 6), although the contrast was now not quite so sharply drawn. The rank orders of the trait differences were similar. Parents were inclined to see improvement with respect to conscientiousness and freedom from vanity, whereas teachers reported little change in these respects (Burks, Jensen, and Terman, 1930).

Teachers of New York City gifted children reported their pupils average or superior in a series of desirable traits (Specht, 1919). Reports by 31 teachers of superior children in St. Paul, Minnesota, are in agreement in finding the gifted children above the average in many traits, including courtesy, cooperation, imaginativeness, inquisitiveness, and willingness to take suggestions. These children have a keen sense of humor and are not inclined to become discouraged. Contrary to an older popular opinion, they are not considered especially forward, domineering, egotistical, or self-willed (Johnson, 1923; Laycock, 1933). Hildreth (1939) found 50 upper centile children, including 20 with IQ's in the 140's or higher, superior in personality traits to matched children of average IQ in the same school. Recorded notations for intellectual, personality, and character traits included nearly five times as many favorable entries for the superior as for the control children, whereas the latter showed excess in the unfavorable traits. The superior children excelled in activity and vivacity, independence, and self-assurance, they had more experiences to relate, their sense of humor was more often noted, as was also their willingness to face difficulties.

Simmons (1939) studied the suggestibility of 47 top centile, special opportunity class

* Data rearranged from B. S. Burks, D. W. Jensen, L. M. Terman, *Genetic Studies of Genius*, Vol. III, *The Promise of Youth* (Table 77, p. 190), Stanford University Press, Stanford University California, 1930. By permission of the publishers.

children, aged 8 to 11, matched for age and sex, with a below-average group. In each of the experimental test situations employed, the group of higher intelligence yielded to fewer suggestions than the lower intelligence group, the differences being statistically reliable. Subjective ratings on independence from others in thinking also showed a reliable difference in favor of the gifted.

Classroom attitudes of high IQ children are found satisfactory and in general superior to the average. The children take active part in class discussions (Johnson, 1923), they respect authority (Woods, 1929), and are responsive to school discipline (Terman, 1925; Witty, 1930). In Root's (1921) study, conformity and traditional orthodox behavior were reported as characteristic of superior as of average children. The favorable conditioning of behavior by home influences is suggested in the conclusions of McGehee and Lewis (1940) from a study of teachers' estimates of the attitudes of their parents toward 45,000 children in 36 different states. Superiority of the parents' attitude was highly correlated with the intelligence of the children. The gifted boys and girls had the advantage of parental attitudes rated as superior in 66 and 61 per cent of the cases as compared with the attitudes toward the normative groups in which 20 and 23 per cent were so rated.

Summary of the Traits of the Gifted. Studies of young gifted children, beginning with Terman's report in 1919 and including the work of Root, Jones, Goddard, and Whipple, are in agreement with the larger, more recent, more strictly defined (IQ 140+), statistically more fully treated results of Terman, Hollingworth, Witty, and their associates, Hildreth, and other contemporary investigators. The various aspects of the background, development, interests, and achievements of gifted children are found to be clearly marked by superiority, characteristically greater the more the trait in question is correlated with intellect. Gifted children are superior specimens physically as well as psychologically, and they tend to express a superior energy in their activities. They come from better homes and in many cases have had better educational backgrounds and opportunities. Yet, as we shall see in the consideration of individual cases, superior environments and educational advantages do not insure the production of crops of gifted children, and in capacity and accomplishment individual gifted children generally appear as unique and isolated individuals even against their superior backgrounds. We must, therefore, believe that inheritance of gifted traits is individual and complex and that training can only develop, never create, gifted capacity.

That there is no one-to-one correlation between intelligence and character traits is no surprise in view of the vast complexity of human personality. However, cumulative evidence seems clearly to demonstrate the better endowment of the gifted and their better training and development in social terms, as compared with average children. Techniques for precise measurement of causal relationships in this realm are not available to present-day research.

Progress of the Gifted from Childhood to Maturity

The relatively large populations of gifted children who have been intensively studied by psychologists no doubt include many all-round, highly superior individuals of whom it is reasonable to expect persistent growth at a level demonstrably above average and sustained continuity with respect to behavior and achievement. Because tests are fallible and the range of tested traits is narrow, some individuals who would rate

below more broadly defined gifted standards are by current practice necessarily included in the groups selected for study. Moreover, test errors and changes in developmental rate, whether constitutionally or environmentally conditioned, lead to score and rating regressions. However, the subsequent histories of children selected as gifted in childhood indicate that the errors and changes are not sufficient to invalidate the selection technique as a basis for group prediction, and the accumulated results point to the ultimate possibility of individual clinical predictions of fair reliability.

Gifted children were first reported at the elementary school level, where their presence was revealed in the earliest individual test surveys and where the problems of their education appeared most urgent. Studies of older gifted children have included (1) follow-up surveys, after a period of years, of groups investigated in childhood and (2) surveys of various young groups not previously studied, adolescents, and college students, usually selected in terms of group test scores, or of youth in relation to academic status. Duff (1929) and Witty (1940*a*) have reported the progress of gifted school children in the grades. Terman and Hollingworth and their associates have contributed the majority of studies of gifted adolescents and college students, and the only studies so far reported of gifted young adults. The data from all these researches are in agreement in indicating relative persistence in the characteristic trait patterns of the gifted as they grow older and continued contrast between them and average children in intellectual achievements and superiority of interests. A summary of illustrative results is presented.

In a preliminary follow-up of more than 1000 gifted children made two years after his first study, Terman *et al.* (1925) found that the typical educational acceleration was continued and the indications of superior ability appeared consistently in the school and home reports. Gains far outweighed losses in deportment, in group activities, in breadth of interests, and in the social adaptability of the group as a whole. Children who had skipped grades were reported to have gained in application and to be more often eligible for further rapid advancement.

In a more detailed follow-up carried out seven years after the first study, data for 900 children were gathered and analyzed (Burks, Jensen, and Terman, 1930). As far as possible the traits and characteristics measured in the first study were again evaluated. Intelligence was rechecked by two individual and two group tests in four population samples. The Stanford-Binet IQ results for children within the appropriate age range disclosed for the boys a small average decrease of 3 points, from 147 to 143; for the girls a sizable loss of 14 points, 149 to 135. The changes were apparently not correlated with age. In the groups of age 13 and under 20 who were given the Terman group test, the boys were significantly superior to the girls in score. The median Terman group test IQ for the retested children was judged equivalent to a Stanford-Binet IQ above 130, thus indicating maintenance of top centile status by 50 per cent of the group. The ninetieth centile was exceeded by 75 per cent. The retest Terman group scores were very little lower than those taken age by age in the high school group tested seven years before. Analysis of factors of environment, personality, health, race, and Stanford-Binet test structure failed to reveal causes of the score decrement. The slight drop in scores for the boys was attributed, in the absence of any other explanation, to a difference in the tests used or to simple regression; for the girls the larger decrement was attributed to these

factors or to a change in developmental rate and age of intellectual maturation. A sex difference in social motivation might also have been involved. Roughly paralleling the IQ scores, the Stanford Achievement Test quotients proved to be a little lower than they were in the first survey. For the boys the drop amounted to 6 points, for the girls, 10 points. Here again test standardization and regression factors were probably involved. Yet the scores were still far in excess of those of average children of like age.

Elementary School. The acceleration of the group in school grade status had continued and the projected Ayres-Strayer standards of educational progress showed no case of retardation. In comparison to the earlier acceleration of 67 per cent of the group, a slight gain had resulted in acceleration for 74 per cent of the boys and 84 per cent of the girls. Grade status continued typically above the chronological norm but far below the mental age status. School attendance continued to be regular, although liking for school had become slightly less strong. Attitude toward school was rated by the teachers as favorable for more than 80 per cent of the children. The amount of time devoted to homework had increased steadily with age. The gifted boys graduated from the eighth grade at the early age of 13 years, 1 month; the girls at 12 years, 10 months (Burks, Jensen, and Terman, 1930).

High School. Lamson (1930) studied the high school careers of 56 gifted children who had been identified as of top centile IQ status before the age of 9 years and placed on the basis of their high intelligence in special opportunity classes. They had entered high school from the special classes on the average before the age of 12 and they were about to graduate at age 16. Compared with a control group of 106 students in the same high school grades, the gifted were significantly superior in scholastic achievement and had a smaller percentage of failures, although in age they were two years younger. The gifted had participated in extracurricular activities to an extent exceeding the control group by 25 per cent. Lack of time and participation in other activities, including the reading of modern current fiction, study of music, and social dancing, prevented greater participation. The gifted impressed their teachers by their intelligence, the general quality of their work, and their sustained effort to an extent significantly in excess of the impression made by the control children. In self-control, general deportment, and appearance, they were rated as somewhat superior to the average pupils; in popularity and in conceit there was little difference between the two groups. In the teachers' estimations general deportment and quality of work improved for the gifted during a 2½-year period. Generally good health was reported for the high school years, and 6 out of 10 of the gifted expressed no regret at having entered high school at an exceptionally early age. Age 13 they considered the most favorable for high school entrance. Four out of five were glad to have had the advantages of the opportunity classes. Reasons for failures, activities participated in, offices held, honors, books read, and attitudes toward scholastic work were reported in detail.

Terman's gifted children (Burks, Jensen, and Terman, 1930) had consistently superior high school reports; a sample of 77 cases won "A" grades in their separate studies about four to eight times as frequently as the unselected high school pupils in the same classes. In every course, including science and mathematics, the gifted girls were given higher average marks than the boys. For the girls the "A" grades amounted to approximately three-quarters

of their school work; for the boys, to something approaching half. In the estimation of the teachers about one-third of the group showed remarkable ability in some special subject or subjects, whereas only 15 per cent were rated as weak. Excellence and weakness generally appeared in the same subjects as before. Parents reported specialized ability in something over 60 per cent of all the cases, including for the boys mathematics, science, debating, public speaking, or mechanical ingenuity; for the girls, art, dramatics, dancing, writing, household art, and music.

Tests of high school achievement showed marked superiority of upwards of 150 gifted children reported above the high school norms (Burks, Jensen, and Terman, 1930). In comprehension of literature (Burch Test) the two-years-younger gifted group rated more than 1 SD above the control mean; in algebra problems (Hotz Test) the average difference is .5 SD. In the Iowa Content Examination, including tests of achievement in English, mathematics, science, and history, the girls exceeded the norm by 1 to 1.5 SD; the boys by 1.5 to 2 SD. The high school senior norms for the separate parts of this test were exceeded by 10 per cent or more of the gifted group. In total score 97 per cent of the gifted boys and 100 per cent of the gifted girls exceeded the control mean.

Characteristic sex differences in preference for school subjects were shown by the gifted group, 241 boys tending to prefer the sciences and to show distaste for ancient languages, 196 girls liking art, English, and modern languages and disliking mathematics and civics (Burks, Jensen, and Terman, 1930). The amount of time spent on general reading outside school studies was slightly greater for the girls, with an average of 7.6 hours per week for them in contrast to 7.2 hours for the boys. After 14 the boys spent more time on home study than on general reading, whereas before this age the opposite was true. For the girls this change occurred at 13. Sex and age differences in reading interests continued, and reading was still preferred to all other occupations by both gifted boys and gifted girls. Active games were preferred to those that required little exercise, and games and exercise were next in preference to reading. About a third of the boys and nearly half the girls stated that they had been greatly influenced by a single "person, book, philosophy, or religion." The strongest influence was most often that of one or both parents. Interest in collecting tended to decline after 14, the boys having continued to make on the average more collections, including a larger number with scientific interest.

Acceleration was characteristic, as before. The boys graduated from high school at 16 years, 10 months; the girls two months younger. In high school and also in college the group as a whole was generally about two years younger than the age norm of their class. More than 80 per cent of the gifted group in high school expressed the intention of going on to college.

Characteristics and Aptitudes of Gifted High School and College Students. Social and personality traits (Raubenheimer-Cady series), when remeasured after a lapse of 4 or 5 years, showed little change in mean scores in similar age ranges (Burks, Jensen, and Terman, 1930). The correlation coefficient was .42 for 150 gifted children twice tested. The Wyman test of intellectual, social, and activity interests showed very small changes in average scores for the children retested 5 years after the original study. However, the correlations between the tests of individuals were not very high, ranging from .15 in activities to .37 in social interests and showing only a mild degree of permanence in interest type as measured by this test.

Personality ratings on 12 traits selected from the 25 used in the earlier investigation in general supported the previous findings in indicating marked divergence of the gifted group from unselected children in intellectual traits, moderate divergence in volitional and moral traits, and similarity tending toward equality in social traits (Table 6). Teachers and parents agreed fairly closely in the rank order of ratings and their estimates showed little change from those made 7 years before. Field visitors' appraisals placed the gifted at or above the hypothetical norms as follows: in achievement, boys 98 per cent, girls 99 per cent; in social adjustment, boys 81 per cent, girls 80 per cent; in environmental conditions, boys 95 per cent, girls 91 per cent (Burks, Jensen, and Terman, 1930).

The good looks of gifted children of high school age may contribute to their favorable social adjustment. Hollingworth (1935) reported that 10 judges rating from photographs agreed in finding the faces of 40 gifted children more attractive than those of a control group.

Tests given for the first time in the California study in 1927–1928 were the Watson Test of Fair-Mindedness, the Terman-Miles Masculinity-Femininity Test, and the George Washington University Social Intelligence Test. For each of these, results have been reported in detail for groups ranging in size from 75 to 175 individuals (Burks, Jensen, and Terman, 1930). In fair-mindedness the gifted differ little from other, generally older, groups of similar education. In mental masculinity adolescent gifted boys and girls resemble college men and women more than they do the youth of their own age. The boys differ from college men in more masculine ratings in the two sections of the Terman-Miles test where intelligence is associated with high masculinity of score; in items where culture, domestic sentiment, and literary taste have a feminizing influence on response, the ratings are less masculine than those of the college students. The gifted girls' profile resembles that of college women in showing a masculine score trend where this is generally correlated with high intelligence. In parts of the test where intelligence and intellectual interests exert little influence (Terman and Miles, 1936) gifted girls respond and score like average groups of their sex. On the Social Intelligence Test the median scores for the gifted are high above the age norms and even exceed the college norms. The high correlation known to exist between the scores on this test and intelligence test scores may largely account for these excessive ratings.

The Bernreuter personality profiles of 36 boys and 19 girls, mainly Jewish, of average age 18 years, 6 months, reported by Hollingworth and Rust (1937) are in general agreement with Terman's personality appraisals of the gifted in showing excess for both sexes in the traits of self-sufficiency and dominance and a lower neurotic tendency as compared to college students and adult norm groups. The differences tend to be significant for the boys, although for the girls they are so only in self-sufficiency.

Of 169 boys past 14 who took the Strong Occupational Interest Test (Burks, Jensen, and Terman, 1930) 23 per cent received "A" ratings in their chosen vocation (indicating interests like those of men in the three highest scoring quartiles in the vocation in question), 50 per cent received "B" ratings (resembling the interests of the men in the given vocation who rate within the lower quartile), and 27 per cent received "C" ratings (resembling the lowest 2 per cent of the men in the occupation in question). These results compare favorably with the scores for Stanford University seniors, who rate 32 per cent "A," 50 per cent "B," and 18 per cent "C" in their

chosen vocations. Chance ratings give only 5 or 6 per cent "A," 25 per cent "B," and 70 per cent "C." The gifted boys, although considerably younger than the Stanford seniors, have, as revealed by this test, already developed almost to an equal extent the interests characteristic of their probable future vocations. Although this is in part due to the fact that young boys of potential college ability resemble one another in showing the characteristic likes and dislikes of chemists and engineers, yet the presence of fair-sized groups of "A" raters in other "most likely" occupations indicates that there are here probably true occupational interests exhibited by gifted boys at a fairly early age.

Scientific aptitude scores of 41 gifted boys measured by the Zyve Test equal as a group the mean for nonscientific faculty members, rating above the mean for unselected freshmen and very close to halfway between the latter and the high average of graduate students in scientific departments (Burks, Jensen, and Terman, 1930).

That the gifted are by no means characterized by studious reclusiveness is shown in their social and leadership ratings and in their community activities. Both boys and girls report social interests, enjoyment in leadership and in managing other people (Burks, Jensen, and Terman, 1930). Eighty-seven per cent of the boys and 96 per cent of the girls report having held one or more offices or honors in a wide variety of extracurricular activities. It proves to be as likely for them to have won notice in any one of several kinds of extracurricular activities as in scholarship. The girls more often participate in dramatics, the boys in student organization and scout troop activities. Yates's (1922) group numbered more than twice as many gifted (28 per cent) as control (12 per cent) leaders in high school activities. Finch and Carroll's (1932) gifted high school seniors had held twice as many elective offices as the average high school pupil.

Studies of school and college leaders and leadership support these results by indicating the extent to which intelligence is a factor in social recognition and administrative distinction. High school honor students have been found to be younger, to rate higher in intelligence, and to graduate in less time than the average, although they carry more extracurricular activities (Zeigel, 1927).

In the reported studies there is no conflicting opinion regarding the value of superior intellect for leadership. Emphasis is sometimes laid on the need for due recognition of other desirable traits (Witty, 1930), but these, too, especially wisdom (prudence and forethought), motivation (will and perseverance), truthfulness, cheerfulness, stability of mood, generosity and unselfishness, conscientiousness, and sympathy, are more often found in conjunction with superior intellect than otherwise (Terman *et al.*, 1925).

Good health has persisted in 77 to 90 per cent of the gifted during the six-year period since the first survey. No more than 1 to 5 per cent report "poor health." Colds, headaches, and worry are relatively infrequent, and no more prevalent in the older gifted children than in the control group measured in 1921 and 1922. As compared with themselves in early childhood, fewer gifted boys but somewhat more gifted girls are reported to show signs of nervousness in the adolescent period. Organic disease is infrequent, occurring in only 4 per cent of the boys and 5 per cent of the girls. Serious eye trouble is present in less than 2 per cent of the gifted, and subnormal hearing shows decrease with age to less than 2 per cent of the group. The gifted children sleep less than they did at a younger age, but they continue to sleep

more at each age than unselected children; their parents report that 98 per cent of the boys and 95 per cent of the girls sleep soundly. Five deaths, or less than 1 per cent, occurred in the 643 members of the regular group in the seven-year period between the first study and the second (Burks, Jensen, and Terman, 1930).

The Gifted Children in College and After. In their college years the gifted children as a group have maintained their status intellectually, academically, and in social adjustments. Their later occupational and economic careers have also developed on the whole favorably. Six reports give psychological test scores of gifted groups in college. The academic and social adjustments are presented in two confirmatory studies. The college progress of Terman's gifted children was briefly reported in 1930 and again in 1940 for the larger population who had progressed so far (Terman and Oden, 1940*a*). Gray (1930) studied the scholastic aptitude ratings, scholastic records, physical measurements, and the extracurricular and social activities of 126 boys and 28 girls who entered Columbia and Barnard colleges at 15 years of age or younger. Although these youngsters had not been identified by high IQ's in childhood, we may tentatively group them with the gifted because their Thorndike Scholastic Aptitude Test scores average as high at college entrance as the means reported by Terman for gifted children in California (Burks, Jensen, and Terman, 1930). Special investigations of the intelligence scores at college entrance or later of groups of gifted children have been supplied by Hollingworth and Kaunitz (1934), Lorge and Hollingworth (1936), and Hildreth (1939).

The data from the follow-up reports concerning late adolescent or young adult mental status are in agreement regarding the extent to which the gifted maintain after 6 to 16 years from their first selection their early demonstrated capacity to reach the highest levels of tested intelligence. Eighty-two per cent of Army Alpha scores of 116 top centile children rated 10 years after first identification by Stanford-Binet test reached the adult top centile norm. Of the remainder all were in high centiles, none regressed to the mean. Gifted boys 18 years of age or older all scored above the ninety-seventh centile. Fifty-seven cases with IQ's 150 or above rated without exception in the top centile. About one-third of the 140's scored somewhat lower (Hollingworth and Kaunitz, 1934). In their CAVD scores, cooperative general culture and general science tests, and Army Alpha scores, and in academic accomplishment, 21 individuals identified as gifted in childhood attained as a group the high standing predictable from their early Stanford-Binet and school achievement test scores (Lorge and Hollingworth, 1936). Data for a selection of these appear in Table 7. The scores reported for the science and culture tests fall for the most part within the upper quartile on the college norms. In the CAVD test 18 out of the entire group of 21 score above the seventy-fifth centile for law school freshmen and A.M. candidates in Teachers College, Columbia University.

Hildreth (1939) reports the American Council Psychological Test scores in senior high school of 70 children identified as to Stanford-Binet IQ before the age of 13. On this test, in which children of average eleventh and twelfth grade ability rate near the fiftieth centile, the mean rating for 12 gifted children with early IQ's of 140+ reaches the 97.5 centile for college students the country over. This result is in agreement with a statement by Wrenn (1935), based on results for 39 of Terman's gifted children, that the gifted of 140 IQ status rate at college entrance at the ninety-

seventh centile on the A.C.P. examination. Fifty-seven of Terman's gifted girls rated a mean score of 84, and 69 of his boys a mean of 87 on the Thorndike College Entrance Examination as reported in 1930 (Burks, Jensen, and Terman). These scores were approximately 1 SD above the Stanford University average for the corresponding years. In 1940 Terman reported the scores of some 400 gifted as rating 1 SD above the "highly selected Stanford population and only a few points below the mean of graduate candidates for the Ph.D. degree in psychology." Gray's young Columbia entrants averaged 92, his young Barnard students 84 on this test, the former rating 1 SD above the Columbia College mean, the latter approximately .3 SD above the Barnard mean.

These various scores at college entrance are in approximate agreement.[1] They indicate (1) that gifted children tend to preserve at late adolescence or early adulthood their high centile test competence; (2) that children with IQ's of 140+ in childhood tend to rate within the top 5 to 10 per cent on the national college entrance psychological test norms and to average scores about 1 SD above the mean of highly selected student distributions; and (3) that a tendency to regression toward the college mean occurs in many cases, more often among the girls than among the boys. Hollingworth's conclusion that the gifted are those at and above the seventy-fifth percentile of college graduates for the country at large perhaps underestimates the Columbia norms and the gifted ability in view of Hildreth's results and Wrenn's conclusion. Further adult scores from larger groups are needed to define more precisely the college and adult test score level of the gifted and to determine the extent, if present, of a regressive tendency in scores from childhood to maturity.

The first large-scale study in adulthood of children identified in childhood as gifted was made by Terman in 1936, sixteen years after his initial cross-sectional survey (Terman and Oden, 1940*a*). Of 1500 gifted subjects on record 93 per cent were located; and of these 755 males and 555 females cooperated with information deemed unusually adequate and reliable, a high record

1 *Group Test IQ and Prediction.* Keys (1940), in a study of the college achievement of University of California students who had been given a Terman Group Test during their high school years, found an average IQ of 111 for the entering college group who failed to obtain the qualifying certificate for the third college year, an IQ of 115 for those who obtained the certificate but did not graduate, an IQ of 117 for those who graduated, and an IQ of 125 for honor graduates. A student whose IQ was 140 or higher on the group test proved to have 100 times as many chances of graduating with honors as the student with an average IQ score. Yet there were 6 of 19 honor students from the IQ range 105–119, and 8 from the range 120–139. Traxler (1940) has reported the median group test IQ of 68,899 college students in 323 colleges as 109, Q_3 117, Q_1 101, in terms of Otis equivalents of American Council Test scores.

These and other similar results raise several questions as yet unanswered by experimental evidence: (1) Were the early group test IQ's of the students scoring at relatively low levels, but later achieving university success, inadequate measures of their ability at the time the tests were given? (2) Had a change occurred for them in the rate of development between the time of the test and the time of graduating from college? (3) Can students adequately measured by IQ's no higher than these achieve college graduation and even distinction by reason of the excellence of nonintellectual personality traits? Terman's 1940 study of the later achievement of gifted children shows that for the top half of 1 per cent in IQ score other factors than the high IQ are involved in young adult success. What then of 130 IQ's, 120 IQ's, and so on? It has been definitely demonstrated by studies such as that of Keys that there are relatively few individuals from the lower levels achieving the more distinguished successes. The formula for the diminishing returns is, however, as yet not determined. Further investigation is needed paralleling Keys' work, also systematic studies for comparison with the gifted and upper centile groups of the personality traits and careers of 130 and 120 IQ's.

in questionnaire response. Parents and teachers added their observations with similar completeness. Two age groups are included in the survey: the elementary school children of 1922 now in their twenties, median age 26; and the high school group of 1922 in the late twenties and early thirties, median age 32. The preliminary report of 1940 combines these in a single group. The reported loss by death, 3 per cent, is probably less than the expectation for a group of this age.

The girls' history is, as would be expected, shorter and less obviously significant than the boys', with only a few exceptional careers to mark the limits of high attainment. Eighty-five per cent of the girls attend college, and of these 90 per cent graduate. Class and student honors are frequent. Of the graduates, one-fifth are elected to Phi Beta Kappa, 3.5 per cent to Sigma Xi; half continue in graduate work, but few go beyond the M.A. degree. A fifth earn part of their college expenses as undergraduates, a third are self-supporting as graduate students. The occupational distribution of the 244 women who have completed their education and are gainfully employed shows 38 per cent in office work or business, 27 per cent in teaching, 9 per cent in music, art, or drama, 5 per cent in library work, 2 per cent in nursing, and 1.6 per cent in medicine. Of those who are not married or gainfully employed a number are engaged in volunteer social work. The average earnings (in 1936) of the high school graduate women are $90 per month; of those who attended college without graduating, $95; of the college graduates, $120. At each level the salaries amount to about half the corresponding income of the gifted boys. Fifty-one per cent of the girls were married at the time of the survey, and of these some 8 per cent had been divorced. The mean age at marriage was just under 23 years. Half the girls married college graduates; and the remaining half, men of more than average education. Four gifted intermarriages have occurred. Inclusion in the gifted groups has not, in their estimation, affected 65 per cent of the girls; 19 per cent record a favorable effect, 11 per cent an unfavorable one, and 5 per cent a mixed influence. The moral record has been good for the group as a whole. Sex delinquencies have been specifically reported for less than 1 per cent; alcoholic excess has been known in a few cases. Marriage and social life rather than intellectual pursuits have, as for girls generally, furnished the goals of the majority of the gifted. A few have achieved the Ph.D. or the M.D. degree or graduate distinction in law or engineering. A small number is carrying on superior administrative, business, or professional work.

Gray's (1930) study of 28 college women of unreported childhood IQ who averaged Thorndike college entrance scores equal to the Stanford gifted girls at the same or a younger age traces a similar picture for the college years. The 28 as a group had fewer college entrance deficiencies than the average student in the same college; three had state scholarship awards as freshmen; 79 per cent graduated, a relatively high percentage; but only 1 girl entered a graduate professional school. General honors were won by 3.6 per cent, special subject honors by 10.7 per cent, and Phi Beta Kappa election by over 21 per cent. One graduate fellowship and one scholarship were granted to members of the group. The health histories were favorable, and physical fitness test scores rated above the college average. In anthropometric tests the 28 were below the college average by reason of being younger; in motor ability, however, they exceeded the norms. They engaged in more athletic and other extracurricular activities than average college women.

Their responses to an emotionality questionnaire indicated more favorable adjustments than those of the comparable norm group. The later history of these students is not available.

Terman's 755 males surveyed sixteen years after their childhood IQ identification contribute a sketch outline of early adult gifted achievement in present-day educational, domestic, occupational, and economic life (Terman and Oden, 1940*a*). Nine out of ten enter college, and of these 95 per cent graduate. The gifted college student is three times as likely as the average to win graduation honors. About 16 per cent of the boys are elected to Phi Beta Kappa, 12 per cent to Sigma Xi, and some of the others win departmental distinction. Two-thirds continue in graduate work and of these 25 per cent receive a Ph.D. or M.D. degree, 25 per cent a degree in law, and 30 per cent the M.A. or some other predoctoral degree. Forty per cent are partially self-supporting as undergraduates, 14 per cent earn their entire expenses. The group as a whole earned more than half a million dollars in the undergraduate years. As graduates one-third are wholly self-supporting. A fourth of the entire group has won scholarships, fellowships, and assistantships to the extent of $200,000. The total record in class and student body honors is above average, and the course grade records are superior. Exceptions are attributed to poor work habits, lack of interest, maladjustment, or deliberate neglect of studies in the interest of special projects or social activities.

Forty-six per cent of the group are married, and of these 8 per cent are divorced. The mean marriage age is 24. The education of the spouse is above average with four of every ten of the wives college graduates. Forty per cent of all the married gifted of both sexes have offspring, numbering for the entire group 350. Seventy-three per cent of the gifted boys report no effects from inclusion in the gifted group; 13 per cent state that the effect has been favorable; 5 per cent regard it as unfavorable. The moral record has been above average. Exceptions include for the boys three criminal records and some cases of chronic alcoholic excess.

The occupational accomplishment of the group seems reasonably appropriate. Of the professions in which 50 per cent of the gifted engage, law recruits 13 per cent; engineering and geology, 10 per cent; medicine, 7 per cent; college teaching, 8 per cent; laboratory research, 5.5 per cent; religious or social work, 6 per cent. About 25 per cent enter semiprofessional or higher business pursuits and the remainder are engaged in office work, skilled trades, retail business, and a variety of other occupations. Less than 1 per cent of the employable members of the group were unemployed in 1936, and none was reported on relief. The salaries (in 1936) of the young adult gifted ranged from an average of $122 at 21 or 22 to $250 at 30. Ph.D. and M.A. graduates earned on the average $200 a month, physicians $217. High earnings include those of a lawyer, $12,000; a radio advertising executive, $10,000; an investment expert, $7000; a college professor, $8000; two musicians, $6000 or more. Some of these individuals may be on their way to the top salary class of adults (E. L. Thorndike, 1939). Half the entire group are launched upon careers worthy of their abilities. The arts have claimed several successful devotees, scientific research a number of others now already known for their publications. Bearing in mind that the financial and industrial depression of the 1930's coincided with the entrance of these youths on their mature careers, we find that the record as a whole is favorable.

Gray's (1930) 126 boys are younger

(under 16) at college entrance than Terman's gifted children (age 17). Their Thorndike entrance examination scores rate higher (92) than the mean (87) reported by Burks, Jensen, and Terman in 1930. Thirty-nine of the 126 had state scholarship awards constituting approximately one-quarter of the total number granted to 25,000 Columbia freshmen in the same period. The total group had fewer deficiencies at entrance than the average student. Eighty-four per cent graduated from college, 79 per cent in four years as compared to 72 per cent for Columbia students generally. Sixteen per cent won Phi Beta Kappa honors, 10.3 general honors, as compared to 8 to 10 per cent and 3.1 per cent, respectively, of their classmates thus distinguished. In correlation with their younger age, Gray's boys were shorter, lighter, and inferior in strength as compared to the average college freshmen; however, they exceeded their own age norms in both height and weight. In interclass athletics and in nonathletic extracurricular activities they participated to a larger extent than their classmates and they were more successful in winning recognition. In emotional adjustment scores they rated more favorably than reported norm groups, and they were, according to their own statements, capable of profiting by early college entrance in spite of the difficulties of such a course. About one-fifth of the group expressed the belief that guidance in establishing habits of thought and work was essential for younger college students, and an equal number stated that in their opinion the superior student is neglected by his parents and college.

As a whole the results of the several researches show the level of attainment reached by the gifted under existing social, economic, and educational conditions. The contrast between the careers of the girls and the boys shows a lower level of economic and professional competence in the former and illustrates a well-known sex difference in social expectation and occupational opportunity. Nor can it be denied that a deeper, psychophysiological contrast may also be involved (Miles, 1935; Johnson and Terman, 1940).

Successful and Unsuccessful Adult Achievement of Gifted Children. In a short survey Terman and Oden (1940*b*) present a fascinating preview of a comparison between the most and the least successful of 600 gifted boys, selected in childhood, and at the time of this survey 23 years of age or older. Success was rated by three judges in terms of the extent to which native intellect had been utilized in life accomplishment. The upper and lower quarters of the resulting distribution were compared with respect to educational and occupational status, intelligence scores, achievement scores and school marks, extracurricular activities, books read, family background, racial differences, marital statistics and offspring, home environment, social adjustment and traits of personality, occupational preferences, masculinity-femininity scores, and pubertal changes. The results are summarized in Table 8. The statistical significance of the enumerated contrasts is not stated in the brief report, but many of the differences seem large enough to be clearly meaningful and the trends revealed by series of small differences may prove cumulatively important.

The successful group had generally the more satisfactory family background in terms of occupational status, marriage permanence, parental education, quality of the home, home instruction, and mental stock as indicated by higher sibling IQ and by fewer cases of abnormality in the relatives. Racially, a relatively small but noteworthy contrast appeared in the greater number of Jews in the success group. In child-

* Data from L. M. Terman and M. Oden, "Correlates of Adult Achievement in the California Gifted Group," *Yearb. Nat. Soc. Stud. Educ.*, 1940, 39(I), 74–84, ed. by G. M. Whipple. Quoted by permission of the Society.

hood the less successful groups learned to read as early as the more successful, reported more books read, and performed approximately as well on school achievement, information, and intelligence tests. Parents and teachers had been able to discern in the successful gifted at a fairly young age slightly more favorable intellectual, social, moral, emotional, and especially volitional traits (Table 9). The successful cent graduated. The disproportion in the graduate schools is even greater. Somewhat more C's than A's had to earn their expenses in college, but five times as many A's as C's received honor appointments with stipends. The contrast in the amount of financial support thus won and in upper class and senior honors is more than 20 to 1 in favor of the A's. The slump in academic grades may too often be traced

Data derived or computed from [1] L. M. Terman *et al.*, *Genetic Studies of Genius*, Vol. I, *Mental and Physical Traits of a Thousand Gifted Children*, Stanford University Press, 1925 (Table 192, p. 542), and [2] L. M. Terman and M. Oden, "Correlates of Adult Achievement in the California Gifted Group," *Yearb. Nat. Soc. Stud. Educ.*, 1940, 39(I), p. 82, (Ed., G. M. Whipple), Public School Publishing Co.

or A group was slightly more accelerated in school than the unsuccessful C's; they reached puberty somewhat younger and during the high school period they showed superiority in school work, school performance tests, and extent of extracurricular activity. The differences in extracurricular activity are large, and they are probably significant in school marks, in Iowa Content Examination scores, and in leadership expressed in terms of the number of activities engaged in. Of the A's 98 per cent entered college, and 90 per cent graduated; of the C's 70 per cent entered and 50 per

to an unsuitable educational régime which retarded the child or youth until he lost interest or forgot how to study.

After college, or in some cases after high school, occupational or professional activity was rewarded by salaries showing a greater than 2-to-1 contrast in the early years and reaching a 3-to-1 difference by age 35. The occupational classification reveals the typical adult contrast of the two groups, with 95.6 per cent of the A's and only 28 per cent of the C's in the two higher brackets. Earning power and general success may be causal in the larger

number of marriages among the A's, but so also may be psychophysiological stability and balance. These factors may be involved in the 1-to-3 contrast in divorce frequency. The authors conclude: "The data reviewed indicate that *above the IQ level of 140, adult success is largely determined by such factors as social adjustment, emotional stability, and drive to accomplish.* To what extent these qualities are the product of environmental influences and to what extent they have a genetic basis, no one can say" (Terman and Oden, 1940*b*, p. 84, *Yearb. Nat. Soc. Stud. Educ.*, 1940, 39 (I). Quoted by permission of the Society.)

Individual Differences among Gifted Children

The large statistical studies of the gifted have necessarily stressed group trends, measured by averages, comparing these when possible with norms for unselected groups. Thus the typical traits and behavior patterns of highly intelligent children have been outlined against the background of the generality. However, as Terman, Hollingworth, and Witty have been at pains to emphasize, gifted children as individuals are not adequately represented by this method alone. The gifted, superior deviates as they are, are farthest perhaps from constituting a stereotype. Each individual is unique in the patterns of behavior that express character and in the traits whose vastly complex integration forms the personality. Essential statistical measurements of central tendencies in the intellectual, emotional, and social aspects of individual behavior result in oversimplified generalizations. These are qualified theoretically, it is true, by mathematical measures of dispersion indicating the wideness of contrasts in each separate trait of the gifted. Only acquaintance with individual gifted children can create the appropriate lively sense of unduplicated human personalities, differing even in the patterns and expressions of their exceptional intellects and in other traits covering the whole wide range of constitutional and functional potentialities.

Well-drawn case studies afford individual illustrations that diversify the interesting individualities whose performance and characteristics furnish the basis for the important statistical studies. Hollingworth, Terman, and others have provided long series of case descriptions indicating some of the possible trait combinations within the gifted group.

Superior mental endowment itself, the qualifying basis for the rating of gifted, may show contrasting characteristics in its expression. Thus the scientific, analytically ingenious, inventive child differs from the literary, generalizing, verbally expressive and retentive, interpretative child. In adulthood the former becomes characteristically the experimental scientist, the latter the writer or lecturer. Hollingworth's D and E illustrate this contrast (Hollingworth, 1926*b*; Burks, Jensen, and Terman, 1930).

Sustained intellectual capacity proved by repeatedly high intelligence test ratings is a characteristic of gifted children. Yet wide individual differences from test to test and large IQ changes are not infrequent with regressive score losses somewhat outweighing gains, especially in the girls. Thus Bertha, in a comfortable superior home and with an IQ of 139, deteriorated in scored IQ to 107 in six years. Clara, a clairvoyant's daughter, showed after six years a drop from IQ 148 to a T.G.T. score far below the gifted mean. In contrast, Terman's Madeline (IQ's 192 and 190) and David (IQ 184, Thorndike score 106) in childhood, and Hollingworth's cases 1 (IQ 190+, CAVD 454) and 20 (IQ 162 and

CAVD 429) in childhood and early adulthood, illustrate persistence in high scoring capacity. Madeline and David, described in detail, are able personalities with varied active interests and achievements (Burks, Jensen, and Terman, 1930).

In school achievement the gifted are superior as a group by whatever measure is applied. Test scores of accomplishment as a whole rate far above the general age norms (Terman and DeVoss, 1924). Yet here also wide individual differences are present in separate subject scores and in the total composite rating. Gray and Hollingworth (1931) have reported subject-quotient ranges for the gifted extending from 100 (average) to the upper test limit (210) and composite-quotient ranges from 119 to 187. The highest and the lowest of these quotients represent vastly divergent performance and competence. Achievement ratios (educational quotient divided by IQ) giving approximate measures of educational capability show extremely wide contrasts in the extent to which gifted children utilize their potential capacity. Lorge and Hollingworth (1936) report 105 and 106 as their highest childhood achievement ratios for 19 gifted children now college graduates, and yet these two scores belong to individuals with IQ's as diverse as 145 and 172. The two lowest achievement ratios, 83 and 85, in the same series, belong to children with IQ's of 162 and 174. Motivation and special influences may make high as well as low intellects more or less effective in the tests and also in the school work they are designed to measure (Tiebout, 1943). Two cases of gifted children with inferior scholarship records illustrate this deviation from the gifted mean. Edwin, IQ 141, failed eight subjects, rated C in sixteen units of work, and was finally asked to withdraw from high school because of his poor standing. His explanation was that he didn't like to work. Glandular disfunction was suspected by medical examiners. Thomas, IQ 142, had a mediocre school record as a result of devoting his time and effort to music, in which he excelled. In contrast with these rare cases whose performance is distinctly poor are the more characteristic gifted who do well in school, find the work in the lower grades relatively easy, score in the superior range on educational tests, lead the class in high school, and win distinguishing honors. Hollingworth's (1942) C, G, and L and Verda, one of Jensen's gifted juvenile writers, are among these (Burks, Jensen, and Terman, 1930).

In nonintellectual traits the gifted range from high to low in test scores and in behavior. Physical, mental, emotional, and social traits show wide deviations from the typical, superior averages of the group as a whole. Statistical expression generally shows about as great divergences from the highest to the lowest trait measures of the gifted as occur in unselected groups. Case studies again give concrete form to the statistics (see especially Burks, Jensen, and Terman, 1930). Beside the characteristically healthy, strong, well-developed gifted from superior stock and excellent homes there are also a few like Terman's Marshall. Hampered in childhood by physical frailty, lameness, poverty, bad heredity, and sordid environment, he became by 1940 a member of the young adult success group. Although coming generally from superior economic and social backgrounds, the gifted group includes the daughter of a Negro Pullman porter and the sons of an inflexible, Austrian-born laborer. Above the average in emotional stability, they number their share of behavior and adjustment problems, of hampering shyness, self-consciousness and inferiority complexes, of overbearing aggressiveness and conceit, of disobedience, dishonesty, laziness, and even a case or two of "queerness" and psycho-

pathy. Lack of motivation may appear or excessive driving ambition; neurotic avoidance of responsibility, and zealous, single track pursuit of personal objectives.

Hollingworth (1931) outlined special sources of personality disability to which the highest IQ's are liable and illustrated the consequences of these under varying conditions (Hollingworth, 1942). Gillingham (1920) described unstable and neurotic children at various high IQ levels. Terman enumerated the emotional adjustment hazards of the most superior deviates (Burks, Jensen, and Terman, 1930). Regensburg (1926) described clinically cases of instability and maladjustment and outlined methods of treatment. Nevill (1937) reported a statistical investigation of maladjusted gifted children referred for clinical diagnosis and guidance. Zorbaugh (1936) has enumerated the specific problems for which gifted children were referred to the New York University Clinic for the social adjustment of the gifted, and which cover the whole range of psychophysiological maladjustment indicators (enuresis, masturbation, stuttering, compulsions and mild obsessions, excessive daydreaming and fantasy, seclusiveness, temper tantrums, quarreling, defiance of discipline, truancy, lying, stealing, sex delinquency, and the like).

Terman described an unstable neurotic girl, IQ 152, a persistently delinquent boy, IQ 143, and a constitutional psychopath, IQ 165, who was finally a suicide. The statistics for high IQ's among neuropsychiatric cases are of interest in this connection. Schott (1931) found 18 patients able to rate a top score on the 1916 Stanford-Binet scale in a tested hospital sampling of 450 cases. The 4 per cent of highly intelligent individuals in this representative psychopathic group roughly equals the expectation as defined by Terman (1916) for the general population.

It is important to recognize that differences and contrasts are present in the superior intellectual trait profiles of the gifted and that these children, like unselected boys and girls, show unfavorable as well as favorable deviations from the group averages in measures of performance and personality. But a well-balanced picture of the gifted as a group shows more successful than unsuccessful members, more who maintain than who lose the superior quality of their intellectual interests and achievements, more who are stable, effective, and well-motivated than unstable, irresponsible, or deficient in ambition and drive. Favorable deviations are more frequent than unfavorable in the scores on tests of accomplishment and ability, whether scientific, literary, or artistic, in scholastic and extracurricular interests, in vocational choices, in indications of mental masculinity-femininity, of fair-mindedness and of social intelligence, of mental independence from suggestibility, of leadership, and of moral responsibility. Case studies of favorable rather than unfavorable deviates among the gifted illustrate the predominating membership of the group as a whole. Many such single cross-sectional pictures are available in which high IQ's are accompanied and supported by superior physical and social traits, excellence in studies and in extracurricular activities, and the favorable opinions of their companions. A few cases studied and described at intervals from childhood to adulthood afford the most striking proof of the persistence of gifted personality. Hollingworth's E, four times described (Lorge and Hollingworth, 1936, and Hollingworth, 1942), and Terman's David, Francis, and Henry Cowell are among the best examples (Burks, Jensen, and Terman, 1930). Adequately representative, in IQ terms, of the group as a whole, they exemplify in personality traits the effective, goal-seeking, eagerly,

patiently, and persistently ambitious whose ability is equal to the demands of their objectives and whose objectives are adequate for the realization of their potential talents.

Adjustment Problems of Gifted Children

The special problems of adjustment of the gifted are not, as was at one time supposed, primarily due to an essential emotional instability. Terman's results showed that children of high IQ's are not as a group less stable emotionally than a control population. On the Woodworth-Cady emotional stability questionnaire they rated as more stable than the control children at every age from 7 to 14. The critical ratios for the group differences were 6.11 for the boys (284 gifted, 258 control) and 7.61 for the girls (248 gifted, 275 control). Ratings of emotional traits by parents and teachers showed a statistically significant advantage of the gifted, and this was further indicated by an excess for them (68 per cent) above the control median. In social traits involving emotional elements a further series of ratings showed approximate equality of the group, 58.5 per cent of the gifted scoring as high as or higher than the average control child (Terman *et al.*, 1925).

Comparing superior with inferior school children, Laycock (1933) found that the superior individuals made superior adjustments. Conklin (1940), investigating the infrequent school failures of top centile children, came to the conclusion that in these relatively rare cases personality factors, as yet unanalyzed, were involved. Witty (1940*a*), following the careers of his 100 gifted children identified ten years earlier, found his group generally superior in poise and stability. Yet exceptions were present, and, although no child was rated as "queer" by his associates, 10 per cent were maladjusted. Of these there were two types: the anxious, withdrawn, insecure, and the indifferent, bored, socially inadequate. The failure of the environment to stimulate maximally and to develop habits of industry was mentioned.

Nevill's (1937) study of behavior problems in gifted children suggests no correlation between IQ and type of emotional difficulty or adjustment, although it does indicate that a high IQ is generally an advantage in accomplishing good adjustment. This research supports the conclusions of Gillingham's (1920) early report in indicating that gifted children, although as a group above average in stability, are not all as individuals free from emotional and social adjustment difficulties. No conclusion as to relative prevalence of problems can be made from either of these reports, as control group data are not available. That Nevill's gifted cases constitute 12 per cent of her clinical practice indicates the social and intellectual status of the clientele in the private clinic where the study was made rather than the incidence of instability among superior children.

Beside the typical constitutional-emotional problems coincident to nervousness, overanxiousness, sensitivity, and other typical personality disorders, and infrequent social problems such as lying and stealing, conditions now known to be less rather than more frequent among gifted than unselected children, there appear in certain of Nevill's gifted patients handicaps perhaps in part specifically related to their high intelligence. These include excessive quickness, resulting in inaccuracy, awkwardness, and clumsiness in writing and handwork when correlated with the younger life age, and impracticality, associated with lack of experience. Complaint is made in several cases of too much time spent in reading, of being self-centered

and bossy, and in a few instances of mixing poorly, being teased easily, solitary, resistant, or bumptious. These problems, more or less closely interassociated in individual children with high IQ's, are similar to those summarized by Hollingworth after years of close personal study of the gifted. Hollingworth's (1936*b*) classification includes: (1) problems of physique (being weaker and smaller than their classmates); (2) problems of adjustment to occupation (preferring self-direction to direction by others); (3) problems involved in "suffering fools gladly" (difficulty in accepting the dogmatism of lesser intellects); and (4) the tendency to be isolated in interests and goals. When a gifted child is also a sensitive or nervous child his adjustment difficulties naturally tend to increase (Hollingworth, 1942).

Nevill and Hollingworth agree that the difficulties inherent in brilliance do not create maladjustment, although they may predispose to unsatisfactory behavior not infrequently based on a sense of inferiority due to relative backwardness in social and physical development. The gifted become ultracritical, self-sufficient, or mentally lazy as a result of their semi-awareness of mental superiority, insufficient social experience, and incomplete independence in the development of personal responsibility. Successful treatment comes through early recognition of the problems and through cooperation of home and school in (1) creating a relatively normal milieu with appropriate social contacts and without overstimulation and (2) in building the intellectual understanding and the social habits of the child to meet the contrast difficulties that cannot be avoided.

Nevill reports that good adjustment occurs when parents and teachers (1) without expecting too much at first and without exaggerating the child's superiority have built in him a healthy natural pride in his powers, (2) have treated him as older intellectually while recognizing his emotional immaturity, (3) have encouraged his all-round development, and (4) have taxed his mental powers sufficiently at school. Hollingworth concludes that "intellectually gifted children between 130 and 150 IQ seem to find the world well suited to their development." They are superior in size, strength, health, and beauty, well balanced emotionally, and of good character; they tend to win confidence and to be granted leadership. Above 150 IQ the conditions may be less favorable.

Both Hollingworth and Terman have given attention to the highest IQ level where they find the need of special opportunity classes and special social adjustment most essential in order to avoid a sense of alienation and resulting negativism. The very exceptional children have few congenial playmates in childhood and little opportunity for normal social contacts with their peers. That 10 cases out of 35 IQ's 170+ are reported by Terman as lacking youthful social intercourse or even being seriously maladjusted is not surprising, in view of these considerations. It is perhaps more surprising that the average for this very high scoring group is only half a step below the mean on a five-step scale of social adjustment and that 64 per cent of the group rate as average or better on the same scale (Burks, Jensen, and Terman, 1930). Case studies of the highest IQ children show that their adjustments and satisfactions are mainly achieved in strictly intellectual fields and that these tend generally to be solitary. Their absorption in their interests and their individual emotional stability equations no doubt condition the extent of their comfort in their almost necessarily restricted social relationships. That their experiences have been sufficiently satisfactory and that they hold their own emotionally under the prevailing

conditions seem to be indicated by the presence of six of them in Terman's (Terman and Oden, 1940*b*) adult success group as contrasted with but two in his failure group.

Potentiality and Realization

The report of gifted accomplishment in young adults confirms the view that equality of IQ in childhood does not insure, although it predisposes to, equality of achievement in maturity. Intelligence is an important factor in accomplishment, but it proves to be only one factor among others, perhaps many others. Interrelationships among the factors may be as important for accomplishment as the presence of the factors themselves. The follow-up studies so far made suggest that more effective personalities emerge when heredity and environment are both favorable. No single unfavorable element in the picture has been found to block accomplishment in the gifted if a sufficient number of others are favorable. Similarly, no single favorable element has proved sufficient to insure the realization of potential ability along the many possible lines of gifted accomplishment or even along a single line. The highest IQ's (170 or 180 and above), although more often predisposing to success than to failure, do not necessarily insure the highest achievement. Nor do they, although sometimes associated with serious problems in childhood development, produce a condition of social maladjustment essentially thwarting (Terman and Oden, 1940*b*; Hollingworth, 1942).

Gifted groups include individuals of many possibilities. Intercorrelations between intelligence and special skills and abilities are generally positive, and the scores of the gifted have been demonstrated as above the average, sometimes far above, in tests and childhood achievements prognostic, under favorable conditions, of later distinguished accomplishment. Both boys and girls are capable of superior literary and artistic work and produce examples of superior merit at an early age, often in the preschool years. However, the social influences of our athletic, industrial, mechanized age are opposed to the cultivation of these gifts in childhood, especially in boys.

History and biography show few examples of high achievement in adulthood along lines requiring special skills of manual or verbal expression where practice has not developed native ability from youth. The economic pressures of our time direct the emphasis of school instruction toward the primary aim of individual self-support. Mechanical invention may be included as an objective in practical education, but the development of literary, artistic, and musical creation is usually secondary and generally occurs only occasionally in individual extracurricular experience. Literary juvenilia of merit in Terman's gifted group were all the work of girls, although boys are known to produce superior literary work in childhood and youth under appropriately stimulating circumstances. Writing has at present little prestige value among boys except occasionally in the homes of successful literary or artistic parents or in schools, generally private schools, where literature is cultivated as a highly valued expression of superior personalities. Lang (1897) believed that youthful literary achievement is a poor indicator of later work of merit, but in the arts the child is father of the man and we are therefore not surprised that Terman's adult gifted include fewer writers than scientists, business administrators, or professional men. It is natural to believe that any sizable group of gifted children probably contains many more who could become successful creative workers than who do, but the

means of developing these latent talents are not available and a valuable potential asset is thus usually wasted.

Scientific aptitude is another example of a talent present in the gifted group to a far greater extent than its probable realization in adult achievement. Social influences are opposed to superior scientific education and development in girls, and few of the potential scientists among them will reach a higher goal than high school teaching. Of the boys with this aptitude, the majority become industrial workers and engineers rather than contributors to the advancement of essential scientific progress.

Talents of superior grade in all the fields of human activity are no doubt present in any large group of gifted children. They are suggested or demonstrated by high scores on appropriate tests wherever these have been applied. No single individual, however, can in our complex society carry to a high level of achievement more than one or two human talents even under the most favorable circumstances. Mathematicians are seldom also superior artists or facile linguists, nor are engineers generally able to achieve high rank as poets or musicians even if talent for the necessary skills had been present in childhood. In science a man can today scarcely master more than a single branch, and literature, music, or art require complete devotion. A practical education, a brief apprenticeship, a few years of ill-paid junior business or professional service, the founding of a home, and the rearing of a family give little opportunity for the development of secondary or even primary talents in superior individuals even under favorable conditions. And conditions are frequently not favorable. Poverty, ill health, excessive responsibilities, social limitations, emotional handicaps increase the burdens of the personal, social, and economic life and prevent the realization in many gifted personalities of their potential capacity. For the feebleminded, society undertakes to lift some of the burdens and cast off the restrictions as far as this may be. The gifted, the potential leaders, discoverers, and creators, however, are usually left to develop their own skills in their own way and in terms of personal initiative alone. Fortunately many of them have the energy, the ability, and the plasticity to make the necessary adjustments, overcome the environmental obstacles, and win the necessary economic support (Bridgeman, 1930). Others, as Terman's (1940) young adult study shows, are more or less exhausted by the struggle and fall by the way. Discovering means of preventing failure and of increasing the effectiveness of the possible life contribution of the gifted is a challenging task. Identifying talent and cultivating it maximally is an essential in the development of the natural resources of a progressive society (Terman, 1939*b*).

The Education of Gifted Children

Systematic attempts to segregate and specially train gifted children have developed in some of the more progressive localities as a practical consequence of the selection and study of the gifted by mental test methods. Many schools emphasize enrichment and individualized instruction within their regular groups. Before these methods were systematically formulated a few far-seeing educators had tried to meet the needs of the brighter pupils by various administrative plans. These included flexibility in promotion, double or multiple track curricula with varying rates of speed, constant and shifting group systems, promotion on the basis of separate subject mastery, and self-reliant programs with or without preparatory training centers for the rapid advancement of the more suc-

cessful pupils at certain crucial points in the curriculum. In these procedures and their variations two aspects of individual and group differences in learning may be recognized: (1) diverse rates of advancement are appropriate for children of varying abilities, and the pupils at widely different levels on the intelligence scale can best be accommodated by some form of segregation or system of diversified progress; (2) wide differences in the amount and complexity of content that can be readily acquired by children of differing degrees of competence can be met by some flexible form of curriculum enrichment.

These principles were recognized and methods based upon them were developed by individual teachers of brilliant pupils long before they became the concern of administrative educators. Parents and tutors of able and precocious children developed their own systems of acceleration and enrichment. Karl Witte, Macaulay, and John Stuart Mill were instructed individually at rates of speed far beyond those of even the most superior private schools or opportunity classes, and the curricula devised for them were designed to cover by the age of 10 or 12 the elements and many of the higher aspects of liberal education, including the languages, literature, history, mathematics, theoretical science, and philosophy. Many other children besides, including Lord Kelvin, physicist, his brother James Thomson, engineer, Grotius, founder of international law, and the philosophers Bentham and Schleiermacher, were prepared by tutors or under flexible school plans which permitted college or university matriculation at the age of 11 or 12, followed by long careers of brilliant and active accomplishment. Men who achieve the distinction of inclusion in *Who's Who* and the notable group of starred American men of science have as a rule passed more rapidly through the elementary and college preparatory school years than the average boy. Enrichment of educational content came to them in part through superior private school instruction, in part through the personal interest of public school teachers, tutors, or friends, and in part as a result of personal initiative (Hollingworth, 1926*b* and 1942; Gray, 1930).

Private schools in the United States and elsewhere are actually carrying on the segregated education of superior pupils. Reports of the Educational Records Bureau (1940, 1943) and other sources indicate that approximately 90 per cent of the children in these schools are average or above in tested intelligence and educational competence, and that 5 to 25 per cent of them are gifted in the technical sense, having IQ ratings of 130+ or 140+. The average rate of learning in private schools is 15 to 20 per cent faster than that in the average public elementary school, an advantage that has generally been utilized in thoroughness and enrichment rather than by accelerated promotion.

Exceptional pupils are not adequately taken care of by the usual routine of the public schools. Often their very presence is not recognized. Thus Terman, among others, found that the more able public school children are discovered more readily in terms of birth date than by teachers' subjective nominations.

Public schools that have adopted multiple track or *xyz* class systems have partially met the need by their segregation of the average (y) from the dull (z), and the high average and superior (x) from the middle group. The x classes in many public schools enroll pupils approximately equal in ability to private school children. But just as the dull classification fails to meet the needs of the feeble-minded, so the above average group cannot sufficiently adapt its needs to its most gifted mem-

bers. Children with IQ's of 140 or even 130 and above have quite different learning needs from the group averaging below 120.

Special classes explicitly for gifted children are a development of the mental test period. Race (1918) reported one of the first where selection was based on IQ tests. The pupils, IQ 120+, were described as healthy, stable, and capable of more and better work than the average. Without excessive effort they covered the prescribed course content in half the regular time. Specht (1919) described in similar terms work of children of the same level of superiority in a segregated New York class. Whipple (1919), Coy (1923), and others have also reported success with above average children. Cleveland (1920) stated that the scholastic records of the segregated gifted children and their extracurricular pursuits exceeded, sometimes considerably, the typical student performance of their class group.

From 1920 onward until 1930 there was a gradual increase in the number of special classes. The children were generally chosen early in the elementary school course. Usually, due regard was given to health and personality factors. The teachers were as carefully selected as the pupils and they were given much freedom in the planning and conduct of the work. The cost per pupil was somewhat greater than in the regular classes, and for this reason small school systems with few high IQ children infrequently attempted segregation.

From 1918 to 1923 educational psychologists in Germany as well as in the United States were experimenting successfully with the segregation of superior children for school instruction. Selection by test, supplemented by teachers' appraisals of health, motivation, and personality, gradually took the place of reliance on either test or teachers' judgments alone. Alert, competent, well-adjusted teachers were given charge of the instruction of the gifted (Lämmermann, 1931). In other European countries mental tests have been used as a basis for the granting of scholarships in special schools rather than for segregation within the regular schools.

In the period from 1923 onward attention was directed in the United States chiefly to the curriculum and problems of enrichment. Early considerations were summarized and discussed by Whipple (1919), Freeman (1924), Stedman (1924), Henry and others, in the *Yearbook of the National Society for the Study of Education* (1924), Hollingworth (1926*b*), Jensen (1927), and Goddard (1928). Later methodology and objectives have been formulated by Adams and Brown (1930), Osburn and Rohan (1931), Dransfield (1933), Cohen and Coryell (1935), and in terms of basic principles by Hollingworth (1942). Bentley (1937), Carroll (1940), Heck (1940), and Garrison (1940) have summarized typical school attitudes and practices in the teaching of gifted children. Bibliographies have been prepared by Newland (1941), Gray (1942), and Hildreth and Ingram (1942).

Intraclass segregation of small groups and individualized project programs are developing where class segregation has proved nonfeasible. Hollingworth (1936*c*), from experience in special opportunity classes for the gifted, advises enrichment in the regular elementary school curriculum, including (1) courses in the development of civilized culture, using the project method; (2) biography of world leaders; (3) the tools of learning, including foreign languages; and (4) special work in art and music, including an introduction to appreciation. In the high school course Cohen, Coryell, and their associates (1935) emphasize the value and importance of teacher leadership and stimulation. Gifted pupils need to be associated

with teachers who are themselves enthusiastic devotees of the subjects they teach and of the culture to which these are essential.

The most usual method of dealing with the rapid progress possibilities of the gifted in the public schools is by the simple expedient of grade skipping. The average gifted child in Terman's group skipped at least one grade, and those who skipped more were reported by their teachers as doing better work than those who skipped less. An unpublished study of Hoskinson is reported by Henry (1924) in which high school and college students who had skipped one or more half grades were found to be characteristically rapid readers, quick learners, industrious, and able to concentrate. They had learned to study independently and they brought from home a good attitude toward school and school work. Eighty-seven per cent believed that the skipping had been advantageous to them. The more recent study of McElwee (1932) in which the personality traits of accelerated children were compared with average and retarded groups finds the traits of the advanced pupils consistently superior. Their attitudes toward school work and their school habits are reported to be especially good.

Results reported by Wilkins (1936) on the high school achievement and social adjustment of accelerated pupils are in harmony with these findings and seem "to give further evidence that the dangers attributed to acceleration (unless of course practiced unwisely) have been largely overestimated."

The United States Office of Education reported, for 1935–1936, 3009 gifted children enrolled in special classes of public school systems in fourteen cities at a cost of $176,672. The enrollment had decreased 25 per cent during the period of financial curtailment beginning in 1930. "The education of gifted children," the report explains, "has always constituted a subject for debate with a rather definite difference of opinion as to the effect of membership in a special class upon their social adjustment. Many fine things are being done for this group without separate organizations for their instruction" (Foster and Martens, 1938, p. 1). In many large cities the *xyz* systems are now expected to take care of intelligence grouping sufficiently to meet the needs of the gifted at the elementary school level. Enthusiasts for segregation repeatedly emphasize the values of the method in making possible the maximal mental stimulation and better social adjustment of the abler pupils (Orleans, 1940). Enrichment within class groups is said to offer a successful solution without the organizational and administrative complexities of specific segregation. Witty (1940*b*) effectively re-emphasized the undemocratic trend of gifted segregation in the public schools. He also contends that homogeneous grouping on a mental test basis is impossible. The evidence from the New York and other opportunity classes seems at variance with this view. Myers (1935) believes that the best all-round development of the gifted child results when he works at school at his own rate but in a regular class of normal children.

Research since 1930 has added little more than general confirmation to the earlier findings regarding the benefit of segregation (Heck, 1940). Lamson's (1930) segregated children excelled in high school above the average of their older classmates. Gray and Hollingworth's (1931) segregated gifted children, devoting only half their time to the prescribed curriculum, rated as high on educational achievement tests as nonsegregated children of equal intelligence who were spending full time on the prescribed work. A study of segregated and

unselected first-grade children by Dvorak and Rae (1929) led to the conclusion that both segregation and enrichment had positive value. Studies by Danielson and Herschberger (reported by Terman and Burks, 1933) record comparisons of special class gifted children with gifted pupils from the regular grades. The subject marks for the former were higher and their participation in art activities, athletics, dramatics, committee work, and office holding was greater. Teachers' ratings of the two groups were approximately equal on accuracy, dependability, and leadership. The former special class group received the higher ratings in cooperation, initiative, and industry. In answering the question "In which grades have you been the happiest?" the segregated twice as often as the nonsegregated mentioned those grades in which the special class experience occurred. A study by Herr (1937) showed that superior children (average IQ 125) completed the work of the seventh and eighth grades in one year without loss in school marks, achievement scores, or extent of participation in extracurricular activities as compared with groups of equal ability who performed the work in a two-year period. Health and attendance were satisfactory in the accelerated group. Personality ratings showed possibly significant differences which are not necessarily indicators of unfavorable effects from the acceleration.

The experimental work with gifted children in which segregated are compared with nonsegregated groups seems to point to the more favorable progress of the former as compared with the latter. The studies are too few to be completely convincing. Enrichment and intragroup instruction may be almost equally effective. The important finding with reference to the education of the gifted relates to the development of attitude and motivation. Gifted children, like others, require adequate opportunity and stimulation, and this can be more or less successfully given with due planfulness under various systems, so long as diverse rates of advancement are permitted and an adequately enriched curriculum is maintained. If segregation is used, selection in terms of total personality assets and needs is certainly desirable.

The Childhood of Genius

Biographical accounts of the early development of distinguished contemporaries or historic geniuses furnish psychological material of special interest for comparison with the observed and tested behavior of gifted children. Rate of mental development, frequency and type of precocious achievement, personality traits, especially the volitional, family background, educational opportunity, and social environment can be traced in biography and measured by the statistical methods of historiometry. It is true that tradition has not infrequently invested geniuses of the past with phenomenal characteristics and has popularly given them personalities unparalleled in contemporary cross-sectional studies. The factual material of reliable biography, however, can be viewed and weighed apart from exaggeration and excessive eulogy. When so examined the data, although often unfortunately too few, are comparable with current records. Gifted children of today undoubtedly include many of the leaders of tomorrow, and the childhood traits of the leaders of the past objectively evaluated can enlighten us about the most superior contemporary personalities.

Inquiry and controversy in this field have centered in the problems of the mental growth, the heredity, the special interests, the cultural opportunities and development, and the early physical and mental health of world leaders. Popular conclu-

sions about these matters drawn from biased selections of illustrative data have gained a hold on popular opinion that gives way only slowly in the face of careful, objective, statistical studies of large representative populations. The view that ability finds a way to distinction, whatever the social handicaps, probably takes insufficient account of the demonstrable advantages in the environment of successful leaders. On the other hand, the opposite opinion that training and opportunity make the man must finally fall before rigorous comparisons of achievements of the equally schooled but unequally gifted. Fallacious evidence of the presence in geniuses generally of instability, psychopathy, delay in development, and degenerative precocity has been brought forward by the fascinating, subjective method of descriptive anecdote (Lombroso, 1891). Conclusions based on selected data of this kind have no place in a scientific natural history of genius, although they may serve the desirable end of stimulating research for proof or disproof.

The first studies of large samples of objective data were made by Galton, who elaborated a statistical psychobiographical method. The superior hereditary background of eminent men of science, letters, art, and public life was demonstrated in every such study (for example, Galton, 1869; DeCandolle, 1885; and Ellis, 1904). Correlation was demonstrated between the appearance of genius and such factors as social and economic security, educational opportunity, and favorable cultural influences. The importance of environmental stimulation for the emergence of ability and the possible veto power of poverty or educational restrictions were emphasized (Ward, 1906). Reviewing his own results and those of others, Ellis advised caution in the interpretation of cause and effect in the nature-nurture composite of genius.

Sully (1886) and Ellis (1904) found healthy, persistent precocity characteristic of leaders and geniuses. Precocity in the field of special interest was demonstrated by 80 per cent in a group of 287 geniuses representing the principal fields of human endeavor. Mental acceleration was noted by the biographers of one-third of Ellis's cases, and only 4 per cent were said to have been "not precocious." Those who failed to show early mental superiority or strong intellectual interest were not among the more distinguished for original intellectual achievement in maturity. "In order to go far," Ellis concluded, "it is evidently desirable to start early."

The first general statistical survey of the boyhood development of great men was Yoder's (1894) study of fifty geniuses and leaders. The tabulated results minimized the importance of poor health stressed by Lombroso, although they showed how in individual instances, as in the case of Dickens, delicate physique could be of advantage in intellectual pursuits. Yoder's great men were above average in size, born of parents in the period of mature energy, and were normal in childhood development and pursuits, including sports. At an early age they had already displayed strong memories, active imaginations, and many of them had shown a scientific spirit of investigation. "Like ordinary men, they were influenced by their environment."

Characteristic advantages in background and education were enjoyed by 1036 noted American men of science selected by their scientific associates at the instigation of Cattell (1915, 1917), who planned, organized, and interpreted the statistics. The national and racial heredity of the scientists showed trends similar to those of the gifted, with the northern European and British stocks preponderant. Professional men contributed a disproportionate share of members to the group. The sex differ-

ence in numbers is commented upon. Contrast in the production of various geographical regions is statistically expressed and interpreted with respect to the influence of universities and great teachers. Thus Massachusetts and Connecticut were, for example, fifty times as likely to rear a distinguished scientist in the period studied as the Southeastern States. Centers of learning where eminent investigators attracted the best students produced many times their share of younger scientific leaders. Thus from Agassiz at Harvard came thirteen first-rank naturalists; from Brünnow at Michigan, a quarter of the leading astronomers of their day. Teaching and inspiration directed the line of study and interest, and the effective expression of native ability was augmented through personal contacts.

The studies from Galton to Cattell showed the importance for achievement of superior innate ability, good heredity, and adequate education. As yet superior ability had been defined in such terms as school achievement, literary or scientific accomplishment, or creative artistic production. These were not interchangeably meaningful. An index of general mental measurement became available in the Binet tests and these, as revised at Stanford, Terman proposed to apply to biographical material for the evaluation of the childhood development of great men. The IQ of Francis Galton thus appraised on the basis of early records proved to be near 200 (Terman, 1917).

To Terman's plan for IQ evaluation the Stanford investigator of the childhood of geniuses added appraisals of heredity, environmental factors, and ratings of personality traits (Cox, 1926). The results may with due caution be compared to the test results and ratings that make up the picture of the gifted children. The subjects of the genius study were 301 persons objectively rated among the 500 most eminent leaders of history and selected as adequately representing adult human distinction. The data from several thousand biographical works pertaining to the youth of these men, gathered into individual case studies, served as the basis for mental and personality trait ratings and evaluations of background and environment. Résumés of these materials are presented in the published study. Three experienced psychologists rated the items concerning mental behavior on an IQ scale, adding also in each case an appraisal of the adequacy of the data for this purpose. The agreement of the series of ratings is indicated by correlation coefficients of the order of .70. Two psychologists rated the environmental factors. One psychologist and one experienced teacher rated a series of personality traits for a representative third of the group. Tabulations of longevity and of fields of activity and a collection of early literary productions were also included in the published report.

The evidence of superior mental capacity in the subjects of this study is unequivocal. No individual, however meagerly reported by his biographers, was rated below average on the sum total of available childhood information. The three psychologists, advised to rate conservatively on the data alone, and as if the identity of the child were not known, found sufficient indication of superior intelligence to justify the conclusion that the group average IQ lies well within the gifted range. Ratings below 140 IQ resulted from regression of estimate when the data were too few for self-corroboration, or when they were of a sort as yet not adequately indexed in IQ terms (Table 10). Data evaluated as equal in reliability to an abbreviated Stanford-Binet test consisting of as many as two items per year-group gave an average IQ of 152. When the data reached the reliability of a Stanford-

TABLE 10

SCALE OF IQ RATINGS OF GENIUSES IN CHILDHOOD AND YOUTH INDICATING INCREASE OF RATING AS A FUNCTION OF COMPLETENESS OF THE DATA *

	Average IQ	*Relative Coefficient*
134 case studies with data equal to 1/12 to 1/2 test item per year group	124	.29
32 case studies with data equal to 3/4 test item per year group	139	.53
54 case studies with data equal to 1 test item per year group	142	.60
41 case studies with data equal to 2 test items per year group	152	.75
13 case studies with data equal to 3 test items per year group	171	.82

* Based on data in Table 8, p. 53, and Table 18, p. 76, C. M. Cox, *Genetic Studies of Genius*, Vol. II, *The Early Mental Traits of Three Hundred Geniuses*, Stanford University Press, 1926. By permission of the publisher.

Binet test of three items per year-group, the average IQ was 171. Psychological and statistical considerations indicated that if all the facts were available for the genius group the average rating would well exceed 160.

Wide individual differences were present in the mental scores of the members of the group as a whole and even in the smaller numbers of the more completely recorded cases. It was not possible to conclude that a high, narrow IQ range accounted for all. Men eminent as soldiers showed least conclusively the childhood behavior associated with high mental test ratings; yet a fairly satisfactory appraisal of their probable average IQ registered above 140. Adequately reported artists and musicians averaged 160; statesmen and imaginative writers, 165; religious leaders and prose writers, 170; scientists, 175; and philosophers, 180. The lowest uncorrected, individual appraisals based on material sufficient for a single, relatively dependable IQ estimate (reliability coefficient .75) were at 135, the highest reached 200. Among the estimates based on more complete and, hence, for this purpose more reliable material were those for John Quincy Adams, 165; Pope and Chatterton, 170; Coleridge, 175; Voltaire and Macaulay, 180; Grotius, J. S. Mill, and Leibnitz, 190; and Goethe, 200. IQ values statistically corrected to offset the error due to brevity in the records gave Darwin, Scott, and Mozart IQ's of 165; Longfellow, Luther, and Faraday, 170; Agassiz and Kant, 175; Dickens and Hume, 180; Davy and Galileo, 185; Berkeley and William Pitt, 190. The correlation between IQ and the rank order of eminence in the group as a whole was low. Eminence in terms of illustrious achievement qualifying for this particular group, although associated with superior intelligence, was therefore not demonstrably a function of the high IQ as estimated. Other traits or circumstances generally rather obviously accounted for the presence of the intellectually lower-scoring members of the group, for the occasional low scores of some who probably deserve much higher ratings, and for the low eminence ratings of a few whose IQ's were found equal to the highest ever reported. The author was of the opinion that even the statistically corrected values were in many cases too low to serve as fully satisfactory measures of these rare intellects. Yet the purpose of the study had been served in bringing to light the levels of intelligence which had been exceeded by the illustrious, as indicated even in the often scanty reports of their early achievement.

Ratings of the fathers' occupations showed the trends of superior heredity and the advantages of background available to the geniuses; 80 per cent of the fathers belonged to Taussig's two upper economic classes. Ratings of home training and discipline of a representative third of the group averaged two steps higher than the assumed norm on a seven-step scale. Breadth, in-

tensity, and kind of interests also proved superior to the assumed mean for children of equal mental age. Intellectual interests, intensity of a single interest, and breadth of interrelated interests rated especially high. Social and activity interests showed a slight negative correlation with the intelligence rating.

Sixty-seven character traits defined by Webb (1915) were made the basis of a personality profile of 100 of the more fully reported geniuses. Ratings considerably above average for the group as a whole were found (1) in four emotional traits: cheerfulness, imaginativeness, esthetic feeling, and excitability; (2) in three emotional-social traits: family affection, friendship, and loyalty; (3) in eleven social traits: fondness for a small circle of intimate friends, impulsive kindness, kindness on principle, trustworthiness, conscientiousness, desire to be liked, sense of corporate responsibility, sense of justice, religious interest, pure-mindedness, wideness and intensity of influence; (4) in two physical activity traits: energy or restlessness and physical bravery; (5) in all of the five positive self-traits: desire to excel, desire to be a leader, adequate self-confidence, self-esteem, and esteem of his own special talents; (6) in eleven intellectual traits: absence of suggestibility, degree to which action and thought are dependent on reason, keenness of observation, attention to detail, extent of mental work bestowed on studies and on special interests, soundness of common sense, originality and creativeness, strength of memory, quickness and profoundness of apprehension; (7) in four traits of persistence: degree to which he works with distant objects in view, degree of will and perseverance, tendency not to abandon tasks in the face of obstacles, or from mere changeability; (8) in balance; and (9) in strength or force of character as a whole. In Table 11 the personality traits are listed in which the geniuses are as distinguished or more so than they are in terms of their superior mental ability. In these traits they rate as a group at or above +1.5 on a seven-point scale in which 0 represents the mean and +3 the upper limit.

The conclusions from the data for geniuses support the view that good heredity and good home training are valuable assets for mature achievement and that superior interests are a basis of desirable stimulation. The youths in the genius group were probably without exception endowed with high, many of them with the highest, intellectual capacity of which human beings are capable. All of them had the capacity and the opportunity to develop motivation of a rarely superior order. The composite in their personalities of intellectual and emotional traits was so integrated and functioned so dynamically as to produce original, creative achievement in science, art, literature, philosophy, religion, or statesmanship. If leaders like these appear from among our gifted children they will probably also be found to possess not only high, often the highest, intellectual capacity, but also superior traits of personality, especially motivating power. Moreover, like these geniuses, they will no doubt benefit optimally from whatever favorable circumstances may enhance the effectiveness of their developing capacities.

The mental and physical health in childhood of fifty representative and well-reported members of this same group of geniuses and illustrious persons was rated and reported on by Miles and Wolfe in 1936. The mean physical health ratings showed 12 per cent of the group above average, 58 per cent average, 28 per cent somewhat below average, and 2 per cent with definitely frail health. In mental health 14 per cent were rated above average 64 per cent at the average, 14 per

TABLE 11

HIGH PERSONALITY TRAIT RATINGS OF ONE HUNDRED GENIUSES IN CHILDHOOD*

(Ratings are averages of two raters on a seven-point scale, +3 to −3, when 0 is the assumed average of the general child population.)

Intellectual Traits:	
Mental work devoted to routine studies	1.7
Independence of thought	1.8
Keenness of observation	1.9
Strength of memory	2.0
Quickness of apprehension	2.0
Originality, creativeness	2.1
Profoundness of apprehension	2.3
Mental work devoted to special pursuits	2.4
Social Traits:	
Trustworthiness	1.7
Conscientiousness	1.7
Wideness of influence	1.7
Intensity of influence on intimates	2.0
Self-traits and Motivation:	
Desire to be a leader, to impose his will	1.7
Correctness of his own self-appraisal	1.7
Correctness of self-appraised special talents	2.0
Belief in his own powers	2.0
Force of character as a whole	2.0
Devotion of effort toward distant goals	2.0
Strength of will in perseverance	2.3
Persistence in the face of obstacles	2.3
Steadfastness of effort	2.5
Desire to excel in efforts	2.6

* Data from Table 49, C. M. Cox, *Genetic Studies of Genius*, Vol. II, *The Early Mental Traits of Three Hundred Geniuses*, Stanford University Press, 1930. By permission of the publishers.

cent as showing mental or emotional weakness, and 8 per cent with considerable or serious mental or emotional weakness. In a single case, that of Chatterton, definite emotional disorganization was clearly present, leading at a young age to suicide. Equated with Olson's Schedule B of mental health for children, the ratings of the fifty geniuses show a similar distribution of percentages reaching or exceeding a certain point on the scale (Table 12). In spite of the differences in method of arriving at the results compared in the table, there is a fair agreement between them, and it may be concluded therefore that the mental health of this representative group of the illustrious was on the average no less satisfactory than that of unselected school children today. A relationship subtle or otherwise between genius and insanity is not indicated by this particular comparison.

The apparent contradiction between these results and the conclusions of Lombroso, Lange-Eichbaum, and others who have found mental peculiarity or psychopathy a characteristic of their geniuses is discussed by Miles and Wolfe. The conclusion is reached that the disagreement among investigators regarding the relationship of genius and psychopathy or insanity is largely due to the definition of the term. Many imaginative geniuses have been unstable emotionally. Men of action, on the other hand, have less often shown psychopathic traits. White (1930) had arrived at a similar conclusion from a study of the adult careers of the entire group of Cox's geniuses.

Gifted Children and Genius

Human beings differ with respect to traits and trait constellations. Both capacities and accomplishments are subject to quantitative and to qualitative measurement, and superiority may therefore be of either kind. Economic necessity generally calls for quantity, cultural progress for quality. Objective psychological measurement has differentiated primarily capacities. Evaluation of products is an interpretative function. The correlation be-

TABLE 12

MENTAL HEALTH RATINGS BY C. C. MILES AND L. S. WOLFE OF 50 GENIUSES IN CHILDHOOD COMPARED WITH THE RATINGS REPORTED BY W. C. OLSON OF 798 PRIMARY SCHOOL BOYS

	Below Average			*Average*					*Above Average*	
Subjective mental health scale	2	2.5	3	3.5	4	4.5	5	5.5	6	6.5 7
Rating on Olson's Schedule B	116	99		82		73	69	66		48
Percentage of Olson's cases at or above a given percentage	98	91		72		59	52	45		5
Percentage of 50 geniuses at or above a given scale point	100	98		82		62	56	40		16

tween capacity and accomplishment has been assumed to be high. Measures or indices of one have often been accepted as satisfactory substitutes for the other. Recent psychological study attempts the difficult task of comparing capacity with accomplishment. The multiple measurable factors are analyzed in each by the method of intercorrelation.

Gifted children selected on the basis of early test performance represent a capacity group. Geniuses selected on the basis of past careers constitute an accomplishment group. Both are superior human specimens deviating exceptionally from the average. The problem of correlation between the factors contributing to the superiority of these two groups and between the traits of the personalities qualifying for membership in each can be approached only indirectly through descriptive comparisons. Such comparisons can give no final answers. They may, however, clear up certain misconceptions, define the problems more precisely, and throw some light on the larger relationships. Perhaps we may better understand what gifted children are and what is meant by genius if we attempt some consideration of their similarities and differences.

The term *genius* is popularly applied to a human being when he has accomplished altogether original creative work of the highest quality, such as is recognized as extraordinary in some valued field of human enterprise. The genius has been most often identified in the arts and in scientific discovery, because here individual origination and independent creation were most obvious. Political leadership has sometimes been recognized as possessing the individual quality essential to genius. Originally restricted to a few fields, the term has been used more and more to designate the individuals endowed with the power for whatever extraordinary feats the culture of the period chose to value as most significant.

In the early development of the genius concept the extraordinary accomplishment was attributed not to human capacity but to divine inspiration. This was the mystical or supernatural theory of genius. Its significance is idealistic and religious; its basis is emotional. It persists even at the present day, though its objects are generally historically remote. It has, unfortunately for the scientific use, tinged the word *genius* emotionally and subjectively, while popularly and poetically emphasizing in a desirable way the high value of original creative activity. The repudiation by some psychologists of the use of the term *genius* or *near-genius* as applied to gifted children may originate in the experience of contrast when elementary school boys and girls, even the brightest of them, are compared with the idealized characters whom we iden-

tify as the great men of history (Lange-Eichbaum, 1928, 1931).

While poets and popular philosophers perpetuated the subjective interpretation of genius, scientists attempted to objectify the picture. The rationalists said genius can be developed through training, but it will be recognized as genius only if it is expressed in production at the right time and place. The sociologists further developed this view, emphasizing environmental influences in the development of the product of genius and in the readiness of the world to accept it (Ward, 1906). Social conditions, they said, not individual accomplishments, are responsible for works of genius. Men of ordinary gifts may, according to this hypothesis, become leaders and be acclaimed as great. This view valuably emphasized the importance of social influences for the development of superior achievements, and in this it is amply supported by results from the studies of gifted children. However, the further conclusion that great leaders are men of mediocre capacity has not been substantiated by scientific evidence at least with respect to intelligence, although it does appear to be true that a rather wide range of superior ability is represented in the world's leadership group (Cox, 1926).

The contributions of clinical psychiatry include the various explanations of genius as abnormal personality function. The attempts to relate genius to insanity have classical roots and show also the influence of the subjective, unique quality interpretation. Pathological material especially available in the biographies of literary geniuses has given support to these efforts. The psychoanalysts belong to the clinical group in their identification of genius as a neurosis or as a compensatory reaction. A valuable contribution from the psychiatric point of view is in the emphasis on the total dynamic function of the personality with its complex factors and deeply conditioned impulses (Reid, 1911–1912; Witty and Lehman, 1930; Schott, 1931).

The relatively small number of insane geniuses in representative groups of the illustrious suggests that the relationship between genius and mental abnormality has been exaggerated (White, 1930). Also the fact that among gifted children, who, however, may not especially include those with subjective and creative gifts, mental as well as physical health has generally rated above the average seems to point in the same direction (Burks, Jensen, and Terman, 1930). It is not known whether this is simply the result of a sound mental hygiene in superior families or a consequence of the repression of subjective factors by the more intelligent children, or a consequence of unintentional exclusion from the studies of psychopathic gifted children.

That many geniuses have shown eccentric traits has been mentioned by Ellis, Galton, and others. How much more eccentric they were than average men has never been stated exactly. The eccentricities of the great have always been of interest to people of lesser accomplishment, and they may be more often reported or weighted with more serious consideration than those of the generality. The evidence from the childhood of eminent men fails to support the view of frequent idiosyncrasy except in the subjective, sensitive individuals already mentioned. Among the gifted children queerness and peculiarity are infrequent. Deviation from the typical, mentally healthy average is not regarded with favor by parents and teachers today. Capable self-control is the popular ideal, and children are encouraged not to be "different." The children who have shown unfavorable emotional developments have not been those among whom later distinction seemed probable (Witty, 1940*b*).

Genius as Most Superior Native Ability

The position of genius at the top level on a scale of ability was first suggested by Galton. His theoretical ability scale, constructed according to the requirements of the normal probability curve, differentiated levels of competence from the lowest (idiocy) to the highest (the genius level) in terms of frequency of occurrence and the correlated statistical measures of deviation from the mean. Although superiority in scale terms was expressed as degree of achievement, Galton emphasized the native capacity factors which made the achievement possible. He devoted much careful research to the definition of scale points as indicators of the statistical frequency of mediocrity, superiority, and eminence, including the high level of distinction of the genius. The lowest level of eminence defined from historical and contemporary statistics of achievement he placed at a point on the scale beyond which not more than one individual in 4000 of the general adult population could rate. Position at this level Galton illustrated in the careers of successful English judges and bishops. Higher levels specifically defined included, first, men of great national reputation, each being as one in 79,000; and, second, the rare illustrious characters of history, who rank as one in a million or more, and include only men of the greatest, internationally recognized distinction. From the life histories of his highest ability groups Galton deduced the basic psychological traits of genius: superior ability, persistent and intense motivation, and great physical power for work. These traits he found in all, but he discovered that they differed in relative weight according to the field of eminent accomplishment.

Galton's ingenious scale is arbitrary and fallible, as are all methods of measuring achievement and capacity. Its merit lies in the application of statistical psychological techniques to the rating and equating of human ability and superiority and in its objectification of the native traits of men of genius as measurable quantities.

The traits of adult genius discovered by Galton have in a relatively recent study been found to characterize illustrious historical personalities in childhood (Cox, 1926). A high general level of accomplishment and versatility which suggested that achievement might have resulted for many in any one of several fields was mentioned by Galton and demonstrated by White (1931) from Cox's data.

Intelligence and ability tests have proved for many specific lines of mental capacity and accomplishment that Galton's theory of the normal distribution of human ability meets the criterion of present-day objective measurement. Terman's results in the study of gifted children show close agreement between the statistics for the distribution of intelligence at the highest levels and Galton's upper segments on the normal curve constructed in terms of the threefold native ability that constitutes "genius." Among Terman's gifted are not a few who possess besides high test intelligence also high motivation and great power for accomplishment. These are especially well represented in the 1940 success group. Had Galton's threefold criterion been applied in the original selection of the California gifted children, there would be statistical grounds for the expectation that somewhere near 4 per cent (about thirty individuals) of those chosen might qualify for classification at Galton's lowest eminence level, a small fraction of 1 per cent (one or two persons) at his second eminence level, but by reason of the relatively

small numbers perhaps none at the level of the "illustrious."

In statistical terms the majority of Terman's group may be as far below the level of Galton's "eminence" as the average 100 IQ child is below the child rating at 120 IQ. We may recall that 4 or 5 per cent, but not generally more, 100 IQ children do sometimes later reach the 120 IQ level in test terms (Merrill, 1938), and this analogy may illustrate the possibility of a similar gain in status from a lower to a higher level on a general achievement or eminence scale. The 1940 report of Terman's success group gives reason to suppose that somewhere near the appropriate proportion of gifted boys who are highly superior in motivation and energy as well as in intellect are on their way to the levels of eminence corresponding to Galton's statistical prediction.

Contemporary psychology views personality at every level as vastly complex. Each individual is recognized to be the product of numerous constitutional elements mutually interacting, and at every stage in the course of their development variously stimulated by many combinations of environmental influences. Individual differences occur in every dimension involving every possible combination of the multiple external and internal factors and their relationships. Rare genius offers no exception, nor does the superior segment of intellectual capacity represented by the gifted children (Carmichael, 1934).

Results of Research and Emerging Problems, 1947–1953

In 1947 the study of gifted children reached the end of an important chapter with the publication of Terman and Oden's *The Gifted Child Grows Up.* Before the second world war research with gifted children had attracted numerous investigators. In 15 years (1927–1941) the *Psychological Abstracts* listed 113 publications in this area, averaging 7.5 studies per year. In the next 5-year period the war influence was no doubt responsible for some reduction in publication. However, in 5 years (1942–1946) 30 publications were listed regarding the gifted, averaging 6 titles per year. Then, in 1947, came Terman's volume, and in the next 5-year period (1948–1952) no more than 10 publications of research results were reported, averaging 2 per year. Perhaps many potential investigators felt that the Stanford study had dealt so broadly and fully with the major problems as formulated that little remained unexplored in the field as previously outlined. The Stanford study had not only built a reliable foundation of sound and dependable factual data, but by careful design this masterpiece of research had now in 25 years of continuing study answered the basic questions posed earlier in the enthusiasm and in the clear light of the psychologies and the statistics of the 1920's. A review at this point of the Terman and Oden report affords the best opportunity for gaining a comprehensive view of the major problems posed, the facts established, and the conclusions and interpretations reached during the important period of research in which study of the gifted flourished as a significant development. Terman was especially qualified by experience and interest to leadership in this period. He was uniquely prepared to utilize effectively mental test instruments from the earliest phase of their development. His sustained enthusiasm, painstaking and indefatigable labor through years of detailed data gathering were shared by his loyal and accurately trained research staff. The gifted subjects, 1528 in number, their parents and other relatives, and their teachers collaborated over the years

thoughtfully and effectively. The results present a unique contribution to research.

In the following pages the reviewer attempts to summarize the major conclusions of this important volume. Thereafter, other pertinent research reports of the late 1940's and early 1950's are briefly brought into view. The trends in research suggested and issuing from the combined material emerge to point out possibilities in new directions.

The Terman and Oden volume brings together the available data on which to base an answer to Terman's question formulated in 1921: "In what respects does the typical gifted child differ from the typical child of normal mentality?" If the pertinent question of the 1950's finds a new phrasing one may readily concede that Terman's great work has contributed largely to effective restatement.

No brief review can do justice to the tremendous Terman-Oden study. Its 400 pages of detailed reporting contain a complete report of the work to date. Following the original plan for the research, the composition and social origin of the gifted groups are set forth, and conclusions are briefly and objectively formulated and statistically confirmed from the results of ratings and measures of traits, characteristics, achievements, and interests. Data from the cross-sectional studies of 1921–1923, 1927, 1936, 1940, and 1945 are brought together topically. The subject matter includes the older and the newer material combined in a comprehensive treatment covering background, vital statistics, general health and physique, mental health and adjustment, and intelligence and achievement test results. The distinctly new studies cover intellectual status in adulthood, educational histories, occupational status and earned income, war records, vocational and avocational interests, interest test data, political and social attitudes, marriage and marital adjustment, and information with statistics regarding spouses and offspring. The final emphasis is on status after 25 years of continuing study of this large group selected in childhood in terms of high IQ. Chapters are devoted to the highest IQ's of all (170+), of whom there are 81; to the Jewish gifted, numbering 122; and to a comparison between the most and least "successful" of the gifted men, with an illuminating comparison of some of them with American Rhodes Scholars.

The work of Terman and his associates probably stands alone in the history of research for its accomplishment of a planned study in verification of stated hypotheses, requiring the cooperation of more than 1500 exceptional human subjects in repeated reports and evaluations and extending over a 25-year period. In consequence of the excellence and accuracy of the data gathering and the promptness of reporting, some of the more significant results of this study became a cornerstone in psychology as early as 1925. In 1940 a preview of the adult status outlined the chief conclusions regarding achievement now amply confirmed by the detailed field study of 1945. The whole volume in its thorough coverage and statistical completeness testifies to the objective sincerity of the research.

From the findings the following significant results point up fundamental facts and relationships.

1. School children representative of the top 1 per cent of tested intelligence are as a group superior in other respects as well. They rate far above the average in physique, social adjustment, personality traits, school achievement, play information, and versatility of interests.

2. From childhood to maturity the gifted have continued to rate above average in health. The mortality rate has never

reached the average expectancy for their age. Serious maladjustment has occurred less frequently in this group than in the general population. As adults the gifted are normal or superior in marital status and sexual adjustment. Their social and political attitudes are not deviant. Their war records are creditable, in many cases distinguished.

3. The gifted have been accelerated in school to an extent amounting to 1 year or a little more at high school graduation. Acceleration has proved to be associated with superior academic achievement, with more extensive college training, and with exceptional adult "success." It has not usually proved to be a handicap to social participation or personal adjustment.

4. In school achievement the gifted have been superior at every educational level. Many have remarkable educational records. Yet, as the authors point out, it is noteworthy that, contrary to the general trend, many individuals have failed to achieve academically at the level of their predicted competence.

5. Close to 90 per cent of the gifted have attended college, and almost 70 per cent are college graduates. Of the men 68 per cent and of the women 60 per cent have completed some graduate university work. This record greatly exceeds the average among whom these individuals attended public schools in childhood.

6. In tested intelligence, the group as adults average about 1.0 SD above the average of college students, and about 2.0 to 2.5 SD above the average of the general population. Half of the gifted are very close to (probably within 4 percentiles of) their original top status. Forty per cent have slipped somewhat more, although two-thirds of the group as a whole scored above the ninety-second percentile. Some 10 per cent have regressed to the eighty-fifth percentile or lower, as compared to adults in general.

7. In excellence in preparation and in vocational achievement the gifted are outstanding. Compared to any like-sized random selection of young adults the group as a whole has now produced many times the expected number of leaders in business and of competent professional men in engineering, law, medicine, college teaching, and other specialties. The least successful fifth of the gifted sample includes a few individuals seriously hampered by poor health or poor personal adjustment. The majority members even of this fifth, although less outstanding than the other four-fifths, compare favorably in their adult accomplishments with average college graduates.

8. The highest IQ's (170+) equaled or exceeded the gifted group as a whole in many respects. In college their records were more distinguished and more of them advanced farther in graduate study. As adults the men of the group achieved more notably. The highest IQ men have been about as well adjusted as the total gifted group; the women, perhaps somewhat less so.

9. The subjects of Jewish descent, although more often coming from homes of lower status than the average among the gifted, have surpassed the gifted Gentiles in achieving higher educational and occupational status. Relatively more of them have reached notable achievement as adults.

The presentation of data and discussions culminating in the important conclusions here briefly summarized is followed by a comparison of the "most successful" fifth of the gifted men with the "least successful." This comparison in terms of adult achievement gives concrete form to Terman's concept of "gifted" and brings his once-designated "geniuses and near-

geniuses" into readily understood and easily classified categories of the American economic, occupational, and educational structures. (For definitions and details of the comparison see especially Chapters 13–15, Terman and Oden, 1947.)

The "most successful", Group A, include outstanding young professional men, business executives, and specialists in the creative arts and in industry. They are compared, in many respects favorably, with American Rhodes Scholars of similar age.

TABLE 13

STANFORD-BINET IQ'S IN CHILDHOOD AND ADULT CONCEPT MASTERY SCORES OF GIFTED GROUPS

Data from L. M. Terman and M. H. Oden, *The Gifted Child Grows Up*, Stanford University Press, 1947.

	Gifted Groups				
				Gifted †

Childhood Stanford-Binet IQ score average	155.0	150.0	152.7	151.5	150.4
CR	3.0				
No. of cases	79	116	56	527	427
Adult concept mastery score average	112.4	94.1	102.9	98.1	93.9
CR	4.2				

Occupational status: * very superior; † superior; ‡ above average.

In adult intelligence score they rate as a group some 2.0 SD above Stanford University students[1] (Table 13).

The "least successful," Group C, are for the most part men of undistinguished achievement, engaged in relatively mediocre pursuits. Their adult intelligence scores are relatively high, although significantly lower than those of Group A. Their average is 0.8 SD above the means of Stanford University student samples.[2]

Comparative results for the two groups appear, as reported in 1940, in Table 8 above. Although selected in terms of adult achievement they show some interesting differences in early development, family background, traits, and relationships. Besides many small differences between Groups A and C some important contrasts are as follows: The A's rated in childhood as more stable emotionally; their social adjustments and significant personality traits

1 R. L. Thorndike (1948) further defines this adult intelligence rating by an ingenious comparison utilizing a method of test conversion involving an adult Gallup Poll, a group of students from colleges in New York City (N = 198), and a smaller group (N = 53) of Columbia doctoral candidates and a few instructors. The gifted men, Group A, rate close to the ninety-eighth percentile of both the poll and the college students. They average in score about 0.5 SD below the mean of the doctoral group.

2 The average adult score of Group C is above the ninety-sixth percentile of Thorndike's poll and above the ninetieth percentile of his college students. Their mean is about 1.1 SD below that of his doctoral group.

were regarded as more favorable; there are fewer "only" children among them. The personality differences increased in adolescence. In early adulthood appreciably more C's than A's appeared nervous and emotionally unstable. Through the high school years the A's had better scholastic records and engaged in more extracurricular activities than the C's. At college age the educational and activity differences were marked. Although the average physical health ratings of the two groups showed little divergence, the A's rated as more energetic in their interests, and more active in social organizations and pursuits. In educational and occupational accomplishment the A's drew farther and farther away from the C's from the early high school period onward. The C's suffered more background disabilities, especially broken homes including divorce or separation of the parents or death of the father. In marriage and marital adjustments the A's excelled. Their spouses were more intelligent, more highly educated, and came from families of higher educational status. In the appraisals of 1945 the A's (judged by their parents, their wives, and themselves) rated appreciably higher than the C's in absence of inferiority feelings, and significantly so in self-confidence, perseverance, and integration toward goals.

Reviewing these differences it appears that the A's deviate in the same direction from the generality as the total gifted sample, and they deviate somewhat more. They are a fairly homogeneous group of well-adjusted, extremely able adults who were once extremely high IQ children. The C's deviate in the same direction as the gifted sample with respect to high test score in intelligence as children and (though relatively less so) as adults, more advanced schooling, and higher adult employment status. But the C's are apparently a more heterogeneous group. Some are unstable, with more than average "nervous" signs and ratings of poor adjustment; "only" children are relatively more numerous among them. Handicaps in terms of parental divorce and the early decease of their fathers are more frequent in this group. But the disadvantages associated with lower social home status appear to present the outstanding factor or handicap. Were more of the C's than of the A's overrated in childhood test scores? As youngsters they were quick, and alert mentally in the test situations, but as time has gone on they have not so highly developed the traits of perseverance and integration toward goals characterizing the success Group A There are implications that some members of Group C are simply well-adjusted lower-middle-class workers who for various good reasons have found congenial skilled or semiskilled employment and have not tried, or have not succeeded if they did attempt, to escape from the social, economic, and domestic groove of their childhood rearing.

In conclusion Terman states that his total sample includes some 20 or 25 men of science "who have either achieved, or appear likely to achieve, a national reputation among their kind"; a number of talented writers; and a dozen or more outstanding medical men and lawyers. Among the currently highly successful financial and industrial operators may be some who will achieve national distinction. With respect to these and others less notable in their accomplishment he has this to say: "We do not . . . know whether they are more happy or less happy than the average person in the generality. We do know that they are better fed, better housed, and better doctored than the average person, that they are in a position to care better for their children, and that they have less reason generally to be anxious about the future."

Investigators familiar with the problems he had to face will agree with Terman that, "considering the scope of the investigation, the limited funds, and the status of psychological methodology at various stages of the research," there is "little to regret regarding the choice of devices, rating schemes, case-history procedures, and other techniques employed." The methods used in selecting subjects "provided a fairly representative population of high IQ's." The methods developed for following the subjects have led to clear-cut and valuable results.

Plans for the future outlined by Terman and Oden include further following of the group, testing all, if possible, of their offspring in intelligence and school achievement, and the gifted themselves at intervals with more adequate intelligence tests than have been hitherto employed. Personality studies are outlined: tests of marital adjustment, psychiatric studies and projective tests, tests of primary personality traits, and somatotypes. The possibilities are great, the authors conclude, and financial limitations should not curtail further essential developments.

The IQ has proved to be an effective selector, and the factual picture of the "gifted" in American culture is viewed by many, especially practical educationists, as a valuable and useful construct. This construct science owes chiefly to the wisdom and perseverance of L. M. Terman. The Stanford data and the goodwill of the gifted subjects afford rich material and possibilities for the further studies projected.

Other Gifted Research

Other investigations reported in the late 1940's and early 1950's follow the same general pattern in emphasizing the superiority of the high IQ's in traits, accomplishments, and promise of adult achievement. Parkyn's (1948) excellent volume reports similar conditions and results for the gifted in New Zealand, adding also suggestive discussion of background factors and an analysis of successes and failures of his superior subject group in the subtests of the Terman-Merrill Binet. Lightfoot's (1951) comparison of superior with retarded children in a New York City school shows the significant advantage of the gifted over the retarded in the traits and conditions measured. This study effectively utilizes Murray's behavioral classification. Ausubel's (1951) well-thought-out development of a technique for measuring prestige motivation indirectly points to general gifted superiority in his group while serving as a pilot effort in the area of social attitude.

R. L. Thorndike (1948) has made a contribution, already referred to, pointing up an inferential corollary of Terman's work: that the gifted label in childhood although favorable is not definitive for superior adult intelligence test status. To Terman's estimate of the regressed mean of the adult gifted as IQ 140 and McNemar's estimate of IQ 134 Thorndike adds his appraisal approximating IQ 128. Thorndike's work brings the Concept Mastery Test developed and employed by Terman into a comparable, if crude, approximation with other scales by equating results for the gifted with other adult intelligence norms. His data afford the basis for a graphic presentation of the score trends in the maturing gifted group. For illustration in this review we have plotted (Figure 1) smoothed approximate paths of score decline from childhood to adulthood of the 30, 50, 67, 87, 99.6, and 99.9 percentiles of Terman's group who when first tested scored within or close to the top 1 per cent on available IQ scales. Position on the Stanford Concept Mastery Test is given in terms of adult test score explicable by

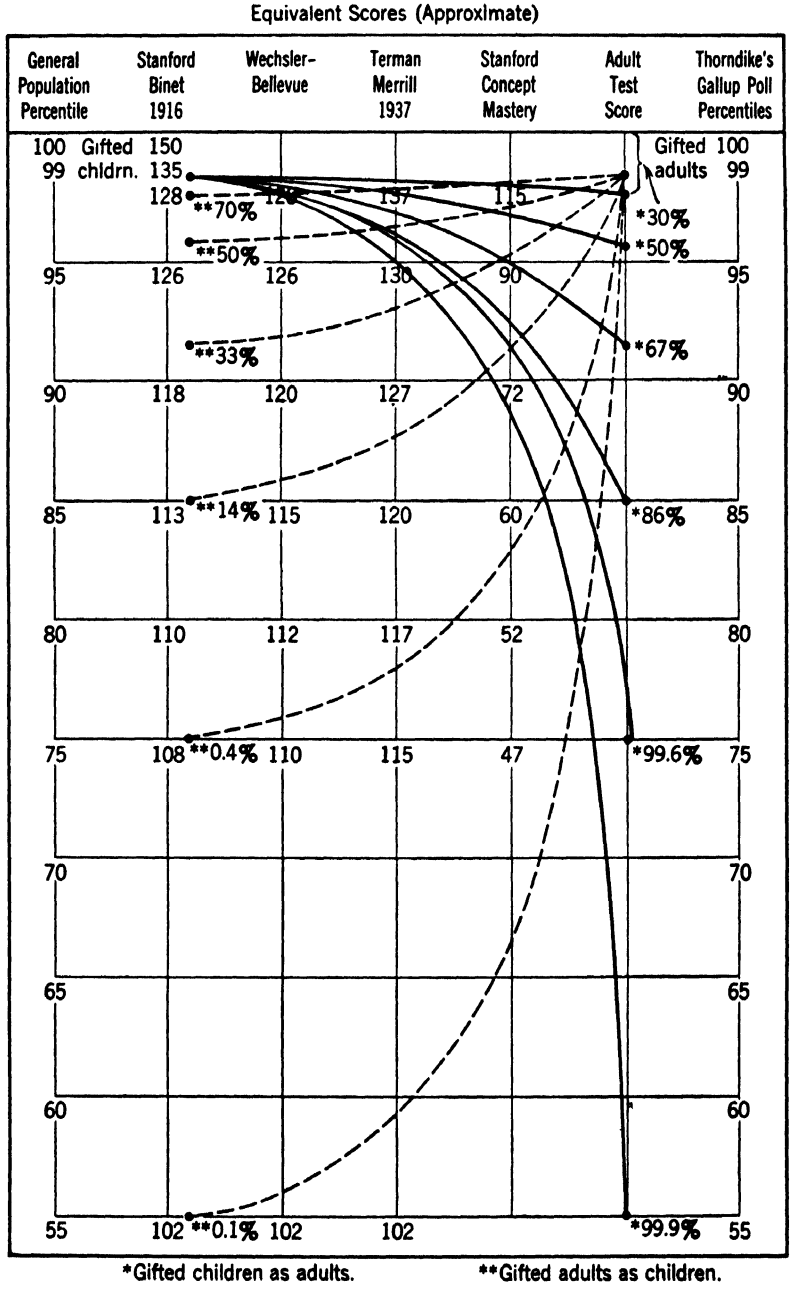

FIGURE 1. Paradigm of gains and losses in IQ from childhood to young adulthood.

comparison with Thorndike's adult Gallup Poll group. Thus, 30 per cent of the formerly gifted children may be said to rate as adults within the top 2 per cent of adults in general, 50 per cent within the top 4 per cent, two-thirds within the top 8 per cent, 86 per cent within the upper 15 per cent. These scale positions on the Stanford Concept Mastery Scale are graphically compared with Stanford-Binet 1916, Wechsler-Bellevue, and Terman-Merrill 1937 IQ's by the use of reported percentile positions on those scales. A paradigm of this type is, of course, crude. Its possible value is in emphasis on the need for further and more dependable measures.

In the same figure hypothetical curves are drawn indicating the possible gain in IQ from childhood to maturity as reported by, among others, Terman, Lorge, and Hollingworth (1936), Keys (1940), Thorndike (1948), and Bayley (1949). These investigators have shown that childhood high IQ's do not account for all the known high IQ's in adulthood. Various causes and factors have been proposed to account for IQ gains with increasing age. Technical faults in test construction, inequalities in social and educational experience, physical and mental changes, and alterations in maturational rates are among the suggested factors producing not only the possibilities for decline demonstrated by Terman but also the perhaps equally important possibilities for rise in IQ from childhood to adolescence or later as suggested in many studies.

Some intelligence ratings reported by Simon and Levitt from the Columbia University Vocational Guidance files are relevant (Table 14). These lend support to some very old assumptions that adult test scores correlate with occupational training, experience, and achievement (sometimes in contrast to childhood ratings) while some individuals of superior test intelligence continue to be found in almost every occupation. Army General Classification Test scores for occupational groups are in line with these results (Stewart, 1947).

‖ Wholesale and retail.

¶ Machinists, mechanics, plumbers, electricians.

Studies of the educational needs of the gifted and reviews of facilities and programs for meeting them complement Terman's findings with respect to the schooling of the gifted, outlining programs to meet some of the conditions his data have so clearly indicated. The *Education of the*

Gifted published by the Educational Policies Commission (1950) reviews problems pertinent to study of the gifted: the rôle of the gifted in a democracy, waste of talent in American life, identification of the gifted, education of the gifted, investment in talent, and an able summing up of the educational challenge in leadership training. The special needs of the "gifted" top percentile and the "moderately gifted" upper 10 per cent are now too often neglected, the Commission specialists conclude. Consideration of the exceptional learning capacity and competence of the groups likely to include many more than their share of specialists and leaders is seen here as essential to increasingly adequate development of human resources.

The Gifted Child edited by Paul Witty (1951) is a useful compendium for teachers of superior children and for educators generally. Prepared under the sponsorship of the American Association for Gifted Children this volume contains 14 reports by individual specialists or groups of educators who present here their conclusions after years of study and experience in dealing with the training of gifted children. The editor outlines the history of the education of the gifted in the United States and surveys current educational practices and provisions for the gifted in elementary and secondary schools. Terman and Oden describe the Stanford Studies, and Pritchard brings together the contributions of Hollingworth. The qualities and preparation desirable in teachers of the gifted are discussed by Ryan, Strang, and Witty. Hobbs writes on community recognition of the gifted, and W. Davis discusses the science talent search. Other topics discussed are methods of identifying gifted children, observations of gifted and talented children in clinics and schools, a high school of science for gifted students, the mental hygiene of gifted children, and school administrative problems in educating the gifted. A summary and recommendations by the editor are followed by an annotated bibliography. Although this volume presents little original research it is a valuable compilation of studies summarizing current attitudes and practices with many thoughtful suggestions and insights from specialists teaching in this field.

Contribution of Research on the Gifted to Related Areas of Investigation

Detailed study of groups of extremely gifted deviates has done more than set up a picture of the "most successful" members of their class. It has, as already noted, verified the usefulness of the IQ technique for early selection of groups likely to include many of those capable of superior development and achievement under existing conditions in our prevailing culture. In doing this it has also indicated that the IQ test does not serve as a magnetized needle, far less as a divining rod, pointing without fail at some innate potential. The studies of the gifted thus lend support to the view that although IQ tests do tend to measure present ability they are probably far from accurate as indicators of native capacity (Cronbach, 1949; Hebb, 1949).

The study of the gifted has further brought to light many of the conditions associated with the appearance of more rather than less high IQ children in a group or community. These results may be compared with the findings of Eells *et al.* (1951) relating IQ scores directly to social class. The high IQ scores of private school children are another indication of the same or a related phenomenon (*Educational Records Bulletin,* 1950). See Table 15. The studies of the gifted have revealed many of the conditions under which, given high IQ's in childhood,

TABLE 15

INTELLIGENCE TEST SCORES OF SCHOOL CHILDREN FROM HIGH AND LOW SOCIAL CLASS GROUPS *

	Social Class	No. Children	Mean IQ	SD	CR	Per Cent Scoring 130 IQ+
Henmon-Nelson Test (ages 9–10)	1. High status old American	226	115.8	16.2	1 and 2 12.6	19.5
	2. Low status old American	322	98.4	15.7	2 and 3 0.8	1.9
	3. Low status ethnic	143	97.1	15.7	1 and 3 11.0	2.1
Terman-McNemar Test (ages 13–14)	1. High status old American	233	114.9	13.1	1 and 2 18.3	12.9
	2. Low status old American	361	93.0	15.8	2 and 3 0.9	0.8

* Data on Henmon-Nelson Test, Terman-McNemar Test and Kuhlmann-Anderson Test (ages 9 and 10) are from Eells *et al.*, 1951. *Intelligence and cultural differences.* University of Chicago Press, Tables 20 and 21. Data on Kuhlmann-Anderson Test (ages 4–17) are from Educational Records Bureau. 1950. 1949 fall testing program in independent schools. *Educ. Rec. Bull.*, No. 53.

high levels of adult achievement are likely to be attained. The evidence that the IQ test becomes an increasingly adequate selector as the favorable or unfavorable factors or conditions accumulate is in line with the view that the intellectual abilities tapped by the test are typical products of the cumulative cultural learning. The results in gifted study are, so far, group results. With respect to individuals the conditions, as in all genetic and child psychology, are seen to be multiple and complex, indicative of intricate biological and social factors, tendencies, and interrelationships.

Further treatment of data already gathered and in part reported may uncover further leads. For example: The Stanford data have been searched and categorized to picture a "success" group reported above and rated in terms of "the extent to which a subject had made use of his superior in-

tellectual ability." These terms were interpreted to include the brilliance of the academic record, the achievement of listing in *American Men of Science* and *Who's Who,* successful professional standing as college teachers, lawyers, medical men, engineers, and business men, with the additional choice of a few outstanding young figures in literature, art, motion pictures, or radio. The specifications are those recognized as describing midcentury American success at the upper economic level perhaps slightly overweighted in the direction of science. Other types of success perhaps less brilliant but no less interesting and potentially valuable might be defined within the gifted group. The gifted who most fully utilize their intellectual abilities and their opportunities to become skilled or semiskilled workers or those whose circumstances and interests lead them into the clerical field may also prove to be significantly identifiable in terms of the conditions of their backgrounds and experience. Even the gifted women offer problems for further analysis in terms of data already gathered. The direction of their interests and efforts toward professional, housewifely, or combined goals may well be associated with factors and conditions already recorded and identifiable.

The studies of the gifted as they now stand and without further amplification lend support to a number of views or hypotheses in four currently active areas of research.

1. Research on the gifted may have somatic implications. Derivation from sound somatic stock, favorable nurture in infancy, the earliest (and later) personal associations and interrelationships with stable and generally well-adjusted people, freedom from nervous symptomatology and personal maladjustment—these are conditions and factors found to prevail among the gifted and to be most frequent among those who continue to develop favorably from childhood onward. The hypothesis that superior innate somatic potentials will tend to become manifest in identifiably superior child personalities is supported by these data. Confirmation is also rendered to the view that favorable conditions increase the tendency for superior behavior to emerge and to maintain its superior developmental level and direction. Are there individuals of greatly superior innate potentialities who by reason of unfavorable prenatal or postnatal conditions fail to develop, in the behavioral channel available, the abilities that will register as of high IQ level and the personalities generally associated with them? Biological and psychoanalytic studies suggest that the answer is "yes." The gifted studies offer little direct evidence with respect to this aspect of the problem. Relevant to the problem of negative outcome for superior individuals, labeled as gifted, are the case studies of once superior individuals who were eventually disrupted emotionally under adverse conditions and disastrous relationships (Burks *et al.*, 1930; Terman and Oden, 1947).

2. Research on the gifted has implications for social psychology. These studies lend support to the view that rôles and goals associated with superior social class are readily acquired by individuals of high IQ and tend to become for them relatively comfortable and flexible channels for social and vocational behavior. The hypothesis that high IQ is an asset in rôle and goal acceptance and in upward social mobility is supported by the data. The hypothesis that easy access to rôles and goals of high social value is an asset in gifted achievement is also supported. The view that high IQ is always an asset even where rôles and goals conflict, as, for example, in the highest IQ women, is not clearly supported by the data. The hypothesis that for many

gifted individuals familial rôles and goals prevail over high IQ in determining life pattern and achievement is supported (Terman and Oden, 1947).

3. Research on the gifted may have implications for studies in motivation. The identifiable physical and personal adjustment factors favorable for the development of exceptionally high test achievement and gifted behavior plus the social class background and experience in which appropriate rôles and goals are learned may to some readers seem sufficiently to account for the emergence of gifted individuals. But the favorable factors still fail to correlate fully with the observed results. And so further measurable variables are still to be sought. Recorded case studies of individual success and achievement at the gifted level suggest the relevance of subcultural or familial contributions in terms of life patterns with typical goals and motivations. The report of the Jewish gifted in the Stanford study supports a hypothesis of a motivational pattern developed in parent-child interrelationships in American Jewish families with gifted children. The gifted Jewish children although coming from relatively lower social class background than the group as a whole emerge with higher IQ ratings in childhood and eventually with higher adult intelligence scores and higher professional and business status than the Gentile gifted. Individual case studies, Gentile as well as Jewish, illustrate diverse home atmospheres and subcultural goals specific in certain groups and tending to develop motivations favorable perhaps to limitation of objectives and rather certainly to excessive exertion toward ends contributing to high IQ scores, to superior school work, and eventually to superior adult achievement (Terman and Oden, 1947). Attitudes of success and failure have been shown to influence intelligence test scores (Lantz, 1945). Under the impetus of motivation to achieve higher military status above-average groups have raised their standing as much as 22 percentiles (Schlesser, 1950). On the negative side, unfavorable home situations, financial limitations and resulting conflicts, parental rejection, sibling rivalry, and especially lack of favorable parental involvement in the gifted child's progress and welfare have been associated with falling IQ, poor school work, and eventually less than optimal adult achievement (Burks *et al*, 1930; Carlson, 1945). Favorable personality changes have resulted from understanding guidance at school and from special types of therapy (Margolies, 1946). Favorable parental attitudes, encouragement, and even sacrifice in conditions of poverty, family solidarity, involvement in the child's progress with varying degrees of pressure, development and maintenance of family interests and customs and of a family tradition rooted realistically in shared family experience, thoughtful consideration by the parents of the welfare and the capabilities of the child —various combinations of these tendencies appear to function as stimulators in the learning and the rôle-taking and may eventually operate, sometimes quite powerfully, toward accepted goals of achievement. The Fels researches include in their design attempts to measure some of these variables. Their results suggest that individual parental attitudes and home climate as differentiated from social class rôle-learning and identification can be measured. An early finding in these investigations that parental behavior indicative of freedom, of emotional warmth, and of acceleratory methods are related to early change in developmental status has been supported by further work. The investigators report that a democratic-acceptant attitude is conducive to mental development. When, in addition, the parental at-

titude is nonindulgent it is conducive to intellectual growth in all its aspects (Baldwin *et al.*, 1945). Measurement of parent behavior by the Fels (Baldwin *et al.*, 1949) or similar scales seems to offer excellent possibilities for defining an additional variable or variables operating in gifted development.

4. Specific situations. The gifted may have achieved their original high IQ scores in consequence of chance factors operating favorably. In the further development of every one of them the special and unique circumstances of their lives continue to operate as stimulators or repressors of the potentials for superior utilization of their superior capabilities, their familial advantages, and their social privileges. In individual instances ill health, financial loss, or a sense of insecurity or inferiority has sometimes acted as a spur to achievement. Detailed biographies and especially autobiographies indicate the varied contributions of innumerable small incidents affecting the course of a life history. In the gifted, so far as reported, the record shows usually cumulative good luck as compared with the generality, but additional specific factors may emerge under further and more detailed scrutiny (Terman and Oden, 1947; Parkyn, 1948). A valuable individual contribution to the understanding of many problems of gifted children is found in the fascinating autobiography of Norbert Wiener (1953). In this volume the cultural and familial background of a prodigy and his remembered experiences in childhood and youth are clearly depicted. Parental forcing is described with sympathetic understanding of a frustrated though able scholar-father who sought self-expression through the achievement of his bright and responsive son. The careers of other contemporary gifted children variously and probably in most instances unreasonably pushed by their parents further illustrate the interaction with precocity of mental and physical vigor, personality traits, and family acceptance of assets and limitations.

The Emerging Personality Patterns of the Gifted

The Stanford gifted as a group are reported living their lives a little more happily and being themselves a little better adjusted, as well as more intelligent, than the average as evidenced in their handling of their personal problems and interrelationships. Otherwise, as far as we know them from Terman, they carry on within the typical American framework and are identified with the typical interests of occupation and social class. Insufficient data are available to trace patterns, styles, or modes of life and development differentiating high IQ variants from other people whom they resemble in social origin, family tradition, etc. Are there tendencies, associated with giftedness, for restriction in some respects and expansion in others of the personality potentials? Roe's studies (1949, 1951) of exceptional adults suggest that by means of projective techniques it may be possible to determine styles of inhibitions and of cultivation of tendencies within accepted rôles characterizing the emerging personalities of people including the gifted, in various walks of life. If and when factor analysis is effectively developed in studies of the gifted and their offspring the results may be expected to clarify the interrelationships of conditions now vaguely perceived.

Research is, of course, limited by the availability of material—in this area, gifted subjects. Terman has achieved access to a large group of gifted individuals, winning their interest and cooperation in a continuing investigation. The protection of individual personal freedom and of anonymity has been an important feature of

the relationship. The sharing of interest in the research by the subjects may eventually make possible cooperation in detailed case studies. If these could be prepared at various stages under the direction of specialists from the different areas of research converging in human personality study they would illuminate many aspects in the complex cluster of problems involved. Furthermore, they might suggest leads for new theory. The studies themselves need not be published in early stages of the investigation. They could be preserved and used as confidential material by qualified scientists working together at a center for research on the gifted. Methodological approaches are opening from many directions, and the scientific horizon is widening around the problems of personality. The availability of the gifted group and their offspring should be protected and further utilized.

The problem of terminology is still puzzling. The Stanford group and others studied are largely high IQ groups. Among them the very intelligent (highly able to function in terms of the central factor in the test) have not been differentiated from the pseudo-intelligent (who owe their perhaps equally high scores to a considerable extent to chance successes or to more or less unrelated abilities) (Magaret and Thompson, 1950). The gifted label has been achieved by varying degrees of superiority at different ages (Cronbach, 1949). Children talented in the arts or in manipulative skills have been little studied. The term "gifted" although widely adopted is also widely questioned, as it appears to derive from an assumption of innate potential or potentials still largely inferential. Even granted the assumption, the conditions of emergence, so far as they appear to have been revealed, are so diversely operative that actually the gifted label may be acquired in childhood by only a fraction of those of equal potential ability.

Conclusion

More and less gifted individuals continue to appear in every age group and in every population. It has now been demonstrated beyond question that persons selected by test as of high IQ at a young age will tend to continue to maintain their high status at later ages. IQ sifting is useful. But it is far from final for achievement prediction. Culture, home and school opportunity, health, and motivation have proved to be factors favorable to superior development in intellect and personality. These factors correlate with IQ, but they are, so far, insufficient fully to account for either intelligence score or demonstrated talents. Gifted children as a group are superior to average children in many respects among which high IQ is but one. Further elucidation of the high IQ or the gifted problem will necessitate comparison of groups homogeneous with respect to other traits and differing only with respect to the one in question. In the meantime detailed individual studies will continue to give helpful suggestions as to the factors that may be involved. The most favorable and appropriate opportunities for the development of every child will tend to clarify the problem, while at the same time fostering the emergence of optimal talents in a maximum number of those potentially most highly gifted.

Chapter 17

PSYCHOLOGICAL SEX DIFFERENCES

Lewis M. Terman and Leona E. Tyler [1]

This chapter is principally concerned with the literature that has appeared from 1920 through 1952. Earlier contributions have not been included since it is generally true that later studies in this area have presented findings that agree with the earlier work but are statistically much sounder. We have confined our attention to studies of children and adolescents, in most cases excluding comparisons of college males and females because of the selective factors which obscure the meaning of the sex differences in this special group. As a rule we have not included studies based on small or obviously biased samples. However, it is the representativeness of the sample and the demonstration of statistical significance, rather than size alone, which has determined how much weight can be attached to any set of results.

The survey is of necessity incomplete. The great majority of the studies summarized have been published in the English language in America or Great Britain. Those from other countries which have found their way into the *Psychological Abtracts* have usually been included, but for most of these only the abstract was read. Material covered here has come largely out of research planned according to the Galtonian tradition, with its emphasis on objective and statistical methods. Much has been written on sex differences from other viewpoints, philosophical or descriptive. The psychoanalytic writers alone have produced a considerable body of writing on this subject. These discussions we have made no attempt to include.

Since the meaning and origin of the sex differences that have been identified are important considerations, it seemed desirable to follow a "tracing-back" procedure in the organization of the material. Studies to be summarized have thus been arranged roughly according to the ages of the subjects on whom they are based, so that the reader may be able to form some judgment as to how early differences appear. This helps us to draw tentative conclusions as to how fundamental they are in human development.

The Physical Background of Sex Differences

Sex differences have been found for almost every physical variable, including body build, gross and fine anatomy, physiological functioning, and biochemical composition. Indeed, every cell in a human body bears the stamp of its sex. As we are here concerned with psychological sex differences, we shall confine our discussion of physical differences to those which would seem most likely to have correlates in the realm of psychological behavior. The reader who wishes to pursue the matter further may well begin with the excellent

[1] The authors wish to acknowledge the assistance given by Winifred B. Johnson, George Kuznets, and Olga McNemar in reviewing the literature which appeared prior to 1941.

graphic and pictorial atlas compiled by Shuttleworth (1951).

Body Size. In general, it can be stated that males are larger than females, although there is a period, between the ages of 11 and 15, when the situation is modified because of the earlier female preadolescent growth spurt. Mean weight of boys at birth exceeds that of girls by approximately 5 per cent. This superiority continues to about 11 years, then rapidly decreases, until at 14 the direction of the difference is reversed, and the mean for boys is about 5 per cent below that for girls. By 15 or 16 boys have regained their former advantage, and by 20, the mean superiority of males is in the neighborhood of 20 per cent.[1]

Mean body length is slightly higher (1 or 2 per cent) for boys than for girls from birth to about 11 years. From ages 11 to 14, girls average taller, but the greatest difference in this direction is only about 2 per cent. Growth in height rapidly slows down for girls after 15 and almost ceases by 17. Height continues to increase fairly rapidly for boys up to 17 or 18 years, and usually does not cease completely until the early 20's. By this time male superiority amounts to something like 10 per cent.

Vital Capacity. Sex differences in vital capacity are greater than those for height or weight and may be more significant for behavior. Because vital capacity is one of the determiners of the sustained energy output which is possible for an individual, it could be one of the factors underlying sex differences in play interests, drive for achievement, and liking for activity and adventure. The superiority of boys in vital capacity is about 7 per cent by age 6, increasing to 10 or 12 per cent at age 10 and to about 35 per cent at age 20. It is particularly significant that the *vital index,* or the ratio between vital capacity and weight, is higher for boys at all ages for which measures have been made.

Strength. Muscular strength is another trait in which boys are superior to girls at all ages for which tests have been reported. In strength of grip of right hand the superiority of boys is about 10 per cent at age 7 and increases slowly to age 14. The curve for girls flattens at 16, that for boys about 3 years later. At age 18 the mean superiority of boys is about 50 to 60 per cent. Sex differences in strength of back and legs are correspondingly great and follow a similar course.

Rate of Maturation. Some of the most marked age shifts in the amount or direction of sex differences are largely functions of the more rapid physical maturation of girls. Maturational differences are especially conspicuous in gonadal functioning. Girls of all races precede boys on the average by 12 to 20 months in pubertal development, and their adolescent growth changes are correspondingly accelerated. In skeletal development girls are superior to boys at birth and increase this superiority at a fairly steady rate until growth is complete. At age 6 girls are a year more advanced in this respect than boys; at age 9, 1½ years; and at 13, about 2 years. Flory (1935) finds in girls a correlation of .637 ± .048 between age of first menstruation and skeletal-months ratings taken at age 11. Dentition also proceeds more rapidly with girls, but the sex difference here is less than for skeletal development (P. Cattell, 1928).

Sex Ratio and Viability. It is well known that human beings show an excess of male over female births (Parkes, 1926; Crew, 1927; Bakwin, 1929; Dublin and Lotka, 1936). The ratio differs with race, but is usually between 103 and 107 males to 100

1 Physical sex differences vary more or less with race and nationality. Unless otherwise noted, the differences referred to in this chapter are for white subjects of predominantly western European descent.

females. For stillbirths the ratio is around 130 or 135, and for miscarriages it is almost 200. Data reported by Bakwin (1929) indicate that the sex ratio for mortality increases with improvement in general health conditions; that is, the more recent the figures and the more favorable the climatic and cultural conditions, the greater the excess of female survivors. Females are more resistant to most infectious diseases. In the period of infancy (under 1 year) seventeen of the eighteen foremost causes of death given by the mortality statistics of the United States showed a mortality sex ratio markedly favoring girls. In childhood and adolescence the girl maintains her superior resistance. The exception at this period is tuberculosis, which shows twice as many female as male deaths in the age period 12 to 27 (Frank, 1933).

Stability of Bodily Function. A number of facts suggest greater stability of bodily function in the male. For example, glandular imbalance is much more common in females, with the possible exception of pituitary disturbance (Rowe, 1928; Dublin and Lotka, 1936; Shuttleworth, 1938). Glandular obesity is usually reported as showing a sex ratio of near 10 to 1. The mental diseases to which females are most prone are those associated with fluctuations of bodily function; mania and depression and involutional mental upset. The male shows less fluctuation than the female in body temperature (Burton, 1939; Murlin, 1939), basal metabolism (Burton, 1939), acid-base balance of the blood (Shock and Hastings, 1934), and level of blood sugar (Rowe, 1928). Females are more prone to flushing and fainting. Girls are more reactive to stress than boys, according to Sontag (1947), but recover more quickly. From such differences it would appear that homeostatic mechanisms operate within narrower limits in the male than in the female. This fact has been proposed (Johnson and Terman, 1940) as a possible explanation of the temperamental or personality differences that have appeared in many studies.

Neuromuscular Tension. There is evidence that the male is geared to muscular reactivity in greater degree than the female. Tics of the muscular-spasm variety seem to be more prevalent in boys than in girls (Terman *et al.*, 1925). At the nursery school level boys exceed girls in motility, according to Goodenough (1930). Hattwick (1937) reports that boys more often jump and squeal excessively, are tense at rest, and stay awake at nap time. Infantile tetany occurs twice as often in boys as in girls (Bakwin, 1929). Gatewood and Weiss (1930), measuring the reactions of the newborn in a stabilimeter, find males more reactive to stimulation as shown by greatly increased respiration rate. This characteristic may also underlie some of the psychological differences in interests and personality traits.

Miscellaneous Physical Differences. In the sensory field the higher incidence of defective color vision among males is well known. With older children and adults auditory defect in the perception of high-frequency tones is more common in males (Beasley, 1938; Ciocco, 1938). Left-handedness, stuttering, and alexia (nonreading) all show a higher incidence for males than for females. (Some believe these three variables to be functionally interrelated.) Epilepsy and mental deficiency are also more common among males (Danby, 1934), though the true difference is probably less than the sex ratio of admissions to state and private institutions would indicate. Scheinfeld (1943) has considered these data with regard to the greater incidence of defects in the male, along with the statistics on viability cited above, as evidence for a general biological superiority of the female.

Overlapping and within-Sex Variability. For all the physical characteristics that

have been discussed there is a large amount of variability from person to person within the same sex, and a large amount of overlapping in comparable male and female distributions. Maleness or femaleness is not an all-or-none characteristic, either physically or psychologically. Beach (1948) has summarized the research evidence with regard to sex hormones and their effects. It would seem to indicate that both the neuromuscular mechanisms and the hormonal secretions capable of mediating masculine or feminine behavior are to be found in both sexes. It is the balance between the two which is important. In the male, the masculine pattern is typically much more sensitive and easily brought into action than the feminine; in the female, the reverse is true. Furthermore, there is no polarity or opposition between the effects of the two types of sex hormones. Either androgen or estrogen can increase the responsiveness of the neuromuscular mechanisms for *either* type of sex behavior. It is a problem of *relative* sensitivities. The mechanisms for male behavior are much *more* sensitive to androgen, those for female behavior much *more* sensitive to estrogen.

To what extent the variability we encounter in psychological traits can be accounted for in terms of the variability in physical and physiological characteristics is still an unsolved problem. The evidence available does not tell us how large a proportion of psychological masculinity or femininity in human beings is linked directly with physical factors. Both Beach (1948) and Seward (1946) call attention to the fact that, as we ascend the evolutionary ladder, biological factors are of progressively less importance in determining sex behavior, and social factors are progressively more important.

There is scattered evidence, however, of some relationship between physical and psychological deviations from the sex norms. Among normal subjects a few low but fairly reliable correlations have been found between physical measures and masculinity-femininity scores on the Terman-Miles M-F test (Terman and Miles, 1936; Gilkinson, 1937). Sheldon (1940) claims to have found significant personality characteristics associated with masculinity and femininity of body build in male college students. Changes in personality in boys with hypogenitalism or adiposity have been reported when injections of testosterone were administered over a period of months. There was an impression of increased aggressiveness shown by a detachment from the family group and a greater tendency to assertiveness (Marquis, 1940). Sollenberger (1940) found a close relationship between the amount of male sex hormone in the urine of adolescent boys and their maturity of interests and attitudes; in fact the correlations reported in this research are so high as to be suspect.

It would seem that both physical and social factors may be involved in producing psychological masculinity and femininity, but the tendency at present is to give the social the greater weight. The method developed by Bayley and Bayer (1946) for the assessment of somatic androgyny (characteristics of the opposite sex) is designed to make possible some definitive research on the subject. So far it has shown (Bayley, 1951) that no consistent relationship between physique ratings and M-F scores on the Kuder Preference Record can be demonstrated for 79 boys and 83 girls in the Guidance and Berkeley Growth studies. Further studies using this technique should clarify the issue.

Sex Differences in Abilities

A tremendous amount of work has been done on differences between the sexes in intelligence and special mental abilities. It

would be far beyond the scope of this review to summarize all these separate investigations. We shall rather begin with the generalizations that seem to be warranted by the bulk of the research evidence and then cite some typical studies, particularly the more recent ones, in connection with each statement. These generalizations are as follows:

1. If there is a difference between the sexes in general intelligence, it cannot be identified by means of our present tests, since some types of problem favor males, others favor females, and there is no satisfactory way to decide which ones constitute more valid indicators of general mental ability (McNemar, 1942).

2. Girls tend to excel on verbal types of problem; boys, on quantitative or spatial.

3. School marks almost universally indicate superior achievement for girls, whereas achievement tests show girls superior in all kinds of language material, boys in science and mathematics.

4. Vocational aptitude tests show boys higher in mechanical, girls in clerical, aptitudes.

5. Ability differences are most apparent at the older age levels in children. Most of them do not show up at the preschool period.

General Intelligence. Much of the confusion arising from conflicting reports based on different samples of the population has been cleared up by the Scottish Mental Surveys. The first of these (1933) involved a verbal group test of practically all the children (except the blind or deaf) who were born in Scotland in a given year, totaling over 87,000. The test was administered when the subjects were between 10½ and 11 years of age. The means for the sexes were almost identical. The 1916 Stanford-Binet was given to a subsample of 500 of each sex. After a correction was applied to free the sample from bias due to overrepresentation of superior children there was no reliable difference between the sexes in mean IQ.

In the second Scottish survey (Macmeeken, 1939) the 1916 Stanford-Binet was given to all living children who had been born in Scotland on one of four specified days of 1926 (444 boys and 430 girls). This is the most nearly perfect sampling in the history of psychometrics, for only a single child who should have been tested was missed. Here again the mean IQ's were almost identical for the sexes.

The issue was somewhat confused, however, by the results of the later Scottish survey reported in *The Trend of Scottish Intelligence* (1949). This time a complete sampling of all children born on six specified days in 1936, 1215 in all, gave mean IQ's of 104.387 for the boys and 100.734 for the girls on the Terman-Merrill Revision, Form L. The difference is 3.24 times its standard error. In contrast to these findings, on the group test given to all children born in 1936, the girls scored 1.74 points higher than the boys, a difference which because of the large numbers involved is also statistically significant. These figures would seem to lend further support to the conclusion that the direction and magnitude of sex differences in intelligence depend primarily on what test is used.

Another good sampling was made by Roberts *et al.* (1935), who gave the Otis advanced test to all children of Bath, England, born between specified dates in 1921 and 1924. The sample included 1336 boys and 1217 girls, aged 9½ to 13½ when the tests were administered. The sex difference was minute and unreliable.

The amount and direction of difference on nonverbal and performance tests depend upon the specific nature of the tests used. Data were reported by Pintner (1924) for 924 subjects aged 10 and for 1346 subjects

aged 12 given his nonlanguage group test. No reliable sex difference was found. Lincoln's (1927) data on 200 to 400 subjects at each age from 7 to 16 given the Dearborn general examination showed only small and inconsistent differences between the sexes. Goodenough (1926) gave sex comparisons for nearly 1600 subjects, ages 6 to 11 years, on her test of drawing a man. The girls were superior at each age, the critical ratios ranging from 0.5 to 2.7. That this is some function of cultural differentiation is shown by the findings of Dennis (1942) and Havighurst, Gunther, and Pratt (1946) that in some Indian societies boys are superior to girls on the Goodenough Test. The previously mentioned Scottish group, consisting of 444 boys and 430 girls born on specified days in 1926, was given between the ages of 9 and 11 a battery of eight performance tests including a form board, a manikin, two picture-completion tests, cube construction, and Kohs block designs. The difference favored boys (CR = 3.74).

It is possible that the increasing use of primary mental abilities tests based on factor analysis will gradually clarify the reasons for the sex differences on some intelligence tests. Hobson (1947), using as subjects several fairly large groups of eighth- and ninth-grade students, found that girls made higher scores on W (word fluency), R (reasoning), and M (rote memory), whereas boys were higher on S (space), and V (verbal meanings). Havighurst and Breese (1947), who tested all 13-year-old children in a typical midwestern community, found that girls excelled on N (number), W (word fluency), R (reasoning), and M (rote memory), the boys on S (space). They found no difference on V (verbal meanings). It is interesting to note that neither study showed male superiority on N, which we might expect on the basis of the school achievement tests, and that the well-substantiated verbal superiority of girls would seem to be one of fluency rather than of meanings and concepts. Male superiority on S is in line with the findings on mechanical aptitude (Bennett and Cruikshank, 1942). Lord (1941) showed that boys as young as fifth-graders are superior to girls in locating places and naming the primary directions.

British psychologists have been particularly interested in the space factor because of its relationship to ability to learn practical skills. Smith (1948), who administered nine paper-and-pencil tests of spatial ability to 100 boys and girls ranging in age from 12.5 to 14.5, obtained a significant sex difference on spatial tests when there was none in verbal intelligence tests. Emmett (1949) has re-analyzed data from several large-scale studies to show that there is a special spatial ability that can be identified by the age of 11, and that boys are clearly superior to girls in tests in which it is involved.

The youngest group for which a sex comparison based on factor analysis is available is in a study reported by Mellone (1944). His subjects were 7-year-olds, 218 boys and 196 girls, who were given a battery of picture tests of mental ability. For the girls, one general factor alone accounted for the correlations, but boys showed a separate space factor as well. This study suggests that mental abilities during the course of development may come to be differently organized or related to each other in the two sexes.

That the abilities on which boys and girls differ may be even more narrowly specialized than the factor analysis studies indicate is suggested by results reported by Duggan (1950). Immediate recall tests administered to mixed groups of secondary school students showed girls to be superior at observational noting and remembering

words, and boys to be superior in remembering numbers.

A report on sex differences in an entirely different sort of ability from those we have been discussing comes from Witkin (1949), who has been working with perceptual situations in which the subject must separate kinesthetic from visual cues in making judgments of the upright. Pronounced sex differences have been found, males at all ages tested showing superiority in this type of perceptual analysis. With the rod-and-frame test the differences were apparent with children as young as 8. The relationship of these differences in perception to other abilities and personality characteristics is being investigated.

Achievement in the Language Areas. Most of the many studies based on school achievement tests have shown girls to be superior in tasks involving the use of language. Stroud and Lindquist (1942), using large random samples of all students who had been given the Iowa Every-Pupil tests from 1932 to 1939, report for the grade school comparisons that the girls are higher on reading comprehension, work study skills, and basic language skills. High school comparisons, probably reflecting some unknown selective factors with regard to continuation in school, show boys superior on everything *except* reading comprehension. Stalnaker (1941), reporting on the English examination of the 1940 College Entrance Examination Board, shows that there are large and significant differences in favor of girls that cannot be explained in terms of selection, since boys average better on the other examinations and on the Scholastic Aptitude Test.

School surveys using reading tests, if they show any significant difference, usually show higher scores for girls. Moore (1939), giving results from a number of school groups ranging in level from eighth grade to college seniors, reports that girls are consistently superior on the Van Wagenen Rate of Comprehension Test, although not all single differences are significant. In a further study (1940), in which he reports speed scores on the Iowa silent reading test for all white pupils in grades 6, 8, 10, and 12 in two southern towns, the only reliable difference (CR = 2.9) favored the girls in grade 8, and this was accompanied by a reliable difference favoring girls on the Otis test of mental ability (CR = 3.5). Jackson (1944) found that the 300 advanced and 300 retarded readers, grades 2 to 6, whom he picked out for an interview study on the basis of a reading test included a disproportionate number of girls in the high group (59.0 per cent) and of boys in the low group (63.3 per cent). A study carried on by Samuels (1943) of all English-speaking first-graders in Phoenix, Arizona, shows girls reliably superior on the Kuhlmann-Anderson intelligence test, reading readiness at the beginning of the year, and reading achievement at its close. When boys and girls were paired for intelligence and school situation, the achievement differences still favored girls. [The Kuhlmann-Anderson intelligence test is one on which girls of all ages consistently get better scores than boys (Lewis, 1945).]

On the other hand, a number of school surveys have not shown any tendency toward female superiority. Heilman's (1933) data for all 10-year-old children in the public schools of Denver showed no sex difference for either of the reading subtests of the Stanford Achievement Tests. Schiller (1934) found no reliable sex difference from her application of the Gates silent reading test to third- and fourth-grade subjects. Results on the Thorndike-McCall reading test have been reported by Thorndike *et al.* (1934) for 266 boys and 200 girls aged 13 to 15 years, and for 785 boys and 905 girls in the eighth grade of New York City public schools. In the first of

these groups there was a reliable difference favoring girls; in the second, a reliable difference favoring boys. McIntyre and Wood (1935) administered tests of reading achievement to approximately 33,000 subjects in Australia. The tests provided separate measures of vocabulary, speed of reading, reading for general meaning, reading for detail, and reading for inference. Only on speed of reading were there consistent and reliable sex differences favoring girls. Millard (1940), in a longitudinal study over the 6-year grade-school period using Courtis growth curves, found some sex differences in the constants in the equations (representing differences in the shape of the curves) but no difference in ultimate achievement. In Jordan's (1937) comparison of high school senior boys and girls in North Carolina on two reading tests, girls were superior to boys, although only one of the differences was statistically significant. On the other hand, score distributions reported by Woody (1937, 1938) on the Traxler silent reading test applied to first- and second-year high school students in a Michigan survey yielded mean differences (computed by Kuznets) that favored boys.

The fact that most of the reading investigations reporting female superiority have been based on speed of reading tests, coupled with the above-cited evidence from the primary mental abilities studies that it is fluency rather than verbal meanings in which girls excel, gives us some clue as to a possible reason for the discrepancies between reported results. This interpretation is substantiated by the work on general vocabulary, in which there appears to be no sex difference. Gansl (1939) used a 100-item multiple-choice test in all regular classes of grades 3 to 8 in two New York City public schools. In one school all the means for ages 8 to 14 favored boys, but only at age 12 was the difference statistically significant. In the other school the differences were neither reliable nor consistent. Schiller (1934) did not find a reliable sex difference on the vocabulary subtest of Thorndike's CAVD given to 189 boys and 206 girls in the third and fourth grades of a Brooklyn public school. Similarly small and inconsistent differences were reported by Bryan (1934) for 100 boys and 100 girls at ages 5 and 6; by Garrett, Bryan, and Perl (1935) for ages 9, 12, and 15; by Broom (1930) for 600 junior high school subjects of each sex; by Hales (1932) for a large group of 12- to 16-year-old Australian subjects; and by McIntyre and Wood (1935) for Australian children aged 9 to 12. The count made by Smith (1926) of words used by 68 boys and 69 girls under age 2 did not reveal consistent differences in favor of either sex, and a vocabulary test devised by Terman and used with 100 children of each sex, aged 2 to 6 years, showed no reliable sex difference.

On the other hand, even in very young children there would seem to be a sex difference in what might be called verbal fluency. The mean age of learning to talk appears to be slightly lower with girls than with boys. According to mothers' reports on 502 gifted children (Terman *et al*, 1925) the difference was approximately 3 weeks, or 5.52 times its standard error. In the same study girls were reported as using short sentences earlier than boys, but this difference was not very reliable (CR = 1.71). There is a possibility, of course, that mothers' reports of this kind are subject to a memory bias favoring girls. Smith (1926) and McCarthy (1930) reported the mean length of spoken sentences among preschool children to be slightly greater for girls, although the age-sex groups in both studies were too small to afford reliable differences.

Several studies indicate a slight superiority of girls in articulation, intelligibility, and correctness of speech sounds. In a

study of speech sounds of 204 preschool children Wellman *et al.* (1931) found differences in correctness of consonant sounds that were fairly reliable at ages 3 and 4 (CR's = 2.6 and 2.5). Differences in the correctness of vowel sounds were not significant. Little and Williams (1937) in a study of speech sounds, intelligibility, and organization, based on 177 preschool subjects and 155 orphanage children of preschool age, concluded that "there is a general tendency for girls to score higher than boys in all areas and at most age levels." This conclusion, however, was not supported by the data which the authors presented. In 18 sex comparisons of the preschool group 9 favored girls, 8 favored boys, and 1 showed no sex difference. Of 15 comparisons for the orphanage group, 9 favored girls, 6 favored boys. The age-sex groups were small, and tests of significance were not given. On the whole, however, the reported results may indicate greater verbal fluency for girls.

The well-known fact that many more boys than girls are stutterers is consistent with these findings. Schuell (1946, 1947) offers some evidence that the difference in the incidence of stuttering may have an emotional rather than an intellectual basis. A questionnaire on family attitudes and treatment was administered to 134 girls and 156 boys, aged 8 to 14. There were statistically significant differences with regard to punishment and praise at home, attitudes toward school, and things worried about. It raises the interesting possibility that the advantage girls have in verbal fluency in general might be related to their more secure emotional attitude, but considerably more research would be needed to substantiate it.

A study by Anastasi and D'Angelo (1952) brings out another aspect of the problem of sex differences in language skills. Their subjects were comparable groups of 50 white and 50 Negro 5-year-olds in day care centers. Besides giving the Goodenough Draw-a-Man Test, they analyzed various language characteristics shown in the children's speech. Girls in both groups scored significantly higher than boys in the drawing test. On the language measures, however, the direction of the sex difference was opposite for white and Negro children. White girls scored significantly higher than boys, but Negro boys scored significantly higher than girls. The authors do not attempt to account for this reversal of trend except to note that it is difficult to reconcile with purely biological explanations.

Achievement in Science and Related Areas. One of the most clear-cut and consistent sex differences at the high school level and above is the difference in science knowledge and achievement. Edgerton and Britt (1944, 1947) have furnished some valuable evidence on this point. In the Science Talent Search, every year from two to three times as many boys as girls apply, which might lead one to expect that the girls would be more highly selected. Yet, in spite of this fact, the boys have each year obtained higher scores on the test. Differences are unquestionably significant and always in the same direction. Jordan (1937) in his survey of North Carolina high school seniors, which included some 8000 boys and 11,000 girls, reported an astronomically large critical ratio in favor of boys on the science section of the achievement test used (CR = 31.7). Learned and Wood (1938) in their valuable study of the achievement of college students reported achievement scores in natural science for 2992 men and 1410 women. The mean was markedly higher for men, the difference being 24 times its standard error. Some interesting supporting evidence comes from a study by Zapf (1945) in which ninth-grade girls are reported to be signifi-

cantly more superstitious than boys of the same age level.

Studies using elementary school subjects ordinarily show differences in the same direction, but less marked. Terman *et al.* (1925) reported achievement test scores for sex groups of about 560 gifted children and an equal number of unselected children, all in grades 3 to 8. The gifted sex groups were closely equated for IQ. On 110 items of science information the difference in means consistently favored boys in both the gifted and unselected groups, though in a majority of the 13 comparisons the differences lacked statistical significance because of the small N's at a single age. Heilman's (1933) study of unselected 10-year-olds in Denver reported a higher mean for 464 boys than for 482 girls on the nature study and science section of the Stanford Achievement Tests (CR = 2.6). Considering the large numbers in the study, this critical ratio would seem to represent a comparatively small difference.

Studies of primary and preschool children on types of thinking that might be assumed to be related to science achievement report no significant sex differences. Bergen (1943) attempted to find out what procedure or sources of information third-grade children would utilize in solving problems of causal relationships. There seemed to be no consistent sex differences. Dickinson and Tyler (1944) found no sex differences in the ability to form concepts at the second-grade level. McAndrew (1943) obtained no significant sex differences in 3- to 6-year-olds in ideas of causality as shown by their answers to questions and their analysis of "tricks." These findings are consistent with the hypothesis that the difference in science achievement is one which develops during the school period and is related more to a difference in interests than to a difference in basic abilities.

Achievement in Arithmetic. Studies based on achievement tests given in grade school are not entirely consistent, but in general they tend to show a slight male superiority in arithmetical reasoning, and either no difference or female superiority in simple computations. As in the case of science, it appears that, the lower the age group tested, the less significant is the difference. Heilman's (1933) study of 10-year-olds in Denver showed girls superior to boys in the arithmetic computation test of the SAT battery (CR = 2.10) and boys superior to girls in the arithmetic reasoning test (CR = 2.68). In his monumental study of the mental and scholastic achievement of London children Burt (1921) reported sex comparisons in seven phases of arithmetical achievement for about 250 of each sex at each age from 8 to 12 years. In oral arithmetic boys were reliably superior at every age. In "mechanical" arithmetic the differences were unreliable except at age 12, where they favored boys. In arithmetic problems the differences were reliably in favor of boys at all ages and were particularly large at ages 11 and 12. In addition, subtraction, multiplication, and division (five age-sex comparisons for each) there were only two reliable differences, both favoring girls in addition. Schiller's (1934) data for 189 boys and 206 girls in grades 3 and 4 showed no appreciable sex differences in computation, but in arithmetical reasoning boys were reliably superior (CR = 4.17). Cunningham and Price (1935) reported the results of arithmetic tests given to approximately 40,000 children in Australia. In the four fundamental processes the differences were small and inconsistent. In "mechanical" arithmetic the differences all favored boys but were not statistically significant. In "problem" arithmetic the differences all favored boys and were highly reliable. Grossnickle (1937) gave a test of "concepts in social

arithmetic" to 667 boys and 670 girls at the end of the eighth grade. The sex difference favored boys and though small in magnitude was statistically significant (CR = 5.4).

At the primary and preschool levels there seems to be little differentiation. Buckingham and MacLatchy (1930) studied the number abilities of approximately 1000 first-grade entrants aged 6 to 6½ years. The subjects were tested in rote counting by 1's and by 10's, counting 20 objects, number selection, and number identification. In all but 2 of 11 comparisons the difference favored girls, the critical ratios ranging from 1.03 to 2.90. Woody (1931) gave an individual inventory test in arithmetic consisting of 205 items to approximately 100 children in kindergartens, 600 in grade 1B, 1800 in grade 1A, and 300 in grades 2B and 2A. Boys were superior in all comparisons, but in no case was the difference statistically significant. The standardization data on which the 1937 Stanford-Binet revision is based afford sex comparisons on concept of 1, concept of 2, concept of 3, concept of 4, counting to 3, counting 13 pennies, counting taps, knowledge of numbers, making change, and arithmetical reasoning. On concepts of 1, 2, 3, and 4, there are 16 sex comparisons by age on percentages passing, of which 11 favor girls and 4 favor boys. In the three counting tests the sex difference favors girls in 11 comparisons, boys in 2. In knowledge of numbers the differences are small and inconsistent. In making change all 6 comparisons favor boys. The most reliable differences are for the test of arithmetical reasoning, the boys being superior in all the age groups.

From the above studies it appears that in arithmetical achievement the sex differences are small at the lower levels represented by routine computation and that they progressively favor boys as we go toward the more complex levels of arithmetical reasoning. In the work reported by Blackwell (1940) there is an interesting suggestion that the mental processes by means of which mathematical problems are solved become differentiated in boys and girls as development proceeds. He made a factor analysis based on a battery of mathematics tests given to 100 boys and 100 girls, aged 13½ to 15 years. The first two factors that emerged were alike for the two sexes, the well-known *g* and a factor he called *o* representing the carrying-out of mathematical operations. The third factor *v* seemed to be more specifically verbal in girls and more like verbal reasoning in boys. A fourth factor was identified for girls but not for boys, a factor which seemed to represent precision or exactness.

Sex Differences in Dispersion. The hypothesis of greater male variability in mental traits has frequently been invoked to explain the preponderance of males among the ranks of both mental defectives and genius. Some supporting evidence has accumulated, but on the whole there is about as much against the idea as in favor of it. Hollingworth (1922) has shown that the excess of males in institutions for the feeble-minded might well be accounted for in terms of biased samplings. McNemar and Terman (1936) made an extensive survey of the most reliable and objective data available on variability of the sexes in physical traits, scholastic achievement, and intelligence. The results for achievement are far from consistent but on the whole afford a slight preponderance of evidence favoring greater male variability. In the less-well-standardized psychological tests the evidence breaks about evenly for the sexes. However, of 33 comparisons based on such standardized tests as CAVD, NIT, the Pressey group test, and the 1916 Stanford-Binet, 29 showed greater variability for males, the mean of the critical

ratios being 1.47. This mean is 8.4 times its standard error. On the other hand, the carefully selected group tested in the standardization of the 1937 Stanford-Binet scales, including about 1500 of each sex, showed no consistent sex differences in dispersion. Perhaps the best data of all come from the Scottish surveys previously mentioned. In the first study, using the group test, the variance ratio is significant at the 1 per cent level. In the second, however, using the Binet test, the variance ratio falls just short of significance at the 5 per cent level. The third (1949) shows a slightly higher standard deviation for girls on the individual test and for boys on the group test. Thus the answer to the question of sex differences in intelligence variability would seem to depend on the nature of the test.

Comparisons of the incidence of gifted boys and girls in the population differ in their findings. A school population of 168,000 in grades 3 to 8 which was sifted by Terman *et al.* (1925) for children of 140 IQ or higher yielded 352 boys and 291 girls who reached this standard, a ratio of about 6 to 5. Of these, 65 boys and 48 girls reached or exceeded 160 IQ, a ratio of approximately 5.4 to 4. A large high school population sifted by the Terman group test yielded 257 boys and 121 girls whose scores were judged to be the equivalent of 140 IQ or higher on the Stanford-Binet, but differential selective factors in the high school samples of boys and girls would keep us from attaching too much importance to this large difference. Witty (1930), on the other hand, found no difference in the proportions of boys and girls in his high-IQ group, and Lewis (1945), in the largest survey ever made of exceptional children, involving the selection of the top and bottom 10 per cent from 45,000 fourth- to eighth-grade children in 455 schools, 310 communities, and 36 states, reported a sex ratio of 146 girls to 100 boys in the high group. Differences in the bases for selection probably underlie the discrepancies in these findings. Terman used teachers' judgments for his preliminary screening, and tested those reported to be the brightest in their schools. However, a statistical study of nominations did not suggest that these favored boys because of prevailing stereotypes. Lewis used the Kuhlmann-Anderson test, which appears to be somewhat overly weighted with content favoring girls.

It seems unlikely on the basis of present evidence that the enormous differences in male and female eminence which all studies of genius show can be accounted for by greater male variability alone. Differences in motivation and opportunities appear to be more plausible explanatory factors.

Sex Differences in Motivational and Personality Traits

Interests. In contrast with the small and often inconsistent differences reported with regard to sex differences in mental abilities, the evidence for differences in interests of the two groups is unequivocal. Furthermore, such differences show up with as much clarity in the primary and preschool groups as in those approaching adulthood. This does not in itself argue for a biological explanation, but it does indicate that any social sex typing which occurs must begin very young.

Plays, Games, and Other Activities. Sex differences are prominent in the play and other spontaneous activities of children in cultures ranging from the very primitive to the most advanced. In part these differences reflect the division of activity that prevails between males and females in the adult population, though not all the plays of children, even among primitives, are imitative of adult behavior.

There are certain general types of plays and games that are common to cultures widely separated with respect to the adult occupational activities (Miller, 1928). Endogenous factors that might be expected to contribute to sex differences in children's play activities include physical strength and energy, motor speed and skills, and the temperamental predisposition to given types of emotional and social response.

Hildreth (1933) reported data on the recreational and play interests of 89 boys and 84 girls in the ninth grade and of 52 boys and 51 girls in the twelfth grade enrolled in one public and one private school. Check lists were given out, and subjects were asked to designate the three games they liked best. Rank orders of games and activities differed as between public and private school, showing the need of wide sampling as a basis for generalizations in this field. Football was chosen almost exclusively by boys. Baseball was most popular with boys, but it also ranked among the five games most popular with girls. There was little difference in basketball, handball, or soccer. Bridge, golf, tennis, and croquet rated higher with girls; boxing, chess, and wrestling with boys. Similar data secured for other activities showed swimming and ice skating about equally popular with the sexes. Rating higher with boys were bicycle riding, driving automobiles, fishing, and camping; higher with girls were social dancing, horseback riding, reading, and attending movies. This study illustrates the growing tendency of girls to participate in games formerly monopolized by boys. That adolescent girls, however, are less interested than boys in athletic activities in general is shown by a study by Hammond (1945) in which activities checked by boys and girls on Youth Center enrollment blanks were correlated and factor-analyzed. Boys were higher on the factor representing athletic activities, girls on the factor covering artistic activities, dancing, etc. A report by Lund (1944) seems to indicate that interest in athletic activity decreases in girls throughout the high school period. The percentages of boys and girls in a high school presenting medical excuses to enable them to get out of physical education classes were compared for each grade from seventh through twelfth. At the seventh-grade level, 6.7 per cent of the boys and 6.8 per cent of the girls presented such excuses. There was little change from year to year for the boys, but the percentage for the girls increased steadily until, at the twelfth-grade level, 7.6 per cent of the boys and 24.3 per cent of the girls presented excuses. Since it seems extremely unlikely that this represents a deterioration in the health of the girls over this period, the trends must be ascribed to differences in motivation.

At the elementary school level also there are marked differences in what boys and girls like to do. In a study of the play interests of 554 gifted and 474 unselected children of grades 3 to 8 Terman *et al.* (1925) reported a "masculinity index" for each of 90 plays, games, and activities. The indices were based on knowledge of, interest in, and time devoted to, the various activities by unselected boys and girls. The masculinity ratings of these 90 activities are here given in terms of standard scores in the order from most to least masculine, the score 13 representing the line of neutrality.

24. Tools.
21. Shooting.
20. Kites, bicycles, marbles, wrestling, boxing, football.
19. Tops, machinery, baseball.
18. Fishing.
17. Bow and arrow, skiing, tug of war, soccer.
16. Stilts, garden work, basketball, pool.

15. Hoops, swimming, rowing, hunting, snap the whip, shinny, racing and jumping.
14. Coasting, hiking, riding, duck on rock, leap-frog, bowling, handball, backgammon, checkers, chess, billiards.
13. (Line of neutrality) Red Rover, pom-pom pull-away, follow the leader, anty over, roly-poly, fox and geese, croquet, volleyball, dominoes, crokinole, parchesi, tiddledy-winks, snap, cards, history cards, geography cards, word building.
12. Jackstraws, postoffice, blackman, fox and hounds, tennis, authors.
11. Tag, hide and seek, puss in corner, dare base, Simon says, playing church, solving puzzles.
10. Jackstones, skating, drop the handkerchief, blindfold.
9. Ring around the rosy, London Bridge, farmer in the dell, in and out the window, cat and mouse, jumping rope, guessing games, charades.
8. Dancing, sewing, playing store.
7. Knitting or crocheting.
6. Playing school.
5. Cooking, playing house.
4. Hopscotch.
3. Dressing up.
2. Dolls.

An outstanding fact brought out by these masculinity ratings is that nearly all the games that involve strenuous activity are definitely on the masculine end of the scale.

Similar results have been obtained by Lehman and Witty (1927) in a series of surveys on children's play activities involving some 17,000 city children and over 2000 rural children. On a list of 200 play activities the children were told to check anything they had done during the past week just because they wanted to, and to indicate the three things they liked best. The results are difficult to evaluate, as sex differences are shown only in the form of graphs and rank-order lists. However, a number of these differences are evident. In the first place, boys are more variable than girls in their play life. Boys more often engage in the following types of activity: active, vigorous plays and games; those involving muscular dexterity and skill; those involving competition; and the more highly organized plays and games. Girls, on the other hand, are more conservative in their play life; they participate more often in sedentary activities and in activities involving a restricted range of action. On the whole, the largest sex differences occur for ages 8½ to 10½, inclusive. After 10½ the similarities in activities become more and more evident as chronological age increases; at least more activities are common to the sexes and the range of interest of each sex becomes narrower. The authors' data on specific games are similar to Terman's.

J. C. Foster (1930) asked 738 boys and 685 girls in the first six elementary grades of Minneapolis schools to list the games (10 or less) played within the last year, indicating whether the game was played outdoors or indoors. She then classified the games into 11 types, using such headings as (1) catching, throwing, kicking, (6) informal dramatization, and (11) group games of the guessing type, for example. There were no very marked sex differences in preference for these 11 classes of games, although the catching, throwing, and kicking games constituted at every age a larger percentage of those listed for boys than for girls. Girls showed a greater interest in the outdoor jumping and hopping games, and, except for age 6, a greater interest in informal dramatizations. Data for individual games in general corroborate the Terman and the Lehman and Witty findings.

One method of identifying interest differences is through the analysis of choices made from play materials. Honzik (1951), using as subjects 163 eleven-year-olds, 164 twelve-year-olds, and 154 thirteen-year-

olds, presented a variety of materials with the request that the child create a dramatic scene for a movie. The boys showed a strong tendency to choose blocks, vehicles, and people in uniform, the girls to choose furniture and people in ordinary dress.

Erikson (1951) has presented some other results from the same study. Not only did these preadolescent boys use blocks a great deal more than the girls did, but they used them in characteristically different ways. There were statistically significant sex differences in the extent to which high structures, ruins, and moving objects momentarily stopped were shown. In these categories, boys were higher. Girls used the blocks to mark off open enclosures, usually the interiors of houses, and they built predominantly static scenes. Erikson analyzes some of the internal evidence suggesting that basic physical and anatomical differences rather than environmental factors underlie these behavior tendencies.

Farwell (1930) tested experimentally the reactions of young children to constructive play materials. The subjects were 125 boys and 146 girls enrolled in kindergarten, first grade, and second grade. The children were taken in small groups to a room equipped with several sets of materials for modeling, building, drawing, painting, sewing, cardboard construction, and paper construction. The time spent by each child on each of the activities during fourteen 30-minute play periods was recorded. The building material gave the largest sex differences, boys at all age levels devoting about 50 per cent of their time to it as compared with 5 per cent for the girls. Girls devoted about 30 per cent of their time to painting and the same amount to modeling. Painting and modeling were also popular with boys, but less so than with girls. In their modeling and painting, the boys showed more interest in vehicles, the girls in articles of furniture. It is interesting to note that a Japanese report by Oyama and Kido (1939) also states that preschool boys choose to model movable objects, girls static ones, although in the abstract available there were not enough supporting data to evaluate the statement.

Data on children's collections obtained by Terman (1925), Lehman and Witty (1927), Witty and Lehman (1930), and Whitley (1929) have shown little or no sex difference in the number of collections made, but a strong tendency for boys and girls to collect different things. Boys are more likely than girls to collect stamps, girls more likely than boys to collect dolls or pieces of cloth. There is a wide diversity for both sexes in types of items collected.

Reading, Movie, and Radio Interests. Sex differences in reading preferences are among the most interesting to be found in any field because of the clear indication they give of a fundamental difference in masculine and feminine interests. At home, at school, and in public libraries the books to which children are exposed are largely the same for boys and girls; yet marked sex differences in reading preferences are evident as early as the primary school grades and persist to adult years. These differences can hardly be due to direct adult pressures, for children are notoriously perverse in reading the kinds of books they find interesting rather than those urged upon them by parents and teachers. Whereas there are girls' games that are practically taboo for boys, there is no comparable pressure to keep boys from reading fiction or girls from reading adventure stories. Because the kind of book a child reads is less noticeable than the kind of play he engages in, reading

largely escapes censorship so far as separate standards for the sexes is concerned.

Studies at high school and elementary school levels practically all agree that girls read more than boys, and that their choices run to milder stories of home and school as contrasted with the active or violent adventure preferred by the boys. Adams (1936), reporting on the use made of the school library by the 17,616 pupils enrolled in 24 high schools, reported that girls exceed boys in number of books read and in frequency of library attendance. In both junior and senior high schools, boys more often read newspapers, whereas girls spend more time on magazines, books, and poetry. Jordan (1921) studied the reading interests of some 3500 children in grades 6 through 12 in three towns and one city. Each child was asked to name in order of preference the 5 books and the 3 magazines he liked best of any he had ever read. Three categories, as classified by the author, accounted for more than 90 per cent of the book choices of each sex: adventure, novels, and stories. Boys showed a definite preference for adventure; girls, for novels and stories. Percentages of total choices were as follows:

	Boys	*Girls*
Adventure	58	18
Novels	18	42
Stories	15	35

In the magazines listed by the children, adventure and science titles were more prominent in the boys' choices, woman's arts in the girls'.

Johnson (1932) obtained data on the reading of 888 boys and 968 girls in 19 different Minnesota schools, grades 6 through 11. The children were asked to keep a detailed record of their reading over a period of 1 month. The most pronounced sex differences were for scientific articles in magazines (46 per cent of boys and 17 per cent of girls) and sports sections of newspapers (74 per cent of boys, 34 per cent of girls). More boys than girls read the crime news and the national news. More girls than boys read the children's page, the society news, the home page, and the advertisements. Among the books reported, there was not one common to the boys' and girls' lists of 10 most frequently read. Preferences of boys for adventure stories, and of girls for stories of home, school, and children, were apparent.

Terman and Lima (1926), with a somewhat younger group, aged 9–15, obtained similar results when 511 gifted children and 808 control children were asked to keep 2-month reading records. The girls in both gifted and control groups read 20 to 30 per cent more books than the boys. The girls read enormously more stories of home and school life and decidedly more emotional fiction, whereas the boys read many more stories of adventure or mystery. Percentages of books falling in certain categories were as follows:

	Boys	*Girls*
Stories of adventure or mystery	56	18
Stories of home or school life	2.5	32
Emotional fiction	3.5	16
Informational fiction, including the classics	15	11
Fairy tales, folk tales, and legends	7	10

The authors also obtained information from 602 gifted and 1225 unselected children as to the books they "had most enjoyed reading last year." As in other, similar studies, all the books receiving most choices were fiction. In the two lists of the 20 most liked by each sex, there were only 5 common titles. These were boys' books that are sometimes read by girls. Boys almost never read girls' books, yet they have a wider range of interests in reading and do less rereading than girls.

Russell (1941), who studied library choices among ninth and tenth graders in Saskatchewan, obtained the same kind of results for this Canadian group as are customarily found in the United States, girls tending to prefer milder adventure and romance, whereas boys chose more active fiction.

Thorndike and Henry (1940) presented a list of fictitious titles to rapid-learning and slow-learning groups in grades 6, 7, and 8, asking them to check those they would like to read. The sex differences in choices were considerably greater than the intelligence differences. The girls, both bright and dull, preferred mild adventure stories about children, love and romance, descriptions of feminine activities, and self-improvement. The boys more frequently chose violent or outdoor adventure, sports, travel, exploration, and war. In some of the other categories the sex differences seemed to depend on the sex of the person mentioned in the title. A similar study by Baumgarten-Tramer (1945–1946) found that 40.1 per cent of the boys' choices were for adventure stories, whereas 52.8 per cent of the girls' choices were for familiar stories, biographies, and "stories of destiny."

The phenomenal popularity of comic books with children has called attention to the fact that there are some reading materials that are very well liked by both boys and girls. Andersen (1948) found in a questionnaire study of 686 seventh- and eighth-grade pupils that for both sexes comic books headed the list of things liked. Witty (1941) and Witty, Smith, and Coomer (1942) found that both comic strips and comic books were ranked high by both sexes, grades 4 through 8, and that, though there were some discrepancies in the ratings given specific magazines, the same ones were ranked high and low by both sexes. A study by Butterworth and Thompson (1951), however, in which the list of comic books used in the questionnaire was based on titles mentioned spontaneously by children in a previous study, shows the same type of sex differences for 1256 subjects in grades 5 through 12 that have been obtained using other varieties of reading matter. Boys prefer adventure and sports; girls prefer adolescent activities, romance, and real people.

Studies of radio listening habits show a trend toward high popularity and not much differentiation. Longstaff (1936), Eisenberg (1936), Clark (1940), and Riccuti (1951) all report data of this sort. Eisenberg shows that, of the 28 programs most popular with boys, all but 8 are found in the 28 most popular with girls, and the correlation between order of preference for the two sexes is .88. What difference there is between the two is of the kind one would expect from the reading studies and shows girls giving higher rank to programs of sentiment and emotion, home scenes, and everyday realities, while boys rank higher programs of mystery, strenuous adventure, and detection of criminals.

In movie interests we find patterns of sex difference similar to those for reading.

	Boys	*Girls*
Adventure	15.3	6.5
Romance	3.9	19.4
Tragedy	3.3	9.2
War	5.1	1.9
Western	20.4	12.0

Written quizzes given by Mitchell (1929) to about 10,000 children in grades 5 to 12 showed significant differences in five of the ten categories into which choices were classified. The percentages for these were as tabulated. Abbott (1927) analyzed ratings obtained from high school boys and girls of 54 films from the "Selected List" of the National Board of Review, and con-

cluded that both sexes want plot, action, and suspense; that the boys like comedy and dislike romance and too much emotion, whereas the girls like romance and appeal to sympathy, dislike comedy, and show greater sensitiveness to ethical questions. Seagoe (1931) and Hicks and Hayes (1938) report differences of somewhat the same sort.

An approach to the problem of differential interests from a slightly different direction was made by Coleman (1931), who analyzed the subjects chosen for written compositions by 5000 children in grades 7 to 12. The children were given three lists of titles, of 36 each (representing 36 categories), and were allowed to choose one title from each list for a composition. Titles that are reliably more popular with boys fall in such categories as current events, famous people, machines, handwork, modern industries, and outdoor activities. Categories appearing reliably more often in girls' choices include children, home life, personal experience, proverbs, religion, sentiment, sympathy, travel, school, literature, art, and human anecdotes. The sex differences here are strikingly like those found for reading interests.

Preferences for School Subjects. Three studies in widely separated places have reported the same types of sex difference in subject preference at the high school level (Book, 1922; Colvin and MacPhail, 1924; Livesay, 1942). Book's populations included 2300 boys and 3400 girls in Indiana. The populations studied by Colvin and MacPhail included a fifth of all high school seniors in Massachusetts, so chosen as to make a representative sampling. Livesay's subjects were seniors in Hawaii high schools. In all three, the boys named science, mathematics, and history or social studies more frequently than did girls, whereas girls more often listed English, commercial studies, or languages as preferred.

Hicks and Hayes (1938) secured data on subjects best liked and least liked by 102 boys and 148 girls in a junior high school, grades 7 to 9. The sex differences followed about the same pattern as those found for high school seniors. Boys more often than girls prefer mathematics, science, and the social studies (history, civics, and geography); English is far more popular with girls.

There is evidence that the sex differences are the same for different ability levels. Blair (1938) has reported subject preferences expressed by mentally superior and mentally inferior children in junior and senior high school in the state of Washington. His population included approximately 200 of each sex in both superior and inferior groups, or more than 800 subjects in all. The superior and inferior groups had IQ's respectively 1 standard deviation above or 1 standard deviation below the mean of their class populations, so that there was a large intelligence difference. For each school subject except history and social science the direction of sex difference is the same in both groups, but in mathematics, science, foreign languages, and especially English the difference is greater for the superior than for the inferior group. The patterns of sex difference resemble those for unselected high school populations. Terman *et al.* (1925), who asked 245 gifted children and 226 control children, aged 11 to 13, to rate 29 school subjects, also found the same preference patterns at both ability levels. The following subjects were rated reliably higher by girls than by boys in both gifted and control groups: drawing, modeling, music (especially singing), dramatics, grammar, folk dancing, and penmanship. Subjects rated higher by boys in both groups were general science and United

States history. However, science, mathematics, and English did not show at this age level the markedly differential appeal for boys and girls that characterizes these subjects in high school.

Another study suggesting that sex differences in preferences are less marked in grade school than in high school has been reported by Sister Columba (1926) for a population of 792 boys and 872 girls in grades 3 to 8 in schools (presumably Catholic) of Washington, D. C. The children were asked to name their best-liked and least-liked subject. On reworking the author's data to take account of varying *N*'s, we find for the total group of six grades only two critical ratios above 2.00 for sex differences on best-liked subjects: more girls than boys named religion (CR = 3.98) and more boys than girls named history (CR = 3.28). On subjects least liked, five differences yielded critical ratios above 2.00: more boys than girls named English (CR = 7.48) and spelling (CR = 2.84), whereas more girls than boys named geography (CR = 3.30), history (CR = 2.89), and arithmetic (CR = 2.36). There was no appreciable sex difference on reading or penmanship. Study of trends from grade to grade showed that there was a moderately consistent trend toward emergence and increase of the sex differences from one year level to another, but every subject showed some irregularities and at least one shift in the direction of the differences. Religion, for instance, was better liked by boys in the eighth grade and much better liked by girls in the seventh; history was more favored by girls in the eighth grade and by boys in the seventh. These larger irregularities could not be attributed to chance factors but would suggest that a subject's appeal to a given sex may be greatly influenced by instructional methods and subject matter content, both of which vary from grade to grade and from teacher to teacher.

Occupational Interests. The numerous studies that have been made of children's occupational preferences show large differences between the sexes at all age levels. Information of this kind probably tells us very little about sex differences in real interests, but it does throw some light on the characteristic ways boys and girls see the sex rôles in our society. We shall merely refer the reader to a few typical studies without discussing them.

Douglass (1922), using the questionnaire method, ascertained the prospective occupation and reasons for choice of approximately half the high school seniors in the state of Washington—1186 males, 1658 females. Alberty (1925) reported the occupational preferences of 1468 boys and 1507 girls enrolled in high school. For more than 300 of each sex the preferences were obtained in three successive years. Girls showed less change of preference than boys, probably because girls have fewer occupations to choose from. Book (1922) reported sex differences in the occupational preferences of 6000 high school seniors in Indiana. Beeson (1928) analyzed the vocational choices of about 2000 high school students in Colorado. Boynton (1936) obtained information from more than 1500 children of grades 1 to 6 in several southern communities. Personal interview methods were used for the first three grades and the usual questionnaire technique for the others. Lehman and Witty (1931) administered the Lehman-Witty vocational attitude quiz to some 13,000 of each sex, ages 8½ to 18½, in two large cities in Kansas, but their material has not been adequately evaluated for sex differences. Williamson and Darley (1935) analyzed the occupational preferences of all Minnesota high school seniors who entered the University of

Minnesota during the 5-year period 1929–1933. Preferences were classified according to the Brussell occupational scale.

The results of such studies are greatly influenced by geographical location and by the limited knowledge children have about the nature of specific occupations and about their own mental equipment. Information as to how a given child's interests, attitudes, likes, and dislikes resemble or differ from those of persons successfully engaged in particular vocations can best be secured indirectly by means of a vocational interest test such as that devised by Strong. Carter and Strong (1933) administered the test to 34 pairs of unlike-sexed twins and to a group of 100 nontwins of each sex from the same high school. The age range was 12 to 20 years, with a mean of 16 for both twin and nontwin groups. The scores for boys were significantly higher on the scales for engineer, chemist, farmer, physicist, and purchasing agent, and small differences in the same direction were found for doctor, psychologist, and mathematician. The scales showing significant differences in favor of girls were those for journalist, advertiser, life insurance salesman, city school superintendent, and certified public accountant. The scales for artist, teacher, minister, and YMCA secretary gave significant sex differences in favor of the girls for the nontwin cases, but for the twin group these differences were not so great. All but one of the occupational interest scales which show higher scores for boys were in the "science" group, and in general the areas where the girls were higher were marked by the use of language and contact with people. (This research used a test designed specifically for men rather than women, so that the most markedly feminine areas were not included.)

In an effort to help Pittsburgh high school students analyze their own special vocational aptitudes and work interests, Miner (1922) devised a blank eliciting information on specific types of work, classified on the basis of the skill required rather than on vocations as they exist in the industrial framework. The largest differences in favor of the girls were for teaching, welfare work, entertaining, and working with records. Favoring boys were the differences in operating engines, construction work, and scientific work. When students were asked their preferences regarding types of work involving stated characteristics, the boys showed significant preferences for work involving much responsibility, calmness rather than enthusiasm, risk or discomfort with greater pay, outdoor activity, planning, giving directions, and dealing with things rather than people. Girls were significantly higher in the choices they made of work involving little responsibility, enthusiasm, indoor activity, carrying out plans, following rather than directing, and dealing with people rather than things. They were less favorable to work involving risk or discomfort with greater pay. These findings are psychologically meaningful and agree closely with the patterns of sex difference found in other areas of children's interests and in the research on adult men and women carried out by Strong and others.

In the Kuder Preference Record (Kuder, 1946) boys and girls are asked to choose between various alternative activities, selecting out of each combination of three the one they like most and the one they like least. Here too sex differences of the same kind are apparent. High school boys come out consistently higher than high school girls on the scales for mechanical, computational, scientific, and persuasive interests. Girls are higher on the artistic, literary, musical, social, and clerical scales. Differences for college students and for adult men and women are all in the same direction.

Miscellaneous Interest Differences. There have been a few studies of children's drawings that point toward interest differences. Hurlock (1943) analyzed the spontaneous productions of adolescents as salvaged from waste baskets, the margins of class papers, etc. Boys draw many more caricatures than girls, whereas girls draw true-to-life pictures of people, animals, and flowers. Boys draw more printed words and are more likely to choose "show-off" or "smart" phrases to ornament.

In general, comparisons of boys' and girls' drawings at the earlier age levels have not shown significant differences in theme. There are two European studies for which only abstracts were available which may show some trends. Fontes (1946–1947) reported that the drawings of girls were more likely to use religious subjects such as God, the Virgin, and the infant Jesus. Only 0.4 per cent of boys' drawings were of this type as compared with 9.1 per cent of the girls'. Baumgarten and Tramer (1943) reported that when 272 Serbian child refugees, 5 to 12 years in age, in camps in Switzerland, were asked to make drawings, the boys drew airplanes, tanks, and battle scenes, whereas the girls drew churches, flowers, landscapes, and household articles. No statistical evaluation was given in the abstract.

Consistent with this difference in choice of subjects for pictures was the finding in three age levels that boys in this country were much better informed about the war than girls were. Meine (194?) found that junior and senior high boys excelled girls in both news information and news habits. Preston (1942) found higher scores on an information test for boys than for girls at the 8-to-15-year level. Geddie and Hildreth (1944) interviewed 21 first graders using questions about the war. Boys knew much more about it and were more interested. The number is small, and no significance tests are given, but the difference is very striking. Of the 12 boys, 11 were enthusiastic or excited, 1 indifferent. Of the 9 girls, only 2 were enthusiastic, 7 indifferent.

Another study, difficult to classify (Katz, 1944), investigated the choices children in grades 2 to 6 made when presented with pairs of traditional and modern paintings. Though the general trend was for an increasing preference for traditional paintings from year to year, the girls were more likely than the boys to choose the traditional. By the sixth grade level, these sex differences had disappeared.

Dietrich and Hunnicott (1948) also investigated sex differences in preferences for pictures. Their subjects, 40 first and second grade children, generally preferred landscapes to interiors, still life, and people. The boys, however, were more likely than the girls to prefer seascapes to landscapes, and the girls more likely than the boys to prefer people to landscapes.

In a study by Tyler (1951) of the interests of first grade children an oral preference record was used from which scores for four general types of activity could be derived, namely, outdoor play, indoor play, paper-and-pencil activity, and helping adults with work. There were enough sex differences on individual items to make possible the construction of an M-F scoring key. Interest scores were correlated with scores on some of the Primary Mental Abilities tests for boys but not for girls. This suggests that interests may be differently organized in the two sexes even at a comparatively early age, with boys tending more strongly to develop interests congruent with their special abilities and disabilities.

It would be difficult to summarize what these miscellaneous studies show, but their findings in general would seem to substantiate research done at the adult level indicating that masculine interests are broader,

less personal, and more diversified than feminine. Their principal interest for us lies in the fact that they indicate that such differences show up fairly early in children's development and in spite of similarity in the educational environment of the two sexes.

Aggressive and Dominant Behavior. One of the sex differences most universally found, which can be traced back from the adult to the preschool level, is in this area. Measures of dominance or ascendance of the type devised by Allport and by Bernreuter almost invariably yield higher scores for males than for females at the high school and college ages. Sex differences in this direction reported by Bernreuter (1933) have critical ratios of 3.38 for high school subjects, 2.74 for college subjects, and 3.97 for older adults. Carter (1935) found a similar sex difference on the Bernreuter dominance scores of 118 pairs of twins enrolled in high schools. Perry (1934) reported a somewhat similar sex difference on this test in the case of 178 men and 144 women in junior college. Another interesting sex difference reported by Perry is that the dominance and self-sufficiency scores of girls were positively correlated with scholarship, whereas no such relationship was found for boys. Bell (1939) reported for large populations sex differences in social adjustment scores yielded by his adjustment inventory. The inventory is so constituted that high scores indicate the presence of considerable social aggressiveness. These scores were higher for males in four separate groups, the critical ratio of the sex differences being as follows: for 251 high school subjects, 2.03; for 414 college subjects, 2.62; for 148 delinquents, 2.07; for 468 adults, 4.35.

Studies based on ratings and behavior observations show the same kind of difference for younger subjects. In a study of self-ratings by 110 boys and 109 girls in the seventh and eighth grades, Hurlock (1927) reports that more boys than girls describe themselves as daring (18.1 vs. 4.6 per cent), fond of a fight (16.3 vs. 8.2 per cent), or proud (38.2 vs. 19.2 per cent). Boys quarrel more than girls. One of the most marked sex differences found by Macfarlane, Honzik, and Davis (1937) in their reputation study of young children of the first three grades was the greater frequency of quarrelsome behavior among boys. Children also condemn this trait in girls more than in boys: the r between "popular" and "not quarrelsome" is .77 for girls but only .48 for boys. Data by Fuxloch (1930) on 500 children of kindergarten and school age indicate that in their free play boys are more pugnacious and more outstanding in leadership than girls.

These characteristic differences are plainly evident at the nursery school level. Using 1600 time-samplings of the behavior of 40 nursery school children, Green (1933*a*) reported an average of 13.4 quarrels for boys as against 10.2 for girls. Boys also quarreled with more children. Another analysis by Green (1933*b*) showed that boys' quarrels were more often physical, girls' more often verbal. Dawe's (1934) detailed analysis of 200 quarrels among nursery school subjects gives 13.5 as the mean number of quarrels for boys as against 9.6 for the girls. Dawe notes that boys are more likely than girls to quarrel over possessions, whereas girls more often than boys quarrel because of interference with an activity. Boys do more striking, girls more pulling and pinching. Boys more often precipitate their quarrels; girls more often take retaliative or objecting rôles. Jersild and Markey (1935) and Roff and Roff (1940) found less sex difference in conflict tendencies at the nursery school level than other investigators have reported.

Goodenough (1931) had mothers keep daily records of the anger outbursts of 26

boys and 19 girls, aged 7 to 82 months. During the period covered the mean number of such outbursts was 45 for boys and 37 for girls. Hattwick's (1937) ratings of 579 nursery school children indicate that in their relations with other children boys more often grab toys (CR = 2.60) and attack others (CR = 2.76), whereas girls more often avoid play (CR = 1.97). The boys exceed girls in all forms of aggressive behavior with the exception of verbal bossing. The author thinks that these sex differences could hardly be due to social pressures, since they were almost equally in evidence from 2 to 4½ years. Caille (1933) also reports more aggressive behavior among boys in a group of 36 nursery school children, aged 19 to 49 months (CR = 2.36). Among 104 children aged 2 to 4 years, Berne (1930) found boys more given to teasing (CR = 3.7) and social conformance more characteristic of girls (CR = 3.2).

Some interesting studies comparing the reactions of boys and girls in a projective doll play situation have been carried out at the University of Iowa. Pintler, Phillips, and Sears (1946), using as subjects 40 boys and 30 girls with an average age of about 4.5, found that the boys showed significantly more aggression in the way they used the dolls and other materials. They were less likely than the girls to use the dolls in the customary stereotyped way. Sears (1951), in a later and more complete report based on equal sex group of 3-, 4-, and 5-year-olds, 150 in all, showed that boys differ from girls not only in the frequency but also in the direction and kind of aggressive acts. They are much more likely to show behavior classified in the "bodily injury" category. Bach (1945) with the same sort of projective situation found highly significant sex differences in 35 preschool children, aged 34 to 64 months. Girls produced a larger amount of doll action than did boys, a higher proportion of affectionate themes, and more verbal ordering and commanding. A greater proportion of the boys' fantasies were of a socially unacceptable nonstereotyped character and were marked by aggressive hostility. Girls concentrated more on socially approved themes to be acted out in the play (e.g., resting) and boys on disapproved themes (e.g., toilet activity). These Iowa investigators are inclined to explain their findings in terms of a sex-typing process dependent on early learning.

The report by Yarrow (1948) on 60 preschool children ranging in age from 3–0 to 5–7 furnishes corroborative evidence of these findings from another area of the country. Boys were more active and aggressive than girls under all the conditions set up in these experiments.

Delinquency and Behavior Problems. Data from courts, from child guidance clinics, and from schoolrooms substantiate the finding that males are more aggressive than females. Sex differences in delinquency are difficult to interpret for various reasons. The sexes are exposed to different temptations and in different degrees. The criteria of delinquency are not the same for boys and girls, and there is differential treatment of the sexes with respect to arrests and disposal of cases. The available statistics probably minimize the actual amount of delinquency among girls as compared with boys. There is one exception, however, to this tendency: the statistics undoubtedly exaggerate the relative sex delinquency of girls because the social tolerance of sexual misconduct by girls is much lower than it is for boys. Healy and Bronner (1926) gave the sex ratio in two large series of juvenile court cases as 2.3 boys to 1 girl. There was close agreement between the Chicago and Boston series. Fortes (1933) reported 808 boys and 59 girls in the records of probation officers of East London, Connecticut.

This is a ratio of 7.3 to 1. Alper and Lodgen (1936) reported probation data for all but two counties in Pennsylvania. The totals were 2533 boys and 748 girls, a ratio of almost 3 to 1.

Maller (1933) noted a marked change in the sex ratio among juvenile court cases during the three decades beginning in 1902. The ratio was about 8 to 1 in the first decade, 4 to 1 in the second, and 2.7 to 1 in the third. In 30 years the number of boys brought before the juvenile court decreased by 20 per cent, whereas the number of girls more than doubled. Maller believes that this rapid change is not primarily a function of altered court procedure and attributes the increase in delinquency among girls to the increasing incidence of parental divorce, which is supposed to have a worse effect on girls than on boys. We doubt the correctness of this interpretation and suspect that the observed trend is largely due to changes in selective factors.

With all these fluctuations in sex ratio from place to place and from time to time, all statistics show that the incidence of delinquency is much greater in boys than in girls. Statistics from all sources report a higher percentage of boy than of girl delinquents charged with offenses against property, and a higher percentage of girl delinquents charged with sex offenses.

Data on sex differences in the problems encountered by child guidance clinics are also of doubtful value because of the selective factors that may affect clinic populations. On the whole, however, they show the same trends as the other figures from more representative populations. For details the reader should consult the report by Schumacher (1933) on 120 consecutive cases of each sex examined in a child guidance clinic, and Ackerson's (1931) analysis of 5000 consecutive cases examined at the Institute for Juvenile Research at Chicago. Percentage frequencies of certain personality problems among 2853 white boys and 1739 white girls in Ackerson's population were as tabulated. The

	Boys	*Girls*
Restless, overactive	19	16
Irritable temperament	19	14
Touchy	13	10
Distractible	12	9
Personal violence	8	4
Request for sanity diagnosis	7	4
Potential sex delinquency	0.1	3

percentages for "potential sex delinquency" illustrate the need for caution in drawing conclusions from such data. Taken at their face value, the figures would suggest that the incidence of potential sex delinquency is 30 times as high for girls as for boys!

Schoolroom studies universally report more problem behavior among boys, but these of course are distorted by the many kinds of bias known to affect teacher attitudes. Haggerty (1925) secured teachers' ratings on the incidence of faults and problem behavior among 800 children in grades 1 to 8. By weighting the faults according to estimated seriousness the author derived a behavior score for each child. The mean scores were higher (more unfavorable) for boys in every school grade. Wickman (1928), who had assisted in the Haggerty study, reported similar scores for 462 boys and 412 girls in Cleveland. Undesirable kinds of behavior that were reported by teachers at least twice as frequently for boys as for girls included truancy, destruction of property, stealing, profanity, disobedience, defiance, cruelty, bullying, and rudeness. The aggressive nature of most of these activities is apparent. The only kind of problem more frequently reported for girls was the writing of obscene notes. Children regarded

by teachers as presenting minor behavior problems included 49 per cent of boys and 35 per cent of girls; those judged to have serious behavior problems were 10 per cent of boys and 3 per cent of girls. Olson (1930) reported similar figures for 1473 boys and 1394 girls.

Williams (1933) secured data in 10 cities on 1343 children regarded by their teachers as problem cases. These constituted 2.4 per cent of the school population covered by the survey. In the problem group the ratio of boys to girls was 4 to 1. Types of behavior more common among problem boys than problem girls were "misconduct in school" (46 vs. 22 per cent), disobedience (45 vs. 23 per cent), and annoying other children (48 vs. 31 per cent). The incidence of 37 types of undesirable behavior, as judged by teachers, was reported by Hurlock and McDonald (1934) for 438 boys and 352 girls in a junior high school attended largely by Jewish children. More frequent among problem boys than problem girls were lying, cheating, truancy, disobedience, rudeness, and bullying.

The studies just reviewed are so typical of their kind that it would be a waste of time to cite others. They corroborate the results of better-controlled studies of sex differences in aggressive behavior, but they also reflect to an unknown extent teacher attitudes rather than pupil characteristics. There are a number of indications that some sort of "halo" effect operates to give girls higher ratings in practically everything. This of course might originate in the unfavorable reaction most people show to aggressive behavior. Ratings secured by Terman *et al.* (1925) for gifted and control groups, each numbering more than 500, showed that under the most careful procedures the ratings contain a "generosity factor" which is differential for sex. Girls were rated significantly higher than boys on almost everything, including "moral" traits like sympathy, generosity, conscientiousness, and truthfulness, and miscellaneous characteristics such as health, physical energy, persistence, common sense, and freedom from vanity. Only on mechanical ingenuity were boys rated significantly higher than girls.

Hayes (1934) had about 400 of each sex, aged 10 to 15 years, rated on a large number of behaviors. The median rating for girls was higher than for boys at every age, the maximum difference being at 14. Langlie (1937) had 170 high school seniors (85 of each sex) rated by several men teachers, and 135 boys and 300 girls rated by several women teachers, on ability to learn, intellectual initiative, industry, scholastic zeal, dependability, and capacity for college work. Median ratings by both men and women were higher for girls on every trait, although college aptitude tests of these subjects averaged slightly higher for boys. Indicative of the greater halo factor in girls' ratings is the higher intercorrelation found for girls than for boys on the various trait ratings.

Rundquist (1941) has presented evidence which he interprets to mean that the practically universal superiority of girls in school marks is related to this rating factor. Whereas at the grade school level there was little difference between boys and girls in the relationship of marks to intelligence test scores (r's from .75 to .79), in junior high there was a considerable discrepancy. For boys the correlations between marks and tests ranged between .42 and .58. For girls they were from .68 to .77. Behavior factors becoming intensified at adolescence might account for these trends.

In general, the comparisons of the sexes with regard to negativism and resistant behavior in very young children show males somewhat higher in these traits.

Goodenough (1928) reported ratings of 380 nursery school children on degree of shyness, negativism, and distractibility during the administration of Kuhlmann-Binet tests. There was no sex difference on shyness. Negativism was reliably more common among boys, but this difference was present only at the upper occupational levels. The peak of negativism was at 18 months for girls, at 30 months for boys. The second study by Goodenough (1929), based on tests of 990 subjects, confirmed the earlier findings. Mayer (1935) found negativistic behavior among 245 children of ages 2 to 5½ years, during the administration of the revised Stanford-Binet scales, to be slightly more frequent with boys, but the difference approached statistical significance only at age 4 (CR = 2.1). Nelson's (1931) mental test data for 91 three-year-olds showed boys to be slightly, though not reliably, more resistant. On the other hand, Levy and Tulchin (1923), reporting on tests of 983 subjects aged 6 to 63 months, show girls slightly more resistant than boys at all ages except 30 months. This may be because they included in the category of resistant behavior every kind of interference with the progress of the test, including crying and inattentiveness.

A somewhat different type of situation was utilized in the studies by Reynolds (1928) and Caille (1933). Reynolds' procedure was to try to get the child to play with blocks while sitting on the experimenter's lap and to engage in imitative play with the experimenter. The mean score for negativism was slightly but not reliably higher for 105 boys than for 124 girls. The age range was from 2 to 5 years. The mean for girls began to drop at 3 years, that for boys at 4 years. Caille's study of 17 boys and 19 girls summarizes evidence of resistance based not only upon mental tests but also upon stenographic records of the speech of each subject during two days of nursery school attendance. Again, resistant behavior was found to be more common with boys.

Suggestibility, which may be thought of as the opposite of negativism, was a favorite subject for investigation in the early decades of experimental psychology but has received much less attention of late. Whipple (1915) presents a summary of the older literature, and more recent studies among children have been reported by Aveling and Hargreaves (1921), Lodge (1926), White (1930), Hurlock (1930), Messerschmidt (1933), and Wegrocki (1934). In general, the sex differences disclosed by these studies are small, but the direction consistently indicates that girls are more suggestible than boys.

Neurotic and Emotional Response. A considerable amount of evidence has accumulated that females are more emotional or less stable than males. Much of the work has been done with adult subjects and thus falls outside the scope of this review. Children and adolescents have, however, been studied by means of paper-and-pencil tests and questionnaires and by more or less well-controlled observation, and the findings show some general trends.

With personality questionnaires, older adolescents show sex differences like those in the adult population, differences which are less apparent or fail to show up at all at the younger age levels. Mathews (1923) gave a modified Woodworth Personal Data Sheet to 575 boys and 558 girls, aged 9 to 19 years. For all ages combined the median number of "emotionally unstable" replies was about 25 per cent greater for girls than for boys, a difference that is statistically reliable. However, between ages 10 and 17, the median of unstable responses for boys decreased from 35 to 14, whereas for girls it increased

from 24 to 37. Only after age 14 were the scores significantly better for the boys. Schubert and Wagner's (1936) Woodworth scores for 229 boys and 248 girls, all high school seniors, showed a much smaller sex difference, but in the same direction. Bernreuter's (1933) test for neurotic tendency (B 1-N), which has much in common with the Woodworth test, yielded scores which were reliably more "neurotic" for females in all the author's standardization groups. The critical ratio in the high school group was 3.94. Carter's (1935) application of the Bernreuter test to 128 male and 108 female twins aged 12 to 19 years also showed girls reliably more "neurotic" than boys. Emotionality, or neurotic tendency, is one of several aspects of maladjustment measured by the Bell Adjustment Inventory. In high school, college, and delinquent populations this inventory yields higher emotionality scores for females than for males. For high school groups the reported CR is 8.51 (Bell, 1939).

When Hartshorne, May, and Maller (1929) gave the Woodworth test to 393 boys and 382 girls in grades 5 to 8, however, they found no reliable sex differences. Cady's modification of the Woodworth test was given by Terman *et al.* (1925) to 532 gifted subjects aged 7 to 14 and to 533 unselected subjects aged 10 to 14. In neither group was there a reliable sex difference at any age.

Using his own psychoneurotic inventory F. Brown (1934) found no significant sex differences in a population of 1663 unselected children in grades 4 to 9. Springer (1938) confirmed this finding. In Springer's study, Brown's inventory was given to 800 children of grades 4 to 9, including 190 boys and 137 girls in a slum district and 237 boys and 236 girls in a good district. Girls of both groups tested slightly more "neurotic" than boys, but the critical ratios were only 1.5 and 1.8.

At the age levels where they occur, these sex differences in emotionality score seem not to be confined to any one segment of the population, although not enough special groups have yet been tested to warrant a certain judgment on this point. As stated above, Bell obtained comparable results in delinquent and nondelinquent groups. Maller's character sketches for testing emotional stability showed about the same sex differences for 103 Parisian children as others have found for children in this country (Kinter-Remmlein, 1933). A comparison of blind and sighted high school students by means of the Clark-Thurstone neurotic inventory (P A. Brown, 1939) yielded even larger sex differences for the blind than for the normal subjects. The CR for the normal group was 3.44; for the blind group, 7.16.

Tests which attempt to get at "affectivity" by asking subjects to check such things as worries and annoyances have not produced entirely consistent results. Sunne (1925) gave the Pressey test to 130 boys and 102 girls in grades 7 and 8 and found that girls checked reliably more worries than did boys. Collins's (1927) data from Pressey tests of 1500 Scotch and English children aged 11 to 15 showed slightly higher affectivity scores for girls with a marked sex difference in the worries test. Zeligs (1939) found that 12-year-old girls checked significantly more worries from a list than did 12-year-old boys. This author also reported (1945) that sixth-grade girls are annoyed by more factors than boys of the same age, and react to a greater degree than boys do to these annoyances. Clear supporting data with significance tests are not provided. On the other hand, Kohn (1937), using the X-O test as revised in 1933, found no sex differences in an orphanage high school population of

149 boys and 118 girls. There may, of course, be some selective factors in the orphanage population accounting for this exception to the general trend. Pintner and Lev (1940) report boys more prone than girls to worry about social and personal inadequacy. These authors administered an inventory of 53 worry items to 270 boys and 270 girls in grades 5 and 6. Some of the differences reported are so unexpected as to suggest that errors may have occurred in data tabulation or else that the boys' responses were inspired by a sense of humor. For example, these boys of 11 and 12 years are reported as worrying more than girls about "being late for supper" (CR = 4.31), "not having a pretty home" (CR = 2.67), and "getting married" (CR = 2.44).

In their analysis of sex differences in responses to individual items of the M-F test Terman and Miles (1936) summarized data from 550 subjects on anger, fear, disgust, and pity. The subjects included 250 in the seventh grade, 200 in the eleventh grade, and 100 college students. The inventory called for a rating of degree of emotion aroused in the subject by each of 34 situations for anger, 40 for fear, 36 for disgust, and 28 for pity. In all three populations and for all four types of emotion, the responses of girls indicated greater affectivity than those of boys. However, for a given emotion the direction of sex difference varied according to the specific situation presented. Whether the emotion in question be anger, fear, disgust, or pity, the items that have low affectivity thresholds for boys are largely different from those that have low thresholds for girls. These qualitative differences, too numerous to review here, are psychologically more interesting than the quantitative differences.

The preponderance of evidence from personality inventories thus indicates somewhat greater emotionality for females. The amount of sex difference varies from test to test but even when small or nonsignificant is almost invariably in one direction. At the same time caution is necessary in the interpretation of pencil-and-paper tests of emotionality. We cannot be sure that boys and girls are equally willing to confess their emotional reactions or that the individual questions in a personality inventory carry always the same meaning for the sexes. The fact that much larger score differences show up for adolescents than for younger children is consistent with the interpretation that boys and girls gradually become aware of what it is acceptable for them to admit. However, a study by Darley (1937) indicated that the greater emotionality shown by females may not be spurious. When college students who had been given tests of maladjustment were clinically interviewed by two experienced counselors, it was found that the excess of maladjustment among women as compared with men was more marked in the clinical diagnoses than in the test scores. The fact that evidence on children obtained from nonquestionnaire methods points in the same direction is likewise important.

A word of caution is also in order with regard to the common use of the term "emotionality" as synonymous with neuroticism. Even if we assume that the subject who scores high on the usual psychoneurotic inventory is properly described as psychoneurotic or as emotionally unstable, it does not follow, as Landis, Zubin, and Katz (1935) have pointed out, that the extremely low-scoring subject is emotionally stable. He may be, but there is a chance that his hypo-emotionality is indicative of a schizophrenic tendency.

In attempting to get away from the difficulties inherent in work with personality inventories, much use is being made of

the so-called projective methods. So far investigations of sex differences by means of the Rorschach test have produced very little in the way of tangible results. Hertz (1942) and Hertz and Baker (1943), after analyzing the records of 41 boys and 35 girls who were given the test at 12 and again at 15, have reported that the girls at both ages show more movement responses than boys, and that at the 15-year level they are also higher in primary C (color predominant over form as a determinant). These differences point toward slightly more introversion and instability in girls than in boys, but both the differences and the groups on which they are based are far from large. Furthermore, the samples seem not to be very representative of the adolescent population. A more satisfactory study from the standpoint of numbers and representativeness is that of McFate and Orr (1949), who have tabulated results from the analysis of 669 Rorschach protocols from 194 adolescents in the California Guidance Study. They too show girls to be more responsive than boys on the Rorschach, both quantitatively and qualitatively. Girls make more use of the color variables, a finding which would seem to fit in with evidence from other sources that emotionality and social responsiveness are feminine traits. The fact that boys are higher on scores ordinarily considered anxiety indicators is not so easily explained, since other types of study have shown girls more anxious than boys. Stavrianos (1942) and Rose and Stavrianos (1943) have reported on younger children, aged 5 to 11, but the data are inadequate to warrant any conclusions. Samples for the separate age groups are too small, important variables such as IQ are uncontrolled, and no significance tests or variability data are given. Further research is obviously needed.

Children's fears have been investigated both by verbal reports and by observational techniques. In general, girls seem to be more fearful than boys at all ages. We have mentioned that Terman and Miles found that girls were higher than boys on the "fears" section of their M-F test. Pintner and Brunschwig (1937) questioned 159 deaf and 345 hearing children of ages 12 to 15 regarding 39 fear situations. Girls of both groups reported more fears than did the boys (CR = 6.15 for the deaf, 4.53 for the hearing group). Pratt (1945), who asked 570 rural children in groups from kindergarten to eighth grade to list fears, found that girls listed significantly more than boys. Jersild, Markey, and Jersild (1933) and Jersild and Holmes (1935) reported interviews with 400 children, 25 of each sex at each age from 5 to 12 inclusive. Twice as many boys as girls reported no fears, and the girls reported a larger number of different fears. In teachers' ratings secured by Wickman (1928) for more than 1600 school children the girls were more often reported as showing oversensitive and fear behavior. Kimmins (1920, 1931, 1937) had 6000 London children, ages 5 to 18, report the last dream they could remember. In the range from 8 to 14 years more fear dreams were reported for boys (19 per cent) than for girls (16 per cent). After 14, fears decreased with boys and increased with girls. Little statistical treatment was presented, so that it is impossible to determine whether these results contradict those obtained by other methods.

Sex differences in fear responses have been reported at the nursery school level. Jersild and Holmes (1935) presented fear situations in the laboratory to 57 boys and 48 girls aged 2 to 5 years. Mean fear scores were higher for girls than for boys (CR = 2.58), and when 29 sex pairs were matched for age the difference was even greater (CR = 3.29). Parental records of

children's fear responses, as reported in the same monograph, showed very little difference in number of fears for boys and girls, the averages being 4.9 and 5.2 respectively. There were marked differences in what constitutes a fear situation. Boys were more afraid of kinesthetic catastrophe; girls were more afraid of strangers and of social mishaps. These differences may be related to the greater muscular activity of boys and the greater social concern of girls. Hattwick (1937) had three independent judges record behavior tendencies of 300 nursery school children of each sex, aged 2 to 4½ years. Girls were reported oftener than boys in several categories related to fear. The ones showing the highest statistical significance were "Stays near adult" (CR = 4.50) and "Avoids play" (CR = 1.97).

Another source of data on emotional differences between the sexes has been the observation of various nervous habits in children. Wechsler (1931) reported on the incidence of nail-biting among 3000 New York children ranging in age from less than 3 years to 18 years. Before 11 years, the sex differences were small and inconsistent; from 11 to 13 the incidence was reliably higher among girls; but for ages after 13 it was reliably higher for boys. Wechsler's method of determining presence of nail-biting by a quick glance at the child's hand has been criticized by Olson (1936) as inaccurate. Billig (1941) found slightly more nail-biters among girls than among boys in the intermediate grades, but gives no statistical significance tests. Michaels and Goodman (1934) reported data on enuresis and "other neuropathic traits" for 255 boys and 220 girls, ages 6 to 16, who attended a summer camp. The information was obtained partly from parents and partly from the subjects themselves by observation and questioning. The tabulated percentages were found for various conditions.

	Boys	*Girls*
Enuresis after age 3	26.1	23.4
Thumb-sucking	17.6	34.1
Nail-biting	45.7	57.1
Speech impediment	23.3	17.0
Tantrums	12.8	16.1
Sleep disturbances	16.1	22.0
Fears	31.1	58.7

The only reliable differences here are the excess of girls with a history of thumb-sucking, nail-biting and fears.

Olson (1929) has made one of the most valuable studies of nervous habits in normal children. His subjects were 225 boys and 242 girls in grades 1 to 6 and 169 children in grades 7 and 8, each of whom was observed during 20 five-minutes periods. The main categories of nervous habits observed gave the following frequencies, in percentages (for 221 boys and 238 girls in the first six grades).

	Boys	*Girls*	*Diff.* / *PE Diff.*
Oral	47	60	4.1
Nasal	28	27	...
Hirsutal	17	28	4.2
Ocular	11	19	3.5
Aural	13	8	−2.5
Genital	5	3	−1.7

Terman *et al.* (1925) obtained data from parents, teachers, and medical examinations regarding various nervous conditions in a gifted population of nearly 600, ages 5 to 13. Parents reported 10 per cent of boys and 13 per cent of girls as having "marked fears." Teachers reported "excessive timidity" for 4.9 per cent of boys and 10.5 per cent of girls and "tendency to worry" for 9 per cent of boys and 12 per cent of girls. The medical records of these subjects showed enuresis still present with 20 boys but with only 5 girls. Cummings (1944) analyzed observations made by teachers of 239 children in school, aged 2 to 7. Symptoms of emotional difficulties

were in this group more frequent in boys, the greatest differences being for daydreaming, cruelty, aggressiveness, obstinacy, and disturbed sleep. Girls were slightly but not reliably more fearful. The nature of the emotional symptoms observed in this study may partially explain why its findings differ from many of the others, since they include aggressive behavior of various kinds.

Blatz and Ringland (1935) have reported a time-sampling study of "tics," a term used by them to include such a wide variety of habits and mannerisms as to involve practically all the children in a normal group. The subjects were 30 boys and 31 girls enrolled in nursery school, kindergarten, and first grade. The mean number of positive notations per child was somewhat higher for girls. Koch (1935) made time-sample observations of nervous habits of 21 boys and 25 girls attending nursery school. Her data were secured in 400 half-minute periods distributed over 8 months. The only reliable sex difference was for the hirsutal-caputal category, for which the average number observed per child was 1.8 for boys and 8.6 for girls. Brackett (1934) recorded time-sampling observations of crying for 17 boys and 12 girls aged 18 to 48 months. The samples are too small to yield reliable sex differences, but there is a trend toward more crying by girls (CR = 1.1). Macfarlane (1938) reported the incidence of various forms of special behaviors for 60 boys and 60 girls observed at each of the following ages (months): 21, 24, 30, 36, 42, 48, 54, and 60. Nail-biting, thumb-sucking, and jealous behavior showed "a small but consistently higher incidence in girls." However, the *N*'s are quite small for the separate categories. On total of extreme behaviors studied there was no appreciable sex difference. Among the 600 nursery subjects studied by Hattwick (1937) the following nervous tendencies were unrelated to sex: enuresis, nail-biting, chewing objects, playing with fingers, picking nose, twitching, holding body tense. Kunst (1948), who made observations on 143 infants in an orphanage, reports more thumb-sucking for boys than for girls.

Michaels and Goodman (1939) summarized case-history data on enuresis beyond age 3 for 500 male and 500 female patients in a state psychopathic hospital. In the 193 case histories that were positive, 56.5 per cent were of males and 43.5 per cent were of females, a reliable difference In 122 cases with whom enuresis persisted after 10 years, 61 5 per cent were males and 38.5 per cent females.

Although there is some disagreement from study to study, if we lump together the numerous kinds of behavior known as nervous habits, it appears that the total incidence of such behavior is probably higher with girls. For enuresis, however, and perhaps one or two other categories it is higher with boys. Unfortunately we do not know enough about the interrelationships of the variables in question to interpret these findings. The fact that they are commonly classed together under a single label is no guarantee that they have the same significance for personality development. It is possible, for example, that enuresis is more of an aggressive attack on a frustrating environment than a simple indication of tension like nail-biting. A factor analysis of time-sampling records might help to clarify the pattern.

There have been a few studies of sex differences in emotional tendencies which are difficult to classify under any of the main topics discussed above. Chrysanthis (1946) questioned 1418 pupils, aged 12 to 18, as to length and depth of sleep, condition after sleeping, and frequency of dreaming. He reported that females dream more frequently and sleep more lightly, but no supporting data were given in the available abstract of the paper. Abel

(1941), using a modified Zeigarnik procedure in which recall was compared for completed and uncompleted tasks, found that girls recalled significantly more incompleted activities than did boys, which would seem to indicate a higher degree of some sort of tension. Child (1946) exposed 298 boys and 305 girls in the first seven grades to an experimental situation which gave them an opportunity to choose between a piece of candy easy to obtain and one difficult to obtain. There was a significant tendency for boys to exceed girls in the choice of the more distant goal. Motivations involved seem to have been drive for achievement, anxiety about being considered lazy, and drive for fun in exercise.

We may summarize the work on emotional responses as a whole by saying that there is fairly clear evidence from a variety of sources that a sex difference exists, that it is in the direction of greater emotional instability in girls, and that differences are identifiable even in the nursery school period. There are still a number of unexplained exceptions to the general trends.

Social Attitudes and Behavior. It is a common belief that one of the characteristically feminine traits is an absorbing interest in persons and personal relationships. That in fact a sex difference exists in this respect is indicated by data from subjects over a wide range of ages. It should be noted, however, that social interest and social participation are by no means the same variable. A number of researches suggest that the female shows more sociality, in the sense of social desire, but that introvertive tendencies and inferiority feelings often inhibit her social participation.

We have already seen that the greater social interests of girls appear in their play activities, in the books they read, and in their occupational preferences. Terman's (1925) sociability ratings of both gifted and unselected children, based on preference for social versus nonsocial plays and games, averaged higher for girls than for boys at every age. Wyman's (1925) word-association test used with these same subjects as a measure of interests also showed girls consistently above boys in social interest and as consistently below them in activity interest.

Symonds (1936) had 784 boys and 857 girls in junior and senior high schools rank 15 "major areas of life concern" according to their interest in reading about or discussing them. The largest sex difference was on personal attractiveness, which had a mean rank order of 5.4 for girls as compared with 8.1 for boys. Manners and getting along with others were also ranked somewhat higher by girls. All these differences indicate greater social interests among girls.

Terman and Miles (1936) found much evidence of the greater social orientation of girls among 550 subjects at the seventh grade, high school, and college levels. From their analysis of sex differences on M-F test items it appears that situations which involve attack on social self-feelings are almost the only field in which girls report more anger than boys. They are more angry at "being socially slighted," "hearing friends unjustly abused," "seeing boys make fun of old people," "seeing someone laugh when a blind man runs into an obstacle," or "seeing a person treated unfairly because of his race." The items expressing care for personal appearance and liking for social gatherings all carried feminine weights in the scoring of this test.

The greater sociality of girls is evidenced even in their dreams. Cason's study (1935) of some 200 subjects ranging in age from 8 years to adulthood showed that girls more than boys dream of home, fam-

ily, and other persons. Schubert and Wagner (1936) found that among 355 high school seniors 62.6 per cent of girls as against 30 per cent of boys reported dreams about members of the family or about dead people. For 517 younger children, chiefly 4 to 12 years, Foster and Anderson (1936) reported 24.5 per cent of girls but only 9.8 per cent of boys having dreams of strange or bad people.

Interviews with 666 children, aged 5 to 12, by Jersild, Markey, and Jersild (1933) showed 12 per cent of "first" wishes by girls to concern siblings, companions, or friends, as against 3 per cent of wishes by the boys. Questioned regarding the best thing that ever happened to them, 14.9 per cent of girls as against 8.3 per cent of boys mentioned such things as parental relationships and other human contacts. Regarding the worst thing that ever happened to them, 15.6 per cent of girls and 8.0 per cent of boys mentioned people or undesirable traits of people. Asked what they liked best, 31 per cent of girls and 23 per cent of boys replied in terms of people or associations with people.

Davis (1932) had mothers of children aged 3 to 12 record 50 consecutive questions asked in the parental presence by 39 boys and 34 girls. Girls asked more questions on social relations (CR = 3.04), boys on causal explanation (CR = 3.07).

Orgel and Tuckman (1935) found that among 235 boys and 75 girls in a Hebrew orphanage 39.1 per cent of boys' nicknames and only 6.7 per cent of girls' are based upon some physical peculiarity or defect, whereas affectionate forms of nicknames account for 32 per cent of those given to girls as against 3.8 per cent of those given to boys. That is, in bestowing nicknames girls manifest more social sensitivity and more personal affection.

Jealousy is one indication of the value an individual attaches to given social relationships, and studies of jealousy all show that it is more prevalent among girls than among boys. S. Foster (1927) and Sewall (1930) found this to be the case with preschool children. Ross (1931) reported that in an older group, aged 6 to 11 years, sibling jealousy was much more common among girls (17 per cent, as compared to 11 per cent for boys).

The fact that gifted subjects (Burks, Jensen, and Terman, 1930) showed no appreciable sex difference on the Moss test of social intelligence is probably attributable to the inadequacy of the test, for Butler's study (1934) of 1600 subjects in grades 8 to 12 showed that girls greatly exceed boys in knowledge of matters having to do with family relationships and social adjustments. McNiel (1944) tested high school freshmen and seniors on understanding of factors underlying behavior. All comparisons showed girls significantly superior to boys.

Sex differences in sociality have been noted at a very early age. Thus Berne (1930), using a rating-scale technique with 82 nursery school children, found that girls show more responsibility for others, more social conformance, and more motherly behavior than do boys. Hübsch and Reininger (1931) reported that, among kindergarten children in Vienna, boys were more concerned with things, girls with personal relationships.

Spontaneous Social Groupings. There have been a number of studies attempting to find out what boys and girls actually do in social situations. Wellman (1926) made observations of the free groupings of 27 boys and 27 girls in a high school population of 113. She found that boys at this age seek a much wider range of companions than do girls. The mean number of companions was 22.2 for the boys as compared with 16.5 for the girls. Campbell (1939) also showed by means of a modified "guess-

who" technique that boys' social relations are less rigidly structured than those of girls. In the ninth-grade group of 75 girls and 77 boys on which his results are based boys associated with more persons than girls, and girls were more given to clique association and more prone than boys to mention unfavorably an acquaintance outside the inner circle. Burks, Jensen, and Terman (1930) reported that at high school age gifted boys often than gifted girls have no close chums.

Adolescent crushes have been studied by Hurlock and Klein (1934). Their subjects included 148 boys and 202 girls in the high school, and 54 men and 155 women who were teachers or counselors. The data secured were memory reports elicited by a questionnaire. More females than males reported having experienced one or more crushes (86.6 vs. 71.6 per cent). Nearly all the homosexual crushes were reported by girls.

Tuddenham (1951, 1952) has studied characteristics related to popularity in first-, third-, and fifth-grade children by means of a guess-who technique similar to that used by Tryon (1939) with seventh and ninth graders. His subjects were 1437 children from 42 classrooms in Berkeley elementary schools. While all good traits included in the test were positively correlated with popularity, giving rise to a large general factor particularly at the first-grade level, among the older age groups the cluster of traits including "real boy," "leader," "good at games," and "takes chances" becomes more closely related to popularity for boys, and the cluster including "quiet," "not a show-off," "not quarrelsome," and "doesn't fight" becomes more closely related to popularity for girls. Girls are rated significantly higher than boys on all good traits, but the sex difference narrows with age.

A series of sociometric studies by Bonney (1942*a*, 1942*b*, 1944) have been concerned with popularity and social acceptance among second-, third-, and fourth-grade children. Girls seem to outrank boys consistently in social success. They are chosen more frequently in the various choosing situations and get higher scores for "mutuality of friendship."

Nursery school studies have been concerned with social success and breadth of social contacts among boys and girls and also with the relative participation in unisexual and bisexual groupings. One of the early studies was by Chevaleva-Janovskaja (1927), who analyzed 888 playground groupings of 276 children, aged 3 to 8 years, in Odessa. She reported greater participation in social groups by boys than by girls and a preponderance of unisexual as compared with bisexual groupings among the preschool children. At a later age range girls were found in bisexual groupings more often than in unisexual (56.84 vs. 43.16 per cent). Challman (1932) recorded 7248 social groupings among 17 boys and 16 girls attending nursery school. Girls showed a trend toward more social participation and higher friendship scores than boys. Green's (1933*a*) time-sampling study of friendships and quarrels among 21 boys and 19 girls in a nursery school indicated that girls make more social contacts than boys in terms of number of children played with, and that unisex groups predominate.

Another time-sampling study of social behavior at the preschool level was made by Parten (1933). Her subjects were 19 boys and 15 girls who afforded 781 groupings for an analysis. Two-thirds of the two-child groups are unisexual. When the data were treated so as to show the five favorite playmates of each child, it was found that 81 per cent of girls' favorites were girls, whereas only 62 per cent of boys' favorites were boys. The most-favored playmate of

each girl was in every case of the same sex, whereas this was true for only 12 of the 19 boys. This fits in with Bonney's finding that girls score higher in social acceptance in the early grades.

What these results would seem to show when we put them together is that girls have an advantage in breadth of social contacts at the preschool and primary grade level that they lose to boys by the time adolescence is reached. A few studies throw some light on the process of attitude change through which this comes about. S. Smith (1939) had 1600 children, including 100 of each sex from 8 to 15, express by a vote whether given traits were more characteristic of boys or girls. The age comparisons indicated that boys' opinions of themselves became relatively more favorable with age, girls' opinions of themselves relatively less favorable. Conversely, with increasing age boys had a relatively poorer opinion of girls, whereas girls had a better opinion of boys.

Kuhlen and Lee (1943) studied 700 children in grades 6, 9, and 12 by guess-who and sociometric techniques. There were at all ages the sex differences one would expect to find on the items "restless" "talkative," "active," "attention-seeking," "enjoys fights," and "enjoys jokes" (boys higher than girls), and "acts older" (girls higher). But the more interesting finding was that, with changes in age, boys were more frequently mentioned as "liking opposite sex," "enjoying jokes on self," "being popular," "being willing to take a chance," and "being enthusiastic." It appears that during this period boys gradually take over the social initiative. Tschechtelin (1945), who administered a 22-trait personality scale to 1542 children and to 485 teachers in 140 classes representing all types of Indiana schools, showed that, while girls' self-ratings were much more favorable than those of boys when compared with teacher and classmate ratings, there was a marked trend for the boys' self-ratings to become higher from grade to grade over the 5-year interval covered (grades 4 to 8).

Character and Reputation. It is part of the traditional beliefs with regard to sex differences that females are superior to males in various moral qualities. Evidence from the previous section that girls are more social in their outlook and more interested in the approval of those around them might furnish some basis for such a difference. There have been a few large-scale research studies in this area. Terman *et al.* (1925) gave a battery of seven character tests to the gifted and control children, aged 7 to 14, whom he studied. It included two tests of overstatement, two tests of questionable interests, a test of honesty, and a test of emotional stability. The first five were taken from a battery devised by Raubenheimer (1925), the last two from Cady's battery (1923). Only three of the seven tests were of the performance type: the two overstatement tests and the test of honesty. The other four were indirect measures, although they were shown to differentiate between delinquent and nondelinquent groups. Boys in both gifted and control groups made worse scores than girls on five of the seven tests. Those which were clearly significant in this direction for the gifted group were "overstatement B" (CR = 3.33), "questionable interests: book preferences" (CR = 2.52), "questionable interests: character preferences" (CR = 3.06), and "social attitudes" (CR = 4.73). In the control group boys were significantly lower only on social attitudes (CR = 3.88) although all differences were in the same direction. Girls in both groups made somewhat worse scores in the performance test of honesty, but in neither group was the difference statistically significant. There was no difference in emotional stability. On weighted total score

for all seven tests, girls were significantly superior (CR = 3.33 for gifted, 3.07 for control).

The most extensive data on sex differences in character tests are those reported by Hartshorne and May (1928). Their tests were for the most part direct measures (performance tests) of "good" and "bad" behavior. They include numerous tests of deception, of service and cooperation, of persistence and self-control, and of moral knowledge. Deception tests included such things as grading papers wrongly, answering items after time was called, peeping when eyes are supposed to be shut, exaggerating scores on athletic contests, etc. In all but one of eight deception tests, a larger proportion of girls than of boys succumbed to the temptation. Clearly significant sex differences were obtained for grading papers at home (CR = 6.10), peeping when eyes were supposed to be shut (CR = 3.41), peeping in a social game (CR = 4.69), and denying types of deception of which they had been guilty (CR = 3.49). There is evidence also that boys behaved more consistently from test to test than did the girls, which is interpreted by the authors as indicating that boys are better integrated than girls in this area of conduct.

Hartshorne, May, and Maller (1929) found sex differences in the opposite direction in their study of cooperative behavior and persistence at tasks. Five tests of cooperation were given to approximately 400 subjects of each sex in grades 5 to 8. In three of the tests subjects were allowed to choose between keeping and sharing proceeds earned or things given them. Another allowed a choice between doing or not doing tasks for the benefit of hospital children. The fifth tested "endurance in cooperation" by having the subject work at a speed task 12 minutes for himself and a second 12 minutes for his class. The results showed the girls significantly more cooperative in three tests. On the other two tests the boys were slightly more cooperative but the difference was not reliable. On total score for the five tests, girls were superior to boys, with a critical ratio (1.9) which almost meets accepted standards of statistical significance.

Persistence was measured in the same population by three types of tests. In one test stories were read to the subject as far as the climax, at which point the climax, in a form very difficult to decipher, was given the child to read. The subject could either persist in reading the climax or go on to a new story. In a second test the subject was given two puzzles at the same time and was told which to begin with. Score was time spent on the first before giving up and turning to the other. In one experiment both puzzles were of the mechanical variety; in another they were magic squares. As a third test of persistence the authors used the scores earned in the "endurance of cooperation" already described. In this set of tests also the mean for girls was a little higher (CR = 1.7).

Inhibition (or self-control) was measured in the same populations by four tests: "picture inhibition," "puzzle manipulation," "safe manipulation," and "story inhibition." All these involved work tasks for the subject to do in the presence of interesting distractions. On every test the girls showed greater self-control (CR's ranging from 2.6 to 5.5).

One of the most interesting findings in this group of studies was that, for everything except the inhibition battery, there was much more difference in the *reputations* of boys and girls with respect to the character qualities being measured than there was in their performance on the tests. Reputation scores were obtained from guess-who ratings and a check list filled out by

teachers. On cooperation, where the critical ratio for the battery of tests was 1.9, the critical ratio for reputation scores was 7.9. Ratings by teachers and by the children themselves showed the same trend. On persistence, where the critical ratio for the test battery was 1.7, it was 7.6 for the reputation scores. On inhibition, the critical ratio for reputation was 5.0, which was almost exactly the same as the one for performance. It would seem that perhaps females get credit for more moral superiority than they actually possess.

There have been a number of other studies of persistence, but the results are conflicting and confusing, largely because the low intercorrelations between various tests designed to measure persistence throw doubt on whether there is a general factor corresponding to the trait name. A subject's score on any one test depends upon the specific nature of the activity involved, on the appeal it has for him, and on the manner in which the task is set. The reader who wishes to examine detailed results is referred to studies by Ryans (1939), Chapman (1924), Cushing (1929), Pinard (1932), Shacter (1933), R. B. Cattell (1935), and Wolf (1938).

The character test data in general indicate that, although sex differences vary according to the specific situation a test involves, there is a tendency for boys to cheat less than girls and for girls to exceed boys in tests of self-control, persistence, cooperativeness, moral knowledge, and moral opinions.

Level of Aspiration. One study by Walter and Marzolf (1951) has compared boys and girls on level of aspiration as measured by the Rotter aspiration board. The subjects were 10 boys and 10 girls selected at random from each of five grades, the fourth, sixth, eighth, tenth, and twelfth. An analysis of variance showed that the only significant differences in goal discrepancy scores were those associated with sex. Girls at all grade levels tended to set lower standards for themselves.

Physiological and Cultural Factors in Sex Differences

A complete understanding of sex differences involves evaluation of the factors producing them. Though no general agreement has been reached in this area, there is some evidence upon which tentative conclusions can be based.

As has been stated in our first section, the sexes differ markedly in their anatomical, physiological, and biochemical characteristics. It seems only reasonable to suppose that these differences might result in psychological predispositions toward some kinds of behavior rather than others. In addition to the studies previously cited by Sheldon (1940), Terman and Miles (1936), Gilkinson (1937), Marquis (1940), and Sollenberger (1940) indicating that some relationship between physical and psychological variables exists, the work reported by Stone and Barker (1939) is pertinent. They gave personality tests to a large population of adolescent girls and found reliable differences in the responses of pre-menarcheal and post-menarcheal groups of a given age. Their data suggest that the menarche brings with it behavior tendencies toward quieter living and toward feminine interests and introverted attitudes.

There is also, however, considerable evidence that the cultural environment is actually not the same for boys as for girls. The social influences to which they are subjected differ in countless and subtle ways. The differential pressures begin early and operate continuously. They are omnipresent in such things as clothing, play activities, restrictions of mobility, experience with money, home and school discipline, parental associations, occupational experi-

ence, educational exposures, and innumerable ideals of conduct and life satisfactions. Only a few of these things have been given any systematic study as yet.

Parent-Child Relationships. Freudians have given great prominence to this factor, but most of the psychoanalytic contributions on the problem are beyond the scope of a discussion that is concerned primarily with objective evidence amenable to statistical treatment.

There have been a few studies of parent preferences. Simpson (1935) interviewed 500 children, 50 of each sex at each age from 5 to 9 years, each of whom was living at home with both parents. The children were questioned about the favorite parent and were shown pictures of home life which elicited responses throwing additional light on attitudes toward parents. Preferring the mother were 69.6 per cent of boys and 61.2 per cent of girls. The difference is fairly reliable, but a large part of it is accounted for by the marked preference of 5-year-old girls for the father. Greatest mother preference was shown by children whose mothers worked away from home and so had acquired a scarcity value. A number of differences in parental treatment of the children were brought out in the interviews. For example, boys were more often spanked by fathers, girls by mothers. Mott (1937), whose subjects were 67 boys and 57 girls, aged 6, found that both boys and girls preferred the mother about twice as often as the father. Hayward (1935), reporting on 180 unselected children, grades 4 to 9, and 140 delinquent children found no tendency to prefer one parent over another.

Meltzer (1941, 1943) used a free-association technique to get at the attitudes of 76 boys and 74 girls, aged 9 to 16, toward their parents. The mother tended to be preferred by both sexes, but to a larger extent by boys than girls. The author states that the deviation from a healthy attitude was more likely to be in a direction of overdependence for girls, insecurity and rejection for boys, but gives no significance tests to support the generalization. An evaluation of the feeling tone of the reactions showed that for girls it was more pleasant, more emotional, and more acceptant than for boys. Though the data on parent preference themselves seem to prove very little in any of these studies, Meltzer's findings suggest that phenomenologically there may be considerable difference in home environment for boys and for girls.

Several other studies support this generalization. Terman (1938) found a number of sex differences in the reports given by 792 husbands and 792 wives regarding their childhood experiences. The women reported stronger attachment to the father than did the men, more conflict with the mother, less childhood punishment, more unhappiness in childhood, and more adequate sex education. Similar differences were found in other marital studies (Terman and Buttenwieser, 1935; Burgess and Cottrell, 1939).

Personal history data and several personality test scores reported by Wang (1932) for 358 college students (203 men and 155 women) gave some evidence of sex difference in the correlates of family background. Introversion in women was associated with lax discipline by the mother and with lack of religious training, but neither of these relationships was found for men. Introversion in men was associated with a history of irregular money allowance, extroversion with regular allowance or regular earnings. Stagner (1938), who used 28 men and 22 women college students as subjects in an attempt to discover the relationship between attitudes toward parents and emotional instability, also found that the significant items dif-

fered somewhat for the two sexes. A Czechoslovakian study by Jurovsky (1948), based on ratings made of their relationships with their parents by 18- and 19-year-olds being given vocational counseling, indicated that boys showed poorer relationships than girls.

Gardner's (1947) study of items checked on a questionnaire by fifth- and sixth-graders shows boys to be slightly more critical than girls of their fathers, although no significance tests are given. Schuell's (1946, 1947) questionnaire study of 134 girls and 156 boys, aged 8 to 14, showed statistically significant differences between boys and girls in what they had to say about both praise and punishment in their homes. In interpreting this material, we should remember that it is probably not so important whether parents *actually* treat boys and girls differently as whether the children *feel* that there is such a difference, since it is the phenomenological reality that shapes the behavior.

Even in areas of experience provided by parents for both boys and girls, the exact nature of the experience is likely to differ for the sexes. Hanson (1933) found from interviews with 39 boys and 59 girls, all of whom had an allowance and managed their own money, that a larger proportion of boys than of girls had had experience in borrowing (44 vs. 30 per cent), lending (39 vs. 18 per cent), investing (75 vs. 43 per cent), and buying clothes (53 vs. 29 per cent). On the other hand, more girls than boys kept accounts.

Newell (1936) studied the effect of maternal hostility upon 35 boys and 40 girls of ages 4 to 18. Results are compared with those from a control group of 36 boys and 46 girls. The author concluded that boys are more aggressive if there is consistent hostility on the part of one or both parents, and that girls are submissive if the father is protective or ambivalent. These conclusions rest on judgments of a rather subjective nature and need to be checked against more objective evidence.

Cavan (1932), in his study of 900 junior high school children, using the Woodworth test of neurotic tendency, found some evidence that girls suffer more from unsatisfactory home relationships than boys do. The answer to the item on which the subject answers whether or not he sometimes wishes he had never been born seems to afford a single index of the neurotic trends measured by the whole test. More girls than boys answered this affirmatively, and the difference between percentages for children from broken and unbroken homes was considerably larger for girls.

Sensitivity to Environment There is a fairly general belief that girls are more susceptible to environmental influences in general than boys, but the data available are somewhat conflicting and do not afford any clear check on the hypothesis. Cavan (1932) in the study cited above presented a little evidence that broken homes have a stronger emotional effect on girls than on boys. Spencer (1938) investigated mental conflict among 192 high school students, 88 boys and 104 girls Although his method of measuring conflict (too complicated to describe here) yielded higher conflict scores for boys, the scores of girls were more closely related to a number of environmental variables, including broken home, irregular church attendance, and being youngest in the family. Engle (1945) states that second- and third-grade girls suffer more from being members of minority groups than boys do, as measured by their deviations from the norms on the California Test of Personality. Neither the differences nor the critical ratios, however, are large enough to carry much weight. Keir (1945), reporting on a questionnaire given to 108 boys and 135 girls, aged 11 to 14, from three London schools that had

been evacuated to other places, stated that there is a slight but definite tendency for girls to pay more attention to people in their immediate environment and to show more emotionally-toned responses.

One of the most satisfactory studies was reported by Maddy (1943). He chose as subjects 319 children in sixth grade coming from professional and semi-skilled occupational groups. With this much difference in family background, there were 16.1 IQ points' difference between the averages for the two groups. On the personality tests used, the Pintner *Aspects of Personality* and the Pressey X-O, girls from the professional families were higher than those from the semi-skilled families in dominance, extroversion, and emotional stability. The boys from the two groups differed only in extroversion The sensed social status had evidently affected girls more strongly than boys

On the other hand, there are several studies that do not point in the same direction. Terman's (1938) study of 792 marriages reported separately for husbands and wives the relationships between marital happiness and a number of variables having to do with family background. Among the relationships that approached statistical significance there were just as many affecting husbands more strongly as affecting wives more strongly, and there were a number of variables showing no husband-wife difference at all.

In Germany, Busemann and Harders (1932) compared the school grades of 473 children of unemployed parents with the grades of 1154 whose fathers were fully employed. Although the authors concluded that girls suffers more effect than boys from parental unemployment, actually their data showed that this sex difference is unreliably small and that it disappears altogether when the comparison is made separately for three occupational classes. Springer (1938) gave the Brown personality inventory to 327 slum children and to 473 children of a good district, aged 9 to 15 years. There was no evidence from the sex differences in adjustment scores in the two environments to show that life in a slum district affects one sex more than the other. The adjustment scores reported by Pintner (1940) for 1400 children who were hard of hearing and for a comparable group of normal children indicated that hearing loss affects the adjustment of boys more than that of girls.

It seems, thus, that the broad generalization that girls are more sensitive than boys to *all* types of environmental influence requires some clarification, although the trend of the evidence is indeed in the direction of greater female sensitivity.

The Concept of Sex Rôles. It seems possible that the effects of both physical and cultural factors in producing psychological sex differences can best be understood if we think in terms of sex rôles as they are formulated in any given society and understood and accepted by the individuals who compose it. Physical differences predispose males toward what are considered masculine rôles, and females toward what are considered feminine rôles, but many social factors operate at the same time to determine exactly what pattern of attitudes and behavior any given individual will accept.

A few studies have been concerned with this problem. Milner (1949) made a thorough and intensive study of 30 early adolescents of the lower-middle and upper-lower social classes. She wished to find out how rôles associated with sex and with social status were affecting personality development. The characteristic most typical for boys was difficulty in impulse control. Most typical for girls was a drive for conformity and the absence of close emotional ties. Whether or not an individual showed

the typical personality seemed to be related to the closeness with which the mother approximated the feminine personality typical of her social group.

Rabban (1950) used a larger number of subjects, 15 boys and 15 girls at each of five age levels: 36, 48, 59, 72, and 102 months. They were divided into two subgroups, one from an upper-middle-class suburban community, the other from a working-class industrial area. By a technique involving toy choice and questioning he attempted to analyze the extent to which children in each age, sex, and class group were aware of their sex rôles. Not much general awareness of sex rôle was shown at the 3-year level, but it became increasingly apparent at each of the following ages. Boys were clearer than girls as to their sex rôles, and the working class clearer than the middle class. Middle-class girls were the latest to develop the sex-rôle concepts.

Sears, Pintler, and Sears (1946) have reported a well-designed study throwing some light on how the sex-rôle concepts develop. In a standardized projective doll-play situation, 3-, 4-, and 5-year-old children were scored for aggression. As in previous studies, there was a marked sex difference in the total amount of aggression shown. The next step was to compare aggression scores for children whose fathers were at home and children whose fathers were away in the Armed Services. The girls showed no difference in aggression, whether they were from father-present or father-absent homes. But the boys from the father-present homes were significantly more aggressive than the others. Differences were most pronounced in the 3-year-olds. These results are compatible with a sex-typing hypothesis, and it is difficult to think of any other which would account for them. Boys who have fathers at home develop by age 3 a concept of masculinity permitting a considerable amount of aggression. Boys whose fathers are absent develop the same concept, but more slowly. It is in evidence in their behavior by 5 but not by 3. Sears (1951) also discusses these results.

The task of evaluating the importance of physical and cultural factors has hardly been begun. In the abilities area, the sex differences probably depend largely on whatever cultural factors are now determining sex rôles. The fact that most of the special abilities investigated do not differentiate the sexes at the earlier age levels, and that they are so closely related to interest differences, would seem to support such a conclusion. In the area of motivational and personality traits, the relationships are considerably more obscure. Most of these differences show up at a very early age. Many of them, like activity interests and aggressiveness, are characteristics that could easily be related to physical and hormonal factors. But it is unlikely that any one of them is determined by physical factors alone. If sex-typing can be shown as early as the age of 3 and in a trait like aggressiveness, as the Sears study seems to indicate, there is certainly reason to expect it to operate in connection with most other characteristics. The unraveling of these relationships is a task for the future—an important task, since a large part of any individual's total adjustment and life efficiency depends upon an adequate understanding of the possibilities and limitations which his sex brings with it.

Chapter 18

PSYCHOPATHOLOGY OF CHILDHOOD

Clemens E. Benda

MENTAL DEFICIENCY

Marginal Forms of Mental Inadequacy

Definitions. In any larger sample of a population, a certain percentage of persons are unable to compete under equal conditions with others of the same age and the same cultural background because of the fact that their mentality is not functioning adequately for the task at hand. If such mental aberrations occur in adolescents or adults who have functioned adequately up to the time of their illness, we speak of mental "illness," a psychoneurosis or psychosis, according to the severity of the disorder and its character. The official definition of mental illness or "insanity" is:

> a condition which renders the affected person unfit to enjoy liberty of action because of the unreliability of his behavior with concomitant danger to himself and others. [Dorland, 1942.]

Though it may be difficult to determine in an individual case whether a mental illness is present, the situation as a whole is quite clear. Everybody realizes also that a mental illness, even of an emotional character, may interfere with the manifestations of what is usually called "intelligence." Nobody will therefore take the outcome of a psychometric examination of intelligence done during a mental illness as a true measure of the degree of intelligence which had been at the disposal of that person under normal conditions, and the testing of intelligence does not serve as a means of differential diagnosis between mental illness and mental "defects."

However, the situation is quite different if we deal with children. Interference with intellectual performance which we may find in children in a variety of disorders of mentation has led to the concept of "mental deficiency" or "feeble-mindedness," and it has been generally assumed for almost one hundred years that a mentally defective person is entirely different from a person with mental illness or "insanity." Although there is no generally accepted definition of mental deficiency, and all regulations dealing with mental deficiency are state and not federal laws, a fairly adequate definition of mental deficiency may be formulated in the following way:

> A mentally defective person is a person who is incapable of managing himself and his affairs, or being taught to do so, and who requires supervision, control, and care for his own welfare and the welfare of the community.

If this definition is compared with that of mental illness, it is obvious that it does not provide an adequate tool to differentiate between the two; and, yet, all legal provisions for the mentally defectives emphasize that the provisions do not refer to "insane" or mentally ill persons.

Historically, the emphasis in definitions of mental deficiency is placed on an impairment of "intelligence." If a mentally dis-

turbed person has sufficient intelligence to perform within the normal range on Stanford-Binet intelligence tests, such person is considered ill but not mentally defective. If, however, the disorder of mentation is severe enough to impair the intellectual performance to a degree outside the average range, the person is usually called mentally

> mind existing before the age of 18 years, whether arising from inherent causes or induced by disease or injury.

Although the use of the term "arrested" development seems to offer a useful differentiation to separate persons with defects of mentation from other groups, the term "incomplete" development becomes meaningless if we realize that psychoneurotic or psychotic conditions are also "fixations" or regressions to earlier developmental stages and that any lack of maturity is actually an "incomplete development of the mind."

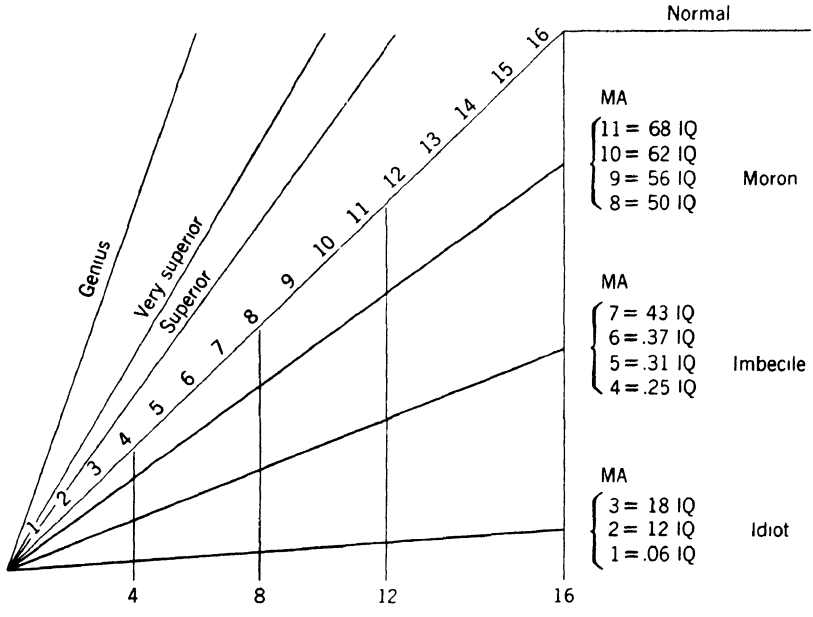

FIGURE 1. Classification of subnormal IQ ratings and corresponding mental ages for adolescent mental defectives of 16 years and above.

defective. It is therefore not surprising that the vast majority of children and young people with any type of mental aberration are considered "mentally defective," and no further differentiation is offered or attempted.

The English law, which offers a standard definition of mental defectiveness based on the *Report of the Mental Deficiency Committee*, or the so-called Wood Report, reads:

> Mental defectiveness means a condition of arrested or incomplete development of

The psychological classification of the whole group of mental deficiency uses three main categories with the common denominator that a defective person has an IQ rating below 70, taking a mental age of 16 as standard level for the adolescent group. The demarcation between imbecile and idiot

is not entirely uniform, and some use an IQ rating of 20 as margin, some of 25. As to the borderline between imbeciles and morons, the line is placed at an IQ level of 50, although 45 would be more feasible in many instances.

In America the expressions "feeble-mindedness" and "mental deficiency" are used synonymously, whereas in England "feeble-mindedness" is reserved for the higher grades which in America are called "morons." It seems preferable that "feeble-mindedness" be reserved for the "marginal" group, or the "moron," because the application of "feeble-mindedness" to the whole field of mental inadequacy implies that we deal with quantitative gradations but not qualitatively different groups. It has to be emphasized that a large percentage of the "feeble-minded" or the marginal group are completely different from persons with severe forms of mental deficiency, the "idiots" or "imbeciles," and the two groups should be kept strictly separate.

It is only in the last few years that it has been recognized more and more that the distinction between mental deficiency and mental illness cannot be maintained unless the term "mental deficiency" or feeble-mindedness is actually reserved for the marginal groups, who are not patients or ill people but persons with an inadequate intellectual endowment. As far as the more severe degrees of mental inadequacy are concerned, an analysis of the group reveals that we are dealing with a great variety of conditions of defective development or diseases of the central nervous system. Although some of the defects and malformations may be relatively stationary, in general there is no true "arrest" of development; and, as long as life proceeds, changes take place which are either an improvement or a progressive disorganization of the nervous system. It is time, therefore, to abandon terms like idiocy or imbecility as diagnostic definitions and to realize that the patients with IQ ratings below 50 are suffering from a variety of conditions which interfere with appropriate mental performance. Since in infancy and childhood we deal with a period of rapid growth and differentiation, any interference with development leads to changes in organization and subsequent differentiation. Moreover, the borderline between mental illness on an infectious or metabolic basis and those total personality disorders which we call schizophrenia, the character of which is not yet entirely clear, is so fluid that from a clinical point of view a differentiation cannot be maintained. This author has therefore proposed that the field of psychopathology of childhood be considered as the realm of developmental disorders of mentation, and that each group be considered according to its own merits.

The human personality as a functioning unit is constantly engaged in interaction with its environment. The behavioral patterns show different aspects in which motor behavior and sensory perception, emotional patterns and a rather abstract faculty called "intelligence" can theoretically be distinguished.

It is impossible within the framework of this chapter to discuss the definition of intelligence in more detail. Many other chapters in this book deal with intelligence and its measurement. One of the difficulties of all definitions of intelligence is that some writers consider human intelligence as that which distinguishes mankind from the animal kingdom; and, although it may be agreed that animals reveal manifestations of a faculty called "intelligence," in talking about human intelligence investigators emphasize those aspects that distinguish mankind from other creatures. In such a definition the ability to judge, to adapt to new situations, to learn from experience is usually emphasized as a characteristic of hu-

man intelligence, although the last item, to learn from experience, is granted to animals, too. However, if we deal with the concept of human intelligence on a more modest scale, we use those factors which were emphasized by Binet when he established the Binet-Simon test, which is the foundation of all later psychometric measures. Binet wanted to tap the faculty of judgment called "good sense," "practical sense," "initiative," and the faculty of adapting oneself to circumstances. From the viewpoint of psychometric ratings, human intelligence ratings can be represented on a quantitative scale in which is charted the degree of intellect which an individual can command at the time of examination. As Figure 2 shows, if the mean average intelligence is standardized at 100 the average range covers a field of IQ ratings between 70 and 130, or twice the standard deviation of 15, with about 2 to 3 per cent of test results above and below this range within 3 times the standard deviation. It is obvious, however, that the number of persons who test below 70 is much larger than the expected proportion of 2 to 3 per cent. The remaining number is composed of persons with pathological conditions which interfere with human intelligence and create a variety of aberrations of mental performance. However, throughout the whole scale of intelligence, mental illness may interfere with mentation at any level of development, and emotional disorders may also influence human behavior at any level of intelligence.

Psychological Ecology. Mental inadequacy involves not only intricate psychological problems which throw light on the complexity of human intelligence and its developmental anomalies but also sociological, educational, and biological problems which deserve attention. As a matter of fact, human intelligence cannot be separated from its biological and sociological environment, and psychological ecology is an important science though still in its very beginning.

The fate of the mentally inadequate person depends greatly on the type of family in which he is born. The inadequate child who is the only inferior member in an average or superior family is, from the very beginning, exposed to discrimination as an inferior member of the group. Discouragement, contempt, and neglect enter into the emotional and mental development from early infancy. Unable to respond adequately to his environment and return affection and attention with equal currency, the inadequate child finds himself exposed to early isolation and exclusion. Such a child is often a source of embarrassment to the other members of the family, who react to his presence with shame and may try to hide the fact of his existence. Parents, siblings, and teachers feel that he is "lazy," "dull," or lacking "will," and the child is usually treated with impatience. Thus, he will develop an inferiority complex and will soon slow down in his attempts to cope with his environment. Discouragement in school will often be so complete that the child will not do the things he knows how to do, and will remain a nonreader and will even lag behind his mental age in other subjects.

The reactions to such an unfavorable situation vary with the constitutional character of the individual and the dynamics to which he is subjected. Many withdraw from contact with their surroundings and indulge in excessive daydreaming and fantasy life. Others struggle to maintain a certain amount of self-respect by overactivity and social enterprises which are often far beyond control. Children of this type get into trouble and are sometimes caught stealing or participating in "unnatural" sexual activities or in other misdemeanors. It has been the custom to blame intellectual inadequacy for such be-

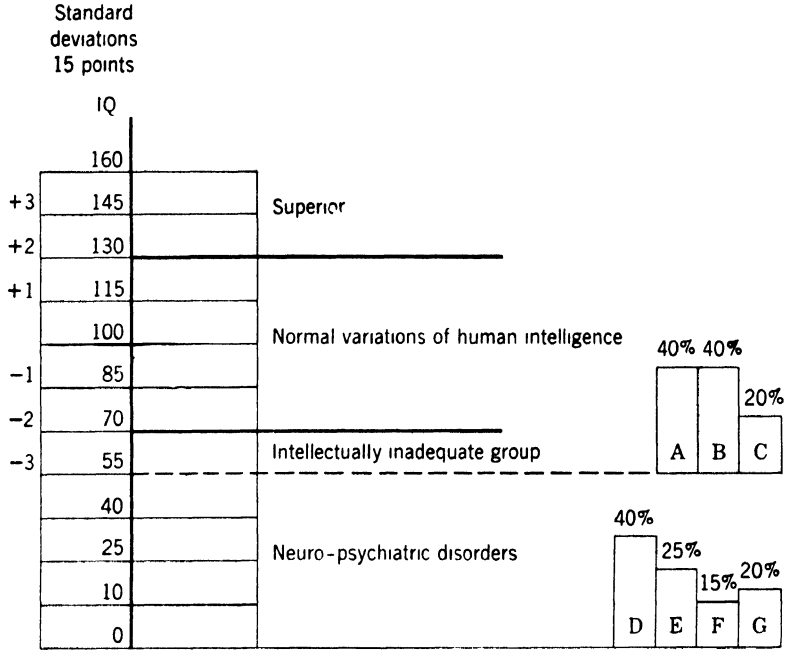

FIGURE 2. Psychological and psychopathological classification of normal and abnormal intelligence scores.

The normal variations of human intelligence are grouped around a mean of 100, and fall into a range ±2 times the standard deviations of 15 points. A certain percentage, about 2.5, of the total falls within 3 times the standard deviations. Theoretically, the normal intelligence falls, therefore, in a range between 55 and 145 IQ rating. The range of intellectually inadequate persons with IQ's between 55 and 70 is composed of three groups:

A. Normal minus variations within 3 times the standard deviations.
B. Genetic oligoencephaly.
C. Accidental cases, due to trauma, infections, metabolic disorders, or emotional disturbances.

The severer forms of mental deficiency, with IQ ratings below a range of 45 to 55, are composed of neuropsychiatric disorders:

D. Prenatal developmental disorders.
E. Traumatic "birth injuries."
F. Infectious diseases.
G. Metabolic disorders; neoplastic malformations; so-called degenerative diseases; and psychoses.

(Taken from C. E. Benda, M. J. Farrell, and C. E. Chipman, The Inadequacy of Present-Day Concepts of Mental Deficiency and Mental Illness in Child Psychiatry. *Amer. J. Psychiat., 107*, 721, 1951.)

havior patterns, but the psychoanalytical study of the emotional development of such children clearly indicates that they react like the normal child and that their behavior patterns are the product of psychodynamic factors and not of the fact that their judgment and mental ability are limited. The final fate of the inadequate member of an average family depends very much on the handling and understanding such a person encounters. Many end in institutions or are hidden, usually in inadequate home arrangements, in which they lead a life far below their capacities.

The moron from an inferior family, or from a family where one or both parents are of low mentality, usually has a different life. Not recognized in early infancy or childhood, such a child usually grows up under unsatisfactory home conditions until a social agency finally steps in. The feebleminded mother, unable to manage a family that is often too large, neglects the children by giving them inadequate food and overlooking early infections. She may attempt to escape by being promiscuous or by leaving the home for many hours of the day or night. The father or both parents are frequently alcoholic. The father, if not feeble-minded himself, may desert the home which is beyond his control. The accident rate in such families is high: burns from water boiling over, open flames, or burning houses are frequently found in children from these families. Others suffer from severe infections, chronic running ears, bone infections, or acute illnesses with involvement of the nervous system, which may increase the degree of mental defect. Other children suffer from severe nutritional deficiencies in infancy, their physical and mental development being delayed through malnutrition. Psychologically, an atmosphere of insecurity is created by neglect of the children, illness, death, and accidents. Thus, many children of this type are never able to develop a firm personality structure.

Lacking physical and psychological mothering, many of these children become psychopathic personalities, with severe emotional disorders lasting over many years, with resultant lack of ability to form any strong emotional attachments. When placed in foster homes through social agencies, they are not likely to make adequate adjustment. Misdemeanors and sexual play, taken in stride by real parents with regard to their own children, are critically judged and condemned in foster children and state wards, and foster parents are often ready to give up a child who does not come up to their expectations or who is not easily handled. Moving from home to home increases the child's feeling of insecurity, and the possibility of making a satisfactory community adjustment vanishes. When near puberty but often before 10 years of age, children of this type are found engaged in delinquencies and attract attention for sexual irregularities. These behavior patterns may be adopted because of the need to please other children, to be accepted as a "regular," as well as to derive primitive libidinous satisfaction from sexual play for themselves. Such activities do not endear the marginal group to the rest of society, and a child of this type finds it increasingly difficult to be accepted. He is, therefore, likely to remain a member of the marginal group throughout life.

The inadequate girl who may be physically well developed is apt to find men who are interested in her, and many girls of this type become public charges because of illegitimate pregnancies. If they marry, they start another family of the same type as that from which they have derived, and the cycle starts another turn, not for "hereditary" reasons or reasons of mere "feeble-mindedness," but by virtue of the complex psychological, sociological, and edu-

cational problems which this group presents.

The mentally inadequate male is less likely to find a female mate of superior intelligence, because girls of normal intelligence will spurn these individuals, who are usually unattractive, dull, slow, and unable to support their courting with adequate funds. The inadequate man is, therefore, condemned to fall back on females of lower mentality, and if he marries we usually find marriage of two inferior people who are utterly incapable of managing their own affairs, let alone a large family with many children.

This rather grim picture of the life history of the mentally inadequate group shows the complexity of the situation. Some states believe that sterilization may be an adequate remedy, but no single measure is adequate to cure this situation because even strict sterilization laws cannot interfere with the parent group which remains in the community. These parents may lead a life which is objectionable, but not enough so to justify any interference by law.

A confirmation of the above observations has been provided by a study on ecological data of 100 moron patients at the Walter E. Fernald School by Thomas Lenthall.[1] Of the institutionalized patients, 80 per cent of the male and 58 per cent of the female patients came from broken homes; 24 per cent of the male and 16 per cent of the female patients were illegitimate; in 7 per cent the father had deserted the family, in 4 per cent the mother; in 3 per cent the parents were divorced, in 1 per cent separated. The father had died in 3 per cent, the mother in 8 per cent; 4 per cent of the fathers and 4 per cent of the mothers were in prison, and in 1 per cent both parents; 3 per cent of the mothers were institutionalized in a state school and 3 per cent in a mental hospital. In addition there were a few other data which accounted for the total percentage mentioned above. Abuse of alcohol by the parents was found in 36 per cent of the male and 22 per cent of the female patients; sexual promiscuity and low moral standards in at least one of the parents were found in 44 per cent. Both parents were of low mentality in 4 per cent and feeble-minded in 5 per cent, although the feeble-mindedness of the parents in the male patients was as high as 10 per cent while none of the female patients had both parents feeble-minded. Feeble-mindedness in the mother alone was found in 14 per cent, and low mentality in 10 per cent. In the father group, low mentality was found in 4 per cent but feeble-mindedness in none, confirming another observation reported before that the feeble-minded male has relatively few marriage chances, and the feeble-minded male usually marries a female of lower mentality than his own.

1 Unpublished material.

The Marginal Group. The person with marginal intelligence is an individual whose mental maturation lags behind that of his contemporaries. Mental maturation is a process which includes the development of judgment and evaluation of a present situation and the ability to adjust to new situations and to utilize previous experiences. It also calls for a certain standard speed of mental functioning which enables the person to compete with others at the same rate of functioning. Children with mental inadequacy lag in every respect behind their age group, and adults of the marginal group never attain the mental maturation necessary to be entirely self-sufficient, especially in a competitive society under most adverse conditions. Not every child with slow mental maturation is mentally defective, and it must be understood that the status of incomplete maturation must be a permanent condition in order to fulfill the diagnosis of mental deficiency.

Delayed maturation may be caused by many different factors. Some children are slow starters or have been traumatized at birth, but they gradually come up to a normal level. Other children may be greatly handicapped by unfavorable original or social or nutritional conditions, and development is delayed but not permanently handicapped. This type of development is well demonstrated by the following case history, which is selected from a large group of similar records:

Barbara is the third of four children. The father is described as a person of limited intelligence who went to the sixth grade in school and started to work at 14. He had a long list of varied employments and filled every kind of job as an unskilled laborer, but was never able to hold any position very long. His work was irregular, and the family needed public aid. He was quarrelsome, not on speaking terms with his own family, and very weak.

The mother was the brighter of the two but had a very unstable personality. She herself had lost her parents when a small child, and was adopted by her grandparents She had a very unhappy childhood, was always in poor health, had rheumatic fever and ear abscesses and was anemic. Psychologically she was described as a very aggressive person who dominated the father, and the psychiatrist who worked with the family felt that the mother was a very cold person in relation to her children, whom she rejected. The children suffered both from the turbulent home situation and from the absence of warmth and love from their mother.

Barbara was more or less of a health problem from birth. She had great feeding difficulties and food idiosyncrasies. When a year old, she was placed in a children's hospital for treatment. She had always been underweight, and weighed less than 17 pounds at 9 months. She could not sit alone, and had not cut teeth at 1 year. She showed temper tantrums, picked up a rattle and hit herself over the head with the result that large bumps began to form. At the children's hospital she was a markedly emaciated, dirty, undernourished baby of 1 year, lying almost lifeless in bed. Her buttocks and back were covered with ulcers. Over her head there were large, hard hematomata. When treated, she gained weight and her mental attitude improved considerably. However, it was difficult to give her an adequate mental rating. There is little known about the history for the following years except that the child had enuresis and temper tantrums, was moody, and started to become a real behavior problem.

The mother became more and more nervous and irritable; she developed cancer, for which she was finally admitted to a hospital. Shortly after the mother had entered the hospital, the house burned down owing to negligence. The neighbors stepped in and provided temporarily for the children, but, when they saw that the father made no plans, the neighbors withdrew and the children were finally taken over by a social agency because of the unbearable conditions in which the family was found.

Placed in a foster home, Barbara wet the bed every night. All sorts of methods were tried to help her but nothing checked the habit. Barbara, in a deep stupor at night which was almost a coma, staggered to the bathroom and back like a person in a daze. One night the child got up herself and walked into the kitchen, probably thinking she was going to the bathroom. Apparently intending to turn on the faucet to get a drink of water, she turned the handles of the gas stove; the gas did not light and the child was nearly overcome by the gas fumes.

During the next year the child improved in her nutritional state and was better behaved except for enuresis. Her school work was poor. Because of her age she was placed in the third grade, and only after it was found that she was completely

unable to do what the other children did was the child examined and tested.

Barbara was a slim, cooperative little girl of 9 years 4 months, of fairly average height and weight. The occiput appeared flattened, apparently from early rickets, the lips were dry and bleeding, the teeth poor, and there were scars all over her back from early ulcers. In a psychological test the child, who was friendly and appeared quite happy under test conditions, scored a Stanford-Binet mental age of 8 years, which gave her an IQ rating of 87. She acted in a much more sophisticated manner than one would expect. She had built up a defense against possible failure through a variety of methods for eliciting cue words from the examiner. Often her

pose was that of absentmindedness and she would say, "Oh dear me, what is that word? I know it so well." The word in question was apt to be a most familiar one which supplied the essential point in an answer. The psychologist concluded, "Barbara's behavior resembles that of a child who is forced to capitalize on a disarming personality to protect herself against her inability to meet requirements set for her."

We may observe here a specific personality reaction, often found in psychopathic children who have had no possibility to develop a firm ego structure. This child has chosen the way of submission and of pleasing the other person at any price. It is to be feared that this girl may engage in promiscuous sexual activities when she grows into adolescence, because to be loved is her greatest need to give her self-confidence, although her need for it will outstrip any possible amount of love and satisfaction she will ever be able to receive. This constant frustration drives personalities of this type from one person to another without ever finding satisfaction or being able to give any returns, for she has never learned what love is or what it means to love others.

The psychometric examination of Barbara shows that her IQ rating of 87 places her within the normal range of intelligence, although she is slow and lags in her judgment about 1 year behind the average. Her school examination shows that she does not adequately utilize her capabilities. Her emotional difficulties have prevented her from learning to read and spell, and she is what is called a nonreader. From an educational point of view, she needs remedial reading; in other subjects, like arithmetic, writing, and language, the child is able to do second-grade work. Her writing, mainly good lettering, indicates that she has an adequate perceptual discrimination for letters and words and could, therefore, be taught to read.

Most mentally inadequate children are not recognized as defective before they enter school, though a careful analysis of the group shows that they are often slow in walking, indifferent to toys as play objects, and frequently slow in vocalizing their needs. Even though they are able to talk in single words at a normal age, use of language as a means of communication is delayed and the children only gradually use their small vocabulary in sentences with minor acquisitions at each age level. Physically they are not conspicuously different from other children, and most of them enter school at the age of 5 or 6 years but are unable to cope with the assignments In smaller communities and schools, these children are usually not recognized as mentally inadequate, and they may either repeat the first grade or be pushed up to higher grades in order to keep them within their age group. Although they actually fail constantly in school, the practice of promoting such children from grade to grade may delay recognition of the degree of inadequacy.

The situation is well demonstrated by the following history:

John was an 11-year-4-months-old boy, of normal height but almost 30 pounds overweight. His overweight was due to voracious eating caused by great emotional insecurity. The psychometric examination showed a mental age of 9 years 1 month, which gave him an IQ rating of 80. The boy offered a great deal of conversation, asked innumerable questions, and showed a great deal of interest which was centered mostly on toys and subjects which would interest a much younger child. His psychological success and failures were scattered over a large range; his basal was at a 5-year level, and he succeeded in some items through 14 years, which was above his chronological age. He showed

FIGURE 4. The correlation chart of an 11-year-old child who failed completely in school shows that the boy scored an IQ of 80 but was a non-reader and non-speller. In his best subjects he scored on a second grade level instead of a fourth grade level which would correspond to his mental age. Psychiatric examination revealed that the boy was not "feeble-minded," as expected by school authorities and in previous superficial examinations, but was "dull normal" and subject to an emotional disturbance which interfered with normal school progress.

fairly good abstract reasoning and verbal fluency, and good rote recall. According to his mental age, this boy should do fourth grade work (chronologically, he would be expected to be in the sixth grade). His actual school tests showed a great inadequacy far below his mental age. He was a nonreader and nonspeller.

Again, reading disability with good form discrimination as revealed in John's writing and other tests indicates that the reading disability is primarily an emotional refusal to learn, and can be overcome if adequate teaching methods are used. However, the application of these methods requires a great deal of knowledge and skill on the part of a remedial reading teacher; most schools do not show sufficient interest or provide sufficient money to acquire adequate special teachers; and the result is that a great many potentially normal children go through school as nonreaders and nonspellers. This in turn results in great emotional stress for the child, who feels constantly left out and who cannot participate in the school activities. Becoming more and more frustrated and restless, many of them are likely to be entangled in social difficulties because of minor misdemeanors, playing "hooky" from school, stealing, and other forms of delinquency.

The school history of John further demonstrates the fact that the average teacher is not able or prepared to spot reading disabilities or to recognize emotionally upset children with low normal intelligence. The boy was entered in school at the chronological age of 5 years, when he was unable to do anything and should have been refused entrance. At the age of 11 he had 6 years of unsuccessful schooling behind him with an immeasurable amount of frustration and the net result that in reading and spelling he was still on a primer, in other subjects on a second-grade school level, achieved by other children after a single year. The school's waste of time and effort and the child's loss and frustration in emotional values represent much greater expense, even in economic terms, than the provision of adequate special teachers would represent to society in general. Our present methods push the marginal group into illiteracy and delinquency, which costs society millions of dollars each year, not to mention the losses in moral and sociological standards, whereas a preventive educational and mental hygiene program would cost a fraction of the money that is wasted by our present system.

The soundness of this assertion may be demonstrated by another case, that of Caroline, whose inadequacy was discovered in the second grade.

Caroline was first tested at the age of 7 years 8 months, when she appeared to be a failure in school. She scored a Stanford-Binet IQ rating of 89, which is well within the average range. However, her mental age of 6 years 10 months demonstrated that she was first-grade material in arithmetic, writing, and other subjects. She had hardly started to understand reading and spelling, for which a mental age of 6 years 6 months is generally assumed necessary.

This child was placed in a good special class, with special attention to reading disabilities. When tested almost 5 years later, she had learned to read well and reading had become a better subject than arithmetic, of which she had learned the initial rules quite easily. The child was still operating on a school level below her mental age, and a psychiatric study demonstrated that she was showing severe emotional difficulties. She appeared rigid in her approach, insecure, and somewhat compulsive. She showed regressive tendencies or, rather, rigid adherence to more immature behavior patterns which made her appear silly, undisciplined, and emotionally unstable. She did most bizarre things in an effort to get attention—talked loudly, shrieked in a high-pitched voice—and was

FIGURE 5. Correlation chart showing original test results at an age of 7 years 8 months, and retest results at an age of 13 years 3 months. The IQ rating has dropped from 89 to 77. Variations in the outcome of IQ tests within less than 10 points may be of no significance, but the drop in IQ rating from 89 to 77 has to be considered significant and shows that original IQ scores in the marginal group must be taken with caution.

satisfied when she drew attention, regardless of whether approval or disapproval.

Some people consider the practice of pushing along a slow child advantageous because it delays the psychological trauma of being removed from a group and placed in special class or under specific conditions, but the harm and damage done far outweigh the benefits of such handling. The mentally inadequate child is not able to absorb the material offered in class or to play along with his classmates on the playground in extracurricular activities, and these facts cannot be ignored. The other children often take advantage of an inadequate child, and abuse him in many respects. The teachers, parents, and other adults rarely have understanding for the handicapped child, and they blame the child for his failures. For this reason, children of this type are often exposed for many years to psychologically unfavorable conditions until their actual deficiency is recognized. It is in this group that the Stanford-Binet and school tests are most useful and enable the examiner to determine the actual mental level on which a child operates. The application of adequate school tests clearly shows the grade level on which such a child is actually able to work. Examinations of many thousands of children of this type reveal the rather monotonous picture that some children in the age group between 9 and 12 years have mental ages of 5 to 7 years and are not even able to do first-grade work. Sometimes they have been in one grade for many years, unable to do a single subject adequately or to absorb the material that they were expected to learn. Years of frustration and disappointment often bring these children to the verge of delinquency, and it is usually a blessing if a psychometric examination eventually reveals the degree of retardation and permits placement either in a special class or in a special school where education and orientation are offered according to the mental age level on which the child is able to operate.

Mental maturation is indeed a biological process which cannot be accelerated by artificial means except in certain specific endocrine disorders. Mentally retarded children are, for instance, rarely able to learn to read until their mental age has reached at least 6 years 8 months to 7 years. It is not uncommon, therefore, that children with a chronological age of 8 or 9 years are absolute nonreaders and nonspellers while in other subjects they are not so conspicuously retarded. The ability to read depends upon the ability to discriminate forms and, therefore, on the development of a specific degree of perceptual discrimination, the stages of which are readily recognizable with the Stanford-Binet test; and it is surprising to see that a child may be able to copy a quadrangle but is unable to copy a diamond, which apparently is a very adequate test for the 7-year level of form discrimination. It is obvious that the child who has not reached the necessary stage of perceptual maturity is not able to do adequate school work on grade levels, and, although intensive training may teach a child to remember certain forms, he never will be able to perceive differences until the process of maturation has reached a stage in which such differential perception comes naturally.

Of course, these remarks do not attempt to cover the field of reading disabilities which are specific disabilities that may occur independent of intellectual retardation. Some highly intelligent persons have certain degrees of reading disability, which are often not actual disabilities but incapacities to absorb the offered material in the way the average child learns to read. Some of these persons have a different perceptual capacity and learn more readily from material offered through auditory or

kinesthetic methods, and it is often a question of changing the technique of teaching rather than a question of intellectual inadequacy or retardation.

The mentally inadequate child shows not only a slower process of intellectual maturation but also a quantitative limitation in the ability to absorb material and to cope with different situations. Therefore, such a person not only lags behind his age group in judgment but is also unable to deal with the same amount of actual material handled by the average person without difficulty.

Persons of this type are, therefore, limited in the scope of their interest, have a short attention span, and are slow in handling various materials. They are often confused by the complexities of modern urban civilization although they may be able to get along, unnoticed, under the more uniform conditions of rural life. The problems of mental deficiency are much more acute in urban communities than in rural areas, and many mentally defective persons are able to remain in the community and do satisfactory work within the limited field of farm activities although they are absolutely unable to deal with the complex situation to which a modern child is exposed in a city.

Mental inadequacy is a biological phenomenon which actually is not restricted to the sphere of intellectual judgment or what is usually called human intelligence. Slowness in reactions makes people of this type awkward in their motor expressions. Thus, it is a misconception to think that mentally dull people are necessarily able to compensate for their mental inadequacy by special physical or manual skill: the opposite is true. Usually, people with mental inadequacy are also slow and inadequate in physical skills, although it may be easier to develop manual abilities to a satisfactory degree than to improve scholastic achievements.

The Moron Group. Analyzing mental inadequacy on a moron level (Figure 2, *A*, *B*, *C*), we may distinguish three different groups. The first is composed of those otherwise fairly normal persons whose mental endowment is below the normal average range of mentality but falls within 3 times the standard deviation of 15. These people are mentally inadequate, "dull," or "morons," but they are fairly normal from a biological point of view, and they form the antithesis to the highly endowed persons of superior intelligence. In any biological sampling the superior variations are counteracted by the so-called minus variations, and any society which accepts its fortunate members must also accept the unfortunate ones and make the most of it. The so-called minus variations or the "subcultural" group form about 2.5 per cent of the average. In reality, however, there is a much larger percentage of mentally inadequate persons, namely about 5 per cent instead of 2.5 per cent. The increase is explained by the presence of pathological types of mental inadequacy, patients who are mentally defective on a genetic basis. The dull intelligence and slowness of mentation are particularities of the "minus-variations," which are otherwise not conspicuous and remain in the community unless social factors make their institutionalization necessary. Those factors have been discussed in the first part of this chapter.

The second group of mentally inadequate persons represents the manifestation of a genetically determined constitutional inadequacy in which mental and physical aberrations are linked together and have become a permanent genetically determined peculiarity. This group may well be designated by the term "oligophrenia vera," or oligocephaly, from the Greek term "oligos," which means little or limited in scope, in contrast to "micros," which refers to an actual deficiency in size as expressed in the

English word "small" or in the medical term "microcephaly." Oligoencephaly is a genetically determined form of mental inadequacy characterized by the combination of intellectual deficiency and more or less physical aberrations from the norm. These persons are not only intellectually but also constitutionally inadequate, and their physical handicaps may manifest themselves in certain anomalies which can be determined in careful physical examinations. The anomalies exist in greater asymmetries between the two halves of the body, asymmetries of the eyes and ears, abnormally high palate, curvatures of the spine, abnormally long and thin fingers, high arched feet, asymmetries between the breasts, unusual flexibility and mobility of the joints, insufficient vascularization of the extremities, and inadequate tonus control of the autonomic nervous system which manifests itself in moist and clammy cold extremities. Anatomical studies by the writer have shown that these anomalies of lateralization are associated with actual anomalies in the development and lateralization of the central nervous system. These aberrations are identical with the condition of myelodysplasia or spinal dysraphism. Anatomical studies of the brain show that the central nervous system is actually less well developed than in the normal average, the size of the brain usually being smaller than normal, the weight less, differentiation less advanced, and the nerve cells of smaller and more irregular structure. Of course, oligoencephaly occurs in all gradations of arrested differentiation, and it is incorrect to limit the diagnosis of oligophrenia to the actual IQ level between 50 and 70. Members of the oligophrenic families cover the whole marginal group; a number of them test within IQ levels of 70 to 80 while in others the IQ may be as low as 45. Within this group, psychometric examinations give an entirely adequate insight into the degree of retardation or maturation which a person has attained. The IQ level in this group remains fairly constant throughout life, and an IQ of 55, 65, or 75 represents a valid measure of the competence and a prognostically valuable standard for determining the future of such an individual. A person with genetically determined oligophrenia is useful in proportion to the IQ rating which he obtains, and the individual can become a useful member of the community according to his capacities and the ability of a society to make use of its members with limited capacities. The problem presented by genetically determined oligophrenia is that these persons are likely to produce offspring in whom, again, a large number of oligophrenic individuals appear. The gradients of oligophrenia may produce more severe defects in later generations, especially if both parents are oligophrenic.

The third group of mentally inadequate persons is composed of those individuals whose development has been impaired through accidental factors. These persons are the unlucky victims of previous prenatal, paranatal, or postnatal diseases which have not been overcome without untoward residues. The degree of limitation depends upon the degree of damage, and the usefulness of such a person depends upon how much compensation can be made for the original damage. From a psychological point of view, such an individual is a member of the mentally inadequate group and deserves the same consideration as other members of this group. From a medical point of view, patients of this type are similar to those in the more severe categories, but are more fortunate because they have been able to overcome some of the orginal damage though some residues have been left.

The Severe Degrees of Mental Deficiency (Imbecility and Idiocy)

The severe degrees of disorders of mentation, which psychologically include the imbeciles and idiots, represent an entirely different group from the one described above as intellectually inadequate. Although the terms "idiot" and "imbecile" may be useful for the psychologist, to indicate the degree of retardation and the mental level on which a person operates, these psychological terms have no medical significance and are only likely to detract the attention from the true problems that are involved.

An analysis of the severe degrees of mental deficiency indicates that the group is composed of persons whose mental development has been interrupted either before birth, at birth, or after birth because of different factors. The differentiation of the disorders according to time has a great value for diagnostic and prognostic reasons, because each type of disorder needs a somewhat different approach. Moreover, it has been increasingly recognized that it is not so much the type of noxious agent which interferes with development as the time in which the noxious factors operate which determines the structural damage and, therefore, the intellectual defect which such an individual manifests. According to time, the disorders of mentation can be classified as:

A. Antenatal.
B. Paranatal.
C. Postnatal.

According to the causes, we may classify the disorders in the following way:

A. Genetic (metabolic) disorders.
B. Exogenous (accidental) disorders.
   1. Traumatic.
   2. Vascular.
   3. Infectious.
   4. Metabolic.
   5. Degenerative and unknown.
C. Emotional disorders: psychoneuroses.
D. Total personality disorders: psychoses.

As the above classifications indicate, it is impossible to introduce one type of classification which would cover the whole field and give a satisfactory understanding of all the different conditions. The rôle of heredity in the causation of mental deficiency and psychoses has been the subject of many arguments since the 1920's. Some people have stated that the majority of mental defects are due to heredity, but, on the other hand, a wealth of experimental data on the production of malformations in the growing fetus has provided sufficient evidence that practically all prenatal developmental disorders can occur on an exogenous basis. Some of the confusion is due to the rather illogical and unscientific use of the term "heredity." At the zero hour of ontogenetic development, each individual starts its course with a different endowment of genetic determinators which are the product of countless generations of ancestral development as a result of the interaction of the organism and its environment, against which the organism maintains its individual entity. It is generally assumed that the genes are the carrier of genetic patterns. The genes are unit processes or determiners which, in chemical terms, are nucleoproteins of the size of a molecule or smaller. The term "heredity" refers to two different concepts: first, to the general "constitution" with which any individual encounters the environmental stress. There is no doubt that the specific constitution of each individual is determined by genetic factors to a large extent, but at the same time the phenotype is greatly influenced by environmental factors which bring certain genetic possibili-

ties to full development while others are partially suppressed.

Secondly, if one uses the term heredity in pathology, one usually thinks of specific disorders, either true gene mutation, loss of certain genes, or abnormal combinations which cause specific defects either of structural development or of metabolism. Such genetic malformations are, for instance, cleft formations like a cleft palate, spina bifida or cranial dysostosis, or specific metabolic disorders of which gargoylism, amaurotic idiocies, phenylpyruvic oligophrenia, and tuberosclerosis are some outstanding examples.

The Antenatal Developmental Disorders. For the majority of studies and observations, life starts at birth, and the trauma of birth is considered the first major event that may bear decisive biologic and psycholic consequences for the future of an individual. We are accustomed to think that intrauterine life is a rather well-protected period in which the growing child is not exposed to major injuries. Research, however, has provided ample evidence that the 9 months of prenatal development are a period of great biological importance, and many of the developmental disorders which produce dysgenetic behavior patterns and physical anomalies are produced during the prenatal period by a noxious agent operating upon the growing embryo. The prenatal developmental disorders are sometimes genetically determined malformations in which genetically determined processes are not completed: for instance, cleft palate, spina bifida, and cleft formations in the spinal cord or central nervous system. The development of any body organ, including the central nervous system, may be interfered with through defective genes which fail to organize specific processes necessary for the completion of the organism. It is often difficult to determine whether a specific malformation is due to genetic defects or to external factors. The presence of the same malformation in different members of a family is frequently the only clue that a malformation is determined through genetic factors.

On the other hand, experimental teratology [*teras* = malformed (fetus)] and experimental embryology have produced overwhelming evidence that practically all malformations found in human beings can be produced experimentally in animals. These studies indicate that the stage of development in which a defect occurs is of greater importance than the pathogenic factor. Malformations can be experimentally produced through any changes in the environment of the growing fetus, and trauma, chemical factors, temperature changes, radiation, interference with oxygen supply, and nutritional and other factors can be used with equal success. It is the time in which the noxious agent is applied that determines what type of malformation will occur.

The time *in utero* can be divided into the organogenetic and organokinetic periods. In the first, which covers roughly 6 to 8 weeks, the structural patterns are laid out and the embryo develops from the fertilized cell to a human organism which is basically organized in the same way as the child who will be born about 7 months later. This organogenetic period is a period of intensive differentiation, with relatively little growth in size and weight. At the end of the organogenetic period, the embryo measures only about 1 inch, but this organism shows the same structural organization as the later human being. The first 8 weeks are characterized by most intensive differentiation, and any noxious factor interfering for as little as several hours to days may interrupt this process and produce a malformation that remains as a defect throughout life if the organism can survive. These acquired developmental

disorders can be arranged as members of a series of stage-specific defects which show transitions from one stage to the next according to the time space under which the teratogenic agents operated. Each malformation also shows a biologic gradient ranging from the full suppression of a specific developmental stage to minor degrees which often may be discovered only if the more severe stages are well known.

It is another established fact that development does not proceed with equal intensity at each part of the organism at the same time. It seems as if the energy of growth is alternately thrown into the various systems and each one attracts the full energy for a period of time until the main force is shifted to another section. Like a game of cards, each player has his turn, and if a chance is missed it may never come again. This definitely irreversible character of development is a fact that many people, including clinicians, shrink from accepting. If one area of development is suppressed the whole balance is altered and the retardation of one part exercises an influence upon other parts which may react either by compensation or retardation, the result being a complex disorder in which the original damage may be obscured.

There is little use in dealing with each malformation in detail if the teratogenic principle is understood. One factor, however, has to be emphasized in relation to any psychological and biological problem dealing with the nervous system: Although the organogenetic phase of the human organism is roughly completed by the third month, and physical malformations due to arrest or defect cannot develop after the completion of this period, the central nervous system is at that time still a mass of undifferentiated ectodermal tissue which completes its major developments not only during the 9 months of gestation but is still quite immature at the time of birth, and important developments take place even after birth.

The stage-specific defects can be marshaled according to the stage through which the organism passes. The migration of the eyes from the lateral aspect of the skull toward a frontal position may be interfered with and the condition of hypertelorism or Greig's disease may occur. The period between the eighth and tenth week, the so-called "neofetal period," seems to be stage-specific for the condition of congenital acromicria (commonly called mongolism), in which again all gradients in the severity of developmental arrest can be found. This stage-specific period of mongolism is identical with the neofetal period of Ballantyne, which is the transitional stage before placental circulation is fully established.

Microcephaly. For the understanding of the psychopathology of mental defect and dysgenetic behavior patterns, it may suffice to outline briefly the gradient of inadequate development of the nervous system. Underdevelopment of the brain runs through the stages of anencephaly to microcephaly, in which the brain itself remains a miniature edition of a normal brain. True microcephaly (microcephalia vera) is a disorder which is often genetically determined, and families with five to seven microcephalic children have been described in the literature. However, microcephaly is by no means always of a genetic nature.

Microcephaly must be divided into the severe degrees of prenatal developmental arrest and those of arrest of skull development occurring after birth. In the latter type, skull circumference and capacity remain below normal but have reached the size of a full-term baby at birth. This type of microcephaly is usually due to paranatal factors, most frequently birth injuries, in which the brain is damaged at

that time and arrest of brain development leads to arrest of the growing head. The former type of microcephaly, the true prenatal developmental defect, can be divided into the genetically determined symmetrical underdevelopment of the brain and types of malformations which occur on an exogenous basis.

organization of mentation and, therefore, that the scale of reactions will be maladjusted. Such persons are mentally defective, usually to a severe degree, and score on psychometric tests in the idiot or imbecile range. However, the different organization of the nervous system will also lead to different types of emotional and

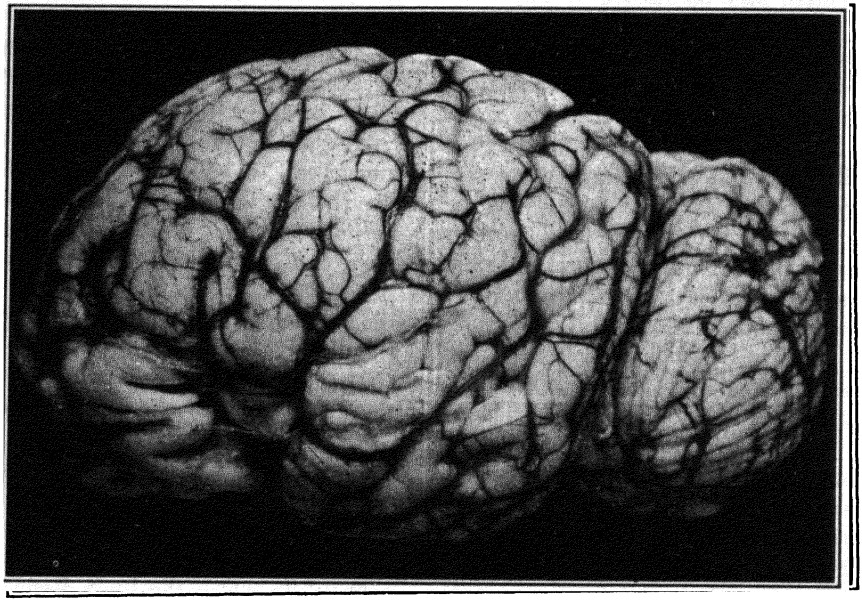

FIGURE 6. Lateral view of brain with agenesis of occipital lobes. The cerebellum is attached to the brain in a horizontal plane similar to some lower animals. This is a manifestation of congenital prenatal anomalies of brain development resulting in microcephaly. (From C. E. Benda, *Developmental Disorders of Mentation and Cerebral Palsies,* figure 29-A, with permission of publisher, Grune & Stratton, New York, 1952.)

The exogenous types of microcephaly include complete lack of fissuration and differentiation of the brain, as found in pachygyria (lissencephaly or the "loaf of bread" brain) and the various types of microgyria, microgyria interna, fissures and clefts as seen in porencephaly, and agenesis of parts of the brain like cerebellar agenesis or certain lobes of the cerebrum, occipital, temporal, or frontal. For the psychologist it is important to know that a person with a different brain structure has a different motor expression, and the behavior patterns of such a child may be best designated as "dysgenetic." With decreased infant mortality and improved life expectancy of these patients, the microcephalic child is now apt to survive infancy and early childhood, and we see more and more individuals with unbelievably small brains survive and grow into adolescence.

The psychological and motor behavioral patterns of these microcephalic children offer interesting aspects for research in

motor behavior. Two factors are striking. Early motor development of the infant does not depend upon the intactness and completeness of the cerebral cortex. Some microcephalic children show surprisingly advanced motor development, and it is a mistake to assume that later intellectual development or expressions of "derivative" intelligence can be judged and tested in the first year of life. The derivative behavioral patterns are by no means identical with early motor patterns of fundamentally subcortical origin. Another aspect is the surprising independence of bodily growth and differentiation from the regulation of the central nervous system early in life. Some children with no brain to speak of, or without function, have a surprisingly good development of their bodies. This, however, is not always true. Many early developmental orders of the nervous system are associated with physical defects of other body parts, and prenatal developmental disorders in general manifest themselves in a variety of biological defects which indicate a general constitutional inadequacy.

Megalo- or macrocephaly. The opposite of microcephaly is not hydrocephaly, as is so often assumed, but megalocephaly or macrocephaly, a rare condition in which the brain attains a much heavier weight than normal. Brain weights of 1770 grams to 2850 grams have been described in the literature, and the author has collected three brains weighing 2615, 2060, and 1930 grams respectively. The heaviness of the brain and increase of mass are not identical with better neurogenic tissue; we deal in macrocephaly with a local gigantism of the nervous system which is a neoplastic malformation.

Hydrocephaly. Internal hydrocephalus is the accumulation of spinal fluid in the ventricular system. This accumulation may assume tremendous proportions; the author has observed a case in which more than a gallon and a pint of spinal fluid were removed at autopsy (1-year-old child, head circumference 28½ inches). The increase of fluid in the ventricular system is associated more or less with complete cortical atrophy. The cortical mantle is pressed against the inner side of the skull, and the skull yields to the pressure by a gradual increase in the size of the head, which may progress rapidly at certain times. In one child of 3 years 5 months, a circumference of 36½ inches was observed.

The main types of hydrocephaly may be divided into four categories: (1) dysgenetic hydrocephaly; vesiculocephaly; hydranencephaly; (2) hydrocephaly due to abnormal production of spinal fluid; (3) hydrocephaly due to obstruction of circulation; (4) hydrocephaly due to abnormal absorption.

The first type is due entirely to early developmental failure of the brain mantle.

The second type is relatively rare and occurs mainly under toxic and infectious conditions associated with what used to be called "meningitis serosa."

Of importance is the third type, in which obstruction of circulation occurs. The main sites of obstructed circulation due to developmental anomalies are in the aqueduct of Sylvius and the exit of the fourth ventricle. Aqueduct stenosis occurs either as a congenital anomaly or, more often, as a result of early infectious ependymitis, gliosis, or tumor formation. The most frequent incidence of hydrocephaly is associated with atresia of the posterior exits of the fourth ventricle, especially the foramen Magendie. The membranous closure of the foramen prevents the spinal fluid from escaping, and the ventricle system is gradually enlarged, leading to atrophy of the cerebrum and a bulging cyst in the posterior cavity of the skull. About 50 per cent of cases of hydrocephaly confirmed by post-mortem examination showed atresia

of the foramen Magendie. Other cases showed a combination of spina bifida, meningocele, and a malformation of the cerebellum which is known in the medical literature under the term "Arnold-Chiari malformation."

also caused by organization of subarachnoid hemorrhages, and chronic hematomas usually lead to increased spinal-fluid pressure. The enlargement of the lateral ventricles and increase of spinal fluid due to lack of absorption is not restricted to children but

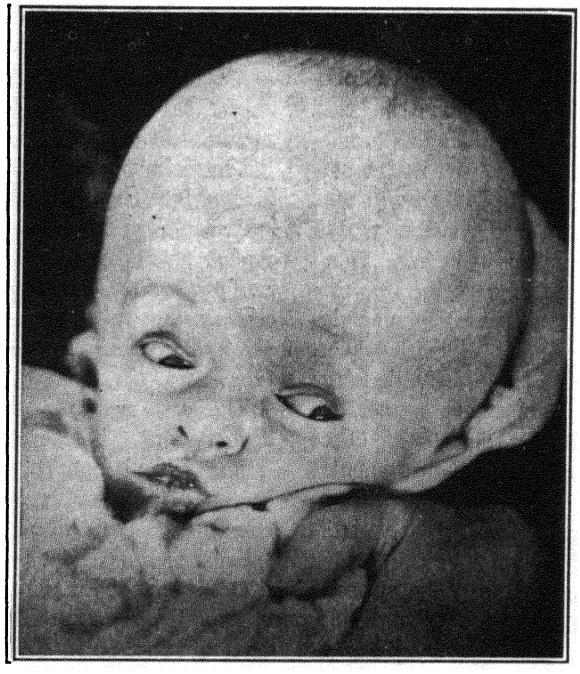

FIGURE 7. Hydrocephaly with increase of head circumference and severe brain atrophy due to increased spinal fluid in the ventricular system.

Hydrocephaly due to interference with the normal absorption of spinal fluid is mainly caused through infectious processes which have primarily caused meningitis and perineuritis, with ensuing fibrotic organization of the meningeal and perineural spaces. Since the spinal fluid escapes through the subarachnoid spaces and is drained partially into the sinus system, the fibrotic organization of these spaces interferes with the adequate absorption, and, therefore, a gradual increase in spinal fluid with enlargement of the lateral ventricles and cortical atrophy will develop. Meningeal fibrosis is is often found in older people and accompanies senile atrophies.

Cranial dysostoses. Several conditions of prenatal developmental arrest are associated with various types of cranial dysostosis or true tumor formations like tuberosclerosis, von Recklinghausen's disease, cranium bifidum, and other anomalies which are primarily of medical interest.

Congenital Acromicria (Mongolism). Of all the antenatal developmental disorders, congenital acromicria (mongolism) is most important for two reasons. The mongoloid child usually comes from a normal family,

with normal parents and normal siblings, and the single incidence of a severe mental defect in a normal family among the average population represents a severe psychological, sociological, and educational problem. Secondly, mongolism occurs about 3 to 4 times among 1000 births, and seems to be on the increase. Among all single types of mental deficiency of severe degree, mongolism now takes the first place, with 10 to 25 per cent, as the most conspicuous single morbid entity.

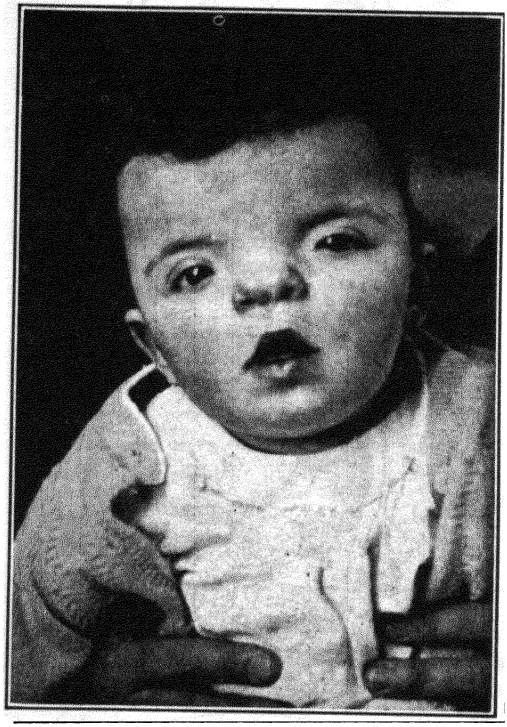

FIGURE 8. Hypertelorism (Greig's disease). *Note* the abnormal distance between the eyes, and duplication of tip of nose, as an expression of abnormal fetal development of the skull.

It was only in 1866 that mongolism was discovered as a specific morbid entity. Up to that time, it had been considered a particular manifestation of cretinism, which has been known in our western civilization for at least 1000 years, if not longer. This situation is still reflected in the remarks of the famous Edouard Séguin in 1866 in *Treatise on Idiocy and Its Treatment by Physiological Method:*

> The lowland cretinism of Belgium, Virginia—with its discrete goiter, its grey and dirty straw-colored skin, bears the same relation to idiocy and imbecility as the more extensive alpine variety. So does *furfuraceous cretinism* with its milk-white rosy and peeling skin; with its shortcomings of all the integuments, which give an unfinished aspect to the truncated fingers and nose; with its cracked lips and tongue, with its red, ectopic conjunctiva, coming out to supply the curtailed skin at the margin of the lids.

FIGURE 9. Mongoloid boy, 9 years of age. *Note* fine silky hair, slanting eyes, depressed nose bridge, dry lips, open mouth, short neck.

It was in the same year that Langdon Down gave his classical description of mon-

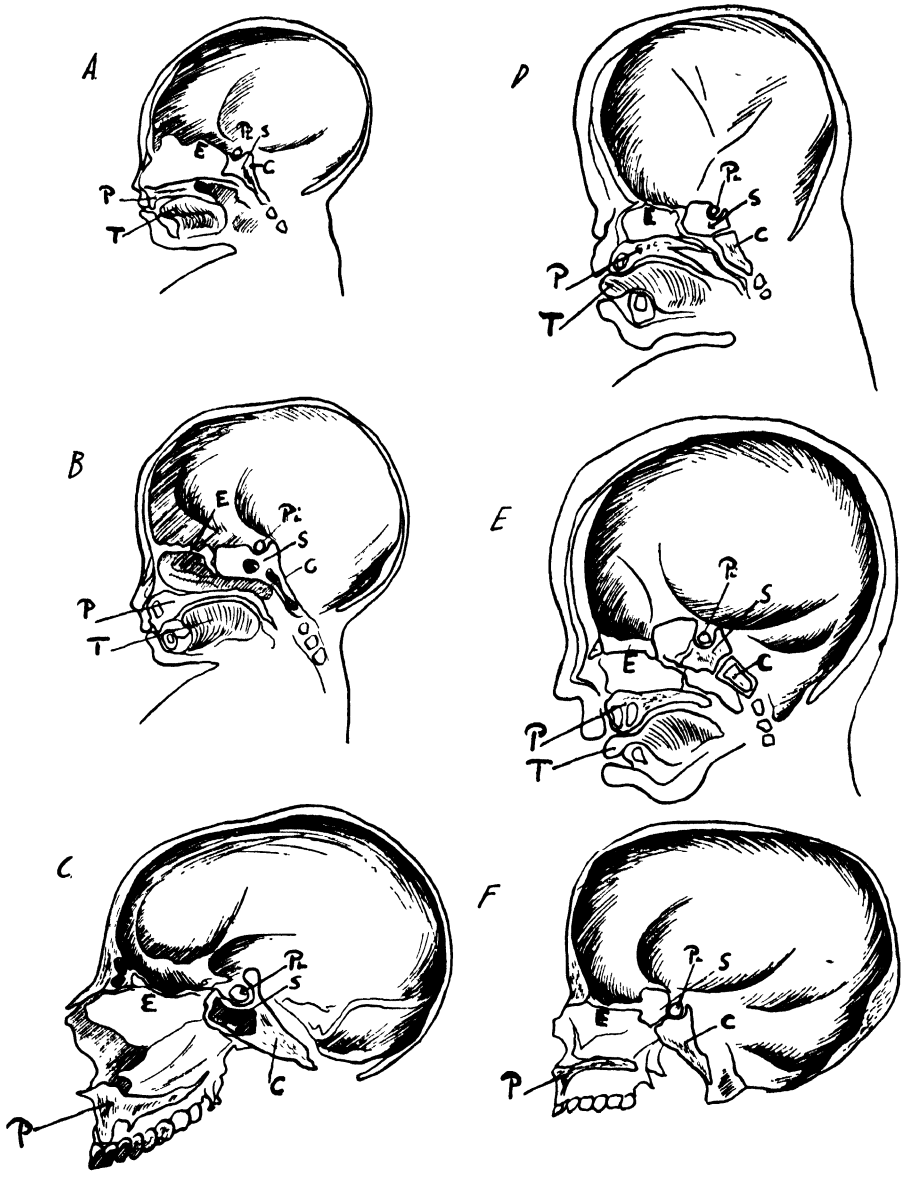

FIGURE 10.

golism, which became the foundation of later research on this condition. However, progress was extremely slow until the late 1930's, when intensive research in the mongoloid malformation was started by this author, which research finally succeeded in discovering the particular pathology which is behind this strange growth disorder.[1]

Mongolism is a combination of mental retardation with a number of physical anomalies which may involve every organ system. Body growth is delayed, and the hands and feet remain small and wrinkled and show abnormal patterns of hand lines and skin ridges. The sex organs are usually underdeveloped, the belly is protruding, and an umbilical hernia is marked. The skin is often primarily soft and puffy; later it often shows a tendency to dermatitis or roughness. The vascular tree is underdeveloped, and marmoration of the skin frequent. The child is usually hypotonic or "double jointed," is late in sitting up and standing, and speech often occurs years after the normal child is expected to speak. All these peculiarities would not give rise to the establishing of a specific morbid entity, for similar patterns can be found in other types of mental defect. What establishes the disorder is the anomaly of the head development, which results in a short, somewhat small head, slanting egg-shaped orbit holes with slanting palpebral fissures, and often a fetal skin fold at the internal angle of the eye called "epicanthus." The nose and nasal cavities are short and underdeveloped, the mouth undersized with a peculiarly shaped palate, and the tongue, which may be of normal size, does not find berth in the small oral cavity. Comparative anatomical studies by the writer have shown that the mongoloid visceral and cerebral skull undergoes a deceleration of growth in the neofetal period (eighth to twelfth week) with a definite shortening and abnormal angulation in the

FIGURE 10. Comparison of normal skull development (*A*, *B*, *C*) and the acromicric growth disorder seen in mongolism (*D*, *E*, *F*). [From C. E. Benda, What is Mongolism (Congenital Acromicria)? *International Record of Medicine, 165,* 75, 1952.]

A. Embryo * (47674). Calculated age, 16 weeks. *Note* clivus and sphenoid body with partial ossification; anterior sphenoid and ethmoid with crista cartilaginous; hard palate is firm and partially ossified; tongue within mouth behind maxillary ridge.

B. Embryo * (47706). Calculated age, 19 weeks. *Note* progress in ossification and increase in size of sphenoid and ethmoid bones.

C. Diagram of normal adult skull. *Note* development of sphenoid and frontal sinuses, great increase in development of visceral skull.

D. Mongoloid premature stillborn. *Note* smallness of clivus and sphenoid body, shortness of anterior cavity, upright grading; shortness of visceral skull; short, thick hard palate; tongue too big, protrudes between jaws.

E. Three-months mongoloid baby. *Note* shortness of clivus; abnormal position of sphenoid; shortness of anterior skull cavity; shortness of hard palate, with tongue protruding.

F. Mongoloid skull of patient about 20 years of age (compare with *C*). *Note* shortness of clivus, abnormal position of sphenoid, remnants of cartilage in sphenoid, shortness of anterior cavity, smallness of maxilla, and shortness of hard palate. The configuration of the skull is essentially the same as in the newborn, and the visceral skull has not participated in the extensive postnatal visceral development seen in the normal.

* By courtesy of Dr. Arthur T. Hertig, Lying-in Hospital, Boston, Mass.

skull basis, and an underdevelopment of the visceral skull. This deceleration of growth at this particular period is the cause of the fetal or unfinished appearance of the mongoloid newborn who has some, though extremely superficial, resemblance to the mongolian race. However, a more thorough analysis of the patterns shows that mongolism is not, as Langdon Down thought, a "regression into the mongolian race"; thus, the unfortunate term should be replaced by a more scientific one like "congenital acromicria." Further studies show that the deceleration of growth in mongolism is not restricted to the skull or the bony system but involves the whole dynamics of central growth regulation. The central growth regulation, which is represented in the neuro-endocrine junction at the subthalamic pituitary system, fails to provide adequate growth to the mongoloid infant and child, and the patient remains in his development between 30 and 60 per cent behind the average. A similar deceleration can be seen in the mental development of these patients. Although it is still customary to talk of "mongolian idiots" the mongoloid child is by no means often an idiot, and mongolism ranges over a wide field of mental levels. There are mongoloid children with IQ ratings as high as in the lower 70's, although the majority of mongoloids remain in an IQ range between 40 and 60. In some patients the slowing-down of mental development is so extreme that the child never exceeds a mental level of about 2 years. According to the wide variety of mental scores, mongolism should not be taken as an absolutely uniform entity, and each child needs individual attention according to his capacities.

The mongoloid child usually comes from a normal family. Needless to say, feeblemindedness or genetic inadequacy in a family is no protection against mongolism, but mongolism is a specific biological variant due to interference in development at a specific critical period, and is definitely not due to genetic factors. The reasons for the slowing-down of neofetal development are manifold. It has not escaped earlier investigators that mongolism occurs often in a large family at the end of the birth line or, rather, when the mother is in her 40's. As early as 1886, Shuttleworth wrote:

> It is remarkable that, in my experience, nearly one half of these children are the last born of a long family.

Newer studies have shown that it is not so much the number of preceding pregnancies which causes mongolism as a manifestation of maternal "exhaustion" as the fact that the mother has entered menopause or is near the cessation of menstruation. During the period of "change of life" the incidence of mongolism does greatly increase. Of women who had a mongoloid child in an age group between 41 and 52, 53.9 per cent were actually in the menopause or had menstrual irregularities before pregnancy. In the same age group, 92 per cent had no children for a period of 3 to 16 years and there was an unusually long interval between the last pregnancy and the child who turned out to be a mongoloid. Often it is a first pregnancy around the maternal age of 40 years which will end in the birth of a mongoloid. Though these data suggest that the cessation of the normal menstrual cycle (which is an indication of the declining power of the ovaries) has something to do with the development of mongolism, this is by no means the only cause. More than 45 per cent of all mongoloids are born to mothers under 35 years of age. However, it is worth while mentioning that the percentage of mongolism in the maternal age group from 18 to 28 is about 0.15 per cent and in a maternal age above 45 it is 9.1–12 per cent.

Analyzing the incidence of mongolism in younger maternal age groups, the inability to become pregnant is most remarkable and ranges from 33 per cent in mothers between 18 and 20 years to 81 per cent in the age group between 31 and 40 years. In the age group between 20 and 40, 38.5 per cent of the mothers had been treated for thyroid trouble. In the majority, these thyroid "troubles" were of a nature of hypothyroidism but in a few instances dysthyroidism or even hyperthyroidism may be suspected. It has also been observed that abortions in other pregnancies were more frequent than in the control material, and intrauterine bleedings during pregnancy have often been observed (38–67 per cent in the maternal age group between 18 and 40). These data and numerous preceding abortions have led Engler to emphasize anomalies in the nidation of the ovum. C. E. Benda indicated that mongolism seems to develop when the ovum fails to find a satisfactory nutritional system with the maternal organism. Previous abortions, endometritis, or unfavorable conditions, for instance in a twin pregnancy, are likely to provide inadequate conditions for the nidation of an ovum. These observations also admit the possibility that over-aged ova which lack vitality are not able to achieve a satisfactory nidation or are slow in general differentiation. In a small percentage of cases infectious diseases (including German measles) were found in the prenatal history, having occurred in the third month of the gestation period.

Summarizing the situation, it may be reiterated that mongolism occurs on the threshold of hormonal or nutritional deficiency of the growing fetus. The maternal organism appears to be unable to produce the proper endocrine environment for the embryo. The necessary adjustments are either delayed or insufficient, the result being that the fetus is deprived of a number of nutritional factors (including oxygen) that are essential for its proper development. The maternal condition is due either to the approach of the menopause (women beyond 40 years of age) or to an insufficient response to fertilization (young women, or women over 30 who had no children before). There is a third group of cases in which mongolism occurs because of the fact that an intercurrent illness has rendered the mother temporarily unfit for a pregnancy.

Cretinism. Compared with the complex nature of the mongoloid deficiency, the condition of cretinism is much simpler and more clearly recognizable, although the actual knowledge about the causation of sporadic cretinism is still scant. Cretinism is due to the inability of the thyroid to provide the organism with sufficient thyroid hormones which are contained in the so-called "colloid" of the thyroid (thyroxin). This happens either in a congenital aplasia of the thyroid or in goiterous ethnic groups where specific geographical conditions of soil, water, and air do not provide adequate iodide for the formation of thyroxin. Cretinism on the basis of geographical factors is called "endemic cretinism" and is distributed over the whole earth in certain mountainous or central areas far removed from the ocean. Cretinism is not due to goiter and is frequently fully developed without it. If goiter is present, it is the manifestation of an inadequately functioning thyroid which is attempting to compensate for its inadequate function by a hypertrophy which is inadequate. The cretin's development is almost completely lacking if there is complete thyroid aplasia. Figure 11 demonstrates a cretin of almost 11 years who resembles an infant of 6 months, and neither his physical and osseous development nor his mental growth has made any progress since the first few months of life. Mentally, the untreated

cretin remains on the lowest level of possible mentation. However, if treated early in life and if the thyroid deficiency is compensated for by adequate thyroid substitutional treatment, he may show a satisfactory physical and mental development and there may be no impairment in IQ ratings at all.

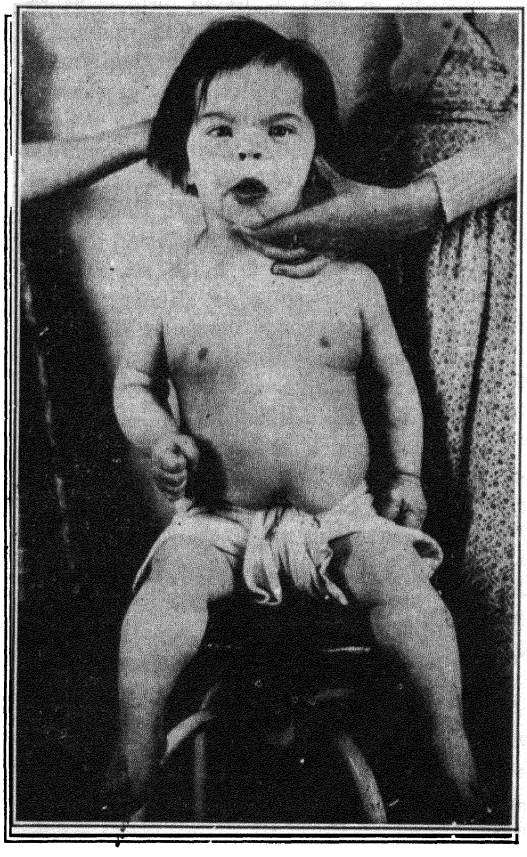

FIGURE 11. Eleven-year-old cretin whose bone age and appearance are that of a child less than 2 years of age. Complete idiocy. No previous treatment. *Note* depressed nose bridge, squinting eyes, thick lips and tongue, pale flabby edematous skin, protruding belly.

Gargoylism and other metabolic disorders. A number of other metabolic disorders have been discovered which show the importance of metabolism in the production of disorders of mentation. Of these disorders, gargoylism is of especial interest because the gargoyle looks in many ways like the mongoloid and the cretin, and has been confused with them. Gargoylism is a genetic disorder and, therefore, often occurs in families in several instances. It develops in different forms, starting sometimes soon after birth (infantile form), sometimes late in infancy or even in early childhood. According to the age, the children have a somewhat different appearance and different degrees of mental retardation, but the basic features are a growth deficiency with severe changes in the osseous system, a large belly with an umbilical hernia, and enlargement of the liver (hepatomegaly). The neck remains short, the head becomes larger, increasing in length and width with indications of hydrocephaly of minor degree. There is often a membranous veil in front of the cornea. Anatomical study shows that gargoylism is a metabolic disorder which involves all organ systems of the body, including the brain. The nerve cells degenerate and often contain huge amounts of fat similar to that seen in amaurotic idiocy. Fat droplets and glycogen are found in the liver, lungs, spleen, and many other tissues, indicating that gargoylism is a metabolic disorder in which a specific enzymatic system either has not developed or breaks down.

Gargoylism has some as yet undefined relationship to other forms of abnormal fat metabolism, the so-called lipoidoses, of which the so-called amaurotic idiocies are best known. In amaurotic idiocy a specific metabolic disorder of fat metabolism is present. Amaurotic idiocies occur at different age levels, with different clinical symptoms and different mental manifestations. Although the infantile form is of

special medical interest, the so-called juvenile form (which develops in an age group between 8 and 12 years and which starts with epileptic seizures and increasing loss of vision) is of greater interest to the psychologist, physician, and educator because patients with the juvenile form of amaurotic

FIGURE 12. Four-year-old child with gargoylism (Hurler's syndrome, lipochondrodystrophy). *Note* strange appearance of child, with enlarged head, depressed nose bridge, thick lips and tongue, short neck. (From C. E. Benda, *Developmental Disorders of Mentation and Cerebral Palsies*, figure 86-A, with permission of publisher, Grune & Stratton, New York, 1952.)

idiocy may have been normal throughout infancy and early childhood before the disorder occurred.

An important disorder of protein metabolism is seen in phenylpyruvic oligophrenia, a metabolic disorder of an amino acid (phenylalanine) which is increased in the blood and secreted in the urine of these patients. For some unknown reason, the enzymatic catabolism of phenylalanine is blocked and a part of this abnormally increased amino acid is excreted in the form of phenylpyruvic acid in the urine. The easy demonstration of this product in the urine makes it possible to establish the diagnosis of phenylpyruvic oligophrenia rather easily. This disorder, which usually dooms the patient to complete idiocy, is a genetic disorder which may affect several members of a family. It often occurs in perfectly normal families and has been observed in some offspring of highly intelligent people who have made great contributions to our society.

Paranatal Disorders. The majority of conditions described in the previous pages are either disorders of development which took place in the prenatal period or metabolic disorders which are determined by genetic factors.* Another large group of disorders of mentation is produced through extrinsic factors which operate at the time of birth. The whole group may be readily summarized under the term "paranatal disorders."

It is well recognized that the time of birth is a critical period for the child and that, therefore, birth is associated with an increased biological risk. Difficulties may start weeks before birth by premature separation of the placenta or abnormalities in circulation which interfere with the nutrition of the unborn. Lack of oxygen and other nutritional factors may produce anoxia of the brain, with severe damage to brain tissue and resulting cystic degeneration of the white matter and anoxic lesions of the gray matter. The actual time of birth multiplies similar dangers, and anoxia or interruption of oxygen supply of the brain, traumatization of the brain through compression, bleedings inside and around the brain, neonatal pneumonia and interference with blood and oxygen circulation due to premature breathing, and anemias with their severe sequelae form the gamut of possible noxious factors which interfere with the health of the newborn child. Few of the children exposed to such

conditions escape entirely unimpaired, and in the majority of them motor disabilities manifest themselves so that paranatal disorders are almost identical with the field of *cerebral palsy*. However, some birth-injured children may show little actual motor disability, the main damage involving so-called "silent" areas of the brain, that is, areas like the frontal lobes the function of which is not immediately apparent and the lack of which is, therefore, not obvious to the observer.

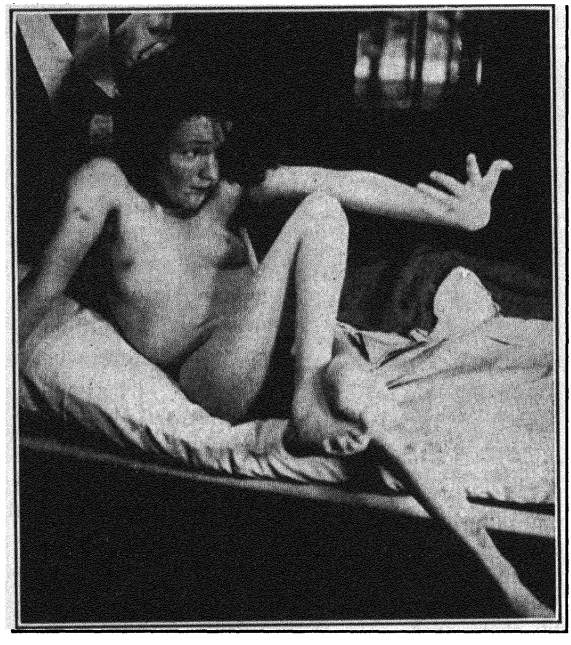

FIGURE 13. Cerebral palsy. *Note* uncontrolled movements of arms (athetoid choreatic movements with flexion and hyperextension of various parts of the extremities, spasticity of lower extremities. This instance of cerebral palsy was due to kernicterus, or the Rh factor. There are many different types of cerebral palsies, mainly due to so-called birth injuries. (From C. E. Benda, *Developmental Disorders of Mentation and Cerebral Palsies*, figure 82-A, with permission of publisher, Grune & Stratton, New York, 1952.)

Cerebral palsy is a disorganization of motor control through damage to the central nervous system. In some individuals the damage does not interfere with "intellectual" development and motor impairment is the only symptom, but in the majority of patients the damage to the brain involves large areas, including those integrative fields serving "intelligence," and may range from a slight developmental retardation to a complete incapacity for intellectual adjustment. The application of psychological ratings like Stanford-Binet mental ages to the child with cerebral palsy is of dubious value and may be useful only for placement in a specific grade or new training program. The brain-injured child manifests a great number of changes in the motor and perceptual fields, and what may appear as "intellectual" deficiency may actually be a perceptual anomaly, as has been demonstrated by a number of investigators (Werner, 1948; Strauss and Lehtinen, 1947; Goldstein, 1936; and others).

To gain a satisfactory insight into the mental abilities of a child with cerebral palsy, one has to observe him on different occasions and retest him at periodic intervals. Any conclusion arrived at in infancy or early childhood may be wrong and misleading, because some brain-damaged children make a very slow start but gain speed after the first years have passed.

Cerebral palsies manifest themselves in different ways, and the neurologist may classify the forms according to certain types of motor disability. Little's spastic rigidity is the most severe type of cerebral palsy, which is often identical with decerebration, in which the cerebrum is severely damaged and the child operates on a lower level of neurogenic integration. On the other hand, traumatism of the cerebellum may lead to ataxia or a form of cerebral palsy which interferes little with intellectual performance. For the psychologist it is most important to realize that motor disability creates a different perceptual climate for the handicapped individual. The inability of the infant and child to conquer the world and to incorporate his environment through the gradual stages of oral, visual, auditory, and tactile exploration creates a different concept of reality, and the child with cerebral palsy therefore needs a substitute for his deprivation in sensual exploration of the world. The child has an increased disability to make a satisfactory emotional contact with his surroundings, and, reciprocally, the environment is easily frustrated and rejects the child who is not able to make any returns in emotional and intellectual gratification. The training of such a child, which has been attracting much interest, is a complex problem which is dependent not only upon the creation of better motor control but also upon the application of a multidimensional approach in which the psychologist, neuropsychiatrist, educator, and, last but not least, parents and close environment have to collaborate intimately with each child.

Although the majority of children with cerebral palsy suffer from paranatal disorders, infectious diseases of infancy contribute another large group to this category. Most children run through the usual infant infections (measles, scarlet fever, mumps, whooping-cough, pneumonia, and others) without damage to the nervous system, but a small percentage are damaged through noxious factors, either actual virus diseases, toxins, or allergic reactions, which cause a variety of pathological features. If damaged before speech and gait are established, the child may be greatly retarded in the acquisition of these skills and remain without speech for many years, even throughout life. If illness occurs in the second year, speech may be lost and return after a long time or inadequately. Speech defects are, therefore, one of the most characteristic "palsies" of the postinfectious organic syndrome. If no "organic" symptoms are manifest, a disturbance of behavioral patterns is not unusual. The child with postinfectious cerebral palsy often shows overactivity and restlessness, disorganization of behavior, aggressiveness, and emotional instability, and the combination of these symptoms is often so characteristic that the postinfectious child can be recognized even with an indecisive history.

PERSONALITY DISORDERS ON A HIGHER INTEGRAL LEVEL

Emotions and Emotional Disorders (Psychoneuroses)

Although many abnormal mental reactions and illnesses are nowadays recognized as "emotional" disorders, the term emotions is still unsatisfactorily defined and no generally accepted theory of emotions is available. In theoretical physics it is not con-

tested that physical facts are without meaning unless a theory attempts to marshal the wealth of observations. In psychology, however, the necessity for theoretical concepts is still little recognized and is often mistaken for love of speculation. Before any progress in the understanding of emotional disorders can be expected, a clearer understanding of "the emotions" and their rôle is necessary, and in the following paragraphs the attempt will be made to offer such a theory, based on the writer's own observations and data presented by other investigators (Cobb, 1950; Yakovlev, 1948; and Papez, 1937).

If we talk of emotional disorders, we obviously mean to differentiate such disorders from other pathological categories, like disorders of intelligence or "cerebration." In emotional disorders we deal, not with disorders of interpersonal relations which are due to abnormal perceptual functions or abnormal intellectual interpretation of experiences and judgment, but with disorders of affects, moods, and the expression of inward feelings which disturb the normal formation of contacts between an individual and his antagonists. Some investigators still use the term "emotions" only for pathological conditions of rage, terror, inhibition, or depressions—briefly, any pathologic exaggeration or inhibition of normal affects, but there is nothing either in the etymology (*e-motion*) or in the accepted meaning of the word which would warrant such limitation.

Each living organism automatically registers its own position in relation to its environment by a status of organismal briefing which is inwardly experienced as a certain "feeling" or "affect" (*ad-facere*) which expresses itself on a somatic level in a certain organization of organismic responses as sensations, and is experienced on a higher integral level as a certain state of changes in tension or mood. Although each feeling has a certain duration, it is dynamic in nature and is related to a previous experience, and it is anticipatory as it is modified by the direction in which the organism moves toward a solution of the present status to reach a condition of lessened tension or equilibrium.

What is experienced inwardly as a feeling may be called the "climate" in which an organism functions. That which is observed as an outward motion (e-motion) is the expressive behavior which the organism activates in order to change its relationship to the environment with which it interacts.

By the term "emotions," therefore, is meant that field of human and animal experiences and behavior which encompasses the immediate responses of a living organism to external and internal stimuli. Although the classical terminology considered emotions an affective state of "consciousness" in contrast to cognitive and volitional states—meaning that any human experience is a part of "consciousness," therefore there cannot be anything actually "unconscious" in our consciousness (though it may be not "focused")—this concept of consciousness has become less and less acceptable to modern psychology. Animals, including man, live through a continuous stream of emotional experiences in which the contact with the outer world is registered in emotional values according to the gratification or lack of gratification which an object of encounter offers. This system of emotional experiences permanently influences any new action and modifies motivations, but it functions on a different level of integration. It has nothing to do with awareness of experiences or motivations, and is not immediately accessible to cognitive consciousness. The field of emotions links nature together on a level of instinctual and libidinous drives, in which animal and man share equally, although

each emotion is private and essentially unsharable because each individual finds himself in a different state of needs and satisfaction. The field of cognition or awareness seems to be reserved to man; although we do not know the "language" of animals, we have reason to believe that the use of human language has introduced into nature a new level of interaction: the level of symbolic representation, which is a specific type of human life. It is for this level of human mentality that psychodynamic psychology wishes to restrict the term "conscious" functions.

Whereas the affective state through which an organism passes leads, on a bodily level, to an organization of autonomic responses, the total of sensations and feelings results in a certain "mood" which represents the organization of organismic responses in toto. The affective condition under which an organism operates is its positional briefing for further action. Changes in mood can therefore be described in different terms. One may either deal with the outward or inward direction of an emotional expression like extrovert and introvert, or with degrees of emotional expressive behavior in terms of acceleration, increased intensity, lack of inhibitions, aggressiveness, elation, or the opposite as expressed in inhibitions, retardation, lack of initiative, etc. Stanley Cobb has presented a possible classification of the emotions, arranging them in a circle with the opposite poles of pleasant and unpleasant and least differentiated and most differentiated. Under pleasant emotions are registered joy, elation (mania), and on a more differentiated level companionship, love, and affection; their opposites are fear, terror, sadness, depression, loneliness.

Whatever system of classification of different moods is used, each will register different intensities, different directions, and sensations of a pleasant or unpleasant nature. In each, emotion manifests itself as an unconscious dynamic behavior which characterizes the position in which an individual finds himself in relation to his internal and external environment. While, therefore, on the one hand emotions are reactions to outward stress and stimuli and a specific mood registers the bearing of an organism with regard to outside forces, on the other hand it is evident that the position of each individual is determined by his own "energy" and driving force, by the direction in which an organism moves on account of his instinctual needs, and by the amount of energy that an organism is able to throw into the battle.

One of Freud's most important contributions is the discovery that the emotional life is conditioned by the instinctual drives and that, therefore, emotional reactions are to be understood only in regard to the needed gratification of a specific drive which determines the action of an individual. The emotional life is centered around the gratification principle, and our affects are determined by their emotional value in relation to the possible gratification of some need. Earlier physiology and psychology considered the whole field of sensations, perceptions, and affects as a system of reactions to stimuli in which the individual behaves rather passively while his actions are determined as reactions to outside stimuli. Freud has demonstrated that the individual is activated and conditioned through his primary instinctual needs, which determine the nature of his emotional experience.

The fundamental drives which condition the activity of an individual, and the "energy" which is behind these drives, have been matters of argument between different schools of biologists and psychologists for almost a hundred years. It is obvious that each situation is actually met in a different emotional state, according to the nature of the drive which is behind the action

and the motives which determine a specific behavior. The more highly integrated the world of an individual, the more complex is the system of motivations that determine emotional responses in their specific character. However, most scientists, in their scientific endeavor to explain the complexity of phenomena by reducing them to one "causative" factor which is supposed to be behind all of it, felt the need to designate one source as the fundamental force behind the whole life or, at least, the psychological complexities. For the vitalist it was "life" itself, this unknown process which distinguished the living cell from inorganic matter, the entelechy of Aristotle, which Driesch renewed; for Bergson it was the *élan vitale*. For other schools, including Freud, it was a basic "energy," libido, or, finally, sex.

It is one of the weakest points in the monumental work of Freud that he himself and his pupils considered it his greatest contribution that he had "discovered" sex as the driving force behind all human psychological activity. This, however, is not actually a discovery but a bold terminological simplification which is even of dubious value as a heuristic principle. If Freud's sex theory means (and Freud was convinced that he had proved this point) that all the emotional gratifications which an individual seeks on different levels of behavior are identical and "nothing but" the need for sexual gratification, this statement disregards the essential difference between "sex" as it appears at the time around puberty and the infantile emotional cravings which a child manifests. This either makes the use of the term "sex" meaningless by applying it to all emotions, or obscures the essential difference between actual sex behavior and general emotional needs. Freud himself was convinced that his sex theory was able to explain the vicissitudes of various instinctual drives, and he was proud to have demonstrated, as he thought, that all emotional needs are evolved from sexual libidinous behavior patterns and these original sexual behavior patterns are modified through inhibition and sublimation by the action of the superego. This "theory" does not do justice to the actual facts, and it confuses an arbitrary interpretation with actual observations. The general need for emotional gratification and well-being, and sexual libido, obviously are not the same. Moreover, the sex drive does not precede all instincts so that the emotions derive from sexual drives; on the contrary, the sexual drive differentiates out of a general unspecific contact behavior and represents a specific drive with specific needs. The need for emotional gratification constitutes a large field of psychobiological needs which, in man, are not organized under the dominance of the sexual drive for almost 15 years. Nature has deemed it wise to delay the development of the sex drive for such a long time, during which numerous channels of gratification are offered to the growing child. Only after a relatively firm ego structure has been developed, and selective emotional behavior has had sufficient time to establish a system of ego-near emotional values, is the sex drive permitted to take its powerful and domineering place within the system of driving forces.

Modern psychoanalysts identify Freud's sexual theory more and more with a general theory of emotions, but this modification of Freud's original concept was not intended by him, nor is it a development of psychoanalytical experience. However, most analysts have now accepted the general theory of emotions as a necessary modification of the sex theory, and in this regard there is fairly general agreement between the analytical school of psychology and other genetic psychologists.

Since any contact formation of an individual is colored by the emotional status through which the organism passes, the laws of emotional life are indeed the foundations of psychopathology as far as this science deals with the unconscious interpersonal relations with other organisms. The life experience of each individual, from the day of birth on, is the history of his emotional experiences through contact with the outer world. Any meaningful contact and, therefore, any experience is an affective experience determined by the individual's instinctual needs and the positive and negative emotional values of an object, regardless of whether this object is alive or inorganic matter. The human race has inherited no "instincts" as species memory of adequate behavior patterns. The individual has to collect his own experience by groping acts of trial and error through which the world is gradually incorporated as the specific environment in which the individual moves. This is not an "objective" environment of objects and matter but a subjective, affective environment of an emotional nature because each object is charged with an emotional value in regard to the subject which encounters it. The drives and emotions are specific action patterns in the stage show which the individual puts on to win his point in striving for individual gratification. This drive is constantly corrected and modified by group behavior and its patterns.

Since the history of emotional contacts reveals the true story of psychological patterning of behavior, which is primarily unconscious and not remembered in the form of symbolic representations, it is obvious that the study of the emotional life history needs an entirely different approach from the classical, experimental, or rational-logic one. Through Freud, psychoanalysis offered for the first time a scientific method of approach to the unconscious through the analysis of dreams or other unconscious manifestations of the emotional orientation which is behind unconscious behavior patterns.

Of course, the emotional orientation of behavior is not the only one: though man has no "instincts" as species memory of adequate behavior patterns, man has language through which the "experience" of the race is pumped into each growing child by means of words which are the currency of symbolized experience. Through the word, each individual participates in the common knowledge of his specific cultural group, and shares with it its species and group memories. As a means of communication, language as such is foreign to the individual's own emotional status, which is determined by his own life history. The problem of expressing individual emotional states and evaluations through the common instrument of language is, therefore, a basic problem of all exchange of feelings in literature and common contact between individuals. Psychoanalysis as a science of the unconscious is also greatly handicapped by the basic fact that it deals with a language-foreign material and yet depends for communication on the currency of words.

The Psychoneuroses

It is impossible to discuss the large field of emotional disorders or "the psychoneuroses" in detail within the scope of this chapter. The previous remarks were made in order to enable the reader to understand the principles of emotional disorders and to find his way through this complex field, even if details of the matter have to be neglected.

Emotional disorders can be defined as affect-conflicts and disorientations. The psychoneurotic patient is disoriented in his instinctual behavior patterns because his own emotional experience has devaluated

the objects of his instinctual and libidinous attraction, and he finds himself in a conflict between the need for gratification of his drive and his past emotional experience which bars him from attaining the desired gratification. The neurotic's own experience, for instance in regard to love and attitudes toward the other sex, may have been a frustrating one through previous exposure to lovelessness, cruelty, or rejection on the part of the mother or another important person on whom he had to rely and who did not live up to the expected rôle. With such a background, he has difficulties in later life in overcoming the negative experiences and in surrendering without distrust and suspicion to a new experience.

Time and again we see how the behavior of the male adolescent and adult is influenced by the life history of his contacts with the other sex, as well as by the rôle which the father played in early childhood. If a weak father deprived the son of the possibility of a satisfactory identification with a maturer person of his own sex, the son is often unable to find his rôle as a mature person in society. The same is true of the woman. While the female child is anxious to have a gratifying emotional relation to the father, in families where the parents are divorced or the family has been deserted by the father and the female child is left with the mother, such a child often has a difficult time overcoming this primary disappointing experience with a father and representative of the other sex. The emotional relationship to the other sex may be impaired by inherent hostility and distrust, and many girls act out their latent hostility in an ambivalent relationship to many different men. Moreover, they take revenge on their parents by unconventional behavior patterns which often lead to promiscuity. Even birth to an illegitimate child may be given by highly intelligent girls who are obsessed with a desire to spite the world in general and their family in particular.

Since early frustration is usually mixed with helpless hostility and craving for revenge which cannot be satisfied except by day dreaming and unconscious hostility, the emotional relations of the neurotic are usually characterized by striking ambivalence, which means the undifferentiated mixture of antagonistic emotions within the same relationship. It is the complex presence of affection and hatred or hostility at the same time which inhibits the neurotic from experiencing gratification without guilt, and not until this ambivalence has been recognized and dissolved is the neurotic able to live in an undisturbed relationship with those people whom he wants to love most.

The life history of a person reflects the history of his emotional contacts with the outer world from the day of birth. The first instinctual need of the newborn is represented in the need for food, which is satisfied by a mother or her substitute. It is quite obvious that not only must the need for food be satisfied in regard to the necessary calories but also the way in which the need is gratified has a great psychological value and is decisive for the establishment of psychological relations between the newborn and his first contacts. What Margaret Ribble has called "psychological mothering" involves the care of the child, the way it is handled, the amount of attention and love it receives, and the well-being which results from such psychological gratification. The life history of many psychoneurotic patients indicates that the first contact of the baby with its mother was highly unsatisfacory. A cold, rejecting mother who does not like her child may often fulfill her duties by following a meticulous schedule of feedings, but her unconscious hostility and rejection may express itself in a hundred small ways. Unsatisfactory home conditions may be the

cause of constant tension, and the infant's first emotional experiences may be associated with great anxiety.

Not only the feeding but also the training of the child is an area in which the personal contact between mother and child is closest and, therefore, most likely to lead to future complications if unsatisfactory. Psychoanalysis has demonstrated the fact that the training period of a child with regard to his excretions is of psychological significance in that at this stage the mother functions in a controlling and often punitive way and the child learns for the first time that it is holding an object of its own which can be used as an object of bargaining to buy emotional gratification in the way of praise, attention, and rewards. Although this phase may easily remain unnoticed for the majority of human beings, the history of many neurotics indicates that the training period was indeed a period of struggle and that an overanxious or overbearing mother had attached undue importance to the excretory functions. Enemas and overmeticulousness are so often mentioned in the history of psychoneurotics who develop what psychoanalysts have called an "anal" character that the fact cannot be denied that the undue attention to the excretory function may create an emotional shift in the individual which often cannot be overcome without special attention (Huschka, 1944).

No doubt the experience of a mother as a cold and unpleasant, unloving person reflects itself throughout life and will tinge later contacts with mothers, wives, and the other sex in general throughout life. On the other hand, a mother may be a very demanding person who talks constantly of the need of being loved, and the need for gratitude because she has "sacrificed" herself and bestowed upon her child such an amount of care. In a growing child with these experiences, a conflict will arise between his actual experience of love which was coldness, rejection, and unfriendliness, and the connotation of the term "love" as a devoted and unselfish attitude, ready to give as much as take, an attitude which does not fit into the emotional experience of the individual. Such a conflict is highly confusing, and the ambivalence of affects may remain throughout life and render such a man unable to love any woman, or vice versa. It is so often found in later life between two persons that his and her love are not the same, which actually means that the experience of what is love in two different individuals is so complex and of such different nature that the two emotional concepts can never be reconciled.

With the growth of the child, his contacts with the outside world become steadily more complex. The relationship to the father as a third person besides mother and child has many potentialities of conflict, especially in families where the relationship between father and mother is not satisfactory. Tension or strife between parents may reflect itself in a competitive fight for the affection of a child, or it may result in rejection, the image of the other parent on whom some of the parental hostility may be centered being seen in the child. A boy striving for the affection of the mother may find himself in a competitive situation with the father, whom the child may wish to displace, a situation which Freud called the "Oedipus complex." This Oedipus situation, the emotional affinity between mother and son and daughter and father, is a natural stage of development which under normal conditions serves to establish attitudes and behavior patterns which are essential for mature relationships. However, abnormal emotional interaction in the Oedipus (and Electra) situation can be the germ of severe neurotic difficulties in later life. A mother who rejects her son as a representant of the male sex, on account

of unconscious or conscious hostility toward the father, may prevent a male child from normal development and force such a child either into a confusing cross identification with the other sex in order to please the mother and be accepted, or may breed overhostility against the mother and the other sex, manifested in overt hostility and cruelty which are so often mixed with sexual relations in later life. On the other hand, a mother who utilizes the affection of the boy and bestows overaffection on him may create in him unwarranted tendencies to replace the father and to compete with him at a time when competition is hopeless. The amount of undrained hostility toward the father, and the fear of his revenge, keeps many adolescents in a rôle of dependency on the mother and in fear of competition with other adult men. Adolescents of this type are often extremely gifted and promising but in the moment of success they are not able to take it, and they destroy their own success by not living up to adult behavior patterns. Their unconscious fear of revenge and fear of competing with other men, on account of their unconscious hostility toward them, keeps these boys unduly tied to the mother and to the protective climate of childhood.

Similar conditions are easily demonstrated for the girl. Since the mother represents not only a person with whom the growing girl has to compete in sex but also the moral traditions which are meant to prevent the girl from premature sexual relations, the mother is often considered with a mixture of hostility and affection, and if hostility outweighs love the female child is easily led to actions which are likely to spite the protective mother and that for which she stands.

Freud has called the individual representation of the total of group behavior and experience the "superego," and a psychoneurotic finds himself usually in a conflict between his individual needs and the values which he has incorporated in his superego and which so often represent a set of values that he does not like and that he considers inhibiting factors on his way to gratification.

Other persons in addition to mother, father, and siblings enter the picture, and contacts with these new persons will again color the future emotional evaluations of persons of similar relationship. Moreover, socialization of the growing youth makes it necessary that his behavioral patterns be fitted into the needs of a larger group. The great complexity of emotional relations between members of a family increases constantly as the radius of contacts of a child increases, but it must be admitted that the basic contacts as they develop in the first years of life in relationship to mother, father, and siblings are of fundamental importance. A child whose early life was satisfactory and happy is usually able to meet new contacts with a firmer ego structure, which will enable him to make satisfactory adjustments. When, however, the ego structure never had an opportunity to develop, every new contact represents a possible danger and a weak ego structure may collapse even under minor stresses. Since, however, at present so many psychologists overemphasize the importance of early childhood experiences, it must also be emphasized that life is a dynamic process which continues to require new adjustments throughout its duration but which also offers possibilities of learning and new adjustments at every period. It is by no means true that all emotional difficulties derive from early childhood experiences. Conflicts arise throughout life at every level of maturation, and at every level there are possibilities of maladjustment which can be dissolved much faster and easier if they are of recent origin.

The typical development of a psychoneurosis in adults follows certain laws which, for instance, Franz Alexander has represented in a scheme. Of his six points, only the first three are important for the understanding of psychoneuroses in children:

1. Precipitating factors. The actual situation with which the patient cannot cope.
2. Failure in the solution of actual problems. Unsuccessful attempts at adaptation of shorter or longer duration.
3. Regression. The replacement of realistic effort to gratify needs by regressive fantasies or behavior.

These three factors can readily be recognized in most emotional disorders of childhood. Children who are not able to cope with new situations show regression and mobilize earlier behavior patterns in order to obtain gratification on a more primitive level. One of the most common and relatively harmless psychoneurotic manifestations is the reappearance of bed wetting in a 3- or 4-year-old child who experiences the birth of a new sibling for which he had not been properly prepared. When he notices that he is suddenly losing much of the attention, if not affection, which he previously enjoyed, and the new arrival centers upon itself a great amount of attention and love, the child regresses to behavior patterns which in his previous experience proved powerful in attracting motherly attention. Moreover, the newborn or infant is not scolded for wetting the bed and soiling the diapers, which is accepted as something natural at that stage, whereas he himself has had to go through a period of strict training in order to get rid of these "bad habits." The older child may easily regress into a stage of identification with the younger sibling, in order to obtain the same amount of attention and gratification for his need that he observes in his younger and often envied sibling. If the sibling is of a different sex, and the increased attention of the mother is not only the natural attention which the more helpless baby requires but is an unconscious preference of the other sex by the mother, either girl or boy, the sibling rivalry may turn into an actual problem of emotional relationships with the other sex.

In children, psychoneurotic conflicts manifest themselves on two levels: first, in so-called "psychosomatic" manifestations; and, second, in behavior disorders with a great variety of expressions. The psychosomatic manifestations are often associated with either disorders of breathing, e.g., in the form of asthma, or disorders in functions of the intestinal tract in the form of persistent constipation or diarrhea. Later in life, the same type of disorder may lead to severe spasms and the development of ulcers. On a higher psychological level, psychoneurotic conflicts are often expressed in children in the refusal to learn to talk and to use language as a common means of communication. During school age, reading and spelling difficulties are often of an emotional nature. In more severe cases, the emotional disorder manifests itself in a regression to stages of earlier development and the patterns of a younger child are adopted. The child either develops excessive dream life and abandons his reality contacts by imaginary gratification through dreams and dealings with dolls and imaginary subjects, or on the other hand, if the ego structure has never incorporated the proper inhibitions of behavior, he may try to compensate for their repression by overactivity and especially aggressive behavior which manifests itself in revolt and hostility, and even delinquency. Of the so-called conversion or hysterical symptoms, blindness or at least difficulty in vision is not too rare. In the field of nu-

trition, overeating is one of the most common expressions of emotional insecurity, in which children, especially boys, want to become big and strong and like adults by consuming a great amount of food. On the other hand, the need in females for being different from the mother, who may be very stout and fat, may result in loss of appetite and very little eating, which under pathological conditions may result in anorexia nervosa, a very severe neurosis which sometimes has a fatal outcome.

From a general psychological point of view it has to be realized that emotional disorders change the set of motivations of a child, and, therefore, his contact with the outer world may be changed in its essential pattern. Children of school age revolt by refusing to learn what they are supposed to learn, by lack of attention or short attention span, by inability to memorize, and by excessive dealing with dreams, especially in the form of ambitious daydreams. Such emotional behavior may lead to complete failure in school, and many children with emotional difficulties are considered stupid, of inadequate intelligence, or even feeble-minded. The evaluation of IQ tests has therefore to be done with the greatest caution, and a low IQ in an emotionally upset person may by no means represent the actual mental capacities. It has also to be remembered that many children of borderline or somewhat dull intelligence are likely to get involved in severe emotional conflicts. It has been demonstrated in discussing the marginal group that hardly any child coming from the marginal strata is spared from severe emotional conflicts which further interfere with the development of an intelligence which may be somewhat inadequate anyway. In any evaluation of a personality, one has therefore to carefully evaluate the set of motivations and emotional contacts which tinge the human behavior to a great extent.

CHILDHOOD SCHIZOPHRENIA

Whereas the psychoneuroses and affect-disorders involve the field of emotional states or moods which determine the organismic bearing and set the patterns of outward expression of internal states, in schizophrenic psychoses we find a disorganization of behavior patterns which involve primarily the formation of contact with reality. It is one of the major contributions of modern child psychiatry to have discovered that schizophrenia, which is the most important mental disease in adolescents and adults, may occur in childhood and infancy. Children with childhood schizophrenia had previously been considered hopeless idiots, and the psychotic child had constituted that group of "defectives" who differed from patients with organic brain syndromes and yet were not accessible to any education or routine training. The "idiot" of a schizophrenic nature was that patient whose condition clinicians and anatomists used to call "functional" mental deficiency because even at autopsy no significant pathology could be discovered with histopathological means available up to now.

It is only recently that newer observations, based on the behavior of adult schizophrenic patients, have taught us to differentiate between mental defect and childhood schizophrenia. The discovery of childhood schizophrenia may throw new light upon the problem of schizophrenia in general, and may explain what actually happens in the schizophrenic patient, because the occurrence of childhood schizophrenia (that means in patients of much less integrated personality with less "experience") gives a clearer insight into the fundamental process. L. Bender (1942) defines childhood schizophrenia as a clinical entity which

> reveals pathology in behavior at every level and in every area of integration or patterning within the functioning of the central nervous system, be it vegetative, motor, perceptual, intellectual, emotional or social. Furthermore this behavior pathology disturbs the pattern of every functioning field in a characteristic way. The pathology cannot therefore be thought of as focal in the architecture of the central nervous system but rather as striking the substratum of integrative functioning or biologically patterned behavior.

Despert (1941) considers the early symptoms to be detachment, lack of emotional relationships, and flatness of affect. Children with schizophrenia reveal

> excessive dependence on the mother, bizarre behavior, temper tantrums, speech and language deviations (infantile autism, obsessive interest in word forms, neologisms).

What is it that distinguishes the schizophrenic child from the idiot? Observations on children with childhood schizophrenia show that these children are quite intelligent in many respects and that, therefore, the application of the term "idiocy" has no meaning and the application of Stanford-Binet or similar intelligence tests is thoroughly inappropriate. Children with childhood schizophrenia may not talk. As a matter of fact, the majority of them do not acquire speech as a means of communication, and it is the absence of speech which so often first brings the patient to the attention of the physician. The schizophrenic child reveals no contact with his surroundings. He walks along without taking notice, and yet observes keenly. He is often interested in even complicated mechanisms, pulling them apart and sometimes, though rarely, putting them together. He avoids obstacles, climbs skillfully, rushes away, looks after his own needs, but does not respond to emotional contact or care to deal in any way with outside matters. That such a child can hear is often demonstrated, as he will stop when briskly called; that he understands can be shown by the fact that he often carries out a command if it is given in an authoritative manner, though he will not listen to pleading or reason. Bender has called attention to the fact that these children often maintain infantile motor behavior patterns; for example, by whirling the child around, the examiner placing a hand on the child's head, the child may maintain the motion like a spinning top. This, however, is not always so, and an observation made by me recently may be of interest:

> One of the children who was tested in this way by the present writer did not continue the spinning motion but had to "unwind" himself, turning backward the same number of times as he had been turned in the original direction. When he walked out of the front door, he had to return through the front door; if he left through the back door he had to come in the same way. Forceful interruption of these compulsive patterns was answered with increased anxiety. This child walked always on the same path which he trod on the lawn, in a complicated zigzag manner; he was not able to go on a straight line. When forced to do so he showed anxiety, but when left to his own impulses he would return exactly the same way as he had come. There was no speech. If left alone, the child would play for hours with the same piece of string, pulling it apart, or picking flowers and pulling their leaves. This obsessive behavior was only interrupted by continuous masturbation or rocking on a bench, which he would continue for hours. Speech was limited to grunting noises, which were always expressed in a monotonous way without modulation. And yet this child found his way around the house, fed himself, used the icebox independently, and rarely broke or damaged anything around him.

If one observes a larger group of children with schizophrenia, they all show similarities. They are well built, often beautiful children, whose physical appearance belies their severe mental aberration. They show an amazingly good memory, returning to the same places and toys even years later and recognizing familiar persons and subjects without difficulty. They do not speak because they have no capacity for acquiring the great variations in expression, rhythm, and modulation which human speech involves and they have no sense of the meaning which is a part of human verbal communication. If the children learn to talk, they use speech in single words or short commands which either express their wishes or are repetitions of commands given to them. Many schizophrenic children refer to themselves in the third person or in the way their surroundings refer to them. Speech is therefore only a repetition of the sounds which they have heard when carrying out certain motions.

The most characteristic fact in some of the more highly organized children with schizophrenia is their compulsive behavior, which makes them appear extremely insecure and forces them to stick at all costs to familiar behavior patterns which have been tested before and which do not seem to involve new risks. If the schizophrenic child is even more severely disturbed, he appears completely disorganized and will not react to emotional contacts or his material surroundings. Having no relationship with the outside world the child handles all matter without concern, is destructive and aggressive, and shows only the most primitive instincts of self-preservation. If these children are playing with toys, they usually disregard dolls or any symbols of human beings. Sometimes, though rarely, animals may be included in the play activity if the child is familiar with them as a steady part of his mental environment. Mostly the child will play with simple blocks, and higher-grade schizophrenic children who permit some insight into their mental functioning indicate that they use blocks and simple forms as representations of persons and animals with the same facility with which other children would pick actual dolls and symbolic pictures.

Understanding the schizophrenic child has made it possible in some instances to draw a child out of his complete isolation (autism). Some of these children have definitely proved that they have high intelligence and that they experience their surroundings in certain ways without the possibility of achieving actual contact. As in adult schizophrenia, the phenomenon of autism or isolation, the lack of "contact formation," appears to be the fundamental disorder. The difference between neurosis and psychosis rests upon the opposite way in which emotional problems are handled. As Alexander (1948) so aptly expresses it:

> The dynamic relation between the ego and the emotional demands is exactly reversed in psychoses and neuroses. In neuroses the ego overpowers the emotional demands and the neurotic symptom is a protest of the restricted impulses; in psychoses the ego yields to impulses, and hence the apparent lack of repression. In psychoses the impulses overpower the ego and it abandons its acquired function of recognizing reality. At the same time the ego loses its other function of harmonizing the different instinctual demands and turns out to be weak in the face of both external reality and the pressure of the primitive unadjusted instinctual impulses.

In other words, the child with childhood schizophrenia does not learn to handle the reality problem or to make what one calls "contact" with reality and an appropriate adjustment to its demands. It is, there-

fore, not chance that one group of childhood schizophrenia manifests itself between 1½ and 2½ years, when the normal child makes the transition from the inward stage to reality testing. The schizophrenic child apparently refuses to accept the outside world as something different from his inside dreams and wishes, and makes no differentiation between his own imagination and the so-called "reality." It is for this reason that speech has no meaning. The possibility of contacting the outside and maintaining the individual strength (ego strength) is apparently not a function of the brain itself, but of the strength of the fundamental drives of the organism which are anchored in the organism as a whole rather than in the central nervous system. It is for this reason that some European scholars have come to talk of schizophrenia as "somatosis." Although this term does not seem to be well chosen because it entirely leaves out the importance of derivative mental functions, it is meant to indicate that it is the strength of the organism with its fundamental drives which seems at fault. Other investigators have emphasized the weakness of the vital drives (Vital Triebe), which seem much less firm than in an individual of normal strength. They consider schizophrenia a contact weakness in which the individual is not able to exert the normal pressure and resistance toward the outside world. There can be little doubt that in some individuals this primary contact weakness and the lack of fundamental drives are due to a genetic inadequacy which is not so much an inadequacy of structural cerebral patterns as of the *vis a tergo* which drives an individual toward its environment in order to seek gratification of its natural needs. The inherited weakness prevents the child from making the transition from the inward orientation to an outward drive, and the child, therefore, remains overdependent and encapsulated in his own world. His weak ego relies on simple defense mechanisms which are primarily of a compulsive character, repeating time and again the same patterns with a complete inability to shift from one pattern to another and to enter the sphere of "effectuation."[1] Children with inherent contact weakness remain, therefore, in their own world. As Alexander (1948) says:

> the psychotic has, in a sense, no respect for reality. It is easier for him to relinquish his contact with reality than to control his own emotions, and as a result he solves his inner conflicts by changing the picture of reality to suit his subjective demands

Besides inherited weaknesses, traumatic childhood experiences are certainly able to produce a similar withdrawal from outside contact. Histories of children with infant schizophrenia indicate that some of them have been exposed to a traumatic separation from the mother either through illness or death, or have experienced some other severe traumatism which may not be enough to harm the average child but may be sufficient to inhibit the progress of a weaker organism. Childhood schizophrenia is likely to become manifest during those critical periods when the child is confronted

[1] The term "effectuation" was coined by P. Yakovlev, who has distinguished three spheres of motility in a paper, "Motility, Behavior, and the Brain":

1. The sphere of visceral motility, which encompasses the change of state of energy within the organism: cell metabolism, respiration, circulation, secretion, etc.

2. The sphere of motility of the outward expression of internal states covers the gamut of the so-called "emotions," i.e., internal motions brought out.

3. The sphere of motility of effectuation, which creates changes in the world of matter and produces work through which the creature impresses itself upon the world of matter, e.g., locomotes, shapes and handles matter, using his own body and parts of it as tools.

This sphere of effectuation is pathologically affected by those abnormal conditions to which the term "psychoses" is usually applied.

with severe changes in its inner and outer environment. The first critical time, as mentioned, is between 1½ and 2½ years, when the normal child makes the transition toward reality contact. The second critical phase is between 6 and 10, when increased demands of school and social life frighten a weak child from forming and exerting stronger drives. Childhood schizophrenia therefore develops frequently in the prepuberty period before the age of 10, and results in a regression to former infantile behavior patterns which have proved to be safe and are now compulsively repeated and maintained. The third most critical period is at puberty, when the sudden appearance of sexual drives forces the developing individual to face the reality of his own sexual nature, and to face the needs of impressing his own sexual character upon his environment and the other sex. Not only the weakness of the fundamental drives themselves but also the psychological need to face reality as a sexual being forces the individual to command a fairly well-established ego structure, in order to achieve a satisfactory compromise between the reality principle and one's own needs for gratification. A weak ego structure may easily break down at that critical period and regress to former behavior patterns which dispense with the need for an aggressive behavior toward reality.

It has long been established that hallucinations and other phenomena of adult schizophrenia are manifestations of regression into a time when there was little difference between the inner and outer world, and the child was able to move around in his imaginary world without limitations. The close relationship between hallucinatory experiences and dreams shows that the schizophrenic individual returns to a dream world. In childhood schizophrenia, where the separation between ego and the outside world has never been completed, we see relatively few hallucinatory experiences and there is no evidence that young children actually have hallucinations comparable to the hallucinations of adolescents and adults. However, certain behavior patterns of schizophrenic children like grimacing, talking to oneself, looking around with sudden lightning glances, mannerisms, shaking of the head, making significant signs the meaning of which is unknown to everybody except the patient himself, outbursts of aggressive or self-mutilating behavior, indicate that the schizophrenic child has a very active inner life which is, however, difficult to interpret because these patients have not yet progressed to a state of differentiation in which they are able to express their thoughts.

Childhood schizophrenia has to be distinguished from other conditions which may produce some similarities in behavioral patterns. Asphyxiation at birth is a frequent reason why children act in a dreamy, half-conscious manner and take no notice of what is going on about them. They may learn eventually to walk but may not talk. Another illness which has some similarity to childhood schizophrenia, although it should be clearly differentiated from it, is dementia infantilis or Heller's disease which occurs often around the age of 3 years and leads to a rapid loss of speech and progressive deterioration although motor patterns are well maintained and no neurological symptoms can be found. Heller's disease is apparently a degenerative metabolic disorder in which the nerve cells undergo severe degeneration and lobar atrophy of the brain (especially the frontal lobes) occurs. Heller's disease has therefore to be considered a manifestation of "the organic brain syndrome."

It has been mentioned that no univocal histopathological data are available in

schizophrenia. After what has been said above, this should no longer surprise the investigator. Schizophrenia is a total personality disorder in which the individual has severed his contact with the outside world and has withdrawn to his own world. Although in many schizophrenics there may be found an undue dependence on a protective environment on account of lack of drives toward the outside world or an organismic weakness which may have a "constitutional" basis of decreased cellular activity and resistance to stress, no one can specify from what sources organismic activity and different rates of vitality derive. We know that the nervous system, the endocrine system, especially the pituitary, adrenals, and gonads, have to do with the phenomenon of vitality, but we also know that no single gland or action is responsible for this basic phenomenon because the action of the glands themselves is a manifestation of basic organismic energy. Although it is, therefore, possible to show anomalies in adrenal or gonadal function, in vasomotor control, or in brain activity (often demonstrable in abnormal electroencephalograms), none of these isolated pathological data can explain the complex phenomenon of behavior patterns as seen in schizophrenia. In childhood schizophrenia the therapeutic problem is primarily that of creating an appropriate environment of a more protective nature, in which the schizophrenic child can develop a stronger ego structure without constant danger.

We have to learn to provide a greater variety of environmental conditions so that a larger number of the population can find facilities for individual development. Our civilization has to make use of all its members according to their own capacities and not according to a fictional "average" where an adequate environment is only provided for a more or less large group near the center of biological and mental variations.

CHAPTER 19

SOCIAL DEVELOPMENT

HAROLD H. ANDERSON AND GLADYS L. ANDERSON

Growth and development are included in the titles of eight preceding chapters in this *Manual*. Unlike some of the other chapters, this chapter cannot be based upon studies that have dealt primarily with the defined title of the chapter, "Social Development." Although many studies are reported and catalogued under social behavior, the scope of this chapter is without limit.

The beginnings of emotional behavior—for example, the early differentiations of emotional responses, the studies of anger, hostility, aggressiveness, jealousy, security and insecurity, laughter, pleasure, sympathy, and sex behavior—are properly included in a chapter on emotional development, as, in fact, they are here (Jersild, Chapter 14). However, practically everything that can be written under emotional development is encompassed within the framework of social development. It is obvious that systematic overlapping of reporting is to be avoided, but occasional cross references to studies and to theoretical discussions will be made.

Similarly, in Chapter 15, entitled "Behavior and Development as a Function of the Total Situation," much of the interaction between the child and his psychological environment is not defined differently from his social development. No attempt will be made in this chapter to repeat the detailed, theoretical formulations and the insightful interpretations of Lewin's topological psychology, though, again, occasional cross references will be made.

Of all the possible areas of overlapping with social development of the child, none could be greater than the area of learning. Since there is a chapter "Learning in Children" (Munn, Chapter 7), no attempt will be made to present a systematic treatment of learning. In all probability much, if not all, social development is inseparable from learning. The mass of research on learning, nevertheless, obliges us to look to the future for the applicability of the principles of learning to human social development.

Even considering the inevitable overlapping, there is to be found in the current psychological literature a vast amount of research and theoretical discussion related to social development that has not been envisaged in the other chapters of this *Manual*.

Under the title of "Social Development" it would be logically possible to outline or to prepare a synthesis of the theoretical structure of all the major works on personality or of all the theories and research reported in the current books on social psychology or to summarize the already "classical" theories concerning social development contained in Freudian psychoanalysis. The writers of this chapter have decided not to undertake such a task. The treatment of social development needs to be consistent with broader areas of overlapping, i.e., it must be consistent with knowledge of the general principles of sci-

ence, with the facts of the biological sciences and the social sciences, and with the principles of values, of ethics, and of harmonious living.

It does seem possible and worth while to attempt to report in a related and consistent way a wide variety of studies, many of which are not related by their authors to other studies or to theoretical assumptions concerning social development. To do this the writers will present a brief review of a concept of growth, which is emerging in more and more places in the psychological literature, and a crude outline or a structure of levels of growth relationships, which can represent at once psychological growth or social development.

Apart from a swift historical review of trends in psychological thinking since 1900, no effort will be made to review the considerable number of early studies, more static in their orientation but none the less representing valued and necessary steps of imaginative and adventuresome psychologists of their day. These earlier studies, including especially a number of studies of European origin, have been well reported by Bühler (1933). The concept of social development is so all inclusive and the experimental studies so numerous that the large and extensive bibliography following this chapter must be understood as an effort to be representative. Numerous investigations, equally worthy, have not been specifically cited.

Trends in Psychological Thinking

During the period following 1900 certain trends appeared out of which present research in social development has emerged.

1. *Discovery of the Individual Person.* At the turn of this century psychologists discovered the individual person. This discovery, although taken so much for granted today as a simple idea, was epoch making at the time. Using the observational and descriptive methods of the natural scientists, Darwin (1877), Preyer (1882, 1888, 1889), Shinn (1893–1899, 1900), the Scupins (1907), and the Sterns (1907, 1909) published their biographies of infants and small children. These reports are historical landmarks.

Binet (1898, 1902) not only developed the battery of *individual* psychological examinations but, long before the time of Adler's (1923) *Practice and Theory of Individual Psychology,* published reports with *psychologie individuelle* in the title. Even in the field of religion, a psychologist, James (1902), published his *The Varieties of Religious Experience.* This "timely" volume left unquestioned the individuality of religious experience.

In 1909, when the Juvenile Psychopathic Institute was opened in Chicago, the best experts in the land thought that delinquency had its base in psychopathology. Six years later this idea was refuted by the director of the institute in an encyclopedic volume to which its author, Healy (1915*a*), gave the significant title *The Individual Delinquent.* Healy not only maintained that one should make a thorough study of the individual delinquent but, anticipating another emerging trend, he demonstrated the importance of the "total situation" about the child as contributing to the delinquency.

2. *Freudian Psychoanalysis.* At the same time that the individual person was being discovered in Paris by Binet and in Cambridge, Massachusetts, by James, he was not only being discovered but analyzed by Freud (1896, 1900, 1904) in Vienna. Psychoanalysis developed very slowly and for a number of years in isolation from psychiatry and academic psychology in both Europe and America. G. Stanley Hall brought Freud (1910) to America where he gave at Clark University a series of lec-

tures on "The Origin and Development of Psychoanalysis."

Freud not only introduced a new dynamic conceptual scheme of thinking about behavior and unconscious motivation but formulated the first systematic statement of personality viewed as a developmental sequence. One of the most remarkable features of this sequence as well as a source of its chief defects lies in the fact that Freud constructed his genetic psychology for normal children out of work with the memories and introspections of neurotic adults. Anna Freud (1951), discussing the unavoidable factors in selection of cases, said:

> This situation as it exists in psychoanalytic work for practical reasons is responsible for a particular trend which has become characteristic for psychoanalytic investigations from the very outset, that is, for the tendency to establish and reconstruct the facts of normal psychology from the distortions and exaggerations presented by pathological manifestations [p. 482].

With the slow development of psychoanalysis came inevitable differentiations by Freud himself and by others as the first formulations were tested and reexamined against successive clinical experiences. These differentiations, each an effort to describe and to interpret and explain behavior, beginning with elaborations, refinements, and differences in interpretation by Jung (translated 1916, 1923) and Adler (1907, 1909, 1923), were followed by a long and still growing succession of psychoanalytic writers. Psychoanalytic theories have since been the subject of investigation by, for example, experimental psychologists (Sears, 1943, 1944), psychiatrists using experimental and observational methods with animals and infants (Levy, 1928, 1934; Spitz, 1945; Spitz and Wolf, 1946; Ribble, 1939, 1943, 1944), learning theorists and anthropologists (Mowrer and Kluckhohn, 1944). Longitudinal studies have also been undertaken (Fries, 1944, 1947; Fries and Lewi, 1938).

Reviewing significant aspects of psychoanalytic development since her father's visit to America, A. Freud (1951) commented:

> Now, after forty years, all this has changed beyond all expectation. There are today more psychoanalysts in the United States than in all other countries of the world put together. There are as many as thirteen Branch Societies of the International Psychoanalytic Association and, linked with them, ten to thirteen Training Institutes for the instruction of future analysts, their number increasing still from year to year. Many scientific periodicals are open to psychoanalytic contributions. Books on the subject are so prolific that even the most diligent worker in the field has difficulty in keeping his knowledge of the literature up to date [p. 477].

3. Discovery of the Whole Child in the Total Situation. It is not clear in how many areas nor in what order the awareness of the importance of the child's environment began to emerge. In the study of delinquency and misbehavior Healy has been a pioneer. Healy (1915*b*) pointed out that dishonesty, like delinquency, was a *situational phenomenon* and not a characteristic of the child himself. He cited cases where dishonesty disappeared when the situational stresses were removed. With the same theme in mind, H. H. Anderson (1929), at the University of Geneva, discussing the work of psychological clinics, devoted a chapter to *L'enfant entier dans la situation entière.*

At a symposium on "The Treatment of Behavior and Personality Problems of Children," Lowrey (1930–1931), chairman,

expressed a general consensus: "These groups [psychiatrists, clinical psychologists, and psychiatric social workers] have finally discovered the human being as the total personality involved in the series of more or less total situations" (p. 56).

From the University of Berlin, Lewin (1933) summarized in English his interpretation of "Environmental Forces," which he elaborated for the first edition of this *Manual* (see Chapter 15).

Frank (1928) outlined a theory of personality development viewed as a product of the learning process. More specifically, he attempted

> to sketch the personality as the outcome of the individual's learning how to manage his physiological tensions, under the tutelage of parents and other adults who present him with various tensional problems in their efforts to mold his behavior into the socially sanctioned patterns [p. 705].

Frank (1936) reversed the perspective of 1909 by stating that it is our culture that is "sick" and not fit for healthy children to grow up in. From this article, "Society as the Patient," has been taken the title for one volume of Frank's (1948) collected writings, most of which are quite within the scope of psychodynamics of social development. Among many others who contributed expository writings are to be found Mead (1934) on the meaning of language and communication, Plant (1937) on the interaction of the child and his culture, Cottrell (1942) on situational fields in social psychology, and Sullivan (1947) on psychiatry as a science of interpersonal relations.

4. *The Multi-discipline Approach.* A fourth trend evident since 1900 is the multi-discipline approach to the study and modification of behavior.

Child guidance clinics. The multi-discipline approach was a conspicuous feature of Healy's first clinic, the Juvenile Psychopathic Institute in Chicago. The Commonwealth Fund combined three of the four trends cited above when, in the 1920's, they established their demonstration clinics. They emphasized the study of the individual, the understanding of the child's interaction with his environment, and the multi-discipline approach. Looking back, one can see that it was inevitable that more systematic efforts would be made to integrate the contributions of persons from many disciplines working together on common problems. The American Orthopsychiatric Association, whose members are psychiatrists, psychiatric social workers, and clinical psychologists, was founded in 1924 to fulfill a need for communication among these disciplines. One criterion for membership in this organization, applicable to each of the disciplines, was practical experience in a *teamwork* relationship with members of the other disciplines. In a literal sense, this organization has represented a very productive kind of *social development* among adult professional workers.

The research institutes. Another type of multi-discipline approach is seen in the research institutes of child welfare established under the aegis of the Laura Spelman Rockefeller Foundation in the 1920's. These institutes followed somewhat the organizational pattern of the Child Welfare Research Station established "by the people of Iowa" at the State University of Iowa in 1917. Although most of the staffs of these institutes were psychologists, they had direct or indirect collaboration in research with physicians, pediatricians, dentists, orthodontists, physiologists, nutritionists, psychiatrists, pychoanalysts, sociologists, anthropometrists, anthropologists, nursery school teachers, and parent edu-

cators. To facilitate communication among research workers from the various disciplines the Committee on Child Development of the National Research Council fostered the founding of the Society for Research in Child Development in the 1930's.

Trends of the times were reflected in the early research publications from these institutes, several of which established monograph series. As research in any discipline is limited by the refinement or elaboration of method, it is understandable that the early research was concerned mainly with studies of physical growth and studies of mental and motor development. Yardsticks, tape measures, and mental tests were already at hand. The trend of research soon turned, however, to the observation, quantification, and statistical treatment of social interaction, social responses, and social development.[1] This swift expansion of emphasis is seen in the titles of the first monographs to appear from four of these institutes.

The first monograph from the Iowa Child Welfare Research Station was Baldwin's (1921) *The Physical Growth of Children from Birth to Maturity.* In the first monograph from the Institute of Child Welfare, University of Minnesota, J. E. Anderson and Foster (1927) explicitly included the child's environment in the title, *The Young Child and His Parents. A Study of One Hundred Cases.* From Teachers College, Columbia University, Child Development Monograph No. 1, by Thomas and her associates (1929), was entitled *Some New Techniques for Studying Social Behavior.* Bott (1933) published *Method in Social Studies of Young Children* as Monograph No. 1 in the Child Development Series of the University of Toronto Studies.

A multi-discipline longitudinal research study was begun in 1929 at the Child Guidance Clinic, Institute of Child Welfare, University of California, Berkeley. Macfarlane (1938), director of the study, made an elaborate report of methodology of data collection and organization for this cumulative clinical study of normal children. From this time on, studies of social response, social interaction, social development, not to mention clinical studies and individual case reports of breakdowns in the process of social development, have appeared in such numbers that further documentation here is unimportant.

5. *Contributions by Other Investigators.* Meanwhile, from widely separated parts, studies of social behavior began to appear in the 1920's. In Vienna, a whole series of imaginatively conceived studies inspired by Charlotte Bühler appeared. These studies have been well summarized by Bühler (1933). In Geneva, from La Maison des Petites and the Rousseau Institute, Piaget (1923) published his report on egocentric language and thinking. In Canada, Bridges (1931) published her *Social and Emotional Development of the Preschool Child.* Isaacs (1931) wrote *Contribution a la psychologie sociale des jeunes enfants,* and (1933) a book in English by a similar title Murchison, with his editorial ear to the ground, founded the *Journal of Social Psychology* in 1930.

6. *Discovery of the Child's Unverbalized Social Defenses.* In addition to the objective, observational studies with their

1 Harris (1953) closed his review of research in the general field of child psychology with a footnote comment on the current disproportion, as he found it, between the numbers of studies reflecting research interests in personality problems and social influences, on the one hand, and the paucity of studies of intellectual growth and motor skills, on the other. "More than thirty excellent quantitative studies of personality disorganization in children appeared this year but cannot be reviewed--for lack of space Likewise, the literature utilizing the case approach has been omitted. A striking feature of this review is the dearth of material on motor and intellectual growth and the development of skills as contrasted with the emphasis on social influences on personality" (p. 27).

quantifiable, statistical treatment, there were other research inquiries in the 1930's, with roots deeply sunk in Freudian psychodynamics, that were distinctly of an individual, qualitative nature. Murray's (1938) *Explorations in Personality* is the best example. Although these studies were made on adults, they introduced techniques for inferring human needs and defenses. Frank (1939) collected a wide variety of these newer concepts under the rubric *projective techniques*, a term that was seized upon with almost too much avidity by psychologists. Projective techniques (Bell, 1948; Abt and Bellak, 1950; H. H. Anderson and G. L. Anderson, 1951), as unstructured materials, offer a minimum of obvious or meaningful threat to the subject. Devised to evoke symbolic expressions of attitude, anxiety, and tension, they reveal to the psychologist hitherto concealed hostilities, aggressions, fears, anxieties, and unconscious defenses. These techniques have opened up new and subtle means for diagnosing deficiencies in social development and obstructions to the social communication process

7. *Psychotherapy with Children.* Psychotherapy, viewed by whatever school or cult, whether regarded as speeding up the growth processes, gaining insight into one's cosmic orientation, learning or relearning, or resolving an obstinate Oedipus, is inseparably related to the problem of social development. In fact, the difficulties in a child's social development or social orientation are usually the symptoms by which a need for psychotherapy is deduced in the first place. Although many books have been written on adult diagnosis and on descriptions of adult disease entities, there were very few books on psychotherapy for adults or children written before 1935. In his excellent treatment of the history of psychiatric therapy, Appel (1944) listed only two books dated prior to 1935 (A. Freud, 1928; and Klein, 1932) which deal with children. The first issue (1930–1931) of the *American Journal of Orthopsychiatry* reported the symposium, mentioned above, on "The Treatment of Behavior and Personality Problems in Children." The symposium produced the judgment, expressed by Lowrey (1930–1931, p. 51), that, although there were many persons competent to write a book on diagnosis, no one at that time was competent to write a book on treatment. The record has validated Lowrey's judgment of the situation in 1930.

In the 1930's there was much self-examination of what clinicians did. Schilder (1938), who had worked with children and adults, published a book with the unmodified title *Psychotherapy*. Rogers (1939) wrote *The Clinical Treatment of the Problem Child*, followed (1942) by *Counseling and Psychotherapy*. Allen (1942) published *Psychotherapy with Children*. In the next 10 years more than a dozen books were produced on specific topics of individual and group psychotherapy with children. It is true that practically everything from depth psychology to doll play and drop-the-handkerchief has in the 1940's been called psychotherapy. It is equally true that significant advances in psychology and psychiatry have been made in the form of more discerning observation and more discriminating interpretation of what happens in the therapeutic process.

Hypotheses, Definitions, and Organization of Concepts

The Process of Science, the Progressive Developing of Conceptual Schemes. It can be seen in the brief presentation of historical trends that a *process of activity has been evolving.* Moreover, this process has certain discernible characteristics that are familiar in other contexts. The discovery of the individual delinquent or of the individuality of reports of religious experi-

ence represented a *differentiation* in psychological perceptions. The concept of the whole child in the total situation evolved into a still more differentiated concept of a relationship of interpenetrating attitudes and activities. The multi-discipline approach represented a conscious effort to test hypotheses against wider and wider experience and to achieve a higher degree of organization of all available relevant percepts. The meaning of interpersonal relationships is slowly becoming verbalized; it, too, is in process. Psychologists are fumbling with words trying to describe to each other something which they tentatively and vaguely call *dynamic*. Like the astronomers who had not yet discovered Pluto but who were agreed that "something is out there," psychologists and psychiatrists are unanimously agreed that they are about to get a better perspective on something important in human relations. They may expect that the new perspective will itself evolve into a still newer organization of percepts.

The vagueness of percepts of social behavior, the inconsistencies in interpretation, the contradictions in definitions, the hundreds of studies reporting slightly different segments of human behavior or segments observed from a slightly different point of view—all this may look like a process of confusion. To the extent, however, that it is *process* it satisfies the criteria of vigorous, lusty, scientific growth.

> The history of science is a history of inadequate and incomplete statements, and every new insight makes possible the recognition of the inadequacies of previous propositions and offers a springboard for creating a more adequate formulation. The history of thought is the history of an ever-increasing approximation to the truth. Scientific knowledge is not absolute but "optimal"; it contains the optimum of truth obtainable in a given historical period [Fromm, 1947, p. 239].

The history of science reveals a struggle to refine observations and to communicate with others. Conant (1947), in attempting to formulate a definition of science, said: "In the early days one sees in clearest light the necessary fumblings of even intellectual giants when they are also pioneers" (p. 18). In fact, for Conant, the very definition of science is in terms of process, of the interweaving of concepts, the mutual stimulation.

> The texture of modern science is the result of the interweaving of the fruitful concepts. The test of a new idea is therefore not only its success in correlating the then-known facts, but much more of its success or failure in stimulating further experimentation or observation which in turn is fruitful. This dynamic quality of science viewed not as a practical undertaking but as development of conceptual schemes seems to me to be close to the heart of the best definition [p. 24].

The Characteristics of Biological Growth.[1] There are two generally recognized aspects of growth that are important both in physiology and psychology. Growth is at once a differentiation (creation of differences) and an integration (organization) of differences. The truth of this observation is perhaps more readily perceived in physiology than in psychology. An illustration from biology will facilitate the definition of a number of terms applicable also to psychological growth.

Figure 1 presents an example of an unfertilized egg living in an environment in which there is a spermatozoon. Each is said to be an individual organism. Each is different from the other in structure and

[1] In the preparation of this chapter the writers have drawn and freely adapted materials from H. H. Anderson (1951, 1952—both by permission of the publishers).

function. Each constitutes a part of the environment of the other. It can be said that the presence of the egg makes a difference in the behavior of the spermatozoon and that the presence of the spermatozoon makes a difference in the behavior of the egg. The phenomenon of this process of relating is called the *confronting of differences. Confronting of differences* is a relationship (process of relating) in which the behavior or presence of one individual or organism makes a difference in the behavior of the other. Without the egg to fertilize,

FIGURE 1. A biological illustration of the confronting of differences.

the spermatozoon in due course loses its identity as a spermatozoon; it dies. Likewise, unless it is fertilized, the egg loses its form and its function as an egg; it also disintegrates.

In the confronting of differences, however, there is necessarily a concept of *integrity* as well as *integerness*. There is not only the fact of difference, but there is an *acting* differently. The egg behaves, *acts,* like an egg, and the spermatozoon behaves, *acts,* like a spermatozoon, and each is biologically free to "be itself." In the hypothesis that growth occurs only through the confronting and the free interplay of differences, there is necessarily a concept of the integrity of differences but also of *action* consistent with this biological integrity. *Confronting* of differences is not necessarily *conflict* of differences. Conflict of differences implies an outside attack against the biological integrity of the cell, from which we derive our concepts of rigidity, defense, disunity, disorganization, and disintegration. To the extent that the process of interplay or confronting of differences represents conflict and its concomitant characteristics of rigidity, domination, attack, one-way communication, disunity, defense, disorganization, disintegration, it can represent lower levels of change, but not the process of unity, integration, growth. In contrast with conflict which represents one-way communication, growth, in a very real biological sense, is a process of *two-way communication* between individual cells or organisms.

It was said that Figure 1 presents an example of an unfertilized egg living in an environment in which there is a spermatozoon. From the standpoint of the biological dynamics of this situation it would be equally true (meaningful) to write the sentence two ways, giving preference to neither the spermatozoon nor the egg. Thus Figure 1 presents also an example of a spermatozoon living in an environment in which there is an unfertilized egg. Actually, neither form of the sentence, nor both together, is satisfactory. Figure 1 represents a momentary cross-section of a process of dynamic interplay between these two individual and different organisms which cannot be adequately sketched or verbalized. In the process in which biologists are interested, that is, conception and growth of an individual, the egg and the spermatozoon are each essential. They are each different; but it is not meaningful to say, or to imply, that one is more important than the other.

> There is neither a struggle of the members amongst each other in the organism, nor a struggle of the whole with the members. . . . Only deterioration or imperfect adaptation of the organism makes members stand out abnormally [Goldstein, 1939, p. 423].

It does not seem either necessary or meaningful to say of Figure 1: (1) that the spermatozoon dominates the egg or *vice versa,* or that one is ascendant over the other; (2) that either the egg or the sper-

matozoon is submissive to the other; (3) that there is anything aggressive or hostile in the behavior of either; or (4) that there is anything in the behavior of either that can meaningfully be said to represent force, coercion, or conflict.[1]

In the process of fertilization (see Figure 2), the egg abandons its structure and its function as an unfertilized egg for a new and emerging structure and a new and emerging function. The spermatozoon also abandons its structure and function as a

FIGURE 2. The "non-coerced" yielding to differences—biological example

spermatozoon for a new and emerging structure and function. Growth comes about through the *confronting of differences*, the *responding to differences*, and the *abandoning* of the individual's self as it is for a new self in process of emerging.

This one-celled, fertilized egg is different in structure and in function from anything that has ever existed before. It is a *differentiated* and *differentiating* organism. Growth is the creation of differences (see Figure 3). Instead of mere reproduction of the structure and function of the original fertilized egg cell, there appear cells that become, for example, nerve tissue, cells that become muscle tissue, others that become bone tissue, and still others that become glandular tissue. Each of these cells is different from the others and from the parent cell in structure and function. Yet through the chromosomes they are all said to have the same biological heredity. This is that aspect of the process that is called *differentiation:* the *emergence of originals.* In both the physiological family of cells and the psychological society of persons there are an infinite number of problems of individual differences.

Growth comes about also through an *integration* of differences. There is a biological oneness of purpose implied in the act of fertilization. In the fertilization of the egg, the egg's chromosomes unite with the chromosomes of the spermatozoon. There is no perfect or complete integration of differences. So far as is known, the pattern of integration could have been different. It represents a "voluntary" or spontaneous abandoning of a momentary status quo. Growth is process. It cannot be forced or coerced; it develops only under propitious

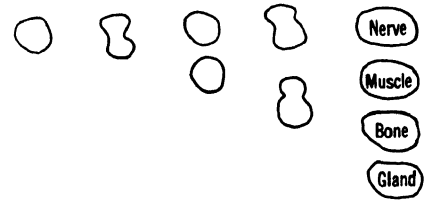

FIGURE 3. Differentiation. "Children are different from their parents and different from each other."

circumstances. It proceeds along a principle of intercommunication and participation of the parts in achieving a more highly differentiated, integrated, organized whole.

As physiological growth tends to achieve an increasing development of individual differences, there is also a continued trend toward an *integration of differences* (see Figure 4). The body lives and grows as a more or less integrated organism. The nerves are not rigid and inflexible but are responsive to the heart, the bones, the

[1] Herein is a difference between concepts of some psychologists and biologists, the difference being a source of confusion mainly to psychologists. There are psychological theories, postulated in various ways, that in nature there is a pervasive conflict; that in human organisms there is an inherent or innate hostility, an aggressive instinct that must be dealt with; and that in human relations one must be either a boot or a doormat, that one is either dominant or submissive. These theories fall short of including the phenomenon of growth as a positive process in nature.

muscles. The glands are flexible in their sensitivity to the needs of the other parts of the body. There is, in fact, a common purpose among differences implied in the biologists' discovery that the individual acts as a whole. There is an expenditure of energy by the parts in such a way that the needs of the entire body are satisfied.

Sinnott (1950, 1952) has discussed the thesis that the protoplasmic basis for biological organization and the basis for psychological behavior are fundamentally the same.

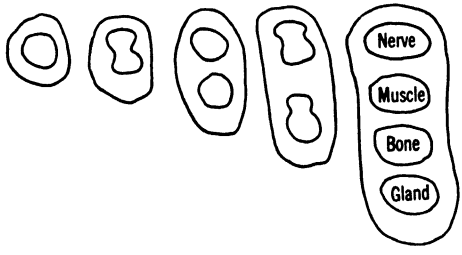

FIGURE 4. Integration of differences. "The child acts as a whole."

> Protoplasm, to be sure, is a complex laboratory of metabolism but let us not forget that it also *builds organisms*. The living machine, unlike any others that we know, grows, develops, and finally reproduces itself. The activities of which it is the seat do not occur at random but are so precisely coordinated that a change in one part is accompanied by specific changes elsewhere. As a result the growing individual does not expand into a homogeneous spherical mass but its growth is more rapid in some dimensions than in others and produces tissues that are differentiated in position and character. "Organism" is a very happy term, for the most significant fact in biology is that protoplasmic systems are *organized*. . . . Organization is the central fact in the life sciences. The autonomy of biology—and I believe the autonomy of psychology also—rests upon this concept.
>
> Organization is evident in various ways. Even in such a loosely integrated body as a tree the growth in length and in thickness of a branch is related to the development of the whole. The embryonic development of an animal shows still more precisely coordinated growth. As cell divisions follow one another and the various organs and tissues become differentiated all things move in harmony [Sinnott, 1952, pp. 458, 459].

It should be pointed out that in regard to the characteristics of growth or the processes of living matter all things are relative: they are found in degrees. In complex organisms are found cells that do not seem to differentiate but "merely" to proliferate. It is not yet clear whether it is these proliferating cells which ultimately destroy the organism upon which they must depend for their existence or whether the cells are themselves products (not to say victims) of biological disorganization at a higher level. Upon this problem of organization and disorganization Sinnott (1952) has made this further comment:

> This organizing, regulatory activity of living stuff is not invariable. It often is upset and may go quite awry. The frequency of tumors, cancers, fasciations, and other "abnormal" growths in animals and plants is ample proof of this. In such cases the cells themselves are often normal and it is only the higher coordinating control that is upset. . . . It must be admitted that this phenomenon (biological organization) still lies, an unexplained, perplexing and challenging fact, at the very heart of biology. It might almost be said that life *is* organization [pp. 459, 460].

In all biological life high differentiation is accompanied by high harmony of the parts. For millions of years biological cells have been "learning" to live harmoniously. Biologists call this evolution. It is a process of the communication between, and the mutual participation of, the parts, of the

confronting and free interplay of differences, of the emergence of originals.

The criteria for physiological growth are two: differentiation and integration. They are not found separate in nature and, in fact, are inseparable. *Differentiation* and *integration* of differences are different aspects of one process—growth.

For the growth processes represented in Figures 1 to 4 inclusive, this much appears meaningful: (1) Growth is a non-coerced *abandoning* or *yielding* of a structure and function as they are for a new structure and new function that are in process of emerging. This is also called *differentiation* or *individuation*. Growth cannot be forced or coerced. This non-coerced *yielding* or *differentiation*, is not to be confused with *submission*, a term used to designate a form of behavior or a relationship that is associated with coercion. (2) Growth occurs only through the *confronting* and *free interplay* of differences. (3) The *confronting of differences*, as related to growth, does not mean conflict of differences. Confronting of differences may represent hostility, aggression, or attack, but to this extent it is foreign to a concept of growth. (4) Growth represents a process of *integrating* differences. (5) The process of integration represents a progressive process of change to higher and higher levels of *organization*, or of meaningful relations between the parts. This aspect of growth is not adjustment; it is invention, the emergence of originals, the creation of differences. (6) A concept of meaningful relations between the parts necessitates a concept of intercommunication.

Criteria for Psychological Growth. The criteria for psychological growth are also two. They are differentiation and integration, though other terms have been introduced for the same criteria.

Differentiation, spontaneity, individuation. In all recorded history man has struggled with two problems of social behavior. The first is how to be an individual; how to have ideas of one's own; how to learn from one's own perceptions; how to develop judgment based upon one's own experience; how to think for one's self; how to be original, imaginative, creative, explorative, experimentally minded, resourceful; how to be one's self; how to be spontaneous in one's behavior; how to have the freedom to act on one's own ideas and on one's own value system; how to grow and develop psychologically at one's optimum; and also, within this freedom, how to listen and how to learn from others

But it happens that in trying "to be one's self" one frequently makes life inconvenient for others In exercising the freedom to act on one's own ideas one often obstructs the initiative of those about him or encounters inconsistent and conflicting value systems. In attempting to be original, explorative, experimentally minded, it almost inevitably happens that one's behavior conflicts with the needs and plans of others, and with their values, biases, prejudices, misperceptions, expectations, and demands.

Integration, harmony. The second great problem that man has struggled with is the reconciliation of individual differences in desires, purposes, motives, goals, values, and actions. Individuals are different, but they must exercise these differences in such a way that there shall be the greatest harmony in the behavior of men. This second problem, that of discovering, developing, inventing, achieving harmony in human behavior, is thus inseparably linked with the first. If men behaved in such a way that each could approximate his optimum of spontaneity and self-development, that, by definition, would achieve the greatest good for the greatest number. The greatest good for the greatest number implies the approach to some kind of optimum develop-

ment, some maximum of individuality, for each member of the social group.

In a sense these two problems encompass the whole of human living. Out of the recognized need for spontaneity and harmony have arisen our concepts of law: contracts, torts, equities, rights. Out of the problem of integration of differences, of securing for *all persons* freedom to be themselves, have arisen our systems of ethics. It can well be maintained that the social development of the child is not separate and apart from, but basic to, these epic strivings. Out of failure to clarify and to reconcile the spontaneities of many persons, wars and strife have developed. Delinquency, neuroses, and the behavior problems of children represent errors of perception, distortion of fact, confusions, failures, shortcomings, obstructions to possible and potential social development of the individuals involved.

The perception and reciprocal communication to others of one's needs and desires, the reciprocal interpretation to others of one's judgments and values, and in meeting human needs the mutual discovery of common purposes among differences at the level of action without coercion, threat, or guilt—this is a crude statement of psychological growth; this is social development. Anything less than this represents, by that much less, a lower level of social development; anything more represents by that much more a higher level of social development.

On the criteria of differentiation and integration Murray and Kluckhohn (1948) have given the following elaboration:

> Furthermore, no conception of personality could be complete without some reference to the developments that occur, most of which can be adequately described in terms of differentiation and integration. "Differentiation" covers all refinements of discrimination in perception, interpretation, and conceptualization, as well as detailed specifications in laying out plans and exact directions and timing in action. Mental differentiation is involved in the appreciation of differences, in the intellectual process of analysis, as well as in the isolation and perfection of specialized action systems and abilities, verbal and manual "Integration" includes the ability to perceive similarities, as well as different kinds of relations between objects and events, to develop a coherent conceptual scheme, to resolve conflicts, to maintain loyalties, to rationalize values, to build a philosophy of life, to coordinate different plans, to think and talk in a logical manner, to organize dynamic systems into a unified whole [pp. 30–31].

Krech and Crutchfield (1948) take the position that not only do the processes of differentiation and integration occur simultaneously but they are aspects of psychological as well as physiological growth. Discussing "higher" levels of stable organization, they stated:

> The growth of the human individual—physically, mentally, and psychologically—can be regarded as a process of simultaneous differentiation and integration. In other words, the individual is constantly growing more complex, and at the same time the complexities are becoming better synthesized [p. 67].

Growth of Civilizations. The concepts of differentiation and integration have been used by Toynbee (1939) in the interpretation of *The Growths of Civilizations.* Toynbee has devoted his highly documented Volume III of *A Study of History* to a discussion of the nature and process of the growths of civilizations: the criteria of growth, the relation between growing civilizations and individuals, the interaction between individuals in growing civilizations and problems of arrested growths in civilizations. For Toynbee, growth of civiliza-

tion is a process of differentiation and integration, the most essential criterion being an increase in self-determination.

> Growth is achieved when an individual or a minority or a whole society replies to a challenge by a response which not only answers the particular challenge that has evoked it but also exposes the respondent to a fresh challenge which demands a fresh response on his part. And the process of growth continues, in any given case, so long as this recurrent movement of disturbance and restoration and overbalance and renewed disturbance of equilibrium is maintained. This is the process of growth as we have observed it in a comparative study of a number of cases; but, although the process may be uniform, the experiences of the various parties that undergo the process are not the same. . . . Each successive challenge that any growing civilization undergoes is apt to differentiate the experiences of its constituent individuals and communities . . . and it is evident that the differentiation is cumulative The longer the series of recurrent Challenge-and-Response-and-Challenge, the greater the progressive differentiation of the parties concerned [p. 377].

Growth is a Positive, Constructive Process. There is nothing in the phenomena of differentiation and integration and of the emergence of originals that can be meaningfully described in terms of domination, submission, aggression, frustration, hostility, mastery, rigidity, compensation, conflict, or even sublimation. Operationally defined, differentiation and integration are proceeding at their maximum under the existing conditions of the organism, of its environment, and of the nature of the interplay between them. Rigidity, submission, mastery, aggression, conflict, hostility, pathology, and disease are terms used to designate conditions, relations, and processes that are low in differentiation, low in integration, or in which the growth processes are abnormally retarded. The emphasis which psychologists have given to mental disease and to these other associated concepts constitutes a negative approach to the understanding of personality. The very concept of *defense mechanism* implies some answer not only to the question "Defense against what?" but also to "Defense for what?" Defense mechanisms are called into play when trouble arises, when "something is the matter," when the environment has interfered with the positive growth processes of differentiation and integration Defense mechanisms are used when the person needs to protect his spontaneity, his autonomy, his own differentiating processes, his integrity, his biological and psychological process of growing.

Fromm (1947) refers to growth and productiveness as the "primary potentials" of man, and to defense mechanisms and destructiveness as a secondary "potentiality" that comes into manifest existence only in case of abnormal, pathogenic conditions:

> man is not necessarily evil but becomes evil only if the proper conditions for his growth and development are lacking. The evil has no independent existence of its own, it is the absence of the good, the result of the failure to realize life . . . the normal individual possesses in himself the tendency to develop, to grow, and to be productive, and the paralysis of this tendency is in itself a symptom of mental sickness. Mental health, like physical health, is not an aim to which the individual must be forced from the outside but one the incentive for which is in the individual and the suppression of which requires strong environmental forces operating against him [pp. 218–219].

Fromm calls attention to similar views that have been strongly emphasized by Goldstein (1939), Sullivan (1947), and Horney (1937, 1945).

It follows from Goldstein, Sullivan, and Horney, and from many others, that the person is inseparable from the environment and that the understanding of the person is possible only to the extent that we understand also the environment. Mead (Chapter 12) and other anthropologists (Kluckhohn and Murray, 1948) have shown that one must understand the culture in which the person lives. For Cameron and Magaret (1951), the understanding of behavior pathology necessitates an understanding of learning in a social situation, the process of interplay between the individual and his environment. From Murphy's (1949) biosocial viewpoint,

> personality is an interaction of organism and culture, and the situation is consequently part of the personality . . . the interpersonal relations depend on the individuals, but . . . the individuals also depend on the relations [pp. 21–22].

Not only the individual *and* his environment but the *process* of *interacting* must be understood. *This process of interacting is social learning* A group of nine persons has attempted by group process to formulate their conceptualizing of personality in interaction. The report of their joint efforts has been edited by Parsons and Shild (1951).

Optimum Growth and a Propitious Environment. It has been mentioned that growth, like everything else a psychologist discusses, exists in degrees. Although the units of measurement or of comparison are often crude or even non-existent, growth may be considered as faster or slower, or as more or less. Theoretically, there are limits beyond which a given individual cannot go. Practically speaking, however, it is difficult to say that anyone ever achieves this highest limit. In other words, a person is growing at his optimum, or he is growing at something less than his optimum. It is helpful to postulate a concept of optimum growth, which necessitates also a concept of propitious environment.

One child is differentiating at a more rapid rate than another of the same age. One mother permits or assists her child to emancipate (differentiate) himself from her faster than another mother. The units of comparisons are coarse and crude, but the comparisons are possible and useful.

The concepts of optimum growth and propitious environment are quite acceptable in other biological sciences and can be equally useful to psychologists. No farmer would expect the same crop from a weedy corn field that he would get from a well-tilled field. No farmer expects the same crop of corn from a mountain field several thousand feet above sea level that he would get from a field in Iowa or Illinois. There are good reasons why cotton is not a commercially profitable crop in Minnesota. Given seed from the same stock, environment plays a determining rôle in the growth process.

It is no more correct to say that the cotton crop of Minnesota is characteristic of the "inherent" or "inevitable" or "predetermined" qualities of the seed used than to say that it is a product of cool nights and a short season. The cotton crop of Minnesota would be a product of the dynamic interplay between the plant and the environment. In Minnesota one cannot bring out the "best" there is in cotton no matter how "good" the seed.

Some children, as Ribble (1943), Spitz (1945), and others have reported, are indeed brought up in a chilly climate; other children, as Plant (1937) and Frank (1948) have tried to tell us, are literally scorched. *Man is not only a product of his environment, in a very real sense man is also a victim of his environment.*

What, then, are the elements of the *hypothetical situation in which an individual*

is approaching his optimum? How many different characteristics can be expected in a situation where a person is growing at something approximating the optimum of his hereditary potential in an optimum environment?

1. There is a minimum of *psychological rejection, environmental press,* or *domination.* This is consistent with the hypothesis that growth is spontaneous and with the well-demonstrated fact that growth cannot be forced or coerced. A minimum of domination is another way of saying that the setting is one in which there is a maximum of being *accepted as one is.*

2. It follows that with a minimum of environmental press or domination there is a maximum of spontaneity. Since one is accepted as he is, there can be the free expression of any ideas, activities, and impulses that occur to the individual.

3. With free expression, there is the maximum of communication to the environment, making possible a maximum of understanding of the person by the environment.

4. Since there are no threats from the environment, a maximum approximation of "true perception" would be expected. That is, perception would not be distorted by concern for what the percept meant for one's personal security. (One is secure when accepted as he is.) This high quality of perception would facilitate the maximum of understanding of others by the person himself.

5. Since there are no threats from the environment, there is a minimum necessity for repressing into the unconscious, and, therefore, a minimum basis for neurosis.

6. Similarly being accepted as he is, the person has no cause for attacking, dominating, or coercing others. Others would show a maximum of spontaneity, of communication, thus facilitating a "richer" interplay of ideas and activities.

7. Because behavior is "circular" in its effects, as we shall discuss later, the relationship between the person and his environment shows a maximum of harmony, of *working with* others. (To the extent that one's spontaneity is not in harmony with the spontaneity of others, one does not continue to be accepted as he is.)

8. In this relation, the term "conflict with the environment" is meaningless. Projective techniques would elicit only expressive behavior; no defense mechanisms would be found. (Defense mechanisms are elicited by environmental threat.)

9. As for emotional behavior, in this situation the person experiences love, ecstasy, delight, and other positive, constructive, creative, pleasant, and satisfying emotions. In this optimum environment are to be found the "inspired moments," the "insightful" flashes of the Gestaltists. Here is the joy of discovery and the thrill in learning. These are moments in a positive growth relationship with one's environment. They are real in themselves. They are not a sublimation of anything.

10. But, one must now add, there is no perfection except by definition. No one is completely accepted as he is, for that would necessitate complete understanding. All things that psychologists observe are relative. There are, however, many human relationships and many situations that satisfy these criteria to a high degree, in which it is not meaningful to speak of conflict or fear of each other, of aggression or attack, of ascendance or mastery. Rousseau (1925 edition), it seems, had this relation in mind when, writing on the social relation of the sexes, he said:

> But in the harmony which reigns between them, everything tends to the common end, and we do not know which con-

tributes the most to it, each follows the impulsion of the other; each obeys and both are masters.

The Place of Value. The concept of a propitious environment may seem to be a departure from the perspective of a scientist. A propitious environment implies direction, goal, choice, and value. It must be remembered, however, that the concepts of growth and development are based on concepts of direction, organization, regulation, and preference. The scientist who studies social development must study all these things, including human choices and human values. The writers wish here to call attention to a recognition of the relation of value to the science of psychology.

Murray and Morgan (1945) freely admitted that attitudes or sentiments are inseparable from a concept of human values.

> Hovering in the background of our minds was a half-formulated program for applying psychological methodology to the study of specified human values and so establishing pragmatic grounds for their tentative acceptance or rejection. There is nothing very unusual or revolutionary about this plan, though at first blush it may bear the look of heresy.
>
> Since, by definition, the object of a positive sentiment is a *value* to the possessor of this sentiment, to investigate the one is to investigate the other. Thus ours has been a study of human values as much as it has been a study of sentiments. . . .
>
> Thus, maintaining all the while his rôle as a scientist, the psychologist should eventually be able to provide formulations for a pragmatic system of values.
>
> This conclusion seems to fly in the face of the axiom that science is not concerned with value. Science describes and explains events but it does not pass judgment on them. It says, "This is what happens; take it or leave it." Arguing from this creed, people have concluded that science can be of no service to man in his search for a satisfactory philosophy. As we see it, however, the exact opposite is true, at least so far as psychological science is concerned [pp. 7–8].[1]

Allport and Vernon (1931), in their *A Study of Values,* developed a test based upon the frames of reference of Spranger (1928). Among other psychologists who have devoted attention to the nature and place of value are Köhler (1938), Wickert (1940), Sherif and Cantril (1945, 1946), Cantril (1949), McClelland (1951), Rokeach (1951), and Grace and Grace (1952).

From Sinnott (1952) the following statement is taken:

> Human individuality and personality, the ego itself, is simply one manifestation of the . . . process by which living matter pulls itself together into integrated and organized self-regulating systems. The goal of the organizing process is a *single, whole individual.* Protoplasm always comes in separate packages. Each center of organization has its own psychical unity. Such a living individual maintains its

[1] One number of the *Journal of Social Issues* for 1949 was devoted to "Social Values and Personality Development." It contained articles by Miller and Hutt (1949) and Hutt and Miller (1949), with commentaries by Titiev (1949) and Mathews (1949). Another number of the same journal was devoted to "Values and the Social Scientist," edited by Benne and Swanson (1950). This number contained a leading article by Geiger (1950) and a symposium of extended commentaries by representatives of the fields of psychology, philosophy, economics, psychoanalysis, education and theology: Ayres (1950), Cattell (1950), Alexander (1950), Wieman (1950), Feigl (1950), Raup (1950), Lippitt (1950), Hobbs (1950), and Churchman (1950).

Still another symposium treating of "Values in Personality Research" was edited by Wolff and Precker (1950) for Symposium No. 1 in *Personality Symposia.* In this number, values were discussed by Josey and Snygg (1950), Klee (1950), Maslow (1950), White (1950), Clark (1950), Auerbach (1950), and Wolff (1950). These authors raised serious question about the neglect of value by persons who think of themselves as scientists.

Tolman (1949, p. 8) made a special point of the place of values in perceptual readiness in animal learning.

identity and endures, even if its material substance is continually changing. The organized pattern of human personality is a surprisingly tough fabric and can survive many vicissitudes. It is a *whole* and must be treated as such.

Even the ancient question of freedom may perhaps be stated in fresh terms in light of the present speculation. It may be interpreted as the translation into action of the regulatory purposes set up in the brain. The purpose and the purposer are one. It is the individual who wills and does, not some agent foreign to it. If this is so, we do what we will, for the desires that arise in us are an essential part of us; and to speak of compulsion here seems meaningless As Whitehead once said, the psychical is part of the creative advance into novelty These biological norms that become desires, purposes and ideas may be true "emergents" that actually break new ground in the universe.

It is even possible to look at the vexed question of value from this biological point of view Values may be said to come from the direction and character of the goals of life, the norms set up in protoplasm and determining the directions toward which an organism moves, either physically or psychically. We may perhaps gain insight on them by studying the cause and orientation of organized living systems. Protoplasm has its preferences, and value judgments are their ultimate expression [pp. 466–467].

That the biological purpose and the purposer are one is a statement very similar to the point of view of Fromm (1947) concerning humanistic ethics: "In authoritarian ethics an authority states what is good for man and lays down the laws and norms of conduct; in humanistic ethics man himself is both the norm giver and the subject of the norms, their formal source or regulative agency and their subject matter" (pp. 8–9). This quotation is only one of many which might be taken from *Man for Himself* to which Fromm (1947) gave the subtitle *An Inquiry into the Psychology of Ethics.* In his book Fromm elaborated his thesis:

> problems of ethics cannot be omitted from the study of personality either theoretically or therapeutically. . . . The divorcement of psychology from ethics is of a comparatively recent date The great humanistic ethical thinkers of the past, on whose works this book is based, were philosophers *and* psychologists; they believed that the understanding of man's nature and the understanding of values and norms for his life were interdependent [p. viii]

Social Development and the Second Law of Thermodynamics

In the past, psychologists, in their development of scientific method, have drawn heavily upon the physical sciences There has been an attempt to extend the multidiscipline approach in the study of man to a closer integration of the physical and biological sciences Attempt has been made, for example, to discover the similarities and differences between communication theory in physics and communication theory in physiology, neurology, and psychology. Since social development is based upon communication it is important to review some of the main concepts in these efforts at cross fertilization (intercommunication and integration) of the disciplines. In Figure 5 we have presented diagrammatically a comparison of some of the concepts of the physical and biological sciences.

Physical Matter: The Closed System. The first law of thermodynamics concerns the conservation of energy or the constancy of energy in a closed system. The second law of thermodynamics concerns a quantity of energy which, while remaining constant in a closed system, tends to decrease in quality and never to increase. While

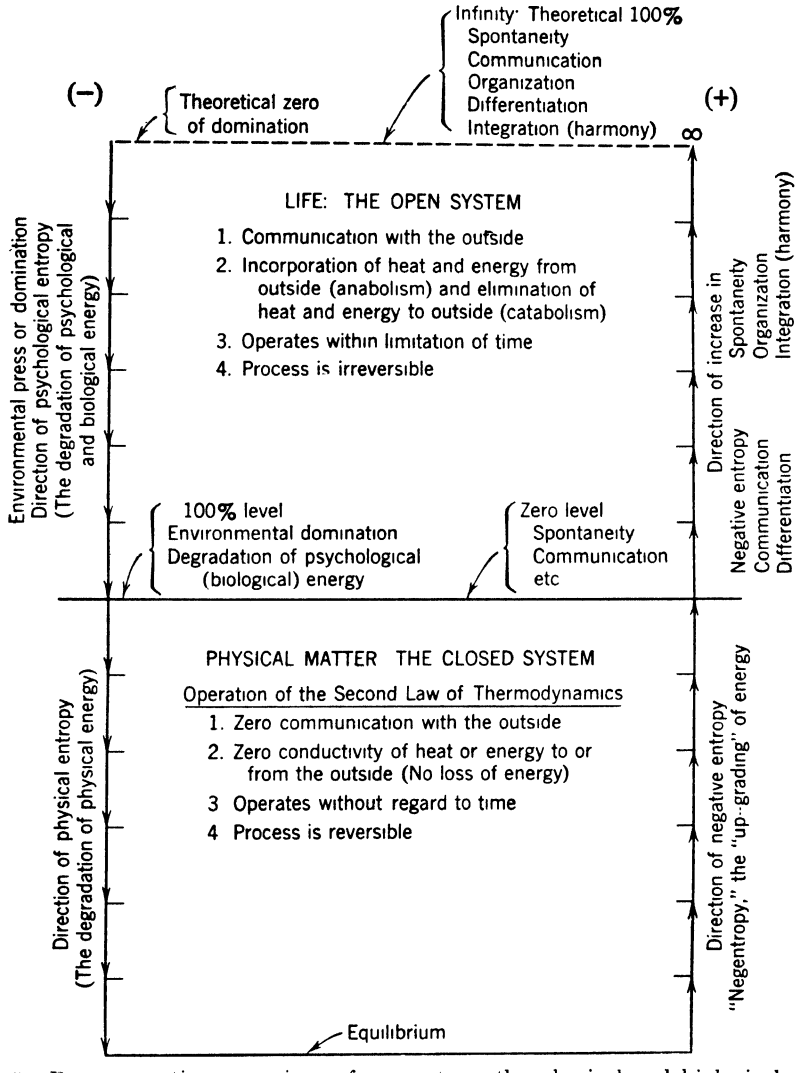

FIGURE 5. Diagrammatic comparison of concepts in the physical and biological sciences.

it appears that no exceptions to the second law have ever been found, physicists have been unable to adapt it consistently to living matter. The closed system in which the law is supposed to operate is a theoretical machine that has no conductivity of heat or communication with the outside. No material enters or leaves it. It operates without friction and without regard to time, and the process within it is reversible. Within this closed system there is no loss of energy, but the free energy changes in quality, ultimately reaching equilibrium. This loss in quality of energy is called *entropy*.

Entropy is a negative concept; it refers to that process in nature wherein energy of high quality is degraded to energy of a

lower quality. *Entropy is the degradation of energy.* It should be noted that physicists do not have a positive concept nor a word in the English language to refer to the positive process of achieving higher levels of organization of energy or the "enhancement" of the quality of energy. Physicists, for example, Wiener (1948, p. 18), struggling with their own concepts and attempting to relate the problems of communication and organization in physics and biology, have referred to the positive process as the "negative of entropy." Brillouin (1949, 1950) has proposed the shortening of the double negative to *negentropy* to express the positive concept of a change to a higher quality of energy.

Life: The Open System. While both laws of thermodynamics apply only to closed systems, man is an *open system* and life is an *irreversible* process. Materials from the outside enter and leave a living organism; there is contact and communication with the outside. Some of the questions as to whether or to what extent man behaves according to, beside, or beyond the laws of thermodynamics have been discussed by von Bertalanffy (1950), Wiener (1948), especially in his chapter on "Progress and Entropy," Brillouin (1949, 1950), Raymond (1950), Krech (1950*a*, 1950*b*), Frank (1951), Ransom (1952), and Anderson (1952, 1953). It seems that in the current writings of these physicists, biologists, sociologists, and psychologists there is a process of differentiation and of integration in their thinking taking place and that a consistency in their thinking can be illustrated by referring again to Figure 5.

If life is an open system, with energy and stimulation flowing both ways, and communication occurring in two directions, then the most open system, the greatest freedom, the greatest flow of ideas out and in, the maximum of communication with the environment is found as represented in the top region of Figure 5. The top of the scale for "Life: The Open System," Figure 5, would also represent a situation or a relationship in which environmental domination, the *degradation of psychological energy,* is at a minimum. The maximum of social development, the optimum, the ideal, the "healthy" relationship from the standpoint of social development and psychological growth, would also be found at the top of Figure 5. This would be the theoretical optimum environment.

It should be pointed out that for all dimensions represented by the ascending scale (+) in Figure 5, the top of the "Open System" is a "theoretical maximum" which is infinity ∞. In Figure 5, for each dimension that increases with the ascending scale, "optimum" and "maximum" are identical. There cannot in nature be "too much" differentiation, integration, communication, organization, learning, "enhancement" of psychological or biological energy, evolution, love, understanding, or social development. The test in nature is the degradation of energy. None of these concepts is related positively to psychological entropy. There has never been found a case of "too much mother love"; "over-learning," by definition, is not "learning." The resources, incentives, and constraints of the environment have been discussed by J. E. Anderson (1944).

Murray and Kluckhohn (1948), writing about the socializing process, stated that an organism can be "over-socialized." There is no inconsistency or confusion with the term as they elaborated it. Over-socializing, to Murray and Kluckhohn, is the operation of the same process of cultural domination which meets our test of *psychological entropy.* They wrote:

> By definition a highly socialized person is just like the majority, the average. Con-

> structive social innovations and intellectual and artistic creations will hardly come from such individuals. Moreover, too great socialization tends to eliminate that spontaneity of response which is of great value in ordinary social intercourse [p. 29].

Any socializing process which tends to level productive energies toward the mean instead of releasing creative energies in the direction of maximum or optimum realization of the individual's potentials is degrading human energy and producing both an individual and a social loss. It is the measure of this individual and social loss which is the measure of psychological entropy. Future research in social development may invent a kind of mathematics of statistical probabilities for the poet's hypothesis "The saddest of these, it might have been."

Psychological Entropy: The Degradation of Energy. In Figure 5, as it is drawn, the degradation of energy would seem to proceed from the top of the figure through both the "Open System" and the "Closed System" in one continuum. Beginning at the top with small degrees of environmental domination (authoritarian relations, psychological rejection, small restrictions on behavior or communication, the "socializing process"), the scale increases downward in domination.

One aspect of the degradation of psychological energy is a diminishing of spontaneity and of two-way communication, which, as mentioned above, can happen only in the "Open System." Authoritarianism and domination, the use of force, threats, and their symbolic forms of shame, blame, and guilt, are a form of one-way communication. Psychologists are studying this "negative concept of the open mind" under such titles as rigidity, ethnocentrism, prejudice, anxiety, the unconscious.

The lowest levels of communication with the outside are to be found near the bottom of the scale for the "Open System." Psychologists and psychiatrists speak of extremely uncommunicative patients as "merely vegetating," or as being psychologically or emotionally "encysted." There is little or no perceptible process of differentiation, growth, or learning in these patients. They are more nearly in a state of psychological atrophy. *Psychological entropy* for them is high; their psychological energy is much degraded. Psychologically, they are living close to the border between life and death. Communication ceases altogether in the "Closed System."

The borderline between the "Open System" and the "Closed System" has so far been crossed by man in only one direction. Movement at this point of Figure 5 is irreversible. Death, the ultimate in degradation of psychological energy, can occur through environmental domination, by overt intent of the environment: by capital punishment or murder. It can occur through slower processes of interacting with the environment: through disease or physical starvation. Infants, according to Spitz (1945) and Spitz and Wolf (1946), have crossed the line through lack of human communication, lack of maternal affection. The second law of thermodynamics, as it is presently formulated by physicists, operates when the individual as a living organism ceases to live, disintegrates, and can be treated as a closed system.

Value in Relating: Psychological Negative Entropy. Figure 5 has a plus sign (+) on the right-hand side of the diagram for the ascending scale and a minus sign (−) for the descending scale on the left-hand side of the diagram. The vertical dimension of the "Open System," Figure 5, represents degrees or levels of relationship between the individual and his environment. A person may be very near the top at one moment, or in one situation, and an instant later the situation (field forces)

may have changed so that he is very much lower on the scale. His spontaneity may be very much curtailed. Communication may be reduced even to defensive misrepresentation or false communication. The interpersonal interaction may be slowed. In a very real sense the dominating environment may be effecting a degradation of psychological and biological energy. A given point on the vertical dimension of the "Open System," Figure 5, like Lewin's (Chapter 15) diagrams of field forces, represents a moment in time, a cross-section of interplay, of interacting between an individual and his environment. It is possible with the successive changes in relationships, with additional communication or failure of communication, for an individual to move up or down or to remain indefinitely at one level of relationship, depending on the nature of the relationship, the demands of the environment, the motives of the person, the extent to which he can or cannot meet his needs, and on his freedom to act Figure 5 represents direction: not direction of motion, but direction of *value in relating*, the *value to the changing individual which the moment of relating holds for him*. Figure 5 represents direction toward or away from the optimum of self-realization, the optimum growth of the individual. The level of *value in relating* is the psychological analogue of negative entropy. Psychological negative entropy is growth, *social development*, creative experience.

Although from moment to moment there may be movement up or down on Figure 5, "Life: The Open System" is still an "irreversible process," and "time is of the essence." It is not possible for a biological organism to relive any moment in time.

Hypothesis of Equifinality of Growth. It may be mentioned here, and it will be referred to briefly again under psychotherapy, that the fact of movement up and down the scale of Figure 5 illustrates another hypothesis: that of the *equifinality* of growth. Von Bertalanffy (1950) has pointed out that in most physical systems the final state of a process is determined by the initial conditions. Growth, on the contrary, he said, is *equifinal;* it is independent of the initial conditions. The goal of psychotherapy is to help the patient move upward on the scale of relating in Figure 5. As there are many ways to express the goals of therapy, there are many ways of attaining the same goal In this hypothesis of the *equifinality* of growth lies the hope of the therapist: that therapy can be a speeded-up growth process and that the client can make up for "lost" time A similar idea has been expressed by Frank (1951, p. 507).

Psychological Entropy and Culture. The concept of psychological entropy as a degradation of energy (with negative entropy as the release of psychological power or energy) is a biological concept of broad application. It represents a functional interplay between an environment and a human being. It holds for infants and for persons of all ages. It would seem to be a test of a propitious environment that could be applied to all cultures Moreover, it is amenable to measurement in quantifiable units and to prediction in statistical probabilities. The amount of psychological entropy for an individual in a given situation can be a test of, for example, "goodness" of parent-child relations or of a school environment. As a test of culture it can be a "common denominator" or a "standard score" by means of which diverse cultures may be compared.

The application of a concept of entropy would simplify many of the semantic confusions in psychology. For example, ascendance, as defined by Allport (1928–1929), Jack (1934), and Page (1936), contains both dominative behavior (high in en-

tropy) and integrative behavior (low in entropy) (see H. H. Anderson, 1937*b*). If psychologists employed the test of entropy, they could avoid the confusion shown in current uses of the term dominance. Where dominance is defined as behavior that is not domineering it is low in degradation of energy. But dominant, by implication and by common usage is high in entropy. Other examples of such confusions have been discussed by H. H. Anderson (1940, 1946*a*) and by Schneirla (1946).

Theory of Probability, "Scientific" Prediction, and Organization. The mathematical basis for the concept of entropy is not different from the mathematics of the theory of probability. Entropy, according to Brillouin (1949, p. 559), "acquires a precise mathematical definition as the logarithm of probability." As entropy increases and energy approaches "equilibrium," probability also increases. Prediction is greatest at the lowest part of Figure 5, and least at the top of the "Open System." Stated the other way, as entropy decreases, that is, as one proceeds upward from the bottom of Figure 5, probability also decreases. Negative entropy, or the enhancement of energy, is today synonymous with the increase of information and the increase of organization in electronic computers, as well as in the higher levels of growth in living organisms.

Socially integrative behavior, the *working with* others, represents a high state of organization. Moreover, it represents the interplay of open minds, the openness to new information, which is one important reason for calling life an "Open System." Conflict, on the other hand, the *working against* others, represents action toward disorganization. Emotional behavior in conflict, such as in fear and anger, is even defined by some psychologists as disorganized behavior. In Figure 5, the degree of organization is highest at the top; it is lower, in conflict, at the middle portion of the scale; and it is lowest at the bottom, in states of atrophy, disease, and disorganization. Wiener (1948) relates "amount of information" not only to a negative concept of entropy but to a concept of organization.

> The notion of the amount of information attaches itself very naturally to a classical notion in statistical mechanics: that of *entropy*. Just as the amount of information in a system is a measure of its degree of organization, so the entropy of a system is a measure of its degree of disorganization; and the one is simply the negative of the other [p. 18].

If it is true, as it appears to be, that the lowest predictability in statistical mechanics, biology, and psychology is to be found at the highest levels of organization, then the most difficult problems of prediction lie ahead of those psychologists who would study the positive aspects of human behavior, social development. This mathematical and methodological difficulty has already been noted in a number of researches. Two examples will be given. Anderson (1937*b*, 1939, 1946*a*) has consistently found that dominative behavior was more reliably *observed and recorded* than integrative behavior. Children, well known to their teachers, were *rated* with high reliability and high validity for dominative behavior (aggression, hostility, conflict), but with much lower reliability and validity for integrative behavior. That is, prediction of conflict and discord was more reliable than prediction of harmony.

Harris, Gough, and Martin (1950) reported similar findings in their study of parent attitudes toward child training practices.

> In reviewing the results—one is impressed with the fact that the negative and less "desirable" aspects of the picture seem to be somewhat better determined. The

> authoritarian and rigidity or "fussiness" complexes show a higher degree of interrelationship than do parent-child integration and permissiveness attitudes. It is perhaps significant that it was more difficult to locate items which would make satisfactory appraisal of these latter dimensions. The writers are willing to suggest that even though a satisfactory number of items was obtained, the resulting correlation would not be so high as the correlations found between the less socially acceptable attitudes. This phenomenon appears to be an incidental illustration of the fact that less socially acceptable or negative statements in personality or attitude tests make sharper discriminations than do more positively stated or desirable aspects of personality [pp. 179–180].

As psychologists, we should be neither surprised nor dismayed at these findings. They are consistent with and predictable from the theory of probability used in physics and statistical mechanics. The continuum in the theory of probability extends from the virtual "dead certainty" at the state of relatively complete degradation of matter, equilibrium, at the one extreme, to the relatively improbable prediction of the emergence of an original at the highest theoretical integration or organization of matter, at infinity (one chance in infinity), in the "Open System." Learning, at the higher levels, thus becomes the emergence of an original, and social development is a psychology of invention.

There is reason to believe that our present methods and concepts in psychological research are still relatively static and but crudely adaptable for prediction in the dynamic problems of social learning and human interrelating. Since there is a chapter "Methods of Child Psychology" (J. E. Anderson, Chapter 1), the implications of entropy and the theory of probabilities for psychological research methodology and prediction in social development are mentioned here only in passing.

Levels of Dynamic Human Interacting

The scales represented in "Life: The Open System," Figure 5, can now be subdivided into differentiable levels of human interacting. The six levels presented in Figure 6 have been adapted from H. H. Anderson (1951). The number of levels could be increased or diminished. As research and observation become more refined the number will probably be increased, an increase being in the expected (predictable) direction of further scientific differentiation. The six levels proposed here are related to each other on a continuous scale of dynamic interplay which decreases as domination increases. They therefore offer practical utility in presenting research reports that bear on social development. Brief comments on selected relevant research will follow a description of these levels.

It will be noticed that in Figure 6, as in Figure 5, there is a vertical dimension downward on the left-hand side of the diagram. This dimension is marked with a negative sign (−), because direction on this dimension is toward disintegration, disorganization, and degradation of energy, all proportionately related to environmental domination.

Similarly, there is a vertical dimension upward on the right-hand side of the diagram. This dimension is marked with a positive sign (+), because direction upward in Figure 6 represents an increase in differentiation, organization, integration, communication, understanding, learning, invention, action, social development, growth, all of which in theory are inversely related to environmental domination.

1. *Socially Integrative Behavior.* The first, or top, level in Figure 6 is called

"Socially integrative behavior." Socially integrative behavior is possible in a relationship in which individuals may come closer and closer together in their understandings and in their actions and still remain different. This is obviously an ideal relationship; for purposes of growth, differentiation can be at its highest where a person is accepted as he is.

radation of his energy) for granted. He continues to like his friends; he continues to enjoy their associations; he bears no hostility for the minor inconveniences. He continues to show high spontaneity in his own behavior and to accept a high degree of spontaneity in theirs. Such a relationship is *socially integrative.* It is basically a *working together;* the use of one's own

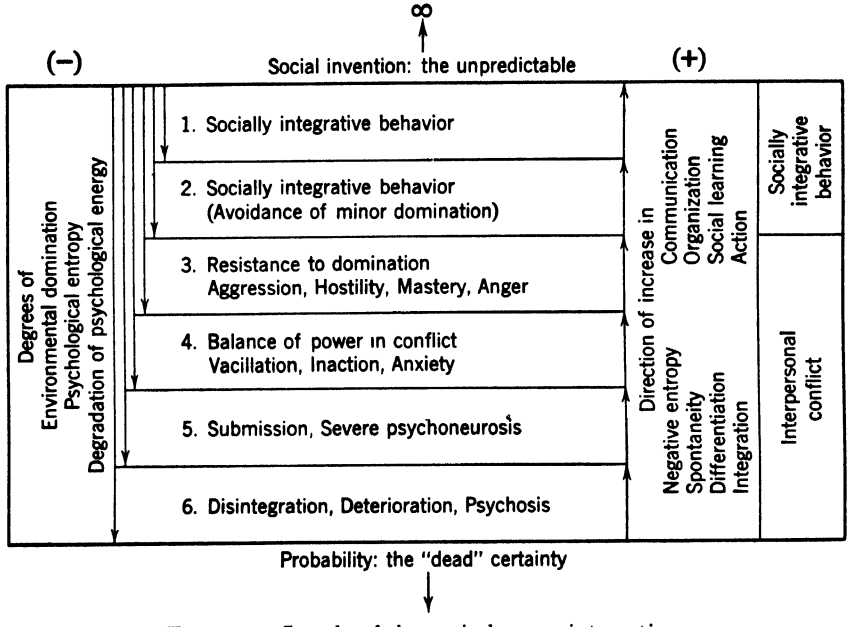

FIGURE 6. Levels of dynamic human interaction.

There is no perfect harmony in human relations. Perfect harmony would require perfect understanding of the desires and purposes of others, as well as of one's self. Since each person cannot be too articulate about his own needs, it would be expecting too much of others to have a perfect understanding of him. At the highest stage of harmony in human relations each person causes some inconvenience to those about him; each person finds his own spontaneity somewhat restricted by the well-meaning behavior of others. Each takes a considerable amount of such inconvenience (deg-

power with others. Each can reveal himself to others and not feel a need to be self-protective. Because each can be essentially himself, each can achieve a high level of communication with and understanding of others. This is not "adjustment"; this is "creative experience" (Follett, 1924), social learning.

In this relationship it is meaningless to speak of conflict, aggression, attack, hostility, fear, or defense mechanisms. Although the socially integrative relationship is an ideal, an increasing number of research studies show that a considerable amount of

human behavior can be properly classified at this level.

2. *Socially Integrative Behavior, Avoidance of Minor Domination.* Figure 6 postulates two levels of socially integrative behavior. It happens at one time or another for most persons that one is obliged to live in some proximity to another and finds the other an obstruction to his spontaneity, to his being himself. If he cannot accept the domination of the other person (often taking the form of cultural and relatively impersonal demands: the "What-will-people-say!" motif[1]) without noticeable loss of his own spontaneity, he tends to avoid the other but to continue otherwise to be himself. Much of the cultural training or so-called socializing of the child falls in this category—or *can* fall in this category, though there are conflicting hypotheses extant. This manner of behavior presumes that the domination, though mild, is too great to be taken in one's stride. It presumes that the domination is great enough to warrant the taking of mild self-protective measures. Withholding information from one's parents and selective conversations with one's friends are symptomatic of such a relationship. Such behavior tells us about the persons in the environment as well as about the individual himself.

In these two highest levels of growth in which there are responses to mild domination, the infringement on one's own spontaneity is not great enough to be classified as frustration and to call forth resistance to the other person or to deflect one's energies from his own essential purposes. Behavior still reflects socially integrative relationships. But where one perceives his situation to be such that it seems desirable to withhold information or to be protectively selective in ideas, there is reduced interplay of communication and therefore less understanding. Where such behavior is found, however, it is not meaningful to say that the persons are in conflict; they are not expending energies in opposition to each other. By an adaptation of the concept of just-noticeable differences used in laboratory psychology, the *avoiding* can be distinguished from the next lower level of personality growth, which is resistance.

H. H. Anderson (1946*b*) made an empirical distinction between two "degrees" of socially integrative behavior in observational studies of teachers' contacts with children.

> It was . . . assumed that a teacher's integrative contact showed a "higher degree" of common purpose when there was objective evidence in the child's behavior that the child was working with the teacher . . . Categories of teacher contacts were separated into situational groupings which were assumed to differentiate (two) degrees of social integration *Integration with no evidence of working together; Integration with evidence of working together.*
>
> Evidence of *working together* consisted in verbal or other expressions which indicated that both teacher and child were pursuing the same goal or were trying to find a common purpose without the *imposition* of goals, desires, or ideas of the one on the other. Thus, in recording the teacher's behavior, this evidence could appear only when the teacher attempted to cooperate with the child in an activity in which he was already engaged or when the child had already given indication that he voluntarily or spontaneously accepted the teacher's ideas or goals as his own. The "acceptance" of the teacher's goals or problems does not include obedience nor conforming under duress [pp. 15–16].

This differentiation of two situational "degrees" of integrative relating was used

[1] The theme of such milder degradations of energy that do not really deflect one from his essential purpose was quite effectively set to music in the song "People will say we're in love" in *Oklahoma.*

by J. E. Brewer (1940, 1946) and was subsequently reported by H. H. Anderson (1943, 1946c), Clifton (1943), Reed (1946), and H. H. Anderson and J. E Brewer (1946). In these studies the data for the two degrees of integrative contacts were reported separately, and their implications for social development were interpreted according to a set of hypotheses. The details of the findings will not be reviewed here.

For the remainder of this chapter these two levels of socially integrative behavior are combined, and no further distinction is made unless explicitly noted. Under socially integrative behavior reports are classified all studies in which the degradation of energy, domination, is at a minimum. Examples are studies of democratic relations in the home, responsibility, rapport, altruism, leadership, sympathy, empathy, needs for affection, cooperation, and friendliness. Studies of group behavior of children in "climates" of democratic leadership are properly classified at this level of relating, but are reviewed by Lewin, Chapter 15. Likewise, studies involving the positive emotions would be classified here, but are reviewed by Jersild, Chapter 14. The test for classifying behavior, or a concept of behavior, at the socially integrative level is that psychological entropy be low, negative entropy high. Fromm's (1947) criterion—and it is a good criterion —would be that "productivity" be high.

3. *Resistance to Domination.* Of the vast proliferation of studies in social development and related areas, by far the greatest number would be classified at this third level of human interrelating (Koshuk, 1941). In these studies the environmental domination—authoritarian restrictions of the parents, the family, and of the complex assortment of cultural institutions—has increased to a point where the concepts of frustration and conflict take on meaning. Moreover, the individual victim of this domination has sufficient spontaneity to attempt to do something about it himself. He uses his *power against* others.

One tends to resist environmental press or domination when it increases to the extent that it actively interferes with the attainment of one's goals and purposes. This is the meaning of the first part of the frustration-aggression proposition "that the occurrence of aggressive behavior always presupposes the existence of frustration" (Dollard, Doob, Miller, Mowrer, Sears, *et al.*, 1939, p. 1).

Thus this level could be given one or more accessory titles: frustration, aggression, hostility, negativism, mastery, anger, ascendance, dominance. These behaviors and relationships are classified at this third level.

It should be noted that these resistant forms of relating are characterized by a relatively high degree of spontaneity and action. Because of the defensive nature of the relating, the spontaneity and the action are at a lower level than is found in the less restricted interplay of socially integrative behavior. Below the level of resistance, both action and spontaneity are conspicuously lowered. When one is uncertain about the strength of his adversary or when one is certain that it is not safe to resist, the response to frustration may take any one or a combination of the forms of the Freudian defense mechanisms and find a lower level of energy output and action in projection, rationalization, aggressive fantasy, displacement, or other inadequate and unproductive symptoms.

In part because resistant behavior is high in action, but more probably because of its nuisance value to other persons, it is more easily observed, more reliably recorded, and therefore more easily and more frequently studied by psychologists.

4. *Balance of Power in Conflict.* When domination increases still further it reaches a theoretical relationship in which strength of the domination equals the ability of the person to resist. This is not represented by a point on any scale; the power relationship oscillates up and down according to the changes in one's perception of the strength and source of attack and one's estimation of his own resources. This is the *balance of power in conflict.*

Balance of power, whether used as a concept in understanding personality, or in interpreting international diplomacy, has meaning only in relations of conflict, in relations in which *energy is being expended against* others. Balance of power is meaningless in relations where either persons or nations are *working with* each other through socially integrative behavior. At the level of balance of power a person's perceptions tend to become noticeably distorted. He is confused as to the source of the domination, as to its strength, or both. From his perception of his relation to the world about him he cannot know whether to attack (and what to attack) or to run (and where to run). In children we call the hesitant, faltering, indecisive behavior at this level "excessive shyness" or anxiety. In students it is worry and nervousness. It represents a distinguishably greater degree of degradation of psychological energy than does aggression or resistance.

Anger, aggression, hostility, resistance represents a response to a relatively highly differentiated (well-perceived) source of attack or fear. When the fear stimulus, that is, the source and the strength of attack, is undifferentiated, the person is said to be in a state of anxiety or vacillation. At this fourth level, and continuing into the fifth and sixth, clarity of perception, communication, and action are all greatly reduced. A shy child cannot say why he is shy, nor can a student give a reason why he cannot study or concentrate. The source of anxiety is often a principal diagnostic problem. Some behavior at this level is regarded as neurotic and is scarcely distinguishable from submission. In the behavior of mice and men it may be "behavior without a goal" (Maier, 1949), or behavior in which the means for attaining the goal is vague or unperceived.

5. *Submission, Severe Psychoneurosis.* A still lower level of personality growth is found in expressions of submission to environmental press. Because of high necessity for conformity and obedience, and the consequently low level of action, behavior at this level, as mentioned above, is often scarcely distinguishable from that at the level of *balance of power.* In vacillation at the balance of power there tends to be more spontaneity, more fluctuating moments of aggression when the person confronts his environment, even though he then retreats. In submission there is frustration and tension.

Psychoneurosis is not a clearly defined diagnostic entity. "Psychoneurosis" is found at all four levels of interpersonal conflict (Figure 6). Much psychoneurotic behavior is found under extreme environmental domination. In therapy such patients, with increasing insight and clarified perceptions, usually move up the scale through these levels of relating before they achieve a socially integrative relationship. No attempt will be made to review the increasing volume of diagnostic and therapeutic studies and clinical case reports of human behavior at this level of relating.

6. *Disintegration, Deterioration, Psychosis.* A person who has retreated from reality into one of the several classifications of psychosis is an example of severe degradation of energy. There is so little confronting that he is even said to be "out of contact" with reality. There is often no discernible communication. It is to

this extent meaningless at this level to speak of learning, or of differentiation, integration, or social development. This is the behavior that is found in cases of pathological fears, in persons who have lived in a tremendously oppressive environment. Here are found persons whose perceptions, if communicated at all, are grossly distorted, even delusional. It is not our purpose here to attempt a classification of personality disorders and mental disease, nor to classify at any of these relationship levels persons with organic difficulties. Some of the problems of children at these two lowest levels of social interaction are discussed in Benda's Chapter 18.

Circular Behavior

The Concept of Circular Behavior. The concept of circular behavior is not new. It is found in Shakespeare and in the New Testament. The behavior itself is within us and all about us. Yet circular behavior, as a term, is found in the index of very few books on psychology. Follett (1924) is the first, according to the writers' knowledge, to have extended the concept of circular behavior as a psychological concept to the interaction of human beings.

The Growth Circle. Through the confronting of differences and the free interplay of differences shown in open-minded discussion, Follett observed the solutions to problems which she, as mediator of labor disputes, thought could not have been devised without the participation of all parties to the dispute. Problem solving in social conflict, for Follett, was not a psychology of adjustment, but a psychology of invention. *Creative Experience,* the title of her book, was the outcome of a circular process of interacting, of the interweaving of experiences. The emergence of originals represented an integration of differences. The free interaction of minds in disagreement was creative. It was not a sequence of stimulus-response behaviors, but a process; the response was not just to a stimulus, but a response to a relating. This circular behavior was creative, inventive; it was a growth circle:

> any psychology of integration, of whatever school, shows us that kind of relation which creates. The psychology of the specific response did not give us the creating relation; the doctrine of circular response involved in the theory of integration gives us creative experience [p. 116].

This appears to be the essence of a dynamic psychology. This is circular behavior in the direction of growth. This is the productive release of energy. The hypothesis of the growth circle is: *integrative behavior in one person tends to induce integrative behavior in others.*

The Vicious Circle. Follett found another kind of circular behavior in persons who could not integrate their activities in a creative direction. This behavior was domination, the use of *power over* others instead of, as in integration, the use of *power with* others. The hypothesis of the vicious circle is: *domination in one person tends to incite domination in others.*

It has been explained above that the situations of life (psychological fields) which constitute the areas of psychological interaction research are not discretely arranged according to the levels of relating diagrammed in Figure 6. One may find himself generally at one level, or he may find both expected and unexpected shifts from one level to another. It is usually possible to find examples of both kinds of circular behavior in any given social situation.

In Figure 6 the *growth circle* behavior is classified at the level of "Socially integrative behavior." The *vicious circle* behavior represents conflict and is placed at the level of "Resistance." When domination

becomes so great that human interaction is largely suspended (as in the "Balance of power") or suppressed (as in "Submission") it is classified below the level of "Resistance" in Figure 6. When interaction is so reduced as to place the relating at one of the three lowest levels of Figure 6 it is not meaningful to speak of circular behavior.

The growth circle relationship, the use of socially integrative behavior in the family, school, industry, or anywhere, is a means of "cutting the vicious circle." The use of *rapport* in the clinical situation (G. L. Anderson, 1951) is a means of cutting the vicious circle. Similarly, psychotherapy, which is basically a socially integrative relationship, is also a means of cutting the vicious circle. Consistent with the emphasis placed in psychology upon negative concepts and on things that disturb us, there are many more references in the psychological literature to the vicious circle than to the growth circle.

Circular Behavior in Research That domination incites domination was a hypothesis consistent with the interpretation that Wickman (1928) gave to some of the data in his study of teachers' attitudes toward children's behavior. Wickman reported that teachers "met aggression with aggression." Wickman's research was not a study of behavior but of attitudes toward behavior.

Observational Studies, Children. In 1935 H. H. Anderson (1937*a*, 1937*b*) undertook a study to determine whether dominative and integrative behavior of preschool children could be defined in such a way as to be reliably observed and recorded, and, if so, to test the hypotheses about circular behavior in the recorded behavior of preschool children.

The method was observational (see page 1205 below). The data were recorded items of behavior. The subjects were preschool children. Two groups lived in an orphanage and constituted a nursery school and a control group of non-nursery school children. Children were taken in pairs to an experimental playroom where they were permitted to play for 5 minutes by themselves, their behavior being observed by the experimenters through a one-way-vision screen.

Each nursery school child was paired at random with five nursery school children from which pairings each child obtained a frequency score for dominative behavior and a frequency score for integrative behavior. The same was true for each control group child. In addition, each nursery school child was paired with five control group children. From these cross pairings, each child received frequency scores for dominative and for integrative behavior.

The Vicious Circle It was found that the nursery school children in the orphanage were more dominating than were the control group children. In the cross pairings, however, the high domination scores of the nursery school children decreased and the lower domination scores of the control group increased—so much so, that in the cross pairings the domination scores of the nursery school children were actually lower than those of the control group.

Girls in the orphanage were not only more dominating than the boys but almost twice as dominating when paired with girls as they were when paired with boys. In both cases the differences were significant. Boys, on the other hand, became about 25 per cent more dominating when paired with girls than they were when paired with boys. In the cross pairings of the sexes the boys rose to a domination score higher than that of the girls.

Moreover, the correlation between the high domination scores and low domination scores in 513 pairings yielded a coefficient of .68.

As reported above, three different analyses of the data gave consistent support to the hypothesis that *domination incites domination:* (1) the cross pairings of the nursery school and control group children, (2) the cross pairings of the boys and girls, and (3) the correlation of .68 for domination scores in the pairings.

The Growth Circle. Analyses were made of integration scores. In the comparison of the homogeneous and cross pairings of orphanage nursery school and control groups none of the differences between mean integration scores was significant. Nevertheless, the dynamic tendencies, though smaller than for domination, were consistent. The higher integrative group, when cross paired, reduced its mean integration scores, and the lower integration group, when cross paired, showed an increase.

In the sex comparisons of integrative behavior there were no differences between boys and girls.

The coefficient of correlation between high integration scores and low integration scores in 514 pairings was .82.

Thus, two separate analyses of the data were consistent with the hypothesis that *integration in one child induces integration in the companion.*

Furthermore, *domination and integration were shown to be psychologically different* and, in this experimental situation, dynamically unrelated. When domination was correlated with integration the coefficients were both low, though negative in sign: −.07 for the child's own scores, −.10 for the domination and integration of the respective companions. These coefficients were based on 1030 pairings.

Two years later the methods of this same study were repeated (H. H. Anderson, 1939) with kindergarten children from quite different socio-economic backgrounds. This study gave consistent support to the hypotheses of the growth circle and the vicious circle.

With the kindergarten children the boys were more dominating than the girls. But even with this sex reversal (of the previous findings with orphanage children) in the cross pairings of kindergarten boys and girls the high mean domination score of the boys dropped and the low mean domination score of the girls increased, the differences in both cases approaching statistical reliability.

On the basis of differences which they reported to be unreliable but to show a high internal consistency, Muste and Sharpe (1947) reported the same circular trend of aggression in the cross pairings of boys and girls:

> boys are more aggressive when paired with boys and less aggressive when paired with girls. While girls are more aggressive when paired with boys than when paired with girls . . . the sex differences are shown to be consistent in (the two) different schools [p. 22].

Correlations from H. H. Anderson (1939) related to the hypotheses of two kinds of circular behavior are given in Tables 1 and 2. They support the hypotheses consistently and significantly.

One other bit of evidence in this study, whose bearing on circular behavior was not pointed out in the original report, is the relation between the teacher's contacts with the child in the schoolroom and the child's

TABLE 1

CHILD'S DOMINATION CORRELATED WITH COMPANION'S DOMINATION SCORES

Subjects	*Number*	*r*
School *X*	63	.85 ± .02
School *Y*	24	.82 ± .05
Preschool (previously reported)	513	.68 ± .02

TABLE 2

CHILD'S INTEGRATION CORRELATED WITH COMPANION'S INTEGRATION SCORES

Subjects	*Number*	*r*
School *X*	63	.65 ± .05
School *Y*	24	.72 ± .07
Preschool (previously reported)	514	.82 ± .01

behavior with a companion in the experimental play situation. The teachers had much higher frequencies of dominative than of integrative contacts with the children. On the basis of low but positive and reliable coefficients of correlation there was some tendency for the child who was most dominated in the schoolroom to be most dominating of his companion in the experimental play situation (H. H. Anderson, 1939, p. 375).

Observational Studies, Children and Adults. H. M. Brewer (H. M. Brewer and H. H. Anderson, 1945) undertook an investigation whose purpose was, in part, to study the nature and degree of relationship between the children's behavior and the teacher's dominative and socially integrative contacts. Her subjects were 32 children in a kindergarten taught by a head teacher and an assistant.

The positive coefficient of .57 between teacher's domination initiated by the teacher and teacher's domination initiated by the child indicated that those children who tended to receive highest frequencies of teacher-initiated domination tended to be highest in encountering domination when they themselves approached the teacher.

When the total *domination* initiated by the teacher was correlated with *integrative* contacts initiated by the teacher, the coefficient of .21 indicated virtually a zero relationship.

The systematic behavior pattern of the teachers shown by the coefficients of .57 and .21 would contribute no "solution" to personality problems of the children. The failure to use integrative behavior in a systematic way with those children who have been more dominated (by the teacher) than others, would mean that the teacher was failing to "cut the vicious circle" of domination and resistance. The teachers would thus be failing to use systematically the most effective technique for giving the misbehaving children status in the room and making them feel that they belonged, and that they had a part to play and a contribution to make. This interpretation was supported consistently in the correlations between the teachers' contacts and the children's behavior

By way of summary, it was reported

that these kindergarten teachers had higher mean frequencies of dominative than integrative contacts; that, among the contacts initiated by the teacher, two out of three were dominative; that, on the other hand, among teacher contacts which resulted from the child's initiative six out of seven were integrative. It was revealed, however, that these teachers were meeting aggression with aggression; that they were systematically inciting resistance and not systematically cutting the vicious circle [p. 156].

J. E. Brewer (1940, 1946), with revised and improved observational methods, made records of the behavior of teachers and children in two second grade rooms in the same elementary school building. There was no systematic factor in selecting the children for one room or the other: the children had been assigned by lot in the first grade and had been promoted as rooms. One teacher was found to be consistently more integrative (democratic) and less dominative; the other was consistently more dominative (authoritarian). The differences were large and statistically reliable.

The children with the more integrative teacher showed significantly higher frequencies of behavior in a number of categories representing spontaneity and initiative and in twelve categories of social contributions to others. All these were consistent with the hypothesis that *integration in the teacher induces integrative behavior in the child.*

The children with the more dominating teacher showed significantly higher frequencies of behavior defined as non-conforming to teacher domination, which supported directly the hypothesis that *domination incites resistance.* In addition, J. E. Brewer found that the children with the more dominating teacher had significantly higher frequencies recorded as conforming, looking up at seat work, "undetermined" child-child contacts (including whispering), and playing with "foreign objects," most of which represent the degradation of energy in the schoolroom. These data supported a quite logical and legitimate extension of the hypothesis that domination incites resistance.

> If it is a pedagogical objective for a teacher to reduce the conflict and increase the harmony in her schoolroom, then the study showed that teacher 2D was defeating her own purpose. Both the analysis of data for mean frequencies and the correlations between teacher contacts and child behavior showed that the more dominating teacher, 2D, was not cutting the vicious circle. Her domination maintained the conflict, at the same time stifling the initiative and spontaneity of the children. And her infrequent integrative contacts were unsystematically used and ineffective [J. E. Brewer, 1946, p. 125].

Reed (1946) used the methods of J. E. Brewer in a follow-up study. Reed's subjects were Brewer's two rooms of children 1 year later with new teachers in the third grade, and the same two second grade teachers 1 year later with new groups of children. Teachers and rooms were designated, 2C, 2D, 3C, and 3D. Teacher 2C was the more integrative, and teacher 2D the more dominative.

Reed found virtually the same differences between the second grade teachers and practically the same differences in the behavior of the new rooms of second grade children. She found a trend of fairly high correlations in the behavior of the second grade teachers from year to year. On the contrary she found practically a zero relationship between the behavior of the children in the second grade and that of the same children 1 year later with different teachers in the third grade. Her conclusion was that there was a tendency toward constancy in the behavior trends of the adults, and great flexibility and responsiveness in the children. These findings have some bearing on the difficult problem of "causation" in a dynamic field of interrelating.

> Coefficients show that the teacher did not take direct issue with those children by meeting the child's aggression toward other children with aggression toward the child himself. Here again teacher 2C was cutting the vicious circle [p. 82].

Of teacher 2D, Reed reported:

> Teacher 2D had no reliable coefficients of correlation between *domination in conflict* and any other type of teacher contact. . . . *Domination in conflict* had no reliable negative coefficients of correlation with any category of child behavior. It had reliable positive relations with *N, dominates other children,* and *M, nonconforming.* This follows out the assumption that domination produces domination or resistance [pp. 91–92].

Reed presented other data to show the existence of the vicious circle and several kinds of evidence that one teacher was cut-

ting the vicious circle; the other teacher was not.

In still another study H. H. Anderson and J. E. Brewer (1946) discussed in even more detail the cautions necessary in interpreting a circular or antecedent relation in coefficients of correlation. They made consecutive studies from fall to winter to see what changes in psychological interplay might be found after the teachers had been with their children approximately 5 months. They reported in summary that in *group contacts* there was no evidence that either teacher was reducing conflict in the room by "cutting the vicious circle" of domination. The report for teachers' *contacts with individual children* was somewhat different:

> Coefficients of correlation showed that in both the fall and winter samplings teacher C was, through her individual contacts, "cutting the vicious circle" of domination; while in both fall and winter samplings teacher D was not. In respect to the child behavior *dominating other children* neither teacher was doing anything systematically to reduce the conflict by *working with* those children who were most in conflict with each other [p. 151].

The studies cited above involved both an experimental free play situation and group behavior of children and teachers in their natural habitat: the schoolroom.

Another type of approach to group behavior is the series of studies of autocracy and democracy in experimentally induced social "climates." Although these studies are reviewed in Chapter 15, they are mentioned here for their evidence on circular behavior. These studies, first reported in a preliminary note by Lewin and Lippitt (1938), followed by Lewin, Lippitt, and White (1939), Lippitt (1939, 1940), were summarized by Lippitt and White (1943).

The "democratic climate" is the productive relation of socially integrative behavior which in the group is circular and self-renewing. There is mutual acceptance of each other and a *working with* each other. One quotation from Lippitt and White (1943) gives some of the characteristics of their concept of morale, which, in turn, is primarily a characteristic of the democratic relationship:

> the somewhat vague term "morale" will be used with a single and relatively definite meaning: it will mean *spontaneous cohesion* in a group. "Cohesion" here means "hanging together" in every respect . . . working together for common goals, thinking in terms of "we" rather than "I," showing friendliness rather than hostility toward other group members, etc. "Spontaneous" here means that the cohesion is a result of attitudes which the group feels to be its own rather than induced by the leader and dependent upon his continued physical or psychological presence in the group.
>
> If this definition is adopted, it can be seen without hesitation that morale was decidedly higher in our democratic groups than in our laissez-faire groups, or in either type of reaction to autocracy [p. 499].

It appears that in the "laissez-faire" climate there was also a considerable amount of domination which produced frustration which, in turn, was interpreted (Lippitt and White, 1943) as a considerable source of "group disruption" and was called by them a vicious circle:

> The vicious circle of frustration-aggression-frustration. . . . In the running accounts of the laissez-faire meetings there was evident a vicious circle involving frustration which led to aggression, and aggression which led, in turn, to mutual frustration. Both the psychological tension which resulted from frustration and the idleness which resulted from the absence of any organized, constructive group activity were apparently conducive to a large amount of

more or less good-natured bickering and competitive horseplay. This aggression, then, tended to "frustrate" the persons who were attacked, especially if these persons were sincerely attempting to start some constructive work. Thus, the work-minded boys who wanted to exercise their "freedom" to do constructive work found it almost impossible to do so. Mutual interference proved to be a highly effective disrupting force [p. 503].

The operation of the vicious circle was also reported by Bishop (1951) in her observational study of "Mother-Child Interaction and the Social Behavior of Children." Bishop suggested the operation of a "circular causation" in her data and pointed out cautions in interpreting causation. Her findings are interpreted in relation to both the vicious circle and the growth circle.

> Specific control on the part of the mother showed positive correlations with the same behavior pattern in the child and with the various measures of child resistance and non-cooperation. . . . These data would seem to indicate that those mothers who tended to show a fairly high degree of specificity of control over their children had children who similarly tended to be specific in their control over the mother and who also tended to be resistant and non-cooperative.

For the growth circle:

> Conversely, a positive correlation existed between suggesting and structurizing behavior by the mother and the various measures of wholehearted cooperation, together with the use of the suggesting types of behavior by the child. . . . It would appear that those mothers who employ less forcible types of control are less likely to instigate non-cooperation and aggressive behavior in their children. The child whose individuality, opinions, and abilities are recognized whenever possible may feel less necessity for asserting his independence in negative responses. There is also an indication that the child reflects in his own behavior the type of control which his mother has used in guiding his behavior [pp. 19–20].

The studies reported above represent recorded observations of actual behavior. Other studies report circular behavior based on attitudes, symbolism, fantasy, and ratings of behavior.

Circular Behavior in Symbolism, Fantasy, and Ratings. Hollenberg and Sperry (1951) studied antecedents of aggression and effects of frustration in the doll play of nursery school children. The antecedents were ratings of frustration and punishment for aggression at home made by intensive interviews with mothers. They reported: "1. Children who are severely frustrated by their mothers at home tend to be more aggressive in doll play than children who are mildly frustrated." They pointed out that their numbers were small, that the findings were in the predicted direction, but that the differences were not statistically reliable. "2. Children who are highly punished for aggression at home tend to be *more* aggressive in doll play than children who are mildly punished" (p. 43). The differences were in the consistent direction, but again not significant.

At the second grade level, H. A. Grace and Lohmann (1952) used incomplete stories involving parent-child conflict in the home. The outcome of the stories was scored according to four categories in a priority rank, and with the indicated percentages of total outcomes. Since emo-

	Per Cent of Outcomes
1. Emotional outburst, physical or verbal attack on parent, or threat to withdraw affection	12.7
2. Constructive	21.5
3. Active opposition	41.9
4. Simple compliance	23.8

tional outbursts and active opposition were both defined in terms of resistance to frustration, or to domination, the findings showed the sum of the percentages for these first and third categories to be 54.6 per cent responding according to the hypothesis of the vicious circle. It should be noted that one might draw the inference that those children showing constructive outcomes (21.5 per cent) had the pattern of "cutting the vicious circle." The remainder, 23.8 per cent, would be classified as showing a pattern of submissive relationships in parent-child conflict.

Graham, Charwat, Honig, and Weltz (1951) investigated aggression as a function of the attack and the attacker. They utilized 50 incomplete statements which indicated the nature (5 kinds) of an aggressive act and the individual (parent, authority, sibling, friend, inferior) who had committed it. The 106 adolescent subjects completed the statements according to what they thought an individual who had been attacked in this way would do. The responses were scored in two categories, as aggressive or non-aggressive, and according to the degree of aggressiveness shown. Only the aggressive responses were reported. The authors found that both the frequency of the aggressive responses and the degree of aggressiveness were a direct function of the degree of aggressiveness with which the attack had been made. They pointed out the similarity between the findings of their paper-and-pencil study and a laboratory study by McClelland and Apicella (1945) in which the strength of aggression seemed to depend on the degree of blocking. That is, the number of aggressive responses increased significantly when the examiner during a frustration procedure increased the intensity of derogatory remarks made to the subject.

With quite a different medium Child, Potter, and Levine (1946) studied stories in children's textbooks in relation to personality development. They reported that the treatment of dominant behavior was such as to teach children that in order to influence the behavior of those around him it is more useful to be helpful than to be aggressive. This would be the growth circle kind of relating. But in situations of aggression the stories in these books did not teach the integrative, problem-solving relationships. The teaching was more at the level of ambiguous, ambivalent, indecisive relations or evasions of the problem.

An extensive series of investigations of the effects of parental behavior on the social development of children has combined the Fels Parent Behavior Rating Scales (Champney, 1941*a*, 1941*b*) and a rating scale of children's actual behavior as observed in the nursery school or school situation (Baldwin, 1946, 1947, 1948, 1949). By a "syndrome analysis" of the behavior rating scales, three fundamental and several minor syndromes of parental behavior were revealed by Baldwin, Kalhorn, and Breese (1945). The three most important syndromes were democracy, indulgence, and acceptance.

Baldwin (1949) reported that democracy in the home was by far the most important of the three factors in accounting for the variability of the nursery school behavior. The variables reflected three sorts of consequences of democracy: (1) higher rating on active, socially outgoing behavior, "the hostile and domineering kinds of activity as well as the friendly kinds"; (2) children in a favored position in their groups, "aggression and bossing are on the whole successful, and they are not likely to have inferior status in the group"; (3) high rating on activities demanding intellectual curiosity, originality, constructiveness. These findings, except for the high rating on hostile and domineering be-

havior and successful bossing, are consistent with the expectations of the outcome of a democratic or socially integrative home atmosphere. If one assumes, as we do, that spontaneity is innate, while harmony must be learned, this inconsistency can be accounted for by a "time lag" in learning to behave harmoniously. In fact, Baldwin, Kalhorn, and Breese (1945) found that the children from democratic homes had actually made up for the time lag:

> By the time the child from the *democratic* home has become of school age his social development has progressed markedly. He is popular and a leader, not so much because he is aggressive and dominant as because he is bright enough to have ideas and is friendly and good natured. Throughout all of his development the child from the *democratic* home seems emotionally secure, serene, and unexcitable. He has a close attachment to his parents and is able to adjust well to his teacher [p. 69].

The effects of indulgence were found to be generally opposite to those of democracy, and the children from the rejecting homes appeared to demonstrate the expected outcomes of the vicious circle relationships.

> The actively and repressively rejected children are marked throughout their development by a highly emotional non-conformist attitude. They rebel against the pressures and restrictions of their environment. Intellectually they are average but their use of their intellectual abilities is below par in terms of originality and creativity [p. 70].

Baldwin, Kalhorn, and Breese (1949) produced a detailed manual for the use of the Fels Parent Behavior Rating Scales, together with data on the reliability of the scale when used by trained raters. Roff (1949) published a factorial study of the intercorrelations of the thirty original rating variables from which he extracted seven factors.

Other Applications of the Concept of Circular Behavior. In the psychological literature one finds other references—rather casual references, for the most part—to circular behavior as such, again with more examples of the vicious circle. Writers have referred to the circular nature of punishment: that it tends to incite resistance or rebellion, or to drive the child into a still lower level of behavior. Healy (1925) noted this in delinquency. Discussing the psychology of the situation he mentioned as an extraordinarily serviceable concept concerning delinquency and delinquents: "*Circular response:* what the delinquent does to society when society does things to him, and, after that, what society does in return, and how he 'gets back' at it" (p. 52).

Referring to punishment, Lewin (1935) said that punishment necessarily created a situation which is an expression of domination inciting resistance. "Thus the threat of punishment creates necessarily a situation in which child and adult stand over against each other as enemies" (p. 142).

That punishment as a form of domination defeats one's purposes with both mice and men is also supported by Maier's (1949) research. If growth, learning, differentiation, integration, invention, problem-solving, or constructive and cooperative behavior are desirable objectives, then domination produces something decidedly less than growth at its optimum. From Maier:

> Constructive and cooperative behavior is characteristic of the individual in a motivated state. This behavior disappears under frustration, a condition in which the individual is likely to become a target for punishment. If it is true that punishment increases frustration, society finds itself in

> the position of punishing individuals who have the least chance of benefiting from it; instead, the very condition that should be corrected is aggravated [p. 204].

One must be cautious in generalizing for the behavior of humans from experiments with animals. Nevertheless, in connection with a concept of "pressure of the environment," of domination, and of the numerous instances from the studies above where teachers were found by the use of domination to be "defeating their own purposes," it is not amiss to cite an experimental investigation of punishment by Estes (1944). At the conclusion of his study, in which he used albino rats, Estes discussed "Punishment in the Practical Control of Behavior."

> Probably the most important practical implication of the present study is the demonstration that a response cannot be eliminated from an organism's repertoire more rapidly with the aid of punishment than without it. In fact, severe punishment may have precisely the opposite effect. A response can be permanently weakened only by a sufficient number of unreinforced elicitations and this process of extinction cannot proceed while a response is suppressed as a result of punishment. The punished response continues to exist in the organ's repertoire with most of its original latent strength. While it is suppressed, the response is not only protected from extinction, but it also may become a source of conflict [p. 37].

Dollard, Doob, Miller, Mowrer, and Sears, and their collaborators (1939) rejected Freud's death-instinct hypothesis that aggression is the expression of the death instinct directed outward and stated: "The basic hypothesis which has been presented is that aggression is always a consequence of frustration" (p. 27). While the experiments were made largely with adults, subsequent work has shown their basic hypothesis equally applicable to children. That this hypothesis was not an old fashioned stimulus-response concept but a dynamic concept of circular behavior was specifically stated: "Obviously this vicious circle—frustration, aggression, interference with aggression, more frustration—tends to be repeated as long as successive acts of aggression suffer interference" (p. 40). For these writers, too, the tendency toward aggression besides being expressed in overt behavior might take several forms such as displacement, or aggression toward "innocent bystanders." Other factors, which they discussed, need to be taken into account such as the strength of aggression, the amount of frustration, whether aggression is directed at the object of the frustration or at others, whether it is vigorous and undisguised or subtle and roundabout It is not clear that catharsis or tension reduction through aggression constitutes a cutting of the vicious circle, or, as Maier and others might put it, freeing the person from his domination-induced fixation.

Mowrer and Kluckhohn (1944) have since used the concept of domination inciting domination and have called it a vicious circle even when the response represents a displacement on a succeeding generation:

> But because of the harshness with which their own infantile tendencies were subdued, many adults in our culture feel impelled to be equally harsh with their children. . . . Acts which are only a phase of the infant's development and merely part of their exploration of reality are damned as "naughty" and treated as if they were manifestations of innate depravity which must be eliminated at once. A vicious circle is thus set up [p. 93].

Jackson and Todd (1948) used the term "vicious circle" precisely as it has been used above. They even have a chapter entitled "Breaking the Vicious Circle," from which the following quotation is taken:

The child's conflicts, unhappiness, and neurotic attitudes provoke negative, intolerant, or anxious reactions on the part of his immediate environment, with repercussions on a wider scale, spreading in concentric circles as the child becomes older and forms contacts with larger groups of individuals. Early in the process a vicious circle is formed: certain attitudes on the part of the child's environment become established which lead to the aggravation of the child's symptoms, and are, of course, confirmed by this turn of events. The more "difficult" the child grows, the greater becomes the pressure of the environment, and the fewer the prospects of modification in the desired direction. The task of the therapist is to break this vicious circle by producing a change in attitude, first in the child, and then through the child in the parent, or whenever possible, by more direct means, in the parents themselves. Once this has been done, a way is open to possibilities of further development and creative adjustment, until finally a "virtuous" circle has been established and a hopeful, positive atmosphere replaces the former atmosphere of hopeless resignation or of sullen revolt [p. 381].

Newcomb (1950) used the concept of the vicious circle under the heading "Toward the Reduction of Hostility."

> To those interested in the reduction of hostility and conflict among groups, many passages in this chapter may have seemed rather discouraging. We have pointed to circular relationships and vicious circles which may seem to suggest that a relationship of conflict, once begun between two groups, can proceed only from bad to worse. Such, however, is not the fact. There is nothing fatalistic or inevitable about the processes by which hostile attitudes are so often expressed. Such circular processes are not necessarily irreversible. There are forms of interaction which reduce the feeling that an outgroup represents a shared threat, as well as those which increase it [p. 604].

Then, without mentioning specifically that cutting the vicious circle is itself a circular process in the direction of social integration, Newcomb explained what he meant by the phrase "going to the roots of the matter" under the topics: "Reducing Personal Susceptibility to Threat Orientation," "Reducing Barriers to Communication," and "Changing Group Norms through Joint Participation." These activities are in the direction of greater communication, greater understanding, and working together in a newly discovered common purpose.

> To the degree that people become involved in some shared interest or in the solution to some common problem, they are perceiving not only the objects of common interest but *also one another* in a common frame of reference. And if this occurs among members of the groups prejudiced against each other, the previous divergent norms which each had attributed to the other tend to give way to the shared norms demanded by the common activity . . . The one essential condition for this kind of interaction, according to present evidence, is sufficient concern over some common problem among some members of both groups to result in joint participation among them [pp. 614–615].

A point of view expressing somewhat more optimism and confidence in the social value of circular behavior is found in Bowlby (1949). Bowlby discussed the use of the concept of circular behavior in psychiatric and analytic child guidance, extended the principle to family interaction, and, consistent with Bion (1948), Bion and Rickman (1943), and Jaques (1947, 1948, 1950), to interaction in group relations and group psychotherapy in industry: "The vicious circle may be broken at any point, the virtuous circle may be promoted at any point." Jaques called the process "social therapy." Social development has been

extended to the community and to industry, and society is now becoming the patient.

A chief ill of society, according to Fromm (1947), continues to be a pervading authoritarianism. But Fromm, too, had an optimistic perspective in which civilization has a chance of saving itself:

> Just as the person who has become sterile and destructive is increasingly paralyzed and caught, as it were, in a *vicious circle*, a person who is aware of his own powers and uses them productively gains in strength, faith, and happiness, and is less and less in danger of being alienated from himself; he has created, as we might say, a "virtuous circle." The experience of joy and happiness is not only, as we have shown, the *result* of productive living but also its *stimulus* [p. 230].

Frank (1951) has reminded us again that we do not even have a language to communicate to each other our ideas about the dynamics of human interacting. Frank sees circular behavior as a positive process of growth through the confronting, communicating, interweaving of differences:

> We need a conception of *trans-actions* which are dynamic circular processes occurring in a field [p. 508].
>
> Today we are beginning to formulate a dynamic conception of organization which, as in embryology, is in terms of field theory. In field theory what we call "parts" are not to be conceived as separate, independent, randomly self-acting entities. The "parts" are what we have selected for observation within a dynamic organized complex; these so-called "parts" are continually acting, reacting, interacting, *transacting*, by a reciprocal circular process as shown in organic functioning. By their dynamic, circular activity the "parts" create and maintain the "whole" which reciprocally organizes and governs the activities of the "parts" and thereby gives rise to that organized "whole," with its dynamic circular relations to the environing field. This dynamic circular activity of "parts-whole" in a field is what we call "organization," which is not an entity or a superior power or force or something imposed upon parts in a dominance-submission relationship, but what arises from this circular process of the "whole" and its "parts."
>
> We cannot pick out one of these "parts" in an organized "whole" and endow it with causal potency as a self-acting agent, forgetting that this "part" and its activity is significant only as a participant in the "whole" which patterns its activity. Thus, in the living organism, every cell, tissue, and organ is engaged in a continuous process of functioning that creates and maintains the intact organism which, in turn, governs what each cell, tissue, and organ does in its specialized functioning, to maintain the living organism as a self-repairing, self-regulating organism [pp. 509–510].
>
> This circular process, of putting the meaning, the stimulus value if you wish, into situations, into people, and then responding to them in terms of what they mean to that individual, does not involve any mysterious subjective entities or psychic operations. It appears as an extension, a refinement, of the basic processes that have been operating for ages but have reached in man a greater complexity and sensitivity not otherwise observable and operate as highly idiomatic processes [p. 513].

Socially Integrative Behavior

The studies involving socially integrative behavior reported above have been cited for their bearing on the circularity of interaction in the direction of growth. There are other studies which bear on socially integrative behavior, the highest level of social development. Because of their methods or the scope of the specific problem they may contribute less directly to an understanding of circular behavior. Still other publications are attempts to define

or refine hypotheses or inferences concerning social development.

Infancy. Many researches have been made in an effort to show the influence of early experiences on later development. On the influence of nursing experience, including breast vs. bottle feeding, length of breast feeding, self-demand vs. scheduled feeding, and weaning, studies have been reported by Levy (1939, 1943), Rogerson and Rogerson (1939), Peterson and Spano (1941), Escalona (1945), Trainham (1945), Aldrich (1947), Kluckhohn (1947), Leighton and Kluckhohn (1947), Moloney (1947), and Klatskin (1952).

Studies of thumb and finger sucking have been reported by Levy (1928, 1934, 1937), Roberts (1944), Davis and Havighurst (1946), Simsarian (1947), and Klackenberg (1949).

Ribble (1938, 1939, 1941, 1943, 1944), Goldfarb (1944, 1945), Spitz and Wolf (1946), and Fischer (1952) have given emphasis to the importance of "mothering." Pinneau (1950), in a special review of Ribble's publications, reported insufficient evidence to support her contentions.

Sphincter control has been a subject of interest to Gorer (1943) and Fries (1946).

Restraint of motion has been studied experimentally by Dennis (1938, 1940) and discussed by Levy (1944) and Greenacre (1944), who have also given summaries of the literature.

Vincent (1951) in a bibliographical survey reported a trend away from dogmatism in infant-care ideas concerning the breast vs. artificial feeding controversy and infant-care disciplines. Senn (1947) edited the proceedings of a conference on the problems of early infancy. The World Federation for Mental Health held a conference on "Mental Health and Infant Behavior" at Chichester, England, reported briefly by Staniland (1952); a fuller report was announced for later publication.

Material from child development and animal studies relating early experience to mental health is found in conference proceedings edited by Scott (1951). Ross (1951) made a study of sucking deprivation in puppies and confirmed the earlier study by Levy (1934). Social behavior in animal infancy has been reviewed by Cruikshank in Chapter 3.

The research and theorizing on the importance of infancy have been critically examined in a scholarly review by Orlansky (1949), whose definite, if negative, conclusions in regard to the effect of certain features of infant care upon personality represent a perceptible trend:

> We conclude that the rigidity of character structuring during the first year or two of life has been exaggerated by many authorities, and that the events of childhood and later years are of importance in reinforcing or changing the character structure tentatively formed during infancy. Or one may substitute Horney's (1939, p. 152) formulation: ". . . the sum total of childhood experiences brings about a certain character structure, or rather starts its development. With some persons this development essentially stops at the age of five. With some it stops in adolescence, with others around thirty, with a few it goes on until old age."
>
> In short, it is contended that personality is not the resultant of instinctual infantile libidinal drives mechanically channeled by parental disciplines, but rather that it is a dynamic product of the interaction of a unique organism undergoing maturation and a unique physical and social environment. This view is in substantial agreement with the position which Horney (1939, p. 70) and Fromm (1941, p. 286), among others, have advocated [p. 39].

Emotional Behavior. Since emotional development is reviewed by Jersild in Chapter 14, only a word will be mentioned

here concerning its relation to social development.

It is no accident nor oversight that psychologists have failed to report any "neutral" emotional experiences. Emotions have been no "fence straddling" experiences so far as the psychological and organic "welfare" of the individual is concerned: they have been either highly organized, top-level growth experiences, or they have been highly disorganized, disrupting experiences. As we have repeatedly remarked, because of the ease with which one observes calamity in nature and the difficulty in perceiving concord, most of the psychological writings on emotions have dealt with disorganizing experiences.

Bridges (1931) divided the emotions genetically into *delight* and *distress*. Similarly, Thompson (1952) twenty years later discussed "two quite different types of emotional behavior: the *pleasant*, or *integrative*, and the *unpleasant*, or *disintegrative*" (p. 288). Leeper (1948) has outlined a motivational theory of emotions to replace emotion as disorganized response.

It is to be noted that the distinction between *delight* and *distress*, *pleasant* and *unpleasant*, *integrative* and *disintegrative* is made precisely at the division on the diagram in Figure 6 between the *growth circle* and the *vicious circle*, and between *socially integrative behavior* and *resistance to domination*. This is the limen where interpersonal conflict becomes meaningful. The consistency which psychologists have shown in these distinctions is a further validation of the arrangement of levels of human interacting shown in Figure 6.

The integrative emotions represent a high level of *working with* the environment in a common purpose, high communication, high security, high spontaneity, high acceptance, high sense of achievement, satisfaction and happiness, high productivity, or approximations of these levels.

Thus, for example, studies in sympathy (Murphy, 1937) and efforts to describe, identify, or measure empathy (Dymond, 1948, 1949, 1950; Cottrell and Dymond, 1950; Kerr and Speroff, 1951; Speroff, 1953) would be classified as studies in psychologically integrative emotions. Hastorf and Bender (1952) have added a word of caution concerning the attempt to measure empathic ability.

Love, in its broadest sense, is not different from socially integrative behavior. It is that socially integrative relationship that has the greatest acceptance, communication, understanding, harmony, interaction, creativity, and the *least* degree of psychological entropy, the *least* degradation of energy. Defined in this way, love of mankind should pervade the earth like the air we breathe,—perhaps *could* pervade the earth in this way. If it did, there would be so much understanding as not to admit a need for special inquiry or interpretation of human behavior by psychologists.

In the past 50 years, however, although much has been written about psychological rejection, no one has prepared a bibliography of studies on "wanted babies." Psychologists have reified the negative. Problem-solving is a "substitute" for anger, and bibliographers are intrigued by "anaclitic depression." Instead of hate being the incapacity to love, love is the absence of hate. In Old Testament theology it was the devil against the angels; in orthodox Freudian theory it is "Love vs. Hate." Love, organization, communication, integration are basic in nature, and everything else, including hate, anger, and the other forms of disorganized interrelating are lesser levels of interaction. In war, conflict, strife, anger, and hate "nobody wins." In love and integrative relating nobody loses.

Popularity, Friendships, and Choice of Companions. Studies of popularity, friend-

ship, and choice of companions represent positive approaches to the study of integrative, harmonious relating. Low scores in these studies usually represent lower spontaneity, lower social communication, lower understanding, lower productivity, lower interacting.

Wellman (1926) made one of the earlier studies of children's choice of companions. Other investigations such as Green's (1933) had the negative approach in a study of quarrels as well as in the study of friendships. Koch (1933) used a paired comparison method to determine degree of acceptability or popularity of preschool children Lippitt (1941), using methods similar to those of Koch, obtained comparable findings. Social compliance and quick adaptation to the nursery school procedures seemed most highly related to judgments of popularity. These results were confirmed by Northway (1943), which probably indicates a stereotype in nursery school "culture" as much as a constancy in children as such.

Bonney (1943, 1944, 1946, 1947) has used sociometric techniques to discover the socially successful child, his social acceptability, and popularity. Other studies have been reported on friendship fluctuations and social status by Horrocks and Thompson (1946), Thompson and Horrocks (1947), Austin and Thompson (1948), and Horrocks and Buker (1951).

Frenkel-Brunswik and Potashin (1944) reviewed sociometric and pre-sociometric (pre-Moreno, 1934) literature on friendship and social acceptance among children. They presented a bibliography of fifty items on interpersonal relations among children.

Friendliness, Cooperation, and Integrative Behavior. Although psychologists and teachers have shown low reliability and low validity in observing or rating the positive, constructive interactions, kindergarten children, according to Hanfmann (1935), had no difficulty in either their perceptions or their preferences. When asked by the teacher with whom they liked best to play, they were able to distinguish the *objective leader* and the *social leader,* and eight of ten children expressed their preferences for these two "leaders" from the two who dominated them by destructiveness and social isolation. Eight of the ten children expressed their preferences for the two children whose behavior was described by Hanfmann as "taking turns," "joint enterprise," "skill in social relationships," "joint play."

Another comparison between adults and children needs further study. Teachers in the ordinary classroom situation in kindergarten and the elementary school grades were consistently more dominative than integrative in studies by H. H. Anderson (1939, 1946*c*), H. M. Brewer and H. H. Anderson (1945), J. E. Brewer (1946), Reed (1946), and H. H. Anderson and J. E. Brewer (1946). Clifton (1943) found some exceptions in second grade teachers. Research workers have not found comparable integration-domination or friendliness-unfriendliness ratios in the free play of children. Children are more friendly than unfriendly by our current measures. Mengert (1931), H. H. Anderson (1937*a*, 1937*b*, 1939), McFarland (1938), Jersild and Fite (1939) found children definitely higher in integration and friendliness and lower in domination and unfriendliness. Jersild (1947) called attention to this relative incidence of hostile and friendly forms of behavior in children's social relationships. He cited unpublished findings of observations by McKinnon (1940) which showed that for children in a relatively free play school situation friendly comments and contacts outnumbered hostile criticisms and

unfriendly contacts in the ratio of about three to one.

Other investigations in which an interest is shown in integrative behavior are illustrated by studies of leadership (Parten, 1932, 1933), altruism (Turner, 1948), the studies mentioned above on democratic climates in homes (Baldwin, Kalhorn, and Breese, 1945, 1949; Baldwin, 1949) and in experimental groups (Lewin, Lippitt, and White, 1939).

Leadership. Leadership is properly a concept that belongs with socially integrative, productive, harmonious human relationships. There is confusion in the definitions of leadership. It would seem that there should be a difference between a person who can elicit the voluntary cooperation of others at a high level of performance and the person who by force or threat or by other means of degradation of psychological energy secures conformity. The concept of leadership would be much simplified and the studies would be more comparable with each other if domination or psychological entropy were eliminated from the qualities of leadership.

Responsibility. Discussing social responsibility as a goal of psychotherapy, Anderson (1946*d*) pointed out that there are two criteria for responsible behavior: spontaneity and harmony, which are the two criteria for growth. Responsibility which is spontaneous from within is often confused with a concept of legal liability which is enforced from without. In responsibility the person himself discovers or helps to define what it takes to live in harmony with others. Responsible behavior is of the very essence of *social learning.* Liability, on the the other hand, covers the behavior of the person for whom harmony in human relations has no meaning. Legal liability is a defined minimum framework of relating within which society has agreed to live harmoniously.

The Vineland Social Maturity Scale (Doll, 1936, 1940) is an instrument designed to assess the child's development in social responsibility for certain developmental tasks which involve others and for regulating the satisfaction of his needs in a way that is harmonious with those about him.

Gough, McClosky, and Meehl (1952) have constructed a personality scale for social responsibility. In their working definition they have included by implication the criteria of both spontaneity and harmony. Responsibility for them is behavior or relating that would be classified as highly integrative.

Social Learning

Since there is a chapter on learning (Munn, Chapter 7), the reader is referred there for general references to learning theory and to such specific application of it as can be made to the life and growth of the child, including his social development. Only brief mention will be made here to a few studies whose findings have some bearing on social learning.

We have said above that responsible behavior is of the very essence of social learning. This follows from the assumption that in personality growth spontaneity is innate while harmony must be learned.

We have discussed a view widely held that the individual cannot be separated from his environment. It is this dynamic process of interacting between the person and his environment that is social learning. Social learning is therefore a function of the environment as well as of the person. The characteristics of the "democratic" home atmospheres reported by Baldwin, Kalhorn, and Breese (1945) and by Baldwin (1949) and the characteristics of certain schoolrooms found by J. E. Brewer (1946) and Reed (1946) represent situa-

tions in which the environment facilitated social learning. The various measures of the behavior of the children from these respective home and school situations confirmed the assumption. In a general way these studies have shown situations in which the demands of the environment were reasonably satisfactorily tempered to the needs and capacities of the child. Demands of the environment, school or home routines, were explained and made meaningful in a way that inspired mutual confidence and general working together for common purposes.

Research in an orphanage (H. H. Anderson, 1937*b*), reported above (also pages 1190–1192), has further bearing on social learning. In the fall of 1934 an experimental nursery school was established in an orphanage. Children were matched for certain criteria and placed in a nursery school and a control group. The control group children continued to spend all day in the cottages, their activities for the most part consisting in sitting on chairs in a circle in the living room "being good." The nursery school children, on the other hand, left the cottages during the day, had plenty of play materials, and were in charge of trained nursery school teachers who encouraged the children to play. After 8 months the two groups of children were observed for dominative and integrative social contacts. No significant differences between groups in integrative contacts were found. In dominative behavior, however, the orphanage nursery school children used significantly more dominative contacts than the control children. How could one explain the findings that nursery school children were more dominating than matched non-nursery school children?

The explanation given was not that the children had "poor" teachers or that the nursery school was a "bad" influence on the children. The explanation was that in total social contacts there was more interaction among the children who had gone 8 months to nursery school than among those who had remained in the cottages all day. The hypothesis was that spontaneity is a "good" thing even if it is expressed in "misbehavior."

If harmony with others must be learned then it seems that children who have been greatly dominated and who are then transferred to a less dominating environment, move up through the levels of relating, illustrated in Figure 6, as a *process of social learning.*

The orphanage nursery school children started at a very low level of spontaneity; they had been very much dominated, and they were tractable and submissive.

The teachers reported that for weeks the nursery school children came each day and simply sat and stared as though they did not believe they *could* play with the toys. After several months the teachers noticed a change. A child would come to the teacher, point to anything, a doorknob, or the plaster wall, and say: "Tell me a story about that." After 8 months in the nursery school the children were found to be more aggressive in a dominating way than their paired companions. The interpretation offered now is that the nursery school children moved from a level of social atrophy and submission, through a process of relating in which they were confused, anxious, indecisive,—where they were not oppressed, but where they behaved as though they did not understand the nature or degree of threat, the balance of *power over* them. As their perceptions increased they became more communicative; their own powers and energies were released, and they became more spontaneous. But they had not had sufficient opportunity (time, experience) to develop perceptual readiness for social learning.

Similar findings have been reported by Lewin, Lippitt, and White (1939). They found a bi-modal distribution of aggression in autocratic groups and asked: "Why is the reaction to autocracy sometimes very aggressive, with much rebellion or persecution of scapegoats and sometimes very non-aggressive?" They offered evidence that both the aggressive and the non-aggressive boys were frustrated.

In terms of the levels of dynamic interplay diagrammed above in Figure 6, the highly aggressive behavior was at the level of "Resistance," the vicious circle. The non-aggressive boys were under stronger domination, greater threat, and were behaving as one would expect at the level of "Balance of Power," or at the still lower level of "Submission."

When these boys were transferred from a highly autocratic group (say, level of "submission") to a democratic group, what happened?

If they behaved like the orphanage nursery school children who were transferred from a highly rejecting to a highly accepting environment, they would show after transfer more spontaneity; they would give some symptoms of anxiety; or their greater spontaneity would take the form of aggression, hostility, disturbance of others.

Lewin, Lippitt, and White reported that there were first of all sudden outbursts of aggression which occurred on the days of transition from a repressed, autocratic atmosphere to a much freer atmosphere of democracy or laissez-faire.

> The boys behaved just as if they had previously been in a state of bottled-up tension, which could not show itself overtly as long as the repressive influence of the autocrat was felt but which burst out unmistakably when that pressure was removed [p. 283].

Baldwin (1949) and Baldwin, Kalhorn, and Breese (1945) found that nursery school children from democratic homes showed the behavior expected at the integrative level, except that they showed hostile and domineering activity as well as the friendly kinds. Is this inconsistency to be explained by unknown environmental circumstances which activate a vicious circle, or as possibly a "time lag" in social learning? By the time that the children were of school age, they had apparently made up the time lag, as quoted previously in this chapter.

Chittenden (1942) undertook to give social training to the most dominative children in a nursery school. Her program was designed to decrease domination and to increase problem-solving and cooperation in social conflicts. On retests after the training program the children showed a significant decrease in dominative behavior although their increase in cooperative behavior was not statistically significant. To the extent of the reduction of dominative behavior, the children were giving significantly fewer reinforcements to the operation of the vicious circle in their interacting with their friends. This may not be a cutting of the vicious circle, but it is a slowing up of the action in the use of *power against* others.

Muste and Sharpe (1947) regarded social learning in small children from a point of view similar to that of teachers who speak of "reading readiness" and similar to that of Tolman (1949) who has spoken of "perceptual readiness" in the learning of animals and in human social learning. Writing on the significance of trends of aggressive behavior with relation to age, Muste and Sharpe said:

> The younger children within the nursery school age range tend to have only brief

contacts with other children, to spend much time in parallel play, and to direct many of their social responses toward adults. Because they are so involved with the interest in sensory experience and independent investigation, there are fewer opportunities for aggressive behavior. As children grow older their exploration is increasingly in the social field. They spend more time in social interchange and their contacts with others are more complex. With the increased vitality of social interchange there is an increase in the frequency of aggression [p. 16].

. . . Many of the aggressive incidents of these young children seem not to have the quality of deliberate attacks upon others. The young child is not able to perceive a situation except from his own point of view and his behavior is initiated by drives toward his own ends He has his own objectives in mind and seeks to fulfill his own desires or interests, taking no heed of the objectives of others. The inhibition of activities for the satisfaction of one's own need because they may mean discomfort for others requires a higher level of social consciousness and a greater ability to project one's thinking beyond the boundaries of self than many of them have attained The two children who had the lowest aggression scores also had the lowest scores in social participation [p. 17].

Psychotherapy and Levels of Interacting

There are many different ways of stating the goals of therapy. Our purpose here is merely to indicate the relation of therapy to the levels of human interacting shown above in Figure 6.

A person whose behavior and whose relations with his environment would classify him at the socially integrative level in Figure 6 has no need for a therapist. He already finds life stimulating and satisfying. He is accepted by others, he can "be himself." He is flexible, not rigid. He can learn by new experience. He is free to change. He has a minimum of repressed experiences and lives largely at a conscious level. He occasionally experiences the joy of discovery. His emotions tend to be more on the positive side. Not being threatened or "rejected," he has little use for defense mechanisms His perceptions, undistorted by personal fears and anxieties, are highly valid. He lives at a high reality level. It must be remembered that all things are relative, that there is no perfection under Heaven except by definition, and that a given person can only approximate the conditions listed above. Persons who approximate even some of these conditions do not need or seek a therapist. It is, in fact, the goal of therapy to achieve these relationships.

Persons who do need a therapist are found in one or the other of the lower growth levels which are grouped under "Interpersonal conflict" in Figure 6. Those who live at the level of "Resistance to domination" still have sufficient spontaneity to be hostile and aggressive. Occasionally one has sufficient spontaneity to seek a therapist. Persons in the lowest level of growth in Figure 6 usually do not seek therapy but are brought by someone else.

In one sense, the task of the therapist is to take a patient at whatever growth level he happens to find him and help the patient move up into a higher level. To do this is therapy. The ultimate goal is to attain the socially integrative relationship. But therapy can be good therapy and still fall short of that goal.

In another sense, it is the task of the therapist to help the patient increase the validity of his perceptions and thus improve his insight. This could be another way of saying that the patient moves from

a lower growth level to a higher level. There is some evidence to justify the hypothesis, at least for functional disorders, that the validity of perception is inversely related to the strength of environmental domination. The validity of perception and the quality of insight decrease as psychological entropy increases. Therapy moves the patient away from the state of low interaction into a situation of high negative entropy.

As there are many ways to express the goals of therapy, there are many ways of attaining the same goal. This is consistent with von Bertalanffy's (1950) concept of *equifinality*. As mentioned above, von Bertalanffy has pointed out that in most physical systems the final state of a process is determined by the initial conditions. Growth on the contrary, he said, is equifinal: it is independent of the initial conditions. In this hypothesis of the equifinality of growth lies the hope of the therapist: that therapy can be a speeded-up growth process, and that the client can make up for lost time.

There is some evidence to show that, consistent with the equifinality of growth, a patient starting at the lowest level of growth tends to move through the successive levels of interrelating and into hostility and aggression before he can attain the upper levels of harmony. A plausible explanation for this is that while spontaneity is innate and can only be suppressed or facilitated, harmony must be learned. A person under heavy environmental domination who has submitted to the domination is low in spontaneity. As the therapist helps the patient to become released from his present or past domination (his neurosis or his fixation), the new and growing spontaneity takes the form of behavior apparently without regard for other persons. The patient has up to this moment depended on someone else to make decisions and to do his social thinking for him. He has not *learned* to evaluate by himself the desires and purposes of others.

More important, he has not learned the meaning of the vicious circle which his own new spontaneous behavior can set up. He has not learned that his new spontaneity will meet resistance to the extent that it is out of harmony with others. Patients in therapy often seem to increase in confusion and in causing trouble to others before they can learn how to act spontaneously and at the same time harmoniously.

It is not sufficient to say that therapy is a cutting of the vicious circle. This is a negative statement. Therapy is a positive process; it is a growth process, social development.

Beyond the release of energy in spontaneity, therapy is a process of social learning in an environment propitious for optimum growth. Conflict, by definition, is disintegrating. Therapy is a restoration of integrative processes.

Commenting on a forthcoming volume French (1952) said:

> In a psychoanalytic treatment we try to help a patient find solutions for unresolved conflicts. By studying this process we hope to get a more vivid picture, not only of the disintegrating effect of conflict, but also of the process of restoration of a more normal integrative pattern under favoring circumstances [p. 240].

A Broadening Concept of Social Responsibility and Social Development

Several other kinds of studies are emerging. Barker and Wright (1949, 1951) and Barker, Wright, Nall, and Schoggen (1950) have reported studies of psychological ecology and the problem of psychosocial development. A community approach by an

interdisciplinary team studying the *constructive* elements in the community has been described by Bronfenbrenner and Devereux (1952). Projects in which a community or an industrial group studies its own problems and, through group participation, plans action in developing answers represent an enlarging scope of the concepts of social development and social responsibility. Examples of such studies are those reported by Bion and Rickman (1943), Bion (1948), Bowlby (1949), Lippitt (1949), and Jaques (1950). Follett (1922, 1924) presented the theoretical structure and suggestions for a plan of action for such positive approaches to creative, inventive problem-solving in industrial and international relations.
