This book is not to be sold outside
the country to which it is consigned
by Wiley Eastern Private Limited.
Sales Area : India, Pakistan, Ceylon and Burma

This book has been published with the assistance of the Joint Indian-American Textbook Program.

Price Rs. 22.50
Price of Original Edition $ 14.95

Published by Anand R. Kundaji for Wiley Eastern Private Limited, J 41 South Extension 1, New Delhi 3 and printed by Sudhir Balsaver at Usha Printers, 6 Tulloch Road, Bombay 1. Printed in India

PREFACE

It has been said that a most serious need of modern psychology is for advanced scientific manuals to bridge the gap between the excellent and varied elementary textbooks in this field and the scientific periodical literature of psychology. This manual is an advanced-level textbook and is intended to be an addition at just this level to the literature of general as well as child psychology. The book is presented as a series of separate chapters, each written by a recognized authority. Its purpose is to provide an accurate and coherent picture of some of the most important aspects of research in the scientific psychology of human development.

Until comparatively recent years most of those who wrote upon the development of individual mental life elaborated essentially speculative theories. They attempted to describe man's so-called inborn instincts or the allegedly *tabula rasa* character of the mind of the young child. The present book is testimony that today psychologists and other scientists by the use of appropriate techniques have established a large body of important and reliable facts concerning the details of human mental development. This book is a clear demonstration that the speculative period in child psychology is past.

Many practical as well as theoretical gains have resulted from the empirical study of the growth of the human mind. It will be clear to the reader of these chapters that it has been possible to formulate hypotheses concerning many specific aspects of mental development. Many of these hypotheses have been tested in the laboratory or in controlled quantifiable social situations. The conclusions so reached are very different from the vague verbal theories of the prescientific era of child psychology.

One who is interested mainly in securing an understanding of adult mental life can gain many new insights into mental processes in general from a study of these chapters. A knowledge of the way in which adult psychological processes develop in each individual is fundamental to a complete understanding of such characteristics. The manual may thus be considered a factual introduction to the understanding not only of child psychology but also of the psychology of the normal adult human mind and even of the abnormal human mind.

The editor has not attempted any modification of the separate styles or points of view of the individual chapters as they are presented. The chapters appear essentially as their authors prepared them. It is believed that the extensive bibliographical references included will be of real value to advanced students and to research workers.

The authors of all the chapters wrote for serious advanced undergraduate students and graduate students as well as for specialists in psychology and in such related fields as education, psychiatry, pediatrics, and medicine in general.

Both as editor of the manual and as the author of a special chapter, I am indebted to Clark University and to the Clark University Press for their generosity in allowing the reproduction in this book of extensive excerpts and the use of other materials

previously published in the *Handbook of Child Psychology, Revised Edition,* which was issued in 1933 by that press.

Both the *Handbook of Child Psychology* and the *Handbook of Child Psychology, Revised Edition,* were edited by Dr. Carl Murchison. I wish to express here my profound appreciation for the pioneer work done by Dr. Murchison in producing these handbooks and other advanced books in psychology. This manual owes much in spirit and content to the foresight and editorial skill of Dr. Murchison.

The years since the presentation of the first edition of the *Manual of Child Psychology* have produced important work in this scientific field. This development has been more active in certain fields related to the study of the child than in others. In this second edition, therefore, more elaborate changes have been made in some chapters than in others. Chapter 18, "The Psychopathology of Childhood," is new. The chapter entitled "The Adolescent" is the contribution of an author not represented in the first edition. An addendum has been added to Chapter 15, "The Influence of Topological and Vector Psychology upon Current Research in Child Development."

Once again I wish to express my appreciation to the authors who have actively cooperated in writing and revising the chapters as presented here.

The favorable reception that the first edition received not only in America but all over the world is indicative of the growing importance of the study of the phenomena of the growth and development of the child. The translation into French of the entire first edition and its publication by the Presses Universitaires de France is one striking example of the favorable acceptance that has greeted the book.

It is hoped that the present revised edition will be of further value to the student of this fundamental and peculiarly human field.

Chapter 1

METHODS OF CHILD PSYCHOLOGY[1]

John E. Anderson

In child psychology, as in any other science, a distinction can be made between *content,* or the facts and generalizations which are welded into a body of knowledge; *methods,* or the techniques and procedures by means of which such content is obtained; and *theory,* or the framework of assumptions within which the science operates. Content, method, and theory can never be completely separated from one another. In the beginning, little concern with method or theory appears because new methods produce results so rapidly that major interest centers upon content. But as science matures, interest in method and in theory grows.

Just as with the human body, a science is composed of many parts which grow at different rates and mature at different times. When a promising method is discovered, one area spurts forward rapidly and engrosses many workers, while another remains relatively inactive. In general, progress is from description to quantitatively formulated relations, and from exploration to principles that subsume wider and wider ranges of fact. As the significant problems are more clearly perceived, designed experiments replace simple observations. At any time the methods in some areas of a science are still exploratory, whereas in others methods are very advanced and precise. Little is gained by thinking of or calling a particular method right or wrong. Rather should we see how better methods give greater insight and more significant generalizations.

In the nineteenth century, so notable for its advance in all fields of science, some observations upon children were made in systematic fashion. The first approach, the baby biography, involved day-by-day recordings of the experiences and behavior of a single child, usually by an interested scientist, himself a parent or close relative. Often simple experiments and measurements were included. Among the many such biographies available, of major historical importance are those of Tiedemann (1787), Darwin (1877), Preyer (1882), the Sterns (1907, 1909), Shinn (1893, 1899, 1900), and the Scupins (1907). Dennis (1949) has summarized some of the beginnings of child psychology.

The next stride forward came with a new method, the questionnaire. Starting with

[1] Because of the limited space available for the discussion of the methods of child psychology, many topics must be given brief and incomplete treatment. To discuss adequately even one section of method, e.g., sampling or indirect measurement, would take as much space as is allotted for this entire chapter. And since the content chapters which follow will, of necessity, to some extent treat method in their particular areas, this chapter in presenting an extensive overview, rather than an intensive analysis of a limited area, suggests sources from which workers can secure information that will help them in scientific work with children.

Difficulty is also encountered in citation and bibliography. To cite all the studies which contribute to method would fill this entire volume. Hence citations are limited to examples or instances, to summaries that integrate substantial amounts of material, and to major contributions to statistical or research methods. It is assumed that several modern comprehensive statistical textbooks are available to the reader.

Hall's (1891) inquiry into the "The Contents of Children's Minds," a deluge of questionnaires advanced the knowledge of children, especially those of school ages (Bradbury, 1937).

With Bolton (1892) and Gilbert (1894), extensive tests of school children were undertaken. Unfortunately, Gilbert, who studied simple functions, obtained low relations with school progress. Had he happened upon complex functions and thus obtained significant correlations, he might have set off what came twenty years later, when Binet and Simon (1905) forged a new method which not only initiated the measurement of intelligence but also gave impetus to the invention of a wide variety of measurement devices in areas such as achievement and personality. Thorndike (1904, 1913, 1914) led in the use of the new techniques with school children and contributed to method in all areas by his emphasis upon statistics. For Watson (1919) the crucial psychological observations are those made upon children, not adults. By stressing objectivity and dismissing introspection, he made infants and children appropriate subjects for psychological investigation, a point of view not held by many of his predecessors.

Although clinical descriptions of defective, abnormal, and delinquent children appeared in the medical and psychological literature almost from the beginning, it was not until Freud's emphasis upon the principle that neurotic symptoms in the adult are the outcome of childhood experience that past histories were studied extensively in order to explain present behavior.

The Gestalt psychologists by directing attention to the origin and change of configurations with experience made studies of children important. Similarly, a biological or organismic point of view based on embryological studies emphasized the genetic history of both the elements and integrated patterns of behavior.

Many of the older discussions on the appropriateness of children as subjects or the need for a special psychological talent for the interpretation of child behavior are now chiefly of historical interest. Discussions of method in child psychology are found in many sources, among which a few of the more extensive are Koffka (1924), Thomas and Thomas (1928), Goodenough and Anderson (1931), Symonds (1931), Anderson (1931, 1933), Lewin (1935, 1936), Jones and Burks (1936), Bühler (1937), Horowitz and Murphy (1937), Murphy, Murphy, and Newcomb (1937), Arrington (1943), Koch (1948), Orlansky (1949), Cattell (1950), and Thompson (1952).

Periodic summaries in the field appear regularly in the *Annual Review of Psychology*, in the *Journal of the American Educational Research Association*, and occasionally in the *Psychological Bulletin*. From time to time the *Yearbook of the National Society for the Study of Education* (1938, 1939, 1940, 1944, 1946, 1947, 1950) brings much material together upon particular topics. Abstracts of current articles can be found in *Psychological Abstracts* and in *Child Development Abstracts*. *The Encyclopedia of Educational Research*, edited by Monroe (1949), is also a very valuable source book.

With the wealth of material upon developmental changes in the behavior of infants, children, and adolescents, and an increased concern with the rôle of the environment in the time dimension, child psychology is coming into its own. Less and less are college or graduate students in the psychological laboratories looked upon as the representatives of the human species for scientific purposes; more and more their behavior is viewed as a phase in a developmental cycle beginning with conception and ending with death.

Childhood is then only a phase of a more general process of growth and development. In child psychology the same human organism is studied as is studied later in adult psychology. Hence, no methods are peculiar to child psychology as such, or to adult psychology as such; instead there are adaptations of particular methods to particular age levels. For example, some of the earlier experiments on children used techniques which previously had been tried on adults. In more recent years methods originally developed with very young children have been extended to the study of adult social groups. There are some advantages in the study of children, in that many of the relations met at the adult level in a very complex matrix are encountered in children at a simpler level that permits the isolation of factors and location of significant relations with less difficulty.

A half century of research has given us a very different picture of the nature of the child from that held in earlier periods. The following brief summary (Anderson, 1944) outlines the essentials of the modern point of view:

1. The child is a growing organism who moves by infinitesimal changes from a single cell to a complex organization of structure and function at an adult level. In this progression, scientists describe the differentiation of new structures and functions, changes in the size and form of structures, and changes in the level and effectiveness of function. They seek underlying principles that will bring understanding of these changes and practical methods of modifying or improving development and function.

2. The child is a spatially separated unit that functions as an organized whole in the situations he meets. This molar characteristic of behavior needs particular emphasis. In the physical and chemical sciences, units of organization can be broken up into component parts, reassembled, and broken up again. As a result, the laws governing organization can be worked out with such precision and exactness as to give exceptional prediction and control. Since neither the child nor his behavior can be broken up and reassembled in the literal sense, difficulties arise in scientific child study. Both the psychological terms and the measuring devices used to analyze behavior into manipulable symbolic units correspond only to functions of the organism as a whole. Thus, when we speak of memory, learning, or emotion, separate acts are classified in terms of similarity, not necessarily on the basis of intrinsic characteristics. Any act may be classified under many different categories, depending upon our scientific purpose. For example, the same act can be classified as sensing, learning, emotion, or memory. This wholeness or functional unity of the child makes necessary methods that seem devious and indirect to the physical scientist.

3. The child lives in a context, itself neither simple nor unitary, which continuously affects his behavior and development. Patterns of stimulation come to him out of this context. And, in turn, by virtue of his own make-up, he selects from that context. At all times there is a reciprocal relation between the human being and this biosocial context. The context can be considered in terms both of the moment and of factors operating in time. Because the child is limited in time, behavior becomes structured, and patterns develop both in the stimulus field and in his own response system. Some stimulus patterns become significant because they modify the developmental stream by affecting practice or social relations. Others remain insignificant because they do not affect this web of relations. Why one pattern is significant and another is not, is a crucial problem.

4. The child is engaged in an ongoing process of development that is not reversible. Because of the interrelations that accrue, neither relations within the child, those within the context, nor their interaction can be reproduced a second time in their exact original form. Behavior at any moment results from the child's history and the stimulation pres-

ent. Hence, concepts of simple or single causes must be replaced by concepts of multiple factors, reciprocal relations, and the progressive recession of causes and the ongoing cumulation of effects.

The Problems of Child Psychology

In approaching the child, the scientist seeks to formulate principles that will bring understanding of children and the prediction of their behavior under various circumstances, in order to surround them with influences and opportunities for better living. The general principles or statements of the relations that exist between and among various factors are expressed in either verbal or numerical symbols, or both, which function as a kind of shorthand to reduce the complexities of life to simpler and more manipulable terms. Note also that these generalizations exist in some form long after the children studied have ceased to be. The children Binet tested have been adults for many years, and some have passed on. What science leaves behind, then, is not a replica or duplicate of what it originally studied, but a series of statements or principles which more or less adequately represent the relations originally studied and which enable others to manipulate and control environments in the present. But the principles when taken together also make some sort of coherent whole. The generalizations are then modified as more data are accumulated. The interactions and combinations of factors are mapped with some accuracy, even though they are only parts of still more complex manifolds. A science is then, in a sense, a series of symbols that represent what can and cannot be done, like the rules of a game. But we do not know the rules in advance; we have to discover them through experience, not casual experience but systematic experience.

These symbols must be clearly defined in order that different scientists may understand each other. In everyday speech, words are defined in terms of themselves, and they become dangerous when they are extended to areas and events to which they have no real reference. To meet this difficulty the scientist wherever possible anchors his concepts and terms to specific measurements and expresses relations in a quantitative way. In some degree, progress in science is a matter of moving from a language which is largely descriptive to a more precise and quantitative language. The problem of method is the problem of how this more precise language can be obtained. In seeking the rules of the game under which life is lived, the scientist assumes that rules exist and that life is itself orderly and coherent in spite of its superficial inconsistencies. As Wiener (1948, pp. 62–63) has well said,

> For the existence of any science, it is necessary that there exist phenomena which do not stand isolated. In a world ruled by a succession of miracles performed by an irrational God subject to sudden whims, we should be forced to await each new catastrophe in a state of perplexed passiveness. We have a picture of such a world in the croquet game in *Alice in Wonderland;* where the mallets are flamingoes; the balls, hedgehogs, which quietly unroll and go about their own business; the hoops, playing-card soldiers, likewise subject to locomotor initiative of their own; and the rules are the decrees of the testy, unpredictable Queen of Hearts. . . . The essence of an effective rule for a game or a useful law of physics is that it be statable in advance and that it apply to more than one case. Ideally it would represent a property of the system discussed which remains the same under the flux of particular circumstances. In the simplest case, it is a property which is *invariant* to a set of *transformations* to which the system is subject.

The psychologist studying children seeks principles of wide scope which will facilitate the understanding, prediction, and control of behavior. He is concerned with (*a*) the fundamental mechanics and dynamics of the developing person; (*b*) the effects he produces upon the environment; and (*c*) the effects the environment produces upon him. Next, he describes the developmental process itself in terms of common trends by (*d*) a successive cross-section or (*e*) a genetic-longitudinal approach. Finally, he describes individual behavior by (*f*) assessing the person at any level; and by (*g*) obtaining a genetic account of him in his total setting.

The Mechanics and Dynamics of the Organism. In any organization of matter in the world of space and time, science assumes that lawful relations exist which can be determined independently of any particular individual or context; i.e., similar principles can be found which operate in many different individuals and in many different contexts. Knowing such principles we gain control over particulars; without knowing them, behavior appears meaningless. The phenomena and principles underlying Weber's law, the distribution of effort, conditioning, and reinforcement would fall under this head. This is the traditional content of psychology. In this area the designed study or experiment, which isolates or systematically varies factors, is basic.

Understanding and significance increase as (1) factors are permitted to operate within their full range in order to avoid generalizations based on small segments of the relations studied; (2) combinations of factors are studied; (3) attention is given to interlocking principles and their fit into explanatory systems. In child psychology another question arises—that of the extent to which the principles hold in terms of age and development, or the amount and character of the changes which are associated with age.

The Effect of the Organism upon the Environment. At any moment the child is a highly organized energy system within a field of forces known as the environment. As he moves forward in time, his relations within this field and to the external world are determined in part by his own make-up. Children differ widely in intelligence, musical capacity, motor coordination, energy level, etc. If these characteristics, both singly and in combinations, can be measured early in the life of the individual, children of various levels can be separated out and their subsequent history or impact on the environment studied. Although, unfortunately, most early separations have been made on intelligence, there is no reason, other than the availability of appropriate measuring devices, why other separations should not be made. The classical example is found in Terman *et al.* (1925, 1947), who followed gifted children into adult life. Baller's study (1936) of the adult accomplishments of subnormals tested in childhood concerns the opposite end of the scale. Glueck and Glueck (1934, 1937) have studied the later careers of delinquent children. An unusual study of children in the same family fifty years later is presented by Smith (1952). More significant generalizations can be made if the separations are made early and children are followed than if the scientist separates his group on the basis of adult performance and works backward, only to find his results complicated by selective factors that are difficult to interpret. In this approach, the individual becomes the independent variable, and his accomplishment, or the psychological environment he constructs for himself, the dependent variable.

The Effect of the Environment upon the Organism. In educating children content is deliberately introduced into the child's

life in order that he may learn. Similarly scientists deliberately produce conditions in order to discover their effects. Questions arise, such as the more effective methods of teaching reading, how to control temper tantrums, what materials to use in geography, whether motion pictures and visual aids improve learning, and whether early training is more important than late training. Sometimes simple and single factors in the environment are modified; sometimes very complex patterns of stimulation are used. In many instances, parallel groups of children exposed differentially to the factors studied are set up. The single factor with a particular effect is the limiting case at one end, and a total environment with all its effects is the limiting case at the other end. Concern is with all types of combinations of factors and all varieties of complexity. Improved skills in statistical techniques make possible many types of analysis that previously could not be made. In this area generalizations are usually expressed in actuarial terms, with prediction within known limits of error for groups and individuals. In many instances, even though the problems originate at a practical level, important generalizations for the mechanics and dynamics of the organism result.

In the past, many studies in child psychology have worked backward from behavior outcomes to antecedent factors. Thus, the histories and behavior of children already delinquent or nondelinquent, jealous or nonjealous, etc., are compared. Sampling and control are set up in terms of an end result. Many generalizations on the effect of home discipline and management are derived from working backward from problem and normal children to descriptions of the homes and neighborhoods from which they come. But if homes of contrasting disciplinary programs that were equivalent in other respects were chosen in advance, and children's subsequent behavior was measured, more significant results would be obtained. Some scientific information is gained from the backward-working approach, and we use it when information obtained by working forward is not available. Greater progress will come as studies move from context to behavior, not from behavior to context. The environmental factor or context becomes the independent variable and behavior the dependent variable.

Some difficulties arise. Suppose that five contrasting environments in terms of distance from civilization are selected and the children measured (Sherman and Henry, 1933); will equivocal results be obtained? No, because any environment that has existed for a long time has exercised a highly selective influence upon its population.

The child coming into an experiment is a representative of a particular environment or context. The need of controlling socio-economic or cultural status becomes evident as more data on the cultural determiners of psychological processes become available. Anderson (1936), Davis and Dollard (1940), Davis and Havighurst (1947), Centers (1949), Havighurst and Taba (1949), Hollingshead (1949), Stendler (1949), and Warner *et al.* (1949) have published studies which show the significant influence of background factors on the behavior of children. Care must then be taken either to control background factors or to measure their effects.

Normative Cross-Section Approach. Children at various ages, grades, or other levels can be measured, tested, exposed to materials, or placed in comparable situations and observed. When results are analyzed in terms of age or level, two important outcomes appear: (*a*) information on the growth process is secured, and (*b*) norms or standards with which the per-

formance of other children can be compared are obtained.

As the child moves from infancy to adulthood, growth takes place. The adult is essentially at a maintenance level. For practical and theoretical purposes, determining the rate and manner of change with time or level is necessary and important. Much literature in child psychology pictures development, e.g., the many studies of motor, linguistic, intellectual, and social skills. Despite the present concern with longitudinal studies, the cross-section study has particular advantages, since new samples drawn from the population in similar ways at each level cross-check upon the data at other levels. Moreover, uniform sampling procedures can be used throughout the age or level series, a principle that does not hold for longitudinal studies, in which the original sampling is modified by the disappearance of some children from the investigations.

If the results obtained from comparable samples at successive age or other levels are secured, a scale becomes available for the evaluation of individual children. The child's present performance can be compared with those of children at his own or at lower or higher levels, and his developmental position in quantitative terms obtained. A powerful instrument emerges for the practical guidance and assessment of growing persons. For norms to be of maximum usefulness, particular care must be taken to secure adequate samples at each level in order to eliminate distortion arising from lack of representativeness. Terman and Merrill (1937) restandardizing the Binet tests used paternal occupation, geographical location, and rural-urban residence, in addition to sex, to control their samples.

In psychological studies, means and standard deviations are seldom smoothed, in contrast with physical-growth studies, where smoothing is more common. Since the sample at each age level is a new and independent one, smoothing to increase the precision of the norms is justified. Although many norms are based on chronological age, other designations of level can be used. Often combinations, such as sex-age-height for weight or sex-age for motor development, give a much better appraisement of the individual.

Genetic-Longitudinal Approach. Although the results obtained from successive cross-sections are of great value, they give approximations rather than accurate representations of the developmental process (Jones, 1939). For example, because children grow at different rates and reach similar developmental levels at different times, a cross-section study places together at the thirteen-year age level many girls well past puberty and many girls months away from puberty.

Longitudinal studies measure the same children at successive periods (Freeman and Flory, 1937; Dearborn and Rothney, 1941). While means and standard deviations can be obtained at each age level, as in the cross-section study, the longitudinal study, in addition, permits: (1) an analysis of the development and growth of each individual child; (2) a study of growth increments, both for the individual and the group; and (3) an analysis in detail of the interrelations between growth processes, both maturational and experiential, because all data have been obtained on the same children.

But it, too, has some disadvantages. No matter how carefully a sample is selected at the beginning, whatever limits the original sample, which is drawn but once, will affect all subsequent data. In some studies families of stable position in the community, such as home owners, are used; in others, communities known to have little mobility are used. But this may mean a sample

that is not typical from the beginning. Casualties because of death, illness, families moving away, and changes in the cooperation of children and parents with the investigator will further distort the sampling at later ages. The investigator should discard data for the incomplete cases, since their use will not only destroy the advantages gained by the longitudinal method but also may actually distort the results (Anderson and Cohen, 1939).

With longitudinal data, other problems appear. Since a cross-section method lumps all individuals of a particular age level together, irrespective of developmental level, treating longitudinal data as though they were cross-sectional data gives no advantage. Shuttleworth (1939) superimposed the periods of maximal rate of physical growth for early- and late-maturing groups, irrespective of chronological age, and made an analysis by plotting curves. Basic similarities in the growth pattern that were not apparent before this treatment were revealed. Markey's (1928) individual curves for vocabulary growth from the baby biographies differ noticeably from the usual growth curves worked out by cross-section methods. Some evidence is available to the effect that the course of animal learning is predictable when equations are plotted for individuals, not groups. This suggests that some of the statistical methods centering in measures of status, i.e., means, standard deviations, correlation coefficients, etc., which are appropriate for cross-section studies have limited use in longitudinal data, for which treatments concerned with progression, rates, increments, and velocity are more appropriate. Courtis (1950), who has applied the Gompertz curve to cross-section data obtained over a range of ages, feels that even for such data statistical methods for studying growth and prediction can be much improved. Honzik (1938) and Anderson (1939*b*) found that measures of intelligence vary in predicting terminal status as measures are separated in time and as the functions measured overlap.

A method of treating longitudinal data in terms of increments that results in good curves of the growth process involves selecting a point at which the maximum number of cases is available, calculating the mean of the measures at this point, then calculating the mean of the increments (or decrements) to the next level, adding (or subtracting) this mean to the mean at the base level, then calculating the mean of the increment (or decrement) to the next level, and adding (or subtracting) it to the base level mean plus the mean of the previous increment, and so on. Standard deviations can also be combined by appropriate formulae. The use of increments eliminates the variance of the individuals in the base at different age levels (Shuttleworth, 1934).

A summary of some of the interpretations of longitudinal data is found in Olson (1949), who developed a method of representing developmental level in what he calls *organismic age*. This is obtained by combining various measures of development which have been scaled in age terms, such as mental age, dental age, carpal age, weight age, grip age, and reading age. Thus when such measures are available for a given child inadequacies of development can be spotted. This assumes, however, that development in its various phases should be uniform and parallel, which may or may not be true. The combination of various dissimilar measures with differing reliabilities into a single scale with equal weights is open to question.

The design of longitudinal studies is simple, unless a control group runs parallel to the longitudinal group. Many more cases must be studied at the beginning in order to allow for selective elimination. Once the children are selected, emphasis is given to the measures to be used and their arrange-

ment in time. Precision is increased by using fixed intervals for testing. Often these come near the child's birthday. In planning, particular care must be taken to anticipate the early data that will be needed for interpretation of later data. Early records should be extraordinarily complete (Macfarlane, 1938) as, once a study is well under way, it is almost impossible to make up deficiencies.

Included under the longitudinal-genetic approach are a number of methods for studying children. The classical baby biography described the development of a single child. Detailed studies of the successive drawings of the same children over a long span of years have been made (Goodenough and Harris, 1950). Descriptive accounts of the development of peculiar or abnormal children are available. More recently extensive and well-planned programs follow the same children for long terms of years and use many methods of measuring and observing the children. With the development of cumulative record systems in schools and clinics, a type of record keeping is coming which should give us many of the advantages of the longitudinal techniques in future studies.

The Assessment of the Individual, or the Horizontal Inventory. At any level an individual can be described as a combination of skills, knowledges, attitudes, emergency reaction mechanisms, etc. For many practical purposes in education, clinical work, and guidance, a horizontal inventory of the child's resources is of value. From the standpoint of science the most satisfactory technique involves plotting his position in each of many areas in terms of established norms or standards on a psychograph. For example, results on intelligence and achievement tests scaled in terms of age can be plotted for a single child. In the absence of standardized instruments, descriptive accounts and ratings are sometimes used or added to scaled measures. Because of the practical value of the horizontal inventory, child psychologists could well give more attention to establishing norms and standards for many behavior patterns. Some norms in the literature center about unusual performances of a laboratory type not related directly to life situations. But norms or standards for such everyday things as dressing habits, ordinary motor performances, and almost all practical skills, except the school skills represented in the achievement tests, are strikingly lacking. In spite of this lack, the assessment function constantly devolves upon the child psychologist.

One outcome of assessment is its possible use for predicting future development. The intelligence test has been demonstrated to have substantial predictive value. For any other assessment procedure, the limits and possibilities of prediction can be worked out. Although actual achievement at any moment is probably more significant for an adult than is a test of potentiality, for the child the problem of potentiality is one of constant concern.

Genetic Account of the Individual in Terms of the Whole Setting. By this unwieldy phrase is meant those studies which attempt to represent the unique character and quality of the individual. It differs from assessment at any single level in that it seeks the background and genesis of present behavior. In its search for generalizations by studying functions common to many individuals, traditional psychology pulls the person apart. But each person is a unique combination with his own history and particular behavior patterns.

In this classification fall the many studies of individual children by the case history, clinical, and psychoanalytic methods. Two points may be made: (1) whereas effective methods are available for describing an individual in terms of single

measurements, little work has been done on combinations and patterns; (2) when achieved, the representation of the pattern, as a whole, may be more accurate, in spite of inaccuracies in single measurements, than the representation in terms of isolated and single characteristics, since the pattern is itself a generalization in which errors may cancel out.

Central Problems of Method

From the recent literature of psychology emerge several problems which bear a significant relation to method in the field of research on children. The first two grow out of the impact of Gestalt psychology, namely, the use of statistical procedures to set up phenotypes rather than genotypes, and the problem of whether prediction in the sense of lawfulness is actuarial or individual. The third problem, that of content, level, and dynamics, creates some confusion in the discussion of measurement, since it is not always clear which of these three aspects of the functioning organism is under consideration; and the fourth grows out of the movement of modern science from exploratory to designed research.

Phenotype and Genotype. Lewin (1935, 1936) criticizes many scientific studies of children on the ground that acts are grouped together because of their similarity when they appear and then treated as though they were distinct and discrete phenomena. Thus Lewin (1935, pp. 15, 16) says:

> Present-day child psychology and affect psychology also exemplify clearly the Aristotelian habit of considering the abstractly defined classes as the essential nature of the particular object and hence as an explanation of its behavior. Whatever is common to children of a given age is set up as the fundamental character of that age. The fact that three-year-old children are quite often negative is considered evidence that negativism is inherent in the nature of three-year-olds, and the concept of a negativistic age or stage is then regarded as an explanation (though perhaps not a complete one) for the appearance of negativism in a given particular case. . . . The statistical procedure, at least in its commonest application in psychology, is the most striking expression of this Aristotelian mode of thinking.

Lewin calls such a mode of classification a *phenotype* and distinguishes it sharply from the *genotype*, in which phenomena antecedent to these appearances are studied. A genotype is a homogeneous context of factors, either simple or complex, that produces effects which may differ widely, whereas a phenotype is a classification in terms of the homogeneity of end results which may have arisen from very different origins. For Lewin the central problem of child psychology becomes the study of genotypes. The *genotype* preserves the natural setting; the *phenotype* separates events from their setting. In actual practice, Lewin's experimental procedures conform to his principle, since he observes the effects on behavior of modifications of the environmental context.

But the Lewin view has its critics. A clear statement is found in Thurstone (1935, p. 44):

> The constructs in terms of which natural phenomena are comprehended are man-made inventions. To discover a scientific law is merely to discover that a man-made scheme serves to unify, and thereby to simplify, comprehension of a certain class of natural phenomena. A scientific law is not to be thought of as having an independent existence which some scientist is fortunate to stumble upon. A scientific law is not a part of nature. It is only a way of comprehending nature. [And further, p. 47] Some social scientists have objected because two individuals may have the same

attitude score toward, say, pacifism, and yet be totally different in their backgrounds and in the causes of their similar social views. If such critics were consistent, they would object also to the statement that two men have identical incomes, for one of them earns when the other one steals. They should also object to the statement that two men are of the same height. The comparison should be held invalid because one of the men is fat and the other is thin. This is again the resistance against invading with the generalizing and simplifying constructs of science a realm which is habitually comprehended only in terms of innumerable and individualized detail. . . . What is not generally understood, even by many scientists, is that no scientific law is ever intended to represent any event pictorially. The law is only an abstraction from the experimental situation. No experiment is ever completely repeated. . . . There is an unlimited number of ways in which nature can be comprehended in terms of fundamental scientific concepts.

Individual and Actuarial Prediction. A related problem concerns the nature of prediction. Some agree with Allport (1940), who feels that because most psychological generalizations are actuarial, that is, are statements of probability for groups, we must search for principles that make prediction possible in the individual case. For instance, when delinquency is said to occur 5 times as frequently among children from broken homes as among those from normal homes, the statement is one of probability. But, for a particular child from a particular broken home, the chances of delinquency may be 0 or 100 per cent or anywhere between.

Two points may be made in criticism of this view. First, prediction in an individual case depends upon the completeness of knowledge. The more we know about the child and his background, the better we can predict his future. For instance, if we know the relation between broken homes and delinquency, our prediction for an individual will be right, let us say, 1 out of every 2 times. If we know the effect of another factor, say whether the home was broken by divorce, desertion, or death, our prediction will be right 2 out of 3 times. If we now add the cultural level of the home, we will be right 4 out of 5 times. If we now add knowledge of the character of the remaining spouse, we will be right 9 out of 10 times. Thus, the accuracy of prediction increases and the error in prediction decreases as we know more about the case. Ultimately a point may be reached when prediction will almost be perfect. At some point, the return from additional knowledge of factors becomes so small that any practical gain in prediction may be balanced against the effort necessary to secure the data. This is a problem in many areas of measurement. For instance, in designing a measure of general intelligence, the cutting-off point for additional subtests comes when their use results in only minimal additions to predictive value. Many tests consist of about 6 different types of subtests. No one would deny that with 12 subtests a more accurate prediction would be obtained and that with 20 subtests prediction would be still more accurate. But most of the variance in intelligence is predicted from the first 6 subtests. Without research one cannot tell how much time or how many measures are necessary to establish a stable and firm predictive measure. But it is clear that the practical problem is establishing a terminal point in the face of diminishing returns.

As more is learned about the combination of factors and their relative significance, prediction improves both for groups and for individuals. In this area there have been significant advances in modern statistical methods centering about the design of experiments to analyze the weight

and contribution of combinations of factors. These developments have come from two sources: from workers in agriculture statistics, notably Fisher (1925, 1936), and from workers concerned with the prediction of performance in practical situations, as in Army, Navy, Air Force, and industrial testing.

Second, although perfect prediction for individuals is the ideal, it is not reached completely even in the physical and natural sciences. Instead, the limits of prediction come to be defined statistically. Thus, it depends upon the number of decimal places to which the analysis of data is carried and the confidence (in the statistical sense) which can be placed in the prediction. For example, the results of developing a photographic emulsion of known constitution in a developer of known constitution for a definite period of time at a constant temperature seem perfect to the naïve person. But the prediction is accurate only within a certain number of decimal places. With more precise measurement, variations will be discovered. For the everyday purpose of developing a print, the prediction is perfect; for the research workers seeking to improve emulsions and developers, it is far from perfect. In terms of the limits within which predictions can be made, the data available to the psychologist differ only in degree from those in other scientific fields.

Much of the difficulty that is encountered comes in the applications of scientific generalizations in the world of practical affairs. The child psychologist shifts from the viewpoint that science is an explanatory system of generalizations to the view that science is a matter of prediction and control of wide practical and of wide theoretical importance. One difficulty centers in the word "cause." In explanatory science he is concerned with the interdependence of variables and is taught that in this framework antecedence is not necessarily efficient *cause* but *association*. Then he moves into the practical world, where cause is quite properly used in another sense. For example, a developed photographic print may be said to have turned black because of the absence of a fixing bath. If a second print is fixed and does not turn black, the statement, "The first print was spoiled because it was not placed in a fixing bath," is accurate. Note that here concern is with obviously practical relations in which, by changing a factor or a complex of factors, a specific, particular, and predictable result is obtained. Similarly, when the reading of a child with a high IQ and normal vision who reads poorly is improved when he works with a tutor, the improvement can be described as the result of the tutoring. Again the result is produced by introducing specific and describable factors into the child's environment. In this sense, prediction has meaning, even though it may not literally be perfect.

There are other difficulties in prediction which, although they apply primarily to groups, may seriously affect interpretation in individual cases. One concerns workers in the practical field who generalize predictions from small differences to widespread practical conclusions. As an example, consider the statement, so often made in books on the teaching of children, that children below 5 or 6 years lack the physical and physiological development of the eye necessary for reading. The literature when examined indicates that a small proportion of children at early age levels have eye difficulties which interfere with reading. A significant difference in the statistical sense can be obtained between various age levels. But is this difference of such general significance that widespread practical conclusions as to the location of reading in the curriculum can be based upon it? When the problem is examined from this point of view, it becomes clear that the overwhelm-

ing majority of children have good visual sense organs, even at a very early age, and that in its anatomical development the eye reaches an adult level very early. Hence, no universal or general factor, either anatomically or physiologically, exists that would prevent most children from learning to read in early childhood. Moreover, when children's manipulation of objects in their spontaneous play is observed, it becomes clear that they make sharp visual discriminations, some of which are as fine or precise as those involved in reading. Hence, the decision as to whether all 3-year-olds or all 6-year-olds in our society should be exposed to reading materials must be made on other than anatomical or physiological grounds.

A surprising number of predictions are made for total populations on the basis of very small differences. To some degree, the nature of the conclusions reached depends upon the particular aspect of the figures on which the person focuses his attention. For example, a survey in the 1930's (Anderson, 1936) showed that 13.4 per cent of Negro young children are without toys. However important it is to correct this deficiency, it is easy to forget that 86.4 per cent of the children are in homes with toys, and to generalize the deficiency into a striking inadequacy. Two errors arise: one is an overemphasis of the proportion with a deficiency; the other is the failure to consider the data in relation to the time series. While data on adverse situations are significant for a particular point in time, from the practical point of view the significant question is the extent to which figures change with time. Did more children in 1949 have toys available than in 1929 or 1909?

Another difficulty in prediction to a practical situation of some importance is illustrated in studies of social status, in which emphasis can go either to the differences between social levels or to the similarities between them. For instance, in the same study the following figures are cited for the presence of telephones in the homes of various socio-economic classes, moving from VII, the lowest, to I, the highest: VII, 17.4%; VI, 24.6%; V, 46.2%; IV, 53.1%; III, 60.0%; II, 84.6%; I, 80.1%. There is a marked difference in the availability of particular items as we move from one social status classification to another. This material can be interpreted either in terms of the sharp difference between groups or in terms of what is common to the groups. For example, attention can go to the 21.4 per cent differences between Class V and Class VI, or to the fact that only 17.4 per cent of the lowest class have telephones as compared with 80.1 per cent of the highest class. Which is the most important? The difference, the commonalities, or the basic trend? Are such data to be interpreted as indicating a sharply separated class structure or as indicating a society in which basically there is homogeneity with differential but overlapping availability of facilities?

To combat the far-too-common overinterpretation of his statements in the practical world, the scientist shows caution in speaking about individual events. Usually he attaches some restriction or limitation that will indicate the amount of risk or the possible error in his generalizations and will show the range within which his generalizations apply.

Content, Level, and Motivation. As a living person in active relation to an environment, the child responds to stimulation with various amounts of energy, makes certain products, shows various skills and knowledge, and functions at certain levels in comparison with other, similar persons. For scientific purposes, it is often helpful to make a distinction between these aspects of his being by dividing them into content, level, and motivation. If we think of the

person for the moment as comparable to a machine manufacturing a product, we can think of motivation as the fuel or energy that goes into the machine to make it run, content as the products made by the machine out of the materials fed into it, and level as the quality of the product. A machine for making cans, for instance, might be motivated by electricity or gas, might produce cans from tin or iron, and might produce cans of poorer quality than another machine, say, of later design.

For persons, content means the retained experience, including both the skills and knowledge, of the person and whatever products result from his action. He draws a house or a barn, spells one word or another, reads a novel or a textbook on physics, produces a play or an opera, speaks English or French, plays cricket or baseball, etc. In measuring content, concern is essentially with the results of his achievement or the products of his activity. Products vary with the culture or environment; i.e., if the child grows up in France he speaks French, if in England he speaks English.

By level is meant the quality or altitude of performance of the person. An expert in any area can turn out products at a high level in comparison with a novice; an older child generally performs better than a younger child. A child with special ability performs better than children without it on a task related to that ability. Since there is always some possibility of a chance production at a high level, the level is usually determined by repeated measurements of the child's performance on the theory that high-level performance manifests itself again and again. Measures of potentiality and the principle of handicapping in sports are based on this theory.

By motivation or dynamics is meant the activity, drive, or energy manifested by the person. A person of high level will not produce in a given situation unless he is motivated. Motivation is measured by placing persons of the same levels in contact with particular contents, materials, and facilities. In general, motivation is also concerned with what is done over a period of time and may involve what is done against pressure or resistance. Content usually can be measured quite directly; level and motivation, which can, in some instances, be measured directly, are usually measured indirectly.

Exploratory and Designed Research. Critics often point out that many research workers collect miscellaneous and unrelated facts, that studies are undertaken without a clear problem in mind, and that much effort goes to the elaboration of the obvious or to reiterating experiments or determining relations that are already known. Sometimes, too, they say that investigators concern themselves with the trivial and do not study the significant problems. Far too often, these critics have in mind an ideal experiment to which no real experiment ever corresponds. Not infrequently, when critics are asked to formulate precisely the general questions they wish answered, their criticisms evaporate because of their inability to put their general questions into a form that makes experimentation possible.

Much effort in modern society goes to counting and tabulating characteristics and events of all types. In the United States the greatest count is made every 10 years at the time of the census. Although careful thought goes into formulating the questions used, census taking is, by and large, a preliminary step in research. The data of the census, once collected, are analyzed in great detail by scientists within and outside the government. In census taking, data are collected first and subjected to later analysis; in designed research, the data collected are limited by the analysis to which

they will later be subjected in accordance with the plan of the experiment.

But it also must be made very clear that a science consists not of a few collections of facts or a few experiments but of a great mass of knowledge and principles with many facets and relations collected over many years. Looking backward, it is easy to say that particular results are obvious. In fact, to the scientist of the 1950's, almost any study prior to 1930 seems obvious. But, in terms of its own time and place, the results are far from obvious. Much of the refined, accurate, advanced, and sophisticated research of today would be impossible without the work done before 1930. The most helpful way of viewing this process, both from the standpoint of a single problem and from that of the development of science, is to make a distinction between exploratory studies and designed research.

Implicit in the experimental method is the assumption that certain phenomena will be observed and recorded under controlled conditions. Formerly the experimental method was sharply contrasted with observation; now it is clear that there is a continuum which runs from casual and incidental observation to rigidly controlled experiment. Further, it is clear that experimenters are limited in their approach to problems and their observation of phenomena. Experimentation is often done in terms of categories or assumptions which do not fit behavior as it occurs. This results in only a portion of the pertinent behavior being recorded. Watson (1919), in observing and describing the emotional patterns of infants under controlled stimulation, projected his knowledge of the well-structured patterns of older persons upon them. Sherman (1927) showed the inadequacy of these descriptions and demonstrated that an investigator is likely to pick out of the behavior manifold only what meets his purpose. A simple example of this principle is found by first outlining a series of categories for social behavior, then using them for the observation of young children engaged in free play. Almost every category will prove inadequate, and much behavior not thought of in advance will appear.

Because the significant aspects of behavior are likely to be missed, it is customary to conduct exploratory or pilot studies on a small group of subjects before the procedure is extended to a large group in order to secure final data. Exploratory research ranging from simple observations to elaborate pilot studies has been done in various research stations for many years. Usually an area or problem is tentatively selected; the procedures are tried out on a small group of children; schedules, ratings, observation blanks, design, etc., are revised; another try-out is made; and so on. Finally the series of procedures and the experimental situation become established. In some instances, investigators begin by observing and recording all that children do in free or controlled situations. These protocols are studied and categories are organized as a basis for further observations. Another procedure involves preliminary experiments on small groups of children at a wide range of ages. For example, an experimenter might work with three 2-year-olds, three 5-year-olds, and three 8-year-olds, in order to discover whether his procedures, instructions, and methods were appropriate at these age levels, and revise in accordance with his experience. Then later the revised procedures would be applied to a large sample of children at each age from 2 to 8 years. Other sampling devices may serve in pilot studies. For example, a few bright, average, and dull children may be selected for the preliminary test of a technique. Another type of exploratory research is commonly used in the design of tests or measuring devices. A very large

number of items from different sources are collected, tried on a group of subjects, and then sorted over by a technique of item analysis in terms of either an internal or an external criterion or both in order to eliminate inappropriate or ineffective items before the final measuring instrument is applied to the subjects in the primary investigation.

In World War II the Army Air Force developed a method of critical requirements or incidents for exploratory research (Flanagan, 1950). In some respects this is an advance over the protocols used on children for many years in that much recurring routine behavior is neglected and emphasis goes to what is significant in the particular situation. For the incidents themselves, however, recording is very complete. Once behavior in a large number of incidents has been described, the protocols are analyzed and dimensions and continua of behavior are worked out on the basis of which various categories, schedules, and techniques of observation or experiments can be developed for a more precise study of the major problems. One particular point was emphasized by Flanagan at a symposium at the 1950 meeting of the American Psychological Association. When reports on critical incidents were collected from highly trained workers and checked against actually recorded incidents, such reports based on recall were found to be reasonably accurate up to about 2 weeks after the incident occurred, but thereafter became progressively less accurate, until at the end of a month they were of very little value. This result emphasizes the overwhelming value of good observation and recording at the time behavior occurs, and shows how, even in well-qualified and conscientious observers, a lapse of time produces retrospective falsification. Pyles, Stolz, and Macfarlane (1935) have shown how falsification occurs in mothers' reports.

Exploratory research has many values: (1) it moves a study quickly from the armchair into the world of children; (2) it often reveals frequent or major aspects of behavior that have been overlooked; (3) by making the refinement of instructions and procedures possible in advance, it avoids the error of changing an experiment while it is in process; and (4) by bringing the ideas of the experimenter and of others to the study at different times and under different conditions, it facilitates thinking and thus improves the design of the project.

From exploratory research, which covers many types of descriptive and ecological studies, investigators move on to studies in which a specific question or problem is stated as a hypothesis which can be verified or disproved. In hypothesis research, emphasis goes to preliminary formulation of all the details of the project, including sampling, measuring instruments, procedures, etc., in precise terms.

In the psychological and social sciences many investigations deal with isolated single problems. So much is this true that scientists are bewildered at the task of integrating this mass of facts into a set of related principles. The traditional approach to this problem was to urge all scientific workers to present their material in such a way, by giving precise descriptions of sampling, experimental design, procedures, and results, that other workers could integrate the results and generalizations with their own studies. But attempts at integration are not too successful because of discrepancies in sampling and procedure. Even when attempts are made to replicate earlier studies, serious difficulty is encountered because of the inadequacies in the descriptions of procedures and techniques.

Modern discussions of the integration of scientific material stress the value of considering integration in the planning and design of the study. Many think of experi-

ments as simple determinations of a single relation. Actually, however, in both laboratory and science as a whole, particular studies are only episodes in a long trend. Although the classic work of Ebbinghaus consists of many single experiments on memory in which, one after another, various factors are controlled, i.e., length of list, time interval, etc., his results when considered in sequence make an orderly whole.

Modern contributions to the problem of integration are many and depend in the main upon mathematical, logical, and statistical concepts. Fisher (1937) raises the question of so designing experiments that for a given expenditure of time and energy they will yield maximum returns and, at the same time, systematically, through the design itself, explore all the essential relations. Design in this sense is not a determination of the relation between one variable and another but an analysis of an entire manifold.

Hull and his students (1940), working with memory, concerned themselves with the logical derivatives and implications of the postulates growing out of our present information, and then laid out a whole system of experiments to explore the entire web of relations by crucial experiments to test and verify particular generalizations. This process checks, eliminates, modifies, or enlarges postulates and principles as work goes forward and substitutes an entire system of explanation for the isolated experiment. Although Hull's work has not been directly concerned with child psychology, the forward-looking student of method should be familiar with his approach.

Lewin (1936), who was concerned with theory and methodology in child psychology, worked out a system which, in the formal sense, is not so complete as that of Hull. Nevertheless, it represents a major attempt to put meaning into an entire area. Both he and his students performed many of the experiments that follow from the basic postulates of the system.

Scientists are now moving from project design to what is coming to be called program design (Marquis, 1948), i.e., planning research in advance for an entire area or region of knowledge. Program design involves a series of hypotheses which are interrelated and interdependent, on the basis of which single projects or experiments can be designed. During World War II, in connection with many military projects, program design was developed in high degree. The procedure usually begins with a careful search and summarization of the relevant scientific literature, followed often by some exploratory research. Then, both through individual effort and group discussion, a series of major postulates and their corollaries are developed. Out of these a series of experiments emerges. As the particular experiments are completed, portions of the underlying conceptual framework are modified and new experiments designed. Systematic planning is substituted for casual and incidental approaches to problems. Elegance and completeness of design are set up as ideals.

But a word of caution is necessary. It has long been recognized that, of two explanations which are equally adequate in explaining behavior, the simpler is to be preferred. This principle, known as the law of parsimony, can be extended from single experiments to a general principle of economy for explanatory systems. If science is a mental shorthand which seeks to minimize mental effort, it follows that any ideal construct is to be accepted or rejected on the basis of the degree to which it facilitates the comprehension of a class of phenomena. Hence, the construct to be accepted as science is the one which has a smaller number of degrees of freedom than the phenomena which the reduction is ex-

pected to subsume (Thurstone, 1935). If two constructs are equivalent, that with the fewer degrees of freedom is preferred. Thus, we come to a principle of economy of explanation which is far too often neglected in some of the complex and fanciful explanations given for the behavior of children and of adults as well.

Sources of Material for Child Study

As the child moves through his course of development, he not only affects other persons but also leaves behind him products and records which are more or less complete. His behavior in various situations may be recorded, and tests and measurements may be made from time to time. All these constitute sources of material for the student of child behavior. Following is a list of sources:

1. *The present behavior of the child, both verbal and nonverbal.* This includes the observations, measurements, and records of behavior obtained in test or experimental situations designed to elicit responses for specific research purposes. The free responses of the child to stylized materials or in the unstructured situations of the projective techniques are also included. Direct observations of behavior in play and social situations increase in value for scientific purposes with systematic and planned recording.

The process of recording behavior is facilitated by many modern devices, such as the motion picture with and without sound and the various methods of sound recording by disk, wire, and tape. These devices have been so perfected that it is now possible to get permanent records of almost any kind of behavior. Although some difficulty is encountered with the voices of young children because of their low intensity, microphones can be installed in inconspicuous places and rooms redesigned to insure good records. The problem of analyzing and symbolizing the masses of material obtained by audio-visual recording presents some difficulties. Problems of interpretation also arise, since what appears overtly may not always indicate what is happening within the person, as shown by a number of the older studies of galvanic response in children.

2. *Products of the child left behind as permanent records.* Such permanent products as drawings, letters written by the child, compositions, and constructions often yield significant data. The value of such products increases as accessory information is available, such as the dates or ages at which the products were made and the conditions which occasioned them.

3. *Records on file in home, school, governmental agencies, health departments, social agencies, etc.* Included are all types of records which are preserved by a variety of agencies dealing with children, such as birth certificates and health records. Of particular value are school records, especially the more recent cumulative records that include much relevant data. Often investigators can save themselves much effort and secure better sampling data, as well as important accessory information, by checking with the schools in the areas in which their studies are undertaken.

4. *Introspections of the child.* Modern investigators pay relatively little attention to this source. They prefer to look upon verbal output as behavior, as in the studies of children's thought processes as revealed in their language (Piaget, 1923). However, modern research has developed many clever indirect devices for getting at the attitudes, tensions, and goals of children which obviate the necessity for introspection.

5. *Memories of the child, or of the adult, of his own earlier life.* Once almost the only source of information on child life, these are now of rather minor importance. They vary both in completeness and accuracy. When checked against records of actual events they are found to be subject to many errors. These errors increase with the passage of time and raise serious question as to the reliance to be placed upon such memories. A central problem is whether such memories reflect the present state of the person or repre-

sent an earlier and real event. Many of the data in psychonanalysis are based upon the childhood memories of neurotic adults. Are these true events or projections of adult difficulties? Modern literature distinguishes two techniques for tapping such measures: (*a*) recording conscious memories, and (*b*) locating more deeply buried memories by free-association processes or projective methods.

6. *Memories of the child's life retained by those who have been associated with him.* Here are included the many effects left behind by the child in his relations with others and more or less adequately retained by them. These have little scientific value because they are likely to be very incomplete, haphazard, and biased. Sometimes, however, they are used. As the distance in time between contact with the child and reproduction increases, the data become less and less valuable.

7. *Measures of the parents, siblings, and other relatives of the child or of the environment, culture, or background in which he develops.* Strictly speaking, these sources do not furnish direct information. But they do make possible the analysis of the observations or measurements of the child's behavior. Not only are they clearly necessary for sampling, but they also make possible the determination of many significant relations. Examples of the use of such accessory data are found in the studies of heredity and environment, of which the Freeman *et al.* (1928), Burks (1928), and Leahy (1935) investigations are good examples; the various community studies, in which such matters as the relation of delinquency to city area (Shaw, 1931), or intelligence to rural or urban residence (Baldwin *et al.*, 1930), are analyzed; or the many studies of socio-economic or cultural status.

It has become possible to secure observations or measures on children at the identical ages at which similar observations were secured on their parents many years ago. There is some evidence that resemblance coefficients in the existing literature are underestimations because comparisons were made between persons who were tested at very different developmental levels; for example, scores on intelligence tests on mothers or fathers who are 30 years old are correlated with scores obtained on their children who are 7 or 8 years old. Because of the difficulty of securing data on children and their parents at identical age levels, organizations that have kept records that go back 20 or 30 years could well explore the possibilities of such research.

Techniques for Securing Data

Many persons make incidental or casual observations of behavior without control of conditions. The results stated either in the form of principles or of anecdotes are of little scientific value, whether made by a scientifically trained person or not, since no one knows how precise the observations were, what kind of a sample was observed, or what factors in the situation set off behavior. This does not mean that the observations were not accurate, but rather that they are of little value for scientific generalization.

Two characteristics of the scientific method are the *careful observation of phenomena as they occur* and the *accurate recording of these observations* in order that they may be tabulated and analyzed. A scientist does not depend upon his memory, but records events as they occur in order to eliminate bias and retrospective falsification. Whenever possible he makes permanent records, as when he writes down a reaction time, fills out a test blank, uses a polygraph, or makes a motion picture or sound recording. When he cannot observe directly, he uses indirect methods, such as reports, interviews, questionnaires, and inventories; these he checks with unusual care. Good scientific work involves not only skill in observation and recording, but also insight into what it is important to observe and record.

Classifying the ways of securing data presents difficulty because methods overlap and a variety of methods are used to achieve similar purposes. Following is a classification based upon the manner in which data are obtained.

Systematic Observation without Control of Stimulation. First come the methods in which observation is systematic but stimulation is not controlled. The research worker uses "natural" [1] situations or situations as they occur in the ordinary life of the child as a basis for his research. Barker and Wright (1949, 1951) call these methods "ecological" research or "habitat" research. But the methods involved have been in use for a very long time.

1. *Narrative records and habitat studies.* The earliest use of narrative records came in the baby biographies, in which attempt was made to describe all behavior from day to day. Later, children's social behavior was observed on the playground or in free-play periods. Often elaborate check lists and codes were developed (Thomas *et al.*, 1929) to analyze the narrative accounts.

Barker and Wright (1949, 1951) have given this method new emphasis by using teams of trained observers, each of whom observes a child for a half hour. Children are followed from early morning until late at night through all their activities. Observers are trained in advance, and some time is allowed to permit children to become habituated to the presence of the observer. After a short period the children go about their business as though no observers were present. Despite the training of the observers, it is necessary, in order to secure a complete account, for an interviewer to question the observer in order to bring out details which were not in the records taken on the spot. From the records and the interview the episodes of the half hour are documented and arranged in a time sequence to become the basic record. An episode closes with a new stimulation, as for example the entrance of a new person, or when substantial movement of the child to another location occurs. Episodes are coded and classified to form the basic data for analysis. It is clear that the child is exposed to great quantities of stimulation and that even in a single day there are many learning situations. This leads to a volley or bombardment view of the determination of behavior, with much reiteration, reinforcement, and feed-back, rather than a conception in terms of relatively isolated single stimulus-response situations.

2. *Situational sampling.* Closely related to the narrative accounts are the techniques in which the observer selects recurring situations and systematically records the child's reactions to them. The situations selected may vary from the introduction of deliberately selected stimuli into the natural situation, as when an investigator makes two different types of toys available in a play period and records the number and length of times boys and girls play with each type, to recording the objects in the normal playroom which a child picks up with his left hand and with his right hand. Or the observer may adopt the museum technique developed by Marston (1925), in which exhibits are set up at stations, and the length of time, the number and type of exhibits stopped at, and the pathway of the children who enter are recorded. Or behavior at home may be compared with that at school, free-play periods with teacher-guided periods, social relations when one companion is present with those when three or four companions are present (Jersild and Meigs, 1939). In addition to obtaining

[1] The criticism so often made that "laboratory" situations are unnatural might equally well be made of all tests and measurements and even of play and projective techniques. Whether they appear "unnatural" to the child is an open question; certainly many children show high interest and motivation and take them in their stride as very normal events.

narrative accounts, Barker and Wright (1949, 1951) stationed observers in the corner drugstore to record all that went on during the day that involved children.

The value of situation sampling arises out of the fact that much behavior that can be produced under laboratory conditions only with difficulty occurs with some frequency in life. The technique is also used with adults in studies of reactions to museum exhibits, advertising on street cars, conversations on trains and at concerts, etc. In studies of the emotional and social behavior of young children *situation sampling* has been of great value. Data obtained from narrative accounts can also be broken up in terms of the recurring situations. Obviously data are obtained more readily when the situations selected occur frequently rather than rarely.

A modification of the situation sampling technique is found in the recording of critical incidents (Flanagan, 1950) mentioned earlier. It is but a step from using situations which occur naturally to deliberately setting up controlled situations which are uniformly presented to many children.

3. *Time sampling.* In order to permit quantification of observations, a closely related technique, known as *time sampling*, developed by Olson (1929, 1934), Goodenough (1928*a*), and Thomas *et al.* (1929), came into wide use. A summary of the results obtained by the method and a discussion of its implications are found in Arrington (1943). The technique introduces no control in the natural situation except recording the number of times a selected type of behavior occurs during a time interval which is held constant and systematically spaced. For example, on the first day the social behavior of child A is observed for 2 minutes, then that of child B, then that of child C, and so on. On the next day each child is observed for 2 minutes again, but the children are taken in a different order. By making a series of such observations at successive periods and summating the frequencies a total score can be secured for each child for all the periods in which he is observed. Such scores lend themselves readily to statistical treatment. Reliability can be determined by correlating scores for odd and even periods, and the number of observations necessary to secure stable results can be determined. The scores can also be correlated with other factors. Time sampling works well with behavior that occurs frequently. The length of the period of observations and the number of observations necessary to achieve stable results vary with the type of behavior studied.

4. *Play techniques.* Another variant of the observational method appears in the play techniques used by clinical workers for diagnosis and therapy with children having adjustment problems, which are now coming to be used for research purposes. Of the projective techniques (see p. 22), these are more like narrative studies or situation sampling than are the personality measures, such as the Rorschach or Thematic Apperception Test, in which the stimulation presented to the child is controlled. Since many children cannot or will not verbalize their conflicts, exposing them to play materials in a free and secure situation may lead to spontaneous expression of anxieties, conflicts, insecurities, and wishes. Many materials have been used: dolls, knives, drawing and painting (finger) materials, puppets, etc. (Fries, 1937; Frank, 1939; Despert, 1940; Axline, 1947; and Bell, 1948). Children have also been encouraged to engage in dramatic play. Sometimes the play itself, sometimes the stimulated conversation, is regarded as the significant outcome.

Concern here is not with the use of these methods for therapy but as sources of generalizations that give insight into the nature

of children. Although studies of reliability and validity are still needed, play techniques have been used with some success as measurement devices in experiments in which contrasting groups are selected, e.g., the comparison of the aggressive behavior of children whose fathers had been away at war with that of children whose fathers had not (Bach, 1946).

Systematic Observation with Control of Stimulation. The characteristic of these techniques is that the research worker presents children with stimulation which is selected and controlled; i.e., the materials presented are laid out in advance, and the reactions of the children to the materials or stimulation are systematically recorded.

1. *Specific measurements.* This includes the many direct measures based on size, time, movement, work accomplished, amount of material retained, errors, etc., and the many indirect measures and tests of complex functions that have been developed over many years by research workers. Basically all record in some fashion a characteristic response pattern to controlled stimulation in quantities that can be manipulated statistically. Examples are measures of height, weight, speed of reaction to a signal, and recall of a series of memorized digits. Because of the wide variety of measurement devices, the specific limitations of each cannot be discussed here. General principles underlying their use are discussed in the next section (p. 33). Whipple (1924) and Greulich *et al.* (1938) present the procedures for many such measurements, and Shuttleworth's (1949*a*) *Graphic Atlas* contains many curves based on measurements. Much of the later portion of this book, covering particular topics, is devoted to their consideration.

2. *Psychometric tests.* Psychometric tests involve presenting children with series of items, problems, or questions laid out in advance, from which part or total scores can be obtained that permit comparison of the child's performance with norms obtained on a standard group. The definition covers a very wide series of measuring devices for capacity, skill, achievement, and personality (Goodenough, 1949*a*, 1949*b*). The procedures for conducting the tests are rigorously defined in order to secure constancy of administration from examiner to examiner and from one time to another. Scoring is standardized and is made as independent of the particular examiner's judgment as possible. It is done by counting, by checking against keys, or by consulting a manual in which specific rules for scoring are laid down and illustrated by examples. The result obtained can be checked by other examiners. Hence, the ideal of psychometric techniques would be standardized, objectively scored, consistently administered, and uniformly interpreted measuring instruments which would give consistent results when repeated after a short period of time and which would be independent of place and of the personality of the individual examiner. The most notable example is the intelligence test.

3. *Experiment.* Even though the experiment is discussed in detail later, it should be mentioned here as a technique for securing data in which both the stimulation and the conditions under which it is presented are deliberately controlled in order to secure an answer to a specific question. An experiment is a step beyond psychometric testing in terms of the number and completeness of the controls applied and usually, also, in terms of the length of time over which measurement is made. Moreover, it may use a variety of measurements and systematic observations.

Personality Measures of the Projective Type. In the 1940's appeared within the psychological field a whole series of new techniques listed under the general heading of projective methods (Bell, 1948; Bender,

1952). These seek to assess the person's emotional or personality reactions as a basis for therapy or correction of personality inadequacies rather than his capacities or skills. Examples are found in the play techniques mentioned earlier (p. 21), the Rorschach ink-blots, and the Thematic Apperception Test. With their value for therapy, we are not here concerned. But their use in the analysis and study of behavior development needs some consideration. As with other methods, projective techniques can be used successively to measure development or at any particular time to assess status. They may also be given before and after an introduced experimental condition in order to measure its effects. They may be standardized or not.

In essence, the child is presented with various neutral stylized or indefinite materials, upon which he can project his own feelings and attitudes and indicate by the character of his responses how he feels. Such materials as ink-blots or the pictures in the Thematic Apperception Test have a vague and indefinite outline and are not as precisely and specifically structured as most visual materials. Where more precise formed material is used, it is so stylized that it can be interpreted in many ways. For example, stylized dolls and equipment permit the child to project identifications and other characteristics upon them, and may even permit him to perceive them as if they possessed the projected characteristics. The better the test materials, the wider the range of interpretations that may be made of them.

The chief differences between psychometric and projective measures may be summarized as follows:

1. *Structuring.* Psychometric tests are highly structured both in the situations presented and in the responses permitted, whereas projective techniques theoretically are not. This distinction is, however, not a sharp one, because the situation in which projective methods are used must be laid out with some care. Further, although some discussions of projective techniques emphasize their freedom from the defects of the ordinary psychometric examination, both scoring and interpretation are dependent upon a trained examiner. In many instances, attempts are made to reach high degrees of constancy in scoring and interpretation by the use of frequency tables and directions.

2. *Subject's awareness of situation.* In projective techniques attempts are made to set up very natural situations, often by making the child feel that the examination's purpose is quite different from its real purpose. Ideally, the person examined does not know what is going on, and, in general, the more he lacks awareness, the more effective is the test. On the other hand, the psychometric test can hardly be disguised, except for young children for whom the skilled examiner creates interest in the test that is similar to that in play situations. However, in the psychometric test the situation is explicitly one of testing, whereas in the projective situation the testing aspect is kept incidental.

3. *Test results.* In psychometric tests, the answers to questions are either right or wrong. As a result the examiner has little to do with the outcome beyond making the subject secure, motivating him to his best efforts, and recording results. The directions for giving and scoring responses are so explicit that it is difficult for the examiner to project his own feelings into the interpretation. With projective techniques, however, there are no wrong or right answers. Hence the examiner may project his own feelings into the results and interpret them in the light of his own background. Not only do examiners often differ markedly in their interpretation of results, but also the training in projective techniques is divided among various schools and their disciples who sharply criticize one another and each of which feels that it has the only true technique. With psychometric techniques it is assumed that any person with

training can acquire the methods of administration and interpretation.

4. *Relation to social pressure.* Some hold that psychometric tests reflect culture, whereas projective techniques are independent of culture and social pressures. For example, an ink-blot can be interpreted by people of widely different cultures. But although many of the projective materials are largely independent of language symbols which vary with culture, it does not follow that nonlanguage materials are independent of cultural effects.

5. *Validity and reliability.* For psychometric techniques validity and reliability are measurable and known, and results can be treated statistically. High consistencies are obtained when studies are made on comparable populations. For many of the projective techniques the reliability and validity are not known. Moreover, many clinicians fail to realize that, when any technique is used for diagnosis, it enters the area of prediction and thus is to be evaluated by statistical processes. Attempts have even been made to use projective techniques for prediction in skill and capacity areas, for which they are not designed.

6. *Best performance vs. typical performance.* Goodenough (1949*a*, 1949*b*) has pointed out a fundamental difference between the psychometric and the projective methods. In a psychometric method, the best possible performance of the child is sought in order that his future performance may be predicted or his level of attainment measured. Conditions which favor maximum performance are desired. With projective methods, on the other hand, the experimenter is not interested in the limits of performance but in the typical or characteristic reactions of the child. He seeks information on how the child feels or how he reacts to circumstances, not information on what he can do when highly motivated.

Ratings. In the use of ratings it is assumed that behavior has already occurred and that an observer can order or classify such behavior on a continuum. At present many types of behavior cannot be measured directly. But such behavior can be described as better than this or poorer than that and thus be placed at a point on a scale which represents an estimate of the amount or quality of the particular characteristic possessed by the subject. Rating techniques fall into two main types: (1) a comparison of stimuli, situations, persons, or products by assigning each to a position or rank-order with reference to every other, as when children are ranked, *first, second, third,* etc.; or (2) an indication of position in comparison with others by marking the point, either graphically, numerically, or verbally, at which he or the behavior under consideration lies with reference to a designated characteristic, as when the child is rated on cooperativeness by indicating whether he is *often, usually, moderately, seldom,* or *never* cooperative. In ordinary speech many such comparisons are made, as when a 10-year-old speaks of his friend as a good catcher or as the best batter, or even when a person is referred to as pretty, or diligent, or lazy. In such statements the existence both of a scalable trait and of a group with which comparisons can be made is implied. Rating techniques, then, are systematizations and quantifications of procedures in common use.

Whether the rater ranks 10 children in order from the best to the least adjusted, or marks the child's adjustment as *excellent, good, average, poor,* or *very poor,* the essential process is the same. The variants in the type of categories, the form of scales, and the method of summating items into a single score are many. Ratings increase in value with the number of raters. Self-rating scales are also in use. The technique has also been applied to children's products, such as drawings and writing. Extensive discussions of the methodology of ratings are found in Symonds (1931), Weiss (1933), Thorndike (1949), etc. Rat-

ings are also widely employed as criteria against which measuring devices, singly or in pooled form, can be validated.

Conrad (1933) found that the reliability of ratings of young children by nursery school teachers and the agreement between judges vary significantly with (*a*) the trait judged, (*b*) the child judged, (*c*) the estimated significance of the trait for the child in question, and (*d*) the confidence with which the judge rates the trait for the particular child. The fact that Conrad's results are somewhat higher than those usually published for older children suggests that some unreliability in ratings can be traced to unequal acquaintance and to contact under different circumstances of the raters with those rated. Ratings improve when equal amounts of observation under similar conditions are provided.

An underlying assumption in the use of ratings is that the trait rated is homogeneous and that the categories describing the steps fall into a linear continuum. For instance, children are frequently rated on "cooperation," "adjustment," "honesty," "perseverance," "sympathy," "self-reliance," etc. Are these traits entities, or are they manifolds made up of heterogeneous factors? Often ratings are greatly improved in the ease and accuracy with which rating is done, and in the reliability of the ratings obtained, by breaking up manifolds into parts. For example, it is better to rate adjustment and honesty separately than to combine them in one category. Whenever possible more objective and discriminating measures should be substituted for ratings.

Sociometric Techniques. By sociometric techniques (Moreno, 1934; Jennings, 1948; Proctor and Loomis, 1951; Clark and McGuire, 1952), we refer to methods of plotting the relations in a group of children. The data for plotting sociograms may be obtained in various ways, such as (*a*) direct observation of social relations, (*b*) asking children to name their friends or to choose classmates with whom they should like to sit, or (*c*), in the "guess who" technique, asking them to choose children who fit a given category or description. If extreme categories only are used, remaining children can be assigned intermediate positions. In sociograms the interrelations between the members of a group are shown by connecting lines which run to and from small triangles and circles which indicate boys and girls respectively. By preliminary inspection, the children who are contacted most often or who are the most frequently mentioned are placed somewhere near the center as more lines come to and from them. Approaches toward or away from a particular child can be indicated by arrowheads of appropriate direction. Various relationships can be indicated by differentiated lines, such as solid, thin, dash, or dotted lines.

When a diagram is plotted for an entire group, a pictorial representation of all the interrelations results. Isolates are children with no lines connecting them with others. Stars are children from whom many lines radiate and toward whom many lines converge. A triangle consists of three children in such close relation to one another that they constitute a subgroup, as shown by many interconnecting lines. A line is a group of children in which relations are consistently in one direction. Subgroups of various size appear with many lines between the members and fewer lines going out to other children.

Another method of diagraming is that of Murphy (1937), who, using squares for boys and circles for girls, placed all the children in two columns arranged from the oldest at the top to the youngest at the bottom. The circle or the square that corresponded to a particular child was placed in the center between the two columns, and lines were drawn from the

squares and circles in one column to show approaches made to the child and to the squares and circles in the other column to show approaches initiated by the child. Types of lines are varied with the different social techniques or activities, and direction arrowheads are used.

By plotting group structures, relations that are hard to grasp when presented verbally are presented pictorially. Sociograms are of practical value in working with children's groups as they clearly point out isolated and overlooked children who need attention. But there is some question about their contribution to science. Scores based on observations or ratings must be obtained before plotting, and they may be analyzed statistically, whether or not they are plotted. As scores they possess the advantages or disadvantages inherent in their particular character and are subject to the qualifications of other scores of the same type with respect to validity and reliability. Moreover, there is always some question about the generalizations that can be drawn, since they are relative to the particular group on which they are obtained. Despite this, sociograms, when used at various age or grade levels, have revealed interesting developmental trends and have confirmed results obtained by other methods of studying social behavior.

Reports and Questionnaires. In using reports, questionnaires, and inventories, it is assumed that the person answering is recording what he already knows or feels. The questions asked may vary from single questions to be answered *in extenso* to a highly structured list in which appropriate responses are merely checked or underlined. Items may cover what the person knows or what he thinks or feels about himself or others. He may be asked to rate himself or others or to compare his performance with that of others. The results, when obtained, may be pooled into subscores or total scores and used for the indirect measurement of personality or other general traits (Hubbard, 1942).

1. *Reports.* Reports include all types of factual statements that the respondent is in a position to know on the basis of observation, previous knowledge, available figures, test results, etc. Many items on a face sheet or the questions asked in the beginning of an interview fall in this classification. For scientific purposes it is necessary to know whether the respondent is in a position to know the facts and whether his reports are accurate. Most investigators cross-check or verify such reports.

2. *Questionnaires.* A series of questions arranged more or less systematically and grouped about a main topic is called a questionnaire. There are two types of questionnaires: (1) those which seek facts which are known to the person answering and (2) those which seek opinions about particular situations, modes of behavior, individual characteristics, matters of policy, training, etc.

Much of the distrust of the questionnaire arises because of confusion between matters of fact and matters of opinion. If a group of experts is asked to give an opinion as to the value of motion pictures for young children, their expression of opinion is of value only in so far as they are qualified to express an opinion. Neither individual nor summated group opinions are equivalent to scientific data based on observation, measurement, or experiment except that sometimes opinion is studied in and for itself. When a questionnaire deals with facts collected from those in a position to know, it may have much scientific value. For example, a questionnaire which enlists the cooperation of mothers in recording the sleep of their children would be of greater scientific value than a collection of their opinions about sleep. Sometimes questionnaires cause persons receiving them to make sys-

tematic observations or to analyze data already in their possession.

Questionnaires aim to secure from many persons observations or opinions which could not be obtained from a single individual. Their accuracy depends on the skill with which they are made out, i.e., the definiteness, specificity, and practicality of the questions, the capacity of the persons answering, the length of time that has elapsed since the occurrence of the events to be recorded, the sampling of persons to whom the blanks are sent, and, what is even more important, within that sampling, upon the characteristics of the sample of persons that reply. Questionnaires are subject to errors of memory, misunderstanding of terms, and mental sets imposed by the questions. In general, verification by other methods is necessary.

3. *Verbal personality and attitude inventories.* There are many questionnaires, check lists of behavior, and inventories covering such aspects of personality and conduct as adjustment, neurotic tendencies, introversion-extroversion, ascendance and submission, social attitudes, fairmindedness, and vocational interests. All have a common characteristic in that the person answers questions about his own attitudes, interests, etc. The inventory does not seek answers to individual items or questions in and for themselves, but is designed to derive a general measure from the answers to many items which can be used either for practical assessment of the individual or for the study of scientific problems. Some inventories can be administered to groups. Although some inventories are loosely called tests, they differ from tests in that there are no right or wrong answers to the items or questions. Irrespective of the correctness or falseness of the answer in terms of objective fact, the responses may be weighted in any direction because of a demonstrated correlation with the criterion for the function which is measured. Hence, predictive value depends upon symptomatic answers to individual items, upon the various patterns of answers, or upon quotients derived from answers or patterns. When subscores are developed the same answer to an item may be scored in one direction for one subscale and in a different direction for another. Items may be printed seriatim, as is the usual custom, or on individual cards, as in the Minnesota Multiphasic. Because most inventories depend on the ability to read and understand the items, their use is limited to children above 8 or 9 years. In some studies devices presented in verbal test form to older children have been read aloud to younger children.

4. *Pictorial questionnaire.* For younger children, and to some degree for older children, various types of questionnaires in which items are presented pictorially rather than verbally have been developed. Much skill has been shown in adapting a wide variety of test, inventory, and other items to pictorial form. A series of pictures in which various human relations are portrayed has been used, particularly in studies of race relations (Radke, 1949) and of social sensitivity (Gates, 1923; Murphy, 1937). Because the method can be used only when there are marked and visible differences between the persons portrayed, it has distinct limitations. Pictorial material is also the basis of the Rorschach method, about which a substantial literature (Hertz, 1942) is developing. This involves evaluation of the child's responses to ink-blots. The Thematic Apperception Test presents children with a series of pictures of somewhat indefinite outline or equivocal meaning and evaluates children's responses.

Interviews. The interview varies from a systematic entering of information obtained from the person interviewed upon a blank prepared in advance to a completely free

situation in which conversation goes forward without any report.

1. *Structured interviews.* Structured interviews usually begin with a face sheet for recording essential sampling and evaluative data, such as name, address, telephone, age, education, occupation of father, and names of siblings. The remaining questions concern the particular area or problem in hand. The advantages of schedules prepared in advance and given systematically are many, especially since the data gathered by haphazard and unplanned interviews are difficult to use for scientific purposes. On a prepared blank the fact that the individual refused to answer, did not have the information, etc., can be checked and appropriate interpretations made in the analysis. But unless this is done, a refusal, a negative answer, or the failure of the interviewer to give the question cannot be distinguished. In interviewing for scientific purposes some record should be made for every question asked. Attention must also be paid to the form of the question and the order in which questions are given (Payne, 1951). An example of an extensive series of interviews laid out by a national committee and obtained from every area of the United States by a planned sampling procedure is found in the White House Conference reports (Anderson, 1936; Burgess, 1934). Research on public-opinion polls and interviews for guidance and for social work are turning the interview technique into a valuable scientific instrument.

2. *Unstructured interviews.* More recently the free or open-end interview has come into wide use, not so much for research as for counseling. But it has research possibilities. If a child is asked, "What is a good boy?" and encouraged to talk freely, a very comprehensive picture of home attitudes on discipline may be obtained. With modern methods of sound recording complete records can be made. Various methods of evaluating or quantifying the material in such interviews to secure scores that picture the child's image or goals are available. The value of such procedures in exploratory research is obvious: frequently from recorded open-end interviews very good structured blanks for subsequent use can be made. The major difficulty with free interviews arises from the omissions which differ from case to case. Although what appears may be said to be symptomatic of underlying tensions, the free interview itself has a somewhat accidental character and differs widely from time to time and from interviewer to interviewer.

Products and Personal Documents. Either because of his own volition or as a result of his instruction, the child may leave behind various products such as pictures he has drawn, constructions he has made, or compositions or diaries he has written. Recorded conversations and interviews may also be considered products. Such products can be subjected to various types of analysis. If the age or the date at which they were produced is available significant age trends may appear. In the past the main analyses have been: (1) in the area of children's drawings, where developmental scales have been laid out and where drawings or paintings have been used to assess personality characteristics, and (2) in the area of autobiographies or diaries, which are often kept by adolescents and which when collected can be analyzed in various ways. The practice of keeping diaries is more common in Europe than in the United States. Controlled diaries (Anastasi, 1948) may also be kept in particular areas of behavior.

Adolescents and young adults have been asked to write their autobiographies, sometimes as class exercises, sometimes as a preliminary to an interview, sometimes in connection with therapy. These so-called per-

sonal documents can be subjected to various types of analysis. Taken at its face value, each such account is the story of a unique individual and, as such, has little or no general significance. But when a number of autobiographies are secured, all written under essentially the same conditions and for the same purposes, it becomes possible to analyze the content. Actually, however, the methods available are still in the early stages of development. A promising method developed by White (1947) and by Dollard and Mowrer (1947) is to go through an autobiography and mark all words or phrases that indicate definite attitudes or responses toward persons, objects, ideas, etc. For example, every phrase that lauds the mother and every one that deprecates her might be marked; similarly every phrase indicating frustration and every phrase indicating aggression might be marked. Since sentences frequently involve clauses which express several relations, the smaller units such as phrases are preferred. While a simple count of the total number of expressions of a particular type is of some value, indices, such as the ratio of the phrases expressing security to those expressing insecurity, or the pleasant expressions over the unpleasant expressions (Anderson, 1952), can be developed and studied. Thus, a series of quantitative measures is secured for which intercorrelations and reliability coefficients can be obtained. Certain difficulties arise, however. Some write short superficial autobiographies concerned with events, not feelings. If a person writes freely and without pressure and describes his reactions rather than objective events, good results are obtained. This happens, particularly, when the autobiography is obtained as part of a counseling or guidance procedure in which the person actively seeks help on his problems.

Similar analyses can be made of a variety of other documents obtained from or about individuals, such as recorded conversations, recorded interviews, case histories, letters, or any exchange in which basic attitudes and feelings appear (Horst, 1941; Allport, 1942). To secure an adequate measure in terms of either an absolute count or the ratio between two counts, the particular phenomenon considered must occur in the recorded material with sufficient frequency to make analysis possible and the figures on which they are based reliable.

Individual Case Study. An individual case study can be used as a source of data for making generalizations. As such, it is to be considered in the light of the *scientific* information it yields. Much material in psychoanalysis and some in the clinical, abnormal, and delinquent fields consists of studies of individual children. Usually a summary of observations and interpretations is presented. The value of the concept of the lawfulness of the individual's own history and the practical value of earlier data in predicting later outcomes for the particular individual is not to be confused with using a single case as a basis for generalization to wide populations. In the former case prediction is justifiable; in the latter the representativeness of the case must be demonstrated, which is literally an almost impossible task. McNemar (1940) says, p. 362, "Surely psychologists have learned that very little light is thrown on, say, delinquent behavior by a minute clinical study of one case, yet we are expected by some to believe that the mysteries of human personality will somewhere be unraveled by an intensive study of just one case."

As an example of the widely varying interpretations that may be given by competent persons to a single case, consult Elkin's 1947 paper. He presented a detailed life history of a delinquent boy to 78 specialists from various fields and found

very little consensus in judgments and interpretations.

Under some conditions, however, individual case studies can yield significant scientific information. An example is found in the Neilon (1948) study, which matched personality sketches written for children of 18 months by one examiner with those written for the same children at 18 years by another examiner. The problem Neilon faced of determining the degree to which the matching is above chance is one common to many types of psychological investigations where descriptions, protocols, diagnoses, case histories, ratings, scores, etc., are to be matched. The psychological and mathematical principles involved are discussed in a number of papers: Zubin (1933), Chapman (1935, 1936), Vernon (1936), and Levene (1949).

Several types of individual case studies are found in the literature.

1. *Case history.* A case history is a collection of facts about a child referred to an agency for one reason or another. It includes material from official records, his own story, the accounts of relatives, teachers, and others, and the results of any examinations or interviews. Although such histories are of practical value for guidance, their scientific value is limited by the fact that the data collected are gathered after the referral. What is in a file often depends upon the interests of the case worker rather than upon a systematic attempt at complete coverage.

2. *Cumulative record.* In modern practice some agencies keep cumulative records in which measurements and observations are recorded at various times as the child develops. This is superior to the case history, both because of its greater completeness and because it avoids the errors of interpretation arising when working backward from an end result. With the wide extension of the testing movement, the improved cumulative records kept in school systems, and the cumulative folders which various social agencies maintain, many more data collected in advance of the event that brings the child to the attention of the agency become available. In time, with more complete records and successive observations of the same children, a wealth of research material will be available that will make possible the solution of many problems previously impossible of attack. Because of the long life span of the human being and his slow progress in a short period of time, the need for the preservation of data in order to make follow-up studies is great. The Baller (1936) and Glueck and Glueck (1934) studies are examples. It should be noted, however, that the follow-up should be very complete; otherwise, incorrect conclusions may be drawn because the cases easily found are more likely to be those with which success has been achieved.

3. *Clinical studies.* Clinical studies refer to the descriptions of pathological or abnormal cases which abound in the older medical literature. They usually consist of notes on the progress of the particular abnormality and are often supplemented by objective data.

4. *Personality studies of unusual children in the literature.* Often there come to attention children who are unusual in terms of capacity or extraordinary experience. Sometimes descriptive studies can be undertaken at the moment and ongoing developmental records obtained. Examples are found in Woolley's (1925, 1926) studies.

5. *Psychoanalytic personality studies.* A psychoanalyst after establishing rapport with his subject attempts to tap underlying memories and secure information regarding the origin of complexes and conflicts, etc. Through this process he seeks to re-educate the patient in order that the patient may achieve a balance or integration of his in-

stinctual drives and the demands the world makes upon him. The analyst's primary purpose is therapeutic. But he obtains many data on the early experiences of his patients, on which sweeping generalizations and systems of explanation of behavior are erected. Most of the theoretical and so-called observational material in the psychoanalytic literature relating to children is based upon neurotic adults' descriptions of their childhood experiences, which are obviously subject to retrospective falsification and confabulation (Wallen, 1942). Whether such accounts correspond to real experiences in their lives as children is open to question (Anderson, 1948). Most of the experimental checks made with normal populations of children on the generalizations made about child life by psychoanalysts have given negative results (Sears, 1942; Ellis, 1950). Note clearly that this criticism is not concerned with the generalizations about neurotic adults but with those about child life which are not based on actual observations of the patients as children but upon the memories which the patients who are a peculiar sample of adults retain of their own life as children.

There are books on child analysis, by Anna Freud (1925) and Klein (1932), which present some cases in great detail and others briefly. As one who knows normal young children reads, it becomes clear that the child is approached from a particular theoretical point of view and that the responses are fitted to that point of view. Little attempt is made to evaluate, no statistical or quantitative material is presented, and no complete statements or records of the analyst's speech and actions or of the child's responses are given. Some of the content seems to be directly or indirectly suggested to the child. Younger children are very markedly suggestible. No attempt is made to control the sampling of children subjected to analysis, nor are precise data over a span of years made available as to the success or failure of the therapeutic treatment. It should be noted that for various types of therapeutic procedures, a control can be obtained by comparing the recovery rate under therapy with the spontaneous recovery rate (Eysenck, 1952). The great difficulty with psychoanalysis as a scientific method lies not so much in its particular theories of behavior as in its acceptance of intuition as a valid method of securing basic data (Ellis, 1950).

One outcome of the psychoanalytic approach is the development of a very complex terminology which is substituted for older and simpler concepts. Although substituting a new term for an older one may give precision to the meaning to be conveyed, the new term in time acquires many connotations and loses its original precise significance. Translating from one set of terms to another disturbs the student. If he will take the trouble to go back to the facts and place the explanations of them in parallel columns, differences in explanation will turn out to be semantic or verbal rather than real. Such a comparison, particularly if age is a factor, may show that some generalizations are impossible. One can contrast the descriptions of the awareness of sex in young children as presented in a number of psychoanalytic studies with the actual findings by Conn and Kanner (1947), who in a direct study of children found that children's concepts of sex develop slowly over many years and follow much the same pattern as other concepts.

Behavior Surveys. A behavior survey seeks to record as much and as wide a range of behavior as can be recorded within the limitations of time and space available. In some of the infant behavior surveys many specific and well-controlled techniques, involving measurements, ratings, systematic observations, interviews and reports, measures of home background, etc.,

are utilized. Behavior surveys may be either cross-sectional or longitudinal. An early example is found in the Blanton (1917) study of infants, with its rather informal descriptions of behavior in many infants. If compared with the earlier Gesell (1928) surveys, which led to the normative schedules, then with the Shirley (1931, 1933*a*, 1933*b*) studies, and the more recent studies of Bayley (1933) and Gesell and Thompson (1934, 1938), the improvement in the descriptions of the procedures and tests, in the use of standard statistical procedures for analyzing the data, and in describing the sampling will be clear. Behavior surveys supplement and are themselves supplemented by the intensive studies of more limited area of behavior. They also often function as exploratory studies which become the basis of designed studies.

Combinations. Actually, in the conduct of any particular investigation, except those which involve very limited segments of behavior, a combination of many techniques for securing data is ordinarily used. From the face sheet describing the child studied, which is a report or questionnaire, through the specific observations used in the study, to the ratings which are often employed as criteria, many combinations are possible. Even the projective techniques, which at first glance seemed not to be usable, have been adapted to experimental projects.

Variations of Techniques with Age

Because of the great changes that take place with growth and development, the techniques for scientific study vary from age to age. Outstanding nodal points are birth which puts the infant into the outside world and makes him available for observation, the appearance of speech which enables the child to report directly on his experiences, and the developing of reading and writing skills which make possible many new and economical varieties of measurement. There follows a summary of the main techniques available by age levels.

Prenatal Behavior. Knowledge of prenatal behavior comes mainly from experimental and laboratory studies of animal fetuses, together with limited experiments and more extensive observations on premature human infants. The difficulties in research are tremendous, and the methods in use constitute almost a science in themselves.

Infants. With infants, experiments, direct measurements, and observations constitute the chief source of material. Because infants' responses are relatively fluid and unstructured, and because the infant lacks language, study in many areas, notably the sensory and perceptual one, is difficult. Numerous ingenious techniques have been developed, such as one-way vision screens, cinema recording, the Gesell observation dome, and the stabilimeter, which is a device for recording the movements of the infant in response to stimulation. A disproportionate number of studies are made on neonates because of their availability in maternity hospitals in large numbers. More than with older children there is a tendency to ignore sampling and take whatever children are available for study. Particular care must be taken to secure complete records, because of the tendency of observers to select only what meets their purpose. For instance, in earlier studies of reflexes, it was assumed that a specific movement in a particular segment would appear in response to stimulation such as stroking the sole of the foot lightly. But later observers who recorded all the responses to such stimulation found much variation and activity in other segments (Jensen, 1932). Most psychologists take some pains to avoid crude anthropomorphic interpretations. But another type of pro-

jection, is equally dangerous, namely, the unconscious assumption that the highly organized and precise patterns characteristic of older children and adults are to be found in infants and very young children. Some of them will be found, but they will be imbedded in a much larger response pattern. Hence, for scientific purposes, especial care must be taken to give complete descriptions of the behavior manifold.

Preschool Children. With preschool children methods involving direct observation and experiments occupy a prominent place. Because of the child's limited language responses and his inability to read and write, many tests and measurements available for older children cannot be used. Moreover, there is some difficulty in securing cooperation and motivation. Many persons who have worked with older children and adults expect quick answers and prompt responses from small children. But Goodenough (1935) found that reaction times are slower and much more variable and had much difficulty in getting young children to respond to a simple signal. Because of the lack of structuring, it is difficult to instruct the child in such a way that his responses will be limited to the matter in hand. Hence, many ingenious methods involving setting the stage or situation and then observing "natural" behavior have been developed. These are best illustrated in the studies on social behavior, in which children have been observed in free-play periods, in experimentally modified social settings, etc.

Older Children and Adolescents. With older children and adolescents every type of direct and indirect measurement, observation, and recording can be used. To some degree, paper and pencil tests, inventories, and check lists supplant direct observation. The older child or the adolescent knows how to read and write, and is more easily motivated, more docile, and better acquainted with test or experimental situations. But he is also more self-conscious and may be very clever at concealing his thoughts and feelings from the observer. Hartshorne and May (1928) developed ingenious methods of offering possibilities of deceptive and honest behavior within a pencil and paper test framework. In recent years methods of observation in "natural" or controlled situations have spread from the preschool field to the older child and offer an antidote to the somewhat excessive concern with pencil and paper tests. In the Lippitt (1940) studies of social atmospheres an excellent example of the use of one-way vision screens and careful recording of direct observations of the group structure and of individual behavior within that structure is found. The sociometric technique of Moreno (1934) and Jennings (1948), which is a combination of interviews, statements of choice, of playmates, dramatic play situations, observations in groups, etc., permits the diagraming of the interrelations and a study of group structures among individuals at all age levels. Since 1940 there has also been much use of the projective techniques.

The Development of Measuring Instruments and the Determination of Their Precision

In the first approach to psychological problems, measures with an obvious and direct relation to the phenomena studied were used. For example, speed of reaction was measured in units of time; memory by the amount retained; learning by reaction time or errors, and the height and weight of children in inches or pounds. These are simple as well as direct measures.

Later "indirect" measures appeared. Because the child as a functional unit cannot be separated into discrete parts, as can a chemical compound or a physical structure, indirect measures become necessary in order

to break up various phases of functioning into manipulable units for analysis and prediction. The classical instance is found in Binet's measurement of intelligence. By the use of multiple criteria—increase with chronological age, teachers' ratings, academic grades, and life success—leverage was obtained that separated out a commonality among tests which superficially bear little resemblance to one another. Intelligence does not correlate perfectly with any one of these criteria, but because the tests are positively correlated with each of them, that is, test scores increase with chronological age, ratings of brightness, school grades, and life adjustment, it can be assumed that, when they are combined into a single instrument, a factor common to all but not identical with any of these criteria will be measured. In measuring this common factor, the contribution of the components increases if their intercorrelations are lower than their correlations with the criteria, since this means commonality of measurement in terms of the criteria without identity or great overlapping in the components. If different criteria are used, a different commonality may appear. Indirect measurement then begins with a series of assumptions, which may be explicit and clearly recognized but often are implicit and not recognized, and ends with an instrument which gains its meaning from those assumptions, however it may be labeled. Failure to recognize this fundamental point causes much confusion and no end of argument and controversy.

The purpose for which the measure is employed often determines whether measurement is direct or indirect. For example, the weight of the child may be used directly to measure weight or indirectly as an index of nutrition or health. Although psychologists are sometimes criticized for using indirect measures, in actual practice tracers, indicators, or indirect measures are common to many sciences. In each instance the relation between the indicator and that which it indicates must be determined. Height is obviously measured by distance on a scale of inches or centimeters, and reaction time in units of time—in fact, for many direct measures the very terms used to designate them describe what is measured. Often direct measures are combined into a team for indirect measurement. For example, an arithmetic test given to measure a child's knowledge of what he was taught the preceding week is direct measurement. But he may be given a standardized achievement test in arithmetic not so much to measure what he knows of what has just been taught as to determine his level of functioning in arithmetic. This is on the borderline between direct and indirect measurement. The questions are indicators or samples of his general level of knowledge. That this kind of test is independent of the particular questions asked is shown by the fact that two alternative forms of a test made up of different items will yield similar scores. Or the arithmetic test may also be a part of an intelligence test battery, as in Army Alpha. Here concern is neither with particular knowledge recently acquired nor with achievement in arithmetic, but with problem solving in arithmetic as an indicator of intellectual level, a still more generalized function.

The details of the measuring devices, both direct and indirect, for the many problems and areas in child psychology cannot concern us here. Their number is legion. However, two interrelated fundamental problems arise in all measurement; one is the problem of *validity*, or the extent to which the device measures what it purports to measure; and the other is *reliability*, or the extent to which consistent results are obtained in successive use of the measuring device.

Validity and the External Criterion. With indirect measures the problem of validity, i.e., the relation between the indicator or tracer and the process of which it is an indicator, becomes of central importance (Guilford, 1946; Stuit, 1947; Anastasi, 1950; Gulliksen, 1950*a*, 1950*b*). Ordinarily validity is regarded as the relation between the scores on the measuring device and the scores obtained for some "outside" criterion or criteria which clearly measure what is purported to be measured. The best criteria are some measures of actual performance over a substantial period of time; the indicator or tests seek to predict this performance from a smaller sample of behavior obtained in a short time. Thus an indirect measure is not identical with a criterion but makes possible its prediction. For instance, if we wished to predict children's ability in drawing, we might collect their drawings for many months in order to get a firm distinction between the poor, the average, and the good drawings by studying all of them. Once the ability of the children in drawing was determined from the many drawings over a period of time, we could then correlate any test of the children with these results, and, if a high positive relation resulted, we might proceed to use the test for predicting drawing without going through the months of observation. In other words, an indirect measure is used because it is more economical than direct measures. If we were to measure intelligence directly in children, hundreds of acts in hundreds of situations would have to be described. For this long process the shorter process of a validated test is substituted. Since a measure is no better than the criteria on which it is based, much time, effort, and money are spent in getting good criteria. To get better tests, measures, and inventories, we need better criteria; in fact, the securing of good criteria is the most important single problem in measurement—the one upon which all else depends. Once good criteria are available, a whole array of statistical and other techniques are available for refinement and improvement.

A measuring instrument may have as many validities as the criteria with which it is correlated; it may be more valid for predicting some criteria and less valid for predicting others. It may also have a variety of subscores which are used for different purposes and to predict different criteria. Coombs (1948*a*) showed theoretically how a test can be made to yield six meaningful scores or indices, and he later (1948*b*) provided a rationale for the estimation of these scores.

A measuring instrument may be validated in a variety of ways. Sometimes the entire distribution of the criteria is used, sometimes extreme or contrasting groups who are widely separated in terms of the criteria, and sometimes even an already developed measuring instrument of known value. For instance, some group intelligence tests have been validated by correlation with Stanford-Binet individual examinations.

In the actual construction of a measuring device each individual item, part, or section of the device is correlated with the criteria, and those items, parts, or sections that show substantial correlations are retained and those that do not are discarded. However, in carrying through this process of item analysis some attention must be given to the intercorrelations of items, parts, or sections with each other, as items that correlate well with the criteria but poorly with each other are better than those that correlate well with the criteria and with each other.

Criterion of Internal Consistency. In developing indirect measures a procedure sometimes referred to as an internal criterion is often added. It is assumed that a total score based on many types of items

or subtests measures more of whatever common function is being measured than does any individual item or part. Hence, by a technique of item analysis which involves correlating each item or part with total score, those items or parts that show little correlation with the total can be eliminated and those that show substantial correlation retained (Gulliksen, 1950*b*; Lindquist, 1950; Davis, 1952). This reduces the length of the instrument to an effective minimum and results in a purer measure of whatever it is that is measured. By factor analysis (Spearman, 1927; Kelley, 1928; Thurstone, 1935, 1947; Guilford, 1936; Thomson, 1939), a similar function can be performed; i.e., it can be determined which test components carry particular loadings and which should be eliminated, purified, or added to in order to increase the effectiveness of the measures of the commonality in question.

Scaling and Standardization. Once a measuring device can be developed and its validity determined, and after it has been purified by means of the criterion of internal consistency, it is modern practice to give the instrument to a new group of individuals to determine the relations between the refined instrument and the criteria. This is often called cross validation. Since such relations obtained on the original data would be spuriously high, the principle that the data from the group used for item selection or validation are not to be used for final validation or standardization is generally accepted. In standardization the instrument is often scaled by giving it to groups of children at various age or grade or other levels which have been sampled from the population in accordance with definite principles and which are large enough to secure stable means and dispersions. With direct measures, the units of measurement are usually definite; the child of 8, on the average, reacts in so many thousandths of a second, is so many inches tall, and remembers so many words after a lapse of time; the child of 9 makes a larger (or smaller) score. Hence, scaling is comparatively simple. For indirect measures the problem of combining measures often based on different units arises.

In age scaling the mean performances of children at various age levels are determined and used as norms. Reference can be made to the normative group through percentiles or standard scores for the group as a whole or any part of it. A method that comes from the Air Force and which may have wide application in studies of children involves the conversion of scores into stanines, which constitute a 9-point scale with the middle interval or stanine 5 from -0.25 to $+0.25\sigma$ and other stanines at 0.5σ above and below, respectively. Stanines offer a ready method of interpreting results and can be used in combination with age norms to indicate the relative position of the child by three digits as 12–9, to show that the child's score lies in the ninth stanine for 12-year-olds.

Sometimes established cutting points, above or below which the individual is classed as defective or normal, neurotic or adjusted, introverted or extraverted, etc., are used. The classical distribution of intelligence quotients in terms of idiot, imbecile, moron, normal, etc., is an example. Often such cutting points are set by practical, social, or legal demands which make the division of the continuum into discrete classes necessary.

1. *Reliability.* The consistency with which a measuring instrument when used several times within a short space of time places those measured at the same level is known as its reliability. Because the child's height today is so little different from what it was yesterday, the same figures should be obtained today as yesterday in measuring it, unless an extraordinarily delicate

scale is available. When measures are repeated and correlated on the same children after a short interval, the size of the coefficients is said to express the reliability of the measure. The greater the consistency, the nearer the coefficients approach +1.00.

The three methods commonly used for determining the reliability of measures involve correlating (1) scores obtained on repetitions of the same measure; (2) scores on two similar but not identical forms of the measure; and (3) the score obtained by summing the responses on odd items with the score obtained by summing the responses on even items. The first method may be vitiated by a differential carry-over of practice effects; the second method corrects for this but necessitates two or more instruments demonstrated in advance to be equivalent; the third is much used, since no practice effects are involved and no second form is necessary. It is, however, an approximation. The determination of reliability is necessary for any measure used for the prediction of the performance of individuals.

The reliability of a scale and standardized measuring instrument can be readily determined. But many of the data available in child psychology are based not upon tests but upon observations resulting from schedules divided into defined categories. For these a reliability measure (perhaps not strictly comparable with that of tests but nevertheless of great value) is obtained by correlating the results of two observers, usually trained in advance, who record the behavior of the same children under the same conditions. When rating scales are employed, the correlation between independent raters or between successive ratings by the same rater after an interval of time can be used. Some investigators use the percentage of agreement between two raters or observers, or between two successive observations or ratings, as measures of reliability. Since no consistent procedures are followed in calculating these percentages, it is difficult to interpret them. More care should be taken to quantify such data in order to permit the use of established correlational procedures. In any event, the use of interperson reliability often produces significant modifications and improvement in observational techniques.

Where children's products, personal documents, or records in projective tests or situations are available, they can be rated or scored by two or more persons independently, each of whom is at the time of scoring ignorant of the others' scoring. This is now known as *blind analysis* and has been extended to diagnosis and classification as well. Here, too, correlation coefficients are to be preferred to the percentages of agreement so often calculated without reference to error formulae.

2. *Heterogeneity and homogeneity or range.* A serious problem arises in the interpretation of reliability, validity, and intercorrelation coefficients obtained on children. Since the size of a correlation coefficient is a function of the homogeneity or heterogeneity of the population on which it is calculated, and since almost every structure and process in children changes in some degree with chronological age, very high coefficients can be obtained by using a wide age range. Reliability coefficients calculated for a level covering a single year can be raised 20 or more points by calculating them for a 3-year age range. Hence, in determining validity and reliability, careful workers usually calculate the coefficients on a narrow age range, usually a single year, in order to eliminate the heterogeneity due to age. When reliability coefficients from different studies are to be compared, corrections for range should be made or comparisons avoided unless some account is taken of the range. Both readers of the

experimental literature and investigators should watch this problem with some care.

Heterogeneity also affects the intercorrelations of separate measures. Intercorrelations for different motor performances over a range of 4 or 5 years, particularly at younger age levels, are exceptionally high and indicate the possibility of developing a scale for general motor skills. But, when calculated over a year range, the reliabilities are so low as to indicate that such a scale cannot be developed. Moreover, the reliability coefficients for motor items decrease rapidly with age, whereas those for intelligence items increase. Thus, the effect of age upon intercorrelations varies with the function studied.

3. *Contamination.* Another problem in determining the relations between any two or more variables, including both validity and reliability coefficients, arises out of the manner in which the relation may be contaminated by the presence of undetected and unmeasured factors. For instance, motivation may affect the performance of children. To the extent that children vary in their motivation, scores are modified in such a way that the interpretation of the relations or scores is affected (Rust, 1931). Usually the effect of a contaminating factor in a large sample is to reduce the correlations obtained and thus obscure the real relations. In some instances, however, it may produce a spurious relation, as when both variables are positively related to a contaminating factor. As the phenomenon of contamination has become recognized, there has been developed an actual statistical technique of deliberately utilizing contaminating factors in order to suppress certain relations and to make others stand out in tests with several different types of scores. The phenomenon of contamination leads to a consideration of the conditions under which relations can best be determined. This involves the reduction of variable errors, whenever they occur, to a minimum as well as the elimination or control of constant errors. The size of a correlation coefficient is not always the result of the actual relation between the factors measured; it may also be affected by poor measuring devices with low validity and reliability and by masking or contaminating factors.

From the foregoing it is clear that the construction of a good measuring instrument is a technical job that requires much ingenuity and skill as well as an understanding of basic principles of measurement and of the appropriate statistical procedures. A good instrument opens up many areas of research that previously were inaccessible. It is unfortunate that so many haphazard, poorly standardized, inadequately evaluated, and inappropriately named devices are put forward. Nowhere is this more evident than in the fields of child psychology and educational measurement, where such a host of devices is available that an annual bibliography that fills a volume is necessary merely to catalog them (Buros, 1949). Excellent discussions of the principles, statistical procedures, and techniques for validating, scaling, standardizing, and determining the reliability of measuring instruments are found in a number of textbooks and an extensive literature of articles.

Sampling

Some of the inconsistencies and contradictions in published research grow out of variations in the selection of the cases studied. Whereas psychologists were formerly much concerned with the precision of measures, the years since 1930 have been marked by great interest in sampling problems. For scientific purposes the children studied in any investigation become the representatives of an *infinite* population, whereas in

practical relations concern is with a *finite* population. A test of reading proficiency is given to a fifth grade. If the tester's interest is only in the performance of the children in that grade, the results obtained have no significance except that of helping the teacher with these particular children. But, if the test is given to establish norms or to compare one method of instruction with another, the children in this particular fifth grade have become the representatives of the children in fifth grades in our society, both at the moment and for some time to come. Hence, the question whether the children are a good sample of fifth graders becomes of paramount importance. It should be clear, however, that a sample representative of all fifth graders or of all 10-year-olds is not always needed. Sometimes the experimenter seeks a sample representative of a subpopulation which can be explicitly defined, e.g., fifth graders of high intelligence or of low intelligence. A study of instructional methods might give different results for these two subpopulations, which in a sense are "competing" groups. Nevertheless, each is representative in the sense that it has characteristics that can be defined and on the basis of which similar samples can be drawn from the population.

In drawing a sample, care must be taken to define the limiting terms with precision. For instance, to say that "problem children" are studied is virtually meaningless, since at least three definitions of such children are current: (*a*) children selected by teachers as difficult (Haggerty, 1925); (*b*) children referred to guidance clinics, courts, or institutions for delinquents (Ackerson, 1931); and (*c*) normal children passing through a particular phase, as in Olson's study of nervous habits (1929).

The necessity of asking the questions, "Of what population is this group a sample?" and "Is it a good sample?" is not always recognized. Some authors carefully and almost apologetically limit their conclusions to the particular sample studied. One may ask, then, why publish at all? Others make extreme generalizations on samples that are neither representative nor adequate in size. One may ask, why publish until some effort has been made to secure a good sample? If conclusions were examined in terms of sampling procedures, many inconsequential studies would not appear.

Implicit in any discussion of sampling is the problem of *statistical significance*. Since the purpose of research is to generalize from a sample to a population, the question whether the results obtained from a given sample arise by chance or are the outcome of the conditions being studied is pertinent. In modern treatments, the *null hypothesis* is assumed, namely, that whatever appears in any particular sample is the outcome of chance. It becomes the obligation of the investigator to prove that his results are not likely to be chance outcomes but are the results of the introduced condition he is studying. He does this by showing the degree of confidence that can be placed in the differences obtained, or the likelihood that they would not occur by chance alone.

Sampling problems first arose in connection with normative studies, since the value of a standard is clearly a function of the sample. Height-weight tables and intelligence test scales are standards against which thousands of individual children will be checked for diagnostic, and practical purposes. If the standards are inaccurate or inadequate, the usefulness of the instrument is substantially reduced.

Is a random sample of humans possible? At first thought it would seem possible to select children at random, but a moment's consideration shows that this is not possible. The essential condition for a random sample is *that each individual in the population is as likely as any other to appear in the sample drawn.* But human beings are social and

live in an environment shot through with selective processes. In cities, families of the same income level live in the same neighborhoods. Each occupation and profession is itself selective. A church, a political group, a social club, a leisure-time activity is selective. Often children in the public schools are thought of as a typical or complete population. Since some children do not enter public school because of mental and physical defects, and others go to private schools, even the kindergarten or first grade is somewhat selective. After school entrance some children progress more and others less rapidly. In a short time the children of a given chronological age are spread out over a number of grades. If one were to study all first-grade children in an area with compulsory education, a better sample would be secured than if seventh or eighth graders in the same schools were tested. Since many children never go to high school and only relatively few get to college, high school and college populations are far from representative. Even the schools and areas within a city are highly selective. Table 1 from Maller (1933) shows the mean IQ's of fifth-grade children in 273 health areas in New York City. The mean IQ for the areas varied from 74 to 120. If a school selected for studying happens to be one with a mean IQ of 74, or with a mean IQ of 119, how typical or valid would the generalizations be?

Stratified Sampling. To meet the problems imposed by the differential selection of human beings by their social environments, various techniques have been evolved for drawing stratified samples from the total population. For example, since the child population of the states varies, an investigator might draw a sample from each state that was proportionate to the total child population of the state. Stratified sampling assumes that the total population can be divided into classes in accordance with known and measurable characteristics. Within these classes the size of the sample selected is proportionate to the size of the class in the total population. Stratified sampling has been given great impetus by the development of public-opinion polls in which such sampling is critical. The poll procedures involve the use of sampling criteria laid down in advance by means of which a sample that mirrors a total population can be selected. See Yule and Kendall (1937) for principles of stratified sampling, McNemar (1946) for a critical discussion of opinion polling, and Peatman (1947) and various other statistics textbooks for procedures.

Students often confuse the meaning of random and stratified samples, particularly because of the modern emphasis on random sampling. Some assume that a randomized sample of a population automatically guarantees a good representation of the total population. Actually, such a representation can be guaranteed for a single sample only

by stratification, unless the sample is itself a very large proportion of the total population. Inspection of a sampling distribution for any statistic reveals that many particular samples selected at random are far from a correct representation of the relation under study. In industrial work with quality control this problem is met by taking a series of random samples. But in psychological work this is not ordinarily done. However, within stratifications based on known characteristics samples are usually drawn at random, particularly if large populations are available to the investigator.

In the selection of stratified samples of children, the following breakdowns are commonly used.

Age. In many earlier studies the numbers of cases at different age levels varied. In modern studies the problem of age sampling is solved by using the same number of children at each age level, say 100 at 2 years, 100 at 3 years, and so on. Age stratification can be further controlled by testing children on their birthdays, or selecting children within 1 month of their birth date, instead of selecting over a range of a whole year within the age classification. This locates the points on an age curve more precisely, increases the accuracy of the determinations, and gives the same results as a larger sample over a wider age range. Selecting a constant number of children at each age level not only improves sampling; it also simplifies calculations and the determination of various statistical constants.

Sex. Some of the earliest studies on children, even those on physical growth, made no distinction between the sexes. But now, since it has become clear that some developmental phenomena differ in the sexes, the practice of reporting results on boys and girls separately is almost universal. The common practice is to use equal numbers of boys and girls. The age sample of 100 children described above would, with sex stratification, consist of 50 boys and 50 girls at each age level. Although an equal sex division is not absolutely representative at all ages of the true proportion of the sexes in the population, it is so close to it that no error is introduced.

Location or Area. In the early standardization of intelligence tests, particular efforts were made to secure children from different areas and parts of the country on the assumption that there was great variation with geographical location. In the past educational standards, the enforcement of school attendance, and the content of the curriculum varied widely. But, as conditions improve in backward areas and as modern means of mass communication develop, these differences tend to disappear. Anderson (1936) found differences with geographical location relatively small in comparison with differences in cultural or socio-economic status. A professional person's son in Alabama lives more like and is more like a professional person's son in Michigan than either is like a laborer's son in either state.

Rural-Urban. One difference in location is of some importance; that of rural or urban residence. Baldwin, Fillmore, and Hadley (1930) found significant differences in intelligence test scores, and the studies of the College Entrance Examination Board have revealed some differences in verbal and problem-solving ability, the former in favor of city adolescents and the latter in favor of rural adolescents. With improved means of transportation, the consolidation and equalization of schools, and the widespread extension of the radio, many of these differences are disappearing. A surprisingly large proportion of all the studies on children that are available in the literature have been done on city children because they are more readily available.

Cultural or Socio-Economic Level. Human societies are divided into strata based on income, educational level, cultural background, and a variety of related factors. Because these strata differ markedly in the facilities and opportunities afforded children, a significant sampling problem arises. Various proposals have been made for its solution. The most common involve selection either in terms of a single factor, such as paternal occupation or income level; or in terms of a series of questions covering occupation, income, possessions, etc., as in the Sims' scale (1928) or the very complete scale of Leahy (1936); or in terms of cultural level, as in the studies of Warner *et al.* (1949).

Many modern studies in child psychology control selection in terms of paternal occupation, which has a distinct advantage, since the occupational distribution for any particular area or section or for the country as a whole can be determined from census data. Paternal occupation is one of the few cultural facts for which universal figures are available. One of the most widely used socio-economic devices is the Minnesota Scale of Paternal Occupations (Goodenough and Anderson, 1931; Institute of Child Welfare, 1950), which divides adult males into seven classifications according to their occupations as in Table 2.

TABLE 2

CLASSIFICATION OF OCCUPATIONS OF EMPLOYED MALES IN THE UNITED STATES

	1940 Census		Sample	
	Total	Percentage	100	50
Class I. Professional	922,156	2.71	3	2
Class II. Semi-professional and managerial	2,436,397	7.16	7	4
Class III. Clerical, skilled trades, and retail business	4,808,143	14.13	14	7
Class IV. Farmers	5,192,658	15.26	15	7
Class V. Semi-skilled occupations, minor clerical positions, and minor business	8,129,266	23.89	24	12
Class VI. Slightly skilled trades and occupations requiring little training or ability	4,954,463	14.56	15	7
Class VII. Day laborers of all classes (including agriculture)	7,584,820	22.29	22	11

To set up a sample of 100 children at any age level, knowing the occupation of their fathers, proportions can be matched by rounding the percentages; or by rounding to even numbers the sample can be split in half to permit control of sex as well as of occupation. The third and fourth columns of Table 2 show samples for 100 and 50 cases, respectively. It should be noted, however, that this sampling is concerned with increasing the accuracy of the mean and standard deviation of the whole distribution, not with determining the differences between occupational groups. If differences between occupational groups are to be determined, precautions have to be taken to secure enough cases in each class to give confidence in the comparisons.

If published data are checked, much sampling is found to be far from typical. Children from the extremes are more readily accessible than children in the middle ranges. Parents in the upper three occupational groups, which contain 23 per cent of the population, tend to be more cooperative, more easily reached, more interested in programs of measurement, and more likely to volunteer or take advantage of an agency set up for children. Some parents in classes VI and VII are in close contact with social agencies, day nurseries, etc. A private school with tuition draws its population almost entirely from classes I and II. A day nursery or a settlement house draws its population from classes VI and VII. Thus classes III and V in the urban areas tend to be neglected, and only very few studies contain representatives of the rural groups in classes IV and VII.

The necessity of controlling occupational backgrounds depends upon the correlation of the particular characteristics studied with occupational status. But a very substantial number of traits, environmental conditions, facilities, etc., have been shown to be correlated in some degree with occupational status (Anderson, 1936).

Combinations of Controls in Sampling. In most investigations in which sampling is controlled, a number of controls are used simultaneously. The most common are age and sex; to these, many modern studies add a control of socio-economic or cultural status. School grade is frequently used. Urban and rural residence are less often added. Either mental age or IQ is sometimes used as a control. The selection of controls depends upon the nature of the study and the size and location of the population available for study. In general, the deliberate control of sampling through laying out criteria in advance is the ideal. Failing control of sampling, it is important, especially for the subsequent integration and interpretation of research findings, to give such complete descriptions of the sampling used in any investigation that the reader will be able to compare the results with other studies and make the integration himself. The minimum is chronological age, sex, socio-economic status, and school grade, with such additional material as mental age and urban and rural residence if it is available.

Use of Readily Obtained Data as a Base for Sampling. Since obtaining a sample which possesses defined characteristics presents difficulties, investigators secure children for study in various ways. One method is to consult school or institutional files and to use the recorded data as a base from which to make a selection. The names of children who meet stated requirements as to age, sex, socio-economic status, intelligence, achievement, etc., can be chosen. Usually a list with at least twice as many names as needed in each defined category is made up. The names are then randomized within the category, e.g., 9-year-old boys of occupational class III, and the children are contacted in order and examined. If a given child cannot be located, the investigator moves on to the next one in the category. Sometimes a large number of available persons are examined, in order to draw a smaller sample which possesses known charactersistics for a more detailed study. For instance, in the Griffiths study (1952) the cooperation of many P.T.A.'s was secured, and thousands of parents filled out a face sheet and a brief inventory of their attitudes toward behavior difficulties. From the face-sheet data a sample meeting defined criteria were selected. The attitudes of the children of these parents toward the same difficulties were obtained, and cross-comparisons of parents and children within various educational and occupational classes were made. By using data on the most readily available large population, much

time is saved and a much more meaningful and precise attack can be made on the problem in hand. Although investigators often find it disturbing to throw away data that have been collected, there are instances in which such elimination increases the scientific information gained from a study. Sometimes it is possible to analyze the data in the rigidly controlled sample for some purposes, and to use it plus all the other data for other types of analysis.

Size of Sample. The size of the sample necessary to secure significant results for a particular problem presents a real difficulty. In the 1930's it was assumed that the more cases used the more significant were the results. Although this principle is still sound, provided the sample is adequate in character, nevertheless most scientific workers are under practical limitations of time, money, and availability of subjects. It then becomes desirable so to design and arrange a study that the results will be significant, without undertaking a great amount of unnecessary experimentation. From modern discussions it is clear that a small sample selected in accordance with criteria rigidly laid down in advance gives more significant and meaningful results than does a larger sample the characteristics of which are unknown. The better public-opinion polls and the sampling techniques used in modern industry are based on this principle. But some students assume that small samples have some peculiar virtue of their own and interpret Fisher's work as supporting that position. But Fisher is quite clear that a large sample is to be preferred to a small sample; his discussion is concerned essentially with securing the maximum scientific information from the sample available and with the ineffective use of disproportionately large samples that yield relatively small returns when more effort put into design and less into collecting data on a large and miscellaneous sample would yield much more scientific information. Harris, Horvitz, and Wood (1948) have outlined methods for deciding on sample size in designing experiments in which specified degrees of accuracy are desired in determining confidence intervals, the significance of means, and differences between means.

The size of the sample also varies with the type of problem under investigation. For instance, reaction time can be determined with great accuracy on a small number of cases, whereas measures of more complex processes need a larger number of cases. Further, the size of the sample depends upon the number of relations involved. Where two variables are studied and extraneous factors are rigorously controlled by the experimental set-up, a smaller sample is necessary than when the weight and pattern of many factors contributing to a complex area of behavior are to be studied without rigorous experimental controls. Precision depends also upon the reliability and validity of the measuring instrument. With coarse instruments more cases are needed to establish whatever trends or relations exist. McNemar's (1940) bibliography and article on sampling closes with this statement: "Perhaps the confidence to be placed in the results of a study should vary directly with the amount of information concerning the sampling and experimental techniques rather than inversely with the square root of the number of cases". (p. 363).

The Organization and Design of Studies

Experimental design is a phrase that has been used for a plan or outline of an investigation that (1) states a problem or hypothesis precisely, (2) defines a population or supply, (3) draws from the population a sample for study, and (4) arranges the

observations and measurements of single and multiple factors in such a way that maximum information will be obtained (Fisher, 1936, 1937). Information as here used means "scientific information," not merely a collection of facts. It refers to facts and principles, and their interrelations. An essential element in design is the deliberate control of the number of cases, the number of samples, and the replication necessary to secure the information wanted. Design implies that the methods of measurement and control, and the sampling procedures, are laid out in advance and are interrelated. Seriatim and isolated experiments are consolidated into single studies in order to secure more scientific information with a smaller number of cases and to evaluate the interaction of factors statistically in a way impossible in one-factor studies. An ideal of design is the securing of maximum information for a given expenditure of time and energy. Fisher and his followers have also provided new statistical tools with which to determine significance, analyze variance, and study interaction.

Design. The problem of design is an old one. In laboratories systematic arrangements to control factors have always been used. Although many such designs have neglected sampling criteria for subjects, much concern with the number and character of the observations necessary for generalization has been shown. For example, Melton (1936) presented an extensive discussion of experimental methodology in learning which has important implications for other fields. Brunswik (1947) presented detailed analysis of experiments in physical and social perception.

The term "design" may be broadened to cover all schemata for investigations, laboratory experiments, and control group studies by means of which observations are systematically structured. The sampling controls set up by Fisher may be regarded as particular instances of a more general problem. Past and projected investigations can be examined with respect to their design, and questions regarding their quality or the adequacy of the design can be raised. Is the design such that information will be obtained? Will the maximum information in terms of the amount of time, money, energy, and number of cases available be obtained? Of these questions, the second is the more important because it implies a type of planning that will enable the investigator to know in advance what he may expect from his efforts and assumes some knowledge both of the variables under investigation and of the specific hypothesis involved.

The plan or schema of published or projected studies may be represented in diagrammatic form, as in the chart showing the technique of the control group on page 47. The Latin square is a diagram of an investigation in algebraic form.

Discussions and demonstrations of the manner in which Latin squares can be used in the design and analysis of psychological experiments are found in Grant (1948). It is clear that the theory and practice of experimental design are advancing with great rapidity. Grant's (1950) article and books by Johnson (1949), Edwards (1950), Cochran and Cox (1950), Anderson and Bancroft (1952), and Kempthorne (1952) summarize modern developments. The implications of postulates for a system of experiments may be put in terms of symbolic logic, as in Hull *et al.* (1940), or in topological diagrams, as in Lewin (1936). Methods of representing design in generalized symbolic form are of great value in planning studies and in thinking through to their outcomes, since they abstract in some degree from the material particular to an investigation and lead to the essential features underlying many different studies.

One can hardly engage in this symbolic process without improvement in the specific study undertaken.

Experiment. The phenomena of interest to science seldom occur in isolation or with such high frequency that observations can readily be made. No matter how careful the recording or how unbiased the observation, progress is slow when science has to await natural occurrences in natural settings. Experiment, or the deliberate attempt to isolate phenomena and reproduce them frequently enough under controlled conditions in order to determine their characteristic relations, then, becomes the primary and basic scientific method.

Not all phenomena, however, are equally adaptable to the use of experimental techniques. For instance, because of the long life span of the human, experiments in human genetics are sharply limited. Investigators turn to short-lived animals, such as the fruitfly, which produce many generations in a short time, in order to control and isolate the significant factors. Similarly, the complexity of the human environment and the irreversibility of behavior make many growth, developmental, and social phenomena not readily susceptible to laboratory experiment. But science has and is developing other techniques for securing data and making generalizations in those instances. One result of these methods is that key experiments can be introduced at some points in the complex manifold.

In making experiments two methods are used either singly or together to control various factors: (1) making given factors constant in order that they may not affect the particular factors under observation, and (2) isolating a factor or purifying a substance by eliminating all extraneous material and then studying its nature and effects. In either method the experiment takes the complex phenomena of nature, breaks them up into segments, studies the action and relations of these segments, either singly or in combination, and arrives at appropriate generalizations. Every experiment is an abstraction, since material is pulled out of its individual context. Whatever the method used, the control is deliberate and in a sense artificial. Thus, in a relatively simple experiment, children similarly motivated and free from distracting influences throw a ball at a target from a known distance in a special room in order that learning may be studied. Or, in a complex experiment, a series of difficult tasks may be set before children working individually, in groups without team structure, or in groups as members of teams, and praise may be given to half the children in these varied tasks and withheld from the other half. Thus the effect of individual effort, effort under social facilitation, and effort under competition may be compared both with and without the special incentive of praise. Such a complex experiment involves a systematic arrangement, with rotation of stimulation and groups in order that the weight and nature of various factors may be determined and compared.

However, in most experiments on children a major difficulty is soon encountered. If an attempt is made to use the same subjects over again with the same or different stimulation, the children will have changed because of growth and the incidental and formal learning which constantly goes forward. Hence, control groups become necessary.

The Control Group. In actual practice experiments are enlarged to include a second group of children in which the particular factors under observation are not introduced and which is periodically measured in the same way as the group of children in the experiment, called the experimental group. The use of an experimental and control group permits comparison between

children subject to and children not subject to an introduced condition. The method of the control group has many ramifications and many modifications. Figure 1 shows its essential features.

In this diagram periodic tests or measurements are indicated by solid lines, the experimental condition by cross-hatched lines, and the absence of this condition by dash lines. The lighter solid lines indicate accessory tests or measurements which might be used to measure transfer or spread because of the introduced condition. Differences between first tests and end tests reveal the immediate effects of the condition introduced, and differences between first tests and final test the permanency of those effects. Measures of the differences between the experimental and the control group can be obtained in a variety of ways, such as dividing the gain in the experimental group by that in the control group or by expressing gains in both groups as percentages of the original score. Such manipulations often clarify thinking about the relations involved.

Such a design can be extended by adding other groups subjected to different conditions. The number of cases used may vary from 2, as in co-twin control, to large populations. Usually in setting up control groups the capacities or present attainments of the children are matched and variations are then introduced into the environment or context. Thus, the experimental group may be exposed to typewriters while the control group is not, in order to determine the effect of typewriters upon spelling, reading, and writing (Wood and Freeman, 1932). Or the experimental group may have geography lessons plus motion pictures, and the control group geography lessons without motion pictures. The experimental group may have one type of instruction in reading, and the control group another. The experimental group may be given intensive training in motor, intellectual, or linguistic skills, while the control group moves ahead in its ordinary environment. But the control group may consist of a group of children that differ markedly in a factor under study, as when children

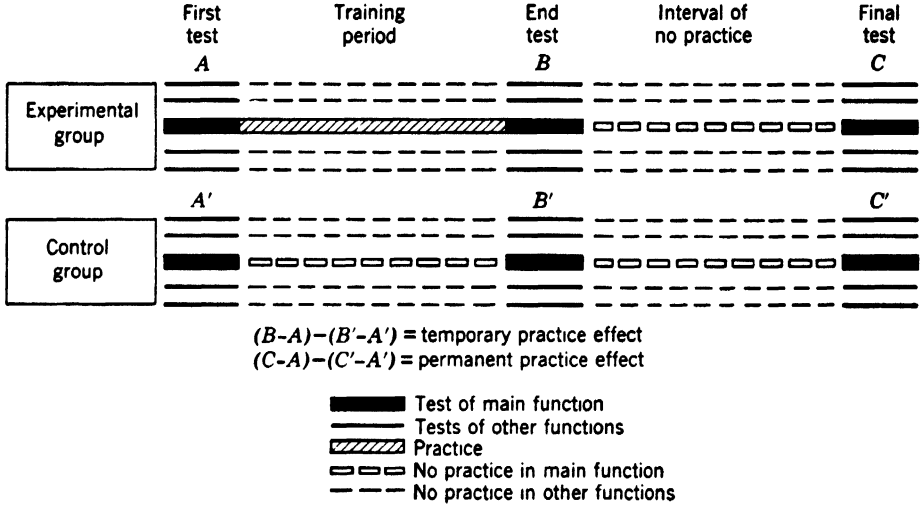

FIGURE 1. Technique of the control group.

of high intelligence are compared with those of low intelligence or children of high musical capacity are compared with those of low musical capacity.

In using a control group an attempt is made to secure a reference line or base from which comparisons can be made. Logically, it seeks to avoid generalizations based upon mere concomitance by taking account of exceptions, that is, by determining whether or not the change occurs in the absence of the particular factor or factors under consideration as well as when they are present. To the naïve observer concomitance often seems of high importance; the scientist must determine whether the concomitance is genuine or accidental. In an only child with a behavior problem, no doubt exists as to the presence of the problem in the particular child. But someone may generalize that "onliness" and "behavior problems" are related.

For the scientist the critical question is how much confidence can be placed in such a generalization—not the fact that the two events occurred together in a particular series of instances. Even additional cases in which only children and behavior problems went together would not eliminate the possibility of bias, sampling errors, or misinterpretation. It is absolutely necessary to secure information on the proportion of only children who do not show behavior problems and on the proportions of non-only children who show and do not show behavior problems. With such a fourfold table based on a sufficient number of subjects the association between being a behavior problem and being an only child can be measured and a generalization made in which the scientist can repose confidence.

Whether control is achieved by artificial and deliberate laboratory methods, by parallel groups, or by statistical analysis, all of which seek to determine net relations, there are three distinct methodological problems. The *first* is the determination of the relations between and interactions among the variables under consideration. This is a matter of descriptive statistics. The *second* is the determination of the confidence to be placed in the relations as determined. This is a matter of the statistics of inference. Confidence, expressed as a measure of significance or as a fiducial limit, involves disproving the null hypothesis by showing the extent to which the results depart from chance. The *third* is the matter of the psychological significance or meaningfulness of the relations found. This should not be confused with statistical significance. For example, differences in hair color among human beings, which statistically are of great significance, are of almost no psychological significance. Or a difference so small that it requires 1000 cases for its statistical demonstration will have no psychological significance (McNemar, 1940). Psychological significance depends upon (1) the fit of the generalizations within the framework of our existing knowledge, (2) their capacity to reorganize thinking and make meaningful data that did not previously fit, and (3) their usefulness in prediction and control.

The Matched Control Group. In this variation of the control group, the children within a defined group are divided into two groups as nearly alike as possible. Through preliminary measurements their status is determined and the best possible matches made within the framework of the group. With one variable involved, the matching is very simple. By putting the top child on the matching variable in the experimental, the second in the control, the third in the control, and the fourth in the experimental group, and so on, with alternating reversals through the population, the means and the standard deviations of the two groups are equalized. As the number of variables on which matching is done increases, the possi-

bilities of matching within narrow limits is reduced and a much larger population is necessary in order to secure precise matches. In the best applications of this technique the criteria for matching are laid down in advance and then adhered to rigidly. Thus, for example, where matching is done on more than one variable, the sexes can be equalized, socio-economic status matched in terms of parents' occupation, chronological age can be matched within 3 months, and IQ within 10 points.

Usually matching on the variable in which the experimental condition is to be introduced is very precise. The choice of matching factors depends upon this variable. If it is positively correlated with another factor, that factor should be controlled; if there is no correlation, control is not necessary. For instance, in studying motor skills, it is usually not necessary, except with very young children, to control either intelligence or socio-economic status, since the correlations between either of these factors and motor skill for homogeneous age and sex group is very low. But in a study of language, with which both socio-economic status and intelligence are positively correlated, both should be controlled. It might appear that, since the means and deviations for both groups on the original measurements are known, a correction could be applied to take care of differences in intelligence and socio-economic status. Although this is partly true, it is likely that any gain in language ability in the course of the experiment would be differential with respect to both intelligence or socio-economic level. Hence, a spurious difference would be obtained even though a correction had been applied.

There is always the possibility of so completely controlling the variables that little or no variation with the experimental condition is permitted. Sometimes more is held constant than should be. This may happen with the matching variables but is much more likely to occur within the materials or procedures used in the experimentally introduced condition. Thus, in an educational experiment, materials, textbooks, and exercises were so closely parallel for two groups compared for two different methods of instruction that no differences were obtained. Yet, in the actual practical use of these methods of instruction, the materials, textbooks, and exercises vary with the method of instruction. In experiments evaluating laboratory instruction in science, matching was done on a preliminary examination, but the final testing was done on the lecture material common to both groups and not on the laboratory content. Gates and Taylor (1926) found little or no difference between an experimental and control group as a result of training in a simple motor skill, whereas Mattson (1933), working with skills of three levels of complexity, found that the results obtained in a controlled experiment varied with complexity. And Jersild (1932), who found little change in motor skills of a simple type, with training, found much change in musical ability, that is, the ability to reproduce pitches and intervals. Since these studies suggest that the results obtained in control-group experiments vary with the measures used to test the effect, the complexity of the process itself, and the type or modality of the process, great care must be exercised in interpreting the results.

One source of statistical misinterpretation is found in the use of measures for evaluating the differences between experimental and control groups. Many investigators have used the formula for significance in which the correlational term is absent. When the phenomena studied are positively correlated with the factors by means of which the matching is done, that formula for the standard error of the difference in which the correlation coefficient is pres-

ent or some modification of it should be used. McNemar (1940) and Peters and Voorhis (1950) discuss the appropriate statistical formulae.

Furthermore, in pairing, controlling a factor such as intelligence also partially controls socio-economic status because of their high positive intercorrelations. McNemar points out that, as one increases the number of variables over which control is exercised, the returns obtained diminish much as do weights in a regression equation, where many overlapping variables are used. Thorndike (1942) points out some of the fallacies in matched group experiments. The question of the number of variables necessary for control for the particular study at hand should be carefully considered in advance, as no rule can be laid down to cover all studies. In most modern studies the variables used for matching are (1) sex, (2) chronological age (or school grade in educational studies), (3) intelligence, (4) socio-economic status, and (5) initial status on the factor investigated.

Solomon (1949) has shown that additional control groups facilitate analysis in experiments in which tests are given before and after an experimental training procedure. In a second control group the pretest is omitted when it might result in an interaction with the training procedure. A third control group, omitting both the pretest and the training procedure, is desirable if an uncontrolled extraexperimental event may affect all groups. The third control group makes pretest effects completely orthogonal to the training effect and permits independent evaluation of the effect of (1) the training procedure, (2) the pretest, and (3) the interaction of pretests and training. (See also Grant, 1950; Canter, 1951.)

Controls Drawn from a Supply. In many studies the individuals in a finite population are paired with children drawn from a supply of cases in the general population. If the supply from which the control group is drawn is large, very precise matching can be done to meet very narrow criteria. Thus the investigator may be able to match chronological age within 10 days on either side of the birthday, IQ's within 5 points, and socio-economic status, sex, and other factors rigidly. The number of cases necessary to secure pairs increases with the number of matching variables used. Thus, in a study by Goodenough (1928*b*), in which children were paired with respect to sex, age, IQ, education of father, education of mother, socio-economic status of the father, and the nativity of parents, a supply of more than 300 children was necessary in order to secure matches for an experimental group of 28 children.

Matching after Exposure to Experimental Conditions. Sometimes in a minor variant of the control-group technique one segment of a fairly large population is exposed to experimental conditions and another is used as control, and the matching is done after the collection of data for both segments. It is often more convenient to test all the children in a classroom or school in order not to interrupt the school routine by drawing out the special cases needed. Later, as the matching is done, the irrelevant cases are discarded. Note that here, too, the criteria laid down for matching must be clearly stated, rigidly adhered to, and the matching done on the first measures obtained, not on the end results.

Ex Post Facto Matching and Analysis. When an extensive series of records is available for a large population, it is possible to select groups in accordance with defined criteria on the basis of the records and to compare them in terms of outcomes. This procedure is called by Greenwood the method of *ex post facto* analysis. Both Greenwood (1945) and Chapin (1947) have devoted much attention to its implications and use, as well as to other methods of de-

sign for sociological data. Essentially it consists of projecting sampling criteria for control purposes on already existing data and rigorously selecting cases which can be defined with high precision in terms of their original status. There is no theoretical objection to the technique. If, for instance, the records of 100,000 children examined 20 years earlier were available and three groups of 1000 cases each of bright, average, and dull children were selected and their careers followed to the present, the results would be excellent. In fact, the method might even have some advantages in that, since the children did not know that they were being studied for a special purpose, the results would not be distorted by awareness of being in a specially selected group. This method must be sharply distinguished from any selection of cases in terms of end results, a method obviously defective from the standpoint of drawing scientific generalizations.

Co-Twin Control. Because nature does an excellent job of pairing in identical twins, the method of co-twin control offers an unusual opportunity for attacking many scientific problems. One or more pairs of identical twins are selected; one member of each pair is exposed to a particular condition while the other child is not so exposed. Pretests are given, followed by exposure and tests and final tests after an interval. Gesell and Thompson (1929), Hilgard (1933), and Strayer (1930) are good examples of such studies carried on for short periods. In these investigations the twins used in the separate parts of the studies were reversed; i.e., in one, twin A was given the experimentally introduced condition while twin B was held as control, and in the next twin B was given the experimental condition and twin A held as control. In the McGraw (1935, 1939) study of *Johnny and Jimmy*, Johnny was given intensive training in motor skills over many months while Jimmy was not. Periodically both twins were given standard developmental tests, as well as tests in the specific functions in which training was given. Later on the twins were reversed for some training, and still later entirely new test and training situations were given to both. The method of co-twin control also permits many variations, not only in setting up parallel groups but also in setting up contrasting groups, as in the study of identical twins reared apart and the many studies of twin resemblances.

An interesting variation of the control-group technique is found in Kellogg and Kellogg (1933), who reared an infant chimpanzee and a human infant under similar conditions and made comparative tests and observations of performance at various intervals.

Control by Groups Rather than by Individuals. Pairing may be done on the basis of groups rather than individuals. For example, a school in a middle economic district in one city may be paired with a similar school in another city of the same size, and so on. In one half the schools instruction of one type is given, while in the other instruction of another type is given or a particular experimental condition is introduced. An excellent example is found in the Wood and Freeman (1932) study of the influence of the typewriter in the elementary school, in which 21 public schools in 8 cities were used as controls and 22 public schools in 8 cities as experimentals, together with 3 private schools for controls and 8 for experimentals. Some 15,000 children participated in the experiment. In this type of study comparisons may be made in terms of schools, grades, and individual children's performance. It is a question whether results of equal statistical and psychological significance might have been obtained with much less expense, time, and ef-

fort by using smaller numbers of children matched for individual performance.

Although the trend of modern statistics is away from large numbers of cases toward small numbers selected in accordance with rigorously defined criteria, there is some difference of opinion in the field of educational research, where large populations are available. Peters and Voorhis (1940), in a chapter on controlled experimentation, stress precise matching of individuals, whereas Lindquist (1940), in an extensive discussion of a variety of control designs for groups, favors the use of schools.

Control by Statistical Devices. In the experiment an attempt is made to isolate or make constant the effect of factors by artificial control of conditions, selection of subjects, etc. By the use of partial correlation a somewhat similar result can be secured. Suppose that the relations among the three variables intelligence, time spent in study, and scholastic success are investigated. After measurements on each of the three variables are secured for a group of children, time of study can be held constant in a partial correlation and the net relation between intelligence and scholastic success determined. Or the obtained variation in scholastic success can be broken down by an analysis of variance into its components and their contribution to the manifold determined after the variation resulting from chance is eliminated. Or two groups of children, one of high the other of low intelligence, can be paired with respect to time spent in study and their scholastic performance can be compared, or the relation between intelligence and scholastic success can be determined for a group of children who vary with respect to intelligence and who are placed under conditions in which all study for equal amounts of time. Thus the same problem is attacked in four different ways, ranging from complex to simple statistical treatments. By deliberate control of factors much of the subsequent need for complex analysis is eliminated. This brings out a very important point with reference to method; in general, control of conditions in advance is to be preferred to masses of measurement accumulated on many cases without control. Good experimental design may make complex statistical procedures unnecessary. But it should also be clear that, in many manifolds involving complex related variables, the relative weight of various factors and of their interaction can be analyzed only by complex statistical procedures. Hence, experimental and statistical methods complement each other and work toward the same goal of maximum scientific information on the particular problem in hand. A good practical rule is to control whatever variance is possible either by deliberate manipulation of conditions or by stratification and to randomize whatever variance remains in order to minimize its effects on the relations under study.

The Evaluation of a Study

Every advanced student and investigator reads many scientific articles and monographs. Such reports on investigations should not be accepted at their face value but read carefully and critically in order to separate out the firm and stable facts and generalizations. The reader's attention is called to the "Standards for Appraising Psychological Research," prepared by Wolfle *et al.* (1949).

Following is an outline that has proved of value both in evaluating studies and in checking on studies that are being planned. In a sense it summarizes much of what has been said in earlier pages. Although it could be extended to include many more details, it has been kept as brief and schematic as possible.

1. *Problem.* Is a significant problem attacked? Is an hypothesis that may be supported or refuted by the data collected set up and clearly stated? Or, if it is a normative or survey study, have adequate precautions been taken to insure that the final results will be of value in understanding children? Is sufficient account taken of the results of past studies and of the interrelation of scientific principles to permit the fitting of the results of this study into the framework of scientific understanding?

2. *Design and sampling.* Is the study so planned that it will give an answer to the problem proposed? Can the design be graphed or represented in other symbolic form? Is the number of cases adequate? How are they selected from the total population? Of what total population or supply are they the representatives? Within the limits of sampling established, is the allocation of cases randomized or subject to bias? Are the sampling and design planned with reference to the later statistical treatment and analysis of the data? If the sampling is not representative is it described so completely that the results may be compared and integrated with other studies? Does the description of the sample include chronological age, mental age, sex, grade location, socio-economic status, geographical location, and any other sampling criteria that are important? Can trends with sampling criteria or their combinations be determined? Does the design yield maximum scientific information for the time and energy expended? If not, how could it be modified?

Are the factors which are controlled described? How are control and isolation achieved? In investigations with control groups, is the sampling in control and experimental groups adequately described and similar or identical? How is matching or pairing done? Is the motivation constant for both groups? If not, is motivation checked on another group? Are the effects of incidental practice and indirect stimulation upon the function known or controlled? Are valid and reliable measurements of the level of proficiency in the primary function and in related variables available for the beginning and the end of the experiment, and after a period of elapsed time?

3. *Measurement.* Are the variables studied described in specific terms and clearly differentiated? How are the various measures of the variables obtained? In what units are they expressed? Is quantitative treatment used wherever possible? Are the measures used valid, reliable, and suitable?

4. *Procedure.* Are the procedures used, e.g., apparatus, tests, measuring devices, observational records, clearly and accurately described? Can the study be repeated from the descriptions given of the sampling, design, and measurement procedures? Are data systematically collected? Are adequate and permanent records kept? Is the method of recording uniform throughout? Are omissions and negative instances recorded? Are the procedures laid down followed rigorously without change throughout the study?

5. *Results.* Are the statistical procedures mathematically sound? Are they adapted to the problem? Are all the essential relations studied? Are all the necessary statistical procedures—number of cases, means, dispersion, percentages, measures of significance, correlation coefficients, etc.—used and presented? Are available errors ascertained and reported, or minimized by appropriate procedures? Have the sources and direction of constant error been checked? Is the quantitative material so analyzed as to bring out the essential relationships? Are interactions or interrelations analyzed? Are the data examined for contamination or masking of significant relations? Are the results clearly and succinctly presented? Do the verbal statements agree with the tabular and quantitative findings?

6. *Conclusions and interpretations.* Are the conclusions warranted by the data? Are they too limited in scope, or do they transcend the data widely? Is statistical significance confused with psychological significance? Are spurious relations or artifacts detected? Are significant trends overlooked? Are the results integrated in the general scientific field? Is

the significance of the findings for related fields pointed out?

Conclusion

In child psychology scientific problems are being attacked in a variety of ways by workers who are becoming more and more concerned with methodology. Child psychology, which at first accepted uncritically almost any observations or results obtained from the study of children, has become more mature. It now critically examines its methods and results and deliberately goes about designing experiments. In many areas the study of the child has moved from the exploratory phase to the comprehensive investigation carried on over a long period. In view of the fact that a science is a growing and developing dynamic system, it would be unfortunate if too much concern with a particular method or too narrow a preconception of what child psychology *should be* were to cut off a manifold approach to the complex problems of the developing person. From today's studies, however inadequate, come the highly developed techniques of tomorrow. Science crawls before it walks, and walks before it runs. And science learns from its experience and modifies its own methods, even though progression is often slower and more uneven than we could wish. Methods do not fall into Victorian classifications of right or wrong, of all or nothing. They are tools which are used, modified, and improved as time passes and problems are met. The scientist of today has a great advantage over the one of yesterday, not in his interest or ability but in the better tools that have been forged in the intervening period. Sin in science consists not in the use of a particular method but in failure to use a more adequate method when it is available for a problem in hand. To understand growth and development, which appear ever more complex as we learn more about them, we need not one but many competent investigators, not one but many and varied investigations.

CHAPTER 2

THE ONSET AND EARLY DEVELOPMENT OF BEHAVIOR[1]

LEONARD CARMICHAEL

Yes,—the history of a man for the nine months preceding his birth, would, probably, be far more interesting, and contain events of greater moment, than all the three-score and ten years that follow it.
—COLERIDGE (1885, p. 301)

The Importance for Psychology of an Understanding of the Early Development of Behavior Patterns

In any complete discussion of child, developmental, or genetic psychology two questions must be asked: When does behavior begin? How does behavior develop during the early weeks, months, and years of life? These two questions may be phrased as one: What is the origin and what is the embryology and early developmental sequence of the behavior patterns which are significant in an understanding of human mental life?

This chapter is written in an effort to deal with these questions. The material brought together here is concerned not only with facts about early human development but also with relevant facts about the development of infrahuman animals. Much more is known in certain respects concerning the early development of life in the animals below man than in man himself, and much of this information has direct bearing upon an understanding of human development.

A knowledge of behavior in prenatal life throws light upon many traditional psychological problems. For example, some of the old questions concerning the relative importance of heredity and environment in the determination of adult human mental life are answered by this study. The contest between empiristic and nativistic theories of perception, the question of whether development is continuous or saltatory, the problem of whether behavior is first general and later specific or first specific and later general, and even the question of the fundamental nature of human learning itself are all illuminated by the facts disclosed in a study of prenatal behavior.

Although reference will be made to learning in this chapter, it is not with learning but with the growth or maturation of behavior that the chapter deals. Howells (1945) has said: "'Maturation' is simply development in which commonly observed differences between individuals are correlated with previous differences in the inner organism rather than in the environment." Minkowski (1947–1948), one of the great students of the early development of behavior, has considered the problem of the beginning of mental development in the fetus. Here he discusses the relationship between the arousal of the fetal senses and so-called mental development.

In the investigation of the early growth of behavior, it is important to remember that at every stage the scientist is describing some reaction of an organism then living in an environment. At every level of development one must think of the organ-

[1] This chapter is a revision of a chapter in this same field previously published (Carmichael, 1933 and 1946).

ism as maintaining itself in its present environment. This last statement sounds like a truism. Actually, however, a great many errors have been made in the study of the early development of behavior by assuming that later performance is somehow implicit or hidden in earlier types of response. This has been called classically "the error of potentiality" (Lange, 1925, pp. 198–200). For example, one who wishes to describe the linguistic performance of a 5-year-old child must describe that performance as it appears at 5. It is not possible to infer the full character of that performance in any given individual from any study of linguistic performance, for example, in the first year of life. The 5-year-old performance is not implicit in the 2-year-old performance. The environment of the third and fourth years is all-important in determining, for example, whether the child at 5 will speak Spanish or English.

The error of potentiality may be avoided quite simply. It is necessary only to remember that the scientist who is dealing with development must study a series of temporally separated stages of growth. These are his facts. The tendencies or "growth processes" which give meaning to the relationship of these various stages are the scientific inferences that he draws. The question thus becomes not: What adult trait is mysteriously hidden in this or that early behavior pattern? but rather: What is the nature of the many developmental stages which actually were preliminary to the particular adult characteristic which is being studied? In the investigation of the prenatal growth of response, this distinction becomes especially important. The older workers in this field almost always wrote on the basis of a preconceived theory. One such view was the "doctrine of recapitulation." This theory saw in every action of the growing individual a complete parallelism with the action in adult life of an evolutionary ancestor of the individual being studied. This view is now discredited as a universal theory, and so are many other alleged explanations of behavior.

In this chapter an effort is made to deal with growth as the histologist deals with the wax reconstruction of the structure which he is studying. This wax-reconstruction method in microscopical anatomy involves the cutting, mounting, and staining of a series of very thin sections of tissue, and then by appropriate techniques the cutting-out of particular details from each one of these sections in layers of wax of proportional thickness. As these cut-out wax sections are put together, a magnified and truly three-dimensional object emerges. In the dynamic field of behavior a similar procedure is often valuable. Thus behavior as a series of temporal stages can be fully described, and then when these stages are viewed in relation to time a real reconstruction of the growth of behavior may be made. Whenever possible in this chapter, behavioral development will be considered in this way.

One reservation must be made here. In later sections of this chapter it will be seen that structures sometimes mature before a normal environment calls them into function. This may be called the law or principle of *anticipatory morphological maturation.*

When Does Behavior Begin?

Many of the older writers on child psychology, such as Compayré (1896, p. 44), allege that the study of child psychology begins at birth. Throughout the history of biological science, however, the incompleteness of this answer has been obvious to certain writers. Today all agree that we must move into the prenatal period in order to determine what Gesell (1928, pp. 303–306; 1929*a*, p. 631) has called the "onto-

genetic zero." The term *ontogenetic* as used here means development in the individual as contrasted with *phylogenetic* or development in the race, or evolutionary series, of the human and prehuman ancestors of man. Ordinarily, in biology, ontogenetic development is taken as beginning at the time of individual fertilization. Of course, in order that fertilization may take place there is antecedent life in both the ovum and the sperm (at least always in the ovum) before fertilization. Scientifically we must still accept the dictum, "All life comes from previous life." The new individual as such, then, may best be considered as beginning from the processes which are initiated at fertilization.

As just suggested, it is impossible to say that fertilization is in all senses the beginning of a new individual, because the reproductive cells trace themselves back through countless generations. Similarly, it is difficult to distinguish between the dynamic processes of structural development and the processes of the organism which may be called true behavior. Such distinctions can be made only by the use of commonly agreed-upon definitions. Ordinarily the beginning of behavior, and hence the starting point of behavioral psychology, is placed at the point where true receptor-initiated neuromuscular activity begins. It is assumed that this point is the one at which activities of the organism take place which involve sense organs and nervous system as well as muscles. Some writers hold that behavior, instead of beginning at the time of the first sensory-neuromuscular response, really *emerges* at this time. The word "emergence" is used by many writers on developmental psychology. Sometimes this word is given an almost mystical definition. When it is used in this chapter its meaning will be a simple one. Here the word emergence will be used to describe a relationship between events antecedent in time and a new and different event which is itself also described. For a critique of the definition of the word emergence, see Lovejoy (1926).

It is easy to deal with the emergent or novel creation of behavior in the abstract, but, when one turns to specific experimental studies of this emergence, the difficulty of the problem becomes clearer. Carmichael has studied in some detail, as will be noted below, the very first responses of many organisms. For example, let us take the guinea pig fetus. Logically, it is clear that there must be a time in growth when stimulation of this organism's receptors will not be effective. Then, at an immediately subsequent time, say 1 second later, when such stimulation is given, behavior results. At time *A* this response is not possible, but after added growth—that is, at subsequent time *B*—it is possible. The possibility of this first response is considered as dependent upon elaborate changes which include growth and which are taking place in the organism under consideration. Let us trace these changes back in the history of the individual. The processes basic to behavior involve the development of the germ cells in the parents and in the parents' parents. The growth and maturation of the germ cells in the parents are necessary, as are the so-called reduction divisions of the nuclear substance of the germ cells, fertilization, cell division, cell differentiation, cell migration, organ formation, and a whole series of other dynamic changes.

As a result of all this growth, a structure capable of making this first behavioral reaction *emerges*. Without these countless antecedent cellular and subcellular processes, the first external response of an appendage or of the trunk of the living organism could not occur. These processes, moreover, must not be thought of as a simple unfolding of preformed organs This old "preformism view" is no longer

held. Rather, at each stage the living organism is now considered to be maintaining itself in a dynamic relationship with the energies and the foodstuffs of its environment. This is not to say that the organism is being formed wholly by its environment, as the other old view, that of "epigenesis," held. Indeed, today it is clear that inheritance and environment always cooperate in development. The old quarrel between preformism and epigenesis is now seen to have been sometimes a battle of words engaged in before the relevant facts were known.

The processes basic to the reproduction of living animals are brought about in a number of different ways. In some animals the egg, after fertilization, continues to develop in protective coverings still within the maternal body. In other animals the egg leaves the body and continues development outside. In many animals the growth of all the fundamental organ systems is complete before hatching or birth. This condition may be considered as characteristic of many vertebrates, some worms, and certain arthropods. In the coelenterates, insects, and vertebrate amphibians, varying stages of growth after the new organism emerges from the egg are the rule. Common usage seems to have established the fact that the first stage of the development of any organism is to be described as *germinal*, the next stage as *embryonic*, and the latest stage preliminary to birth as *fetal*. The word *larval* is used to characterize independent, living, but organically immature organisms.

In describing larval development, two classes of such growth, direct and indirect, have been set up. In the first of these, development is linear—that is, each developmental stage produces an organism which is in most respects more like the adult than was the organism in its preceding stage. In the case of indirect larval development, however, organs often of a high order of complexity are produced which are later destroyed before maturity is reached. The term *metamorphosis* is applied to development of this latter sort. The terms *larval* and *pupal* are applied to describe stages in indirect development. Too little is known concerning the effect of environmental modification during the larval stage upon adult animals. This is a field in which more experimental investigation is almost certain to be done. For example, what influence will certain experimentally induced forms of activity in the wormlike larva have upon the fully developed *imago*, such as an adult butterfly? It is interesting in this connection to notice that among the older writers even on so-called inherited human instinct many examples were taken from types which pass through larval stages. (Cf. Bergson, 1911, pp. 172–176, and McDougall, 1923, pp. 69–71.)

The degree of maturity reached before the new organism begins an independent existence varies markedly from type to type. In so-called *oviparous* species, such as most fish and certain amphibians, eggs are laid as single cells and are subsequently fertilized after they have left the mother's body. In *viviparous* animals, such as certain fish and most mammals, on the other hand, all the early developmental stages are normally passed within the mother's body. Between these two extremes are the so-called *ovoviviparous* organisms, in which fertilization takes place before the egg is laid. Birds are good examples of this type. It is interesting to note that the so-called evolutionary level does not give a clear indication of the sort of reproduction which may be expected of an animal. The common dogfish bears its young inside the body until they are developed so that they may have an independent existence. On the other hand, the monotremes among the primitive mammals lay eggs.

There are, moreover, certain forms in which favorable or unfavorable environmental conditions seem to determine the fact of the hatching of eggs inside or outside the mother's body (Hertwig, 1912, p. 151).

Among the mammals it is also interesting to note that there is a great diversity in the degree of development that has been reached at the time of normal birth. Thus, as will be noted in more detail below, the young of the opossum are born in many respects as relatively early embryos, as contrasted with the newborn guinea pig, in which almost full-grown characteristics are observed (Hartman, 1920; Avery, 1928, pp. 258–265). This fact should be kept in mind at all times as these pages are read. To put this in another way, it may be said that the behavioral age or even the "mental age" of different species of mammals is very different at the time of birth.

Corner (1944) in his admirable book, *Ourselves Unborn: An Embryologist's Essay on Man*, presents a clear description of the anatomical development of man, taking into account its aberrations. He says: ". . . we begin our lives in continuance of a long past and in progression toward an unseen goal; that life is precarious from the first day to the last. . . ."

The Development of Behavior in the Lower Vertebrates

There are stages in the morphological development of the fish, amphibian, reptile, bird, infrahuman mammal, and man which are so similar as to make the study of one form important for a complete understanding of the development of other forms. This fact has long been recognized in anatomical embryology. By analogy, the same may be held to be true of behavior. Care must be taken, however, not to pretend to see homologies of behavior until by direct observation such homologies can be shown to exist. Figure 1 gives a somewhat too idealized picture of some of these relationships. For example, in certain forms nourishment during the entire fetal period is provided by the yolk of the egg in which the developing organism originated. This means that behavior in connection with alimentation is less important in such types than in others in which at an early developmental stage the ingestion of food is necessary. In spite of this difficulty, the study of fish and amphibians has provided much information of importance to one who would understand the gradual development of behavior. Swenson (1928*a*) has courageously attempted to set up seven fundamental acts of behavior as basic to the responses of lower vertebrates, mammals, and even man. These forms of behavior are progression, respiration, ingestion, expression, excretion, phonation, and reproduction. The fact that some of these processes can be studied in the amphibian larva as well as in the human infant makes the complete understanding of the simple organism especially important. Coghill (1929*c*, pp. 1004–1009) and others (Windle and Griffin, 1931, pp. 180–184) have developed this point of view in various papers.

The best history of the development of the study of vertebrate embryos is given by the scientist who did so much for the study of behavior that he may be considered the founder of the experimental study of early behavior. This man is William Preyer, late professor of physiology at Jena. His book, *Specielle Physiologie des Embryo. Untersuchungen über die Lebenserscheinungen vor der Geburt*, published in 1885, may be taken as the starting point for all subsequent investigation in this field. Part of this fundamental work has been translated by Coghill and Legner (1937).

In this basic work Preyer summarizes and reviews a good many observations made on the early movements of fish em-

bryos. Some of these studies were based on the observations of fish embryos growing after definitely dated periods of fertilization. In general, on the day following the first trunk movement the first head movement is noted. Then, in a few days, ener-

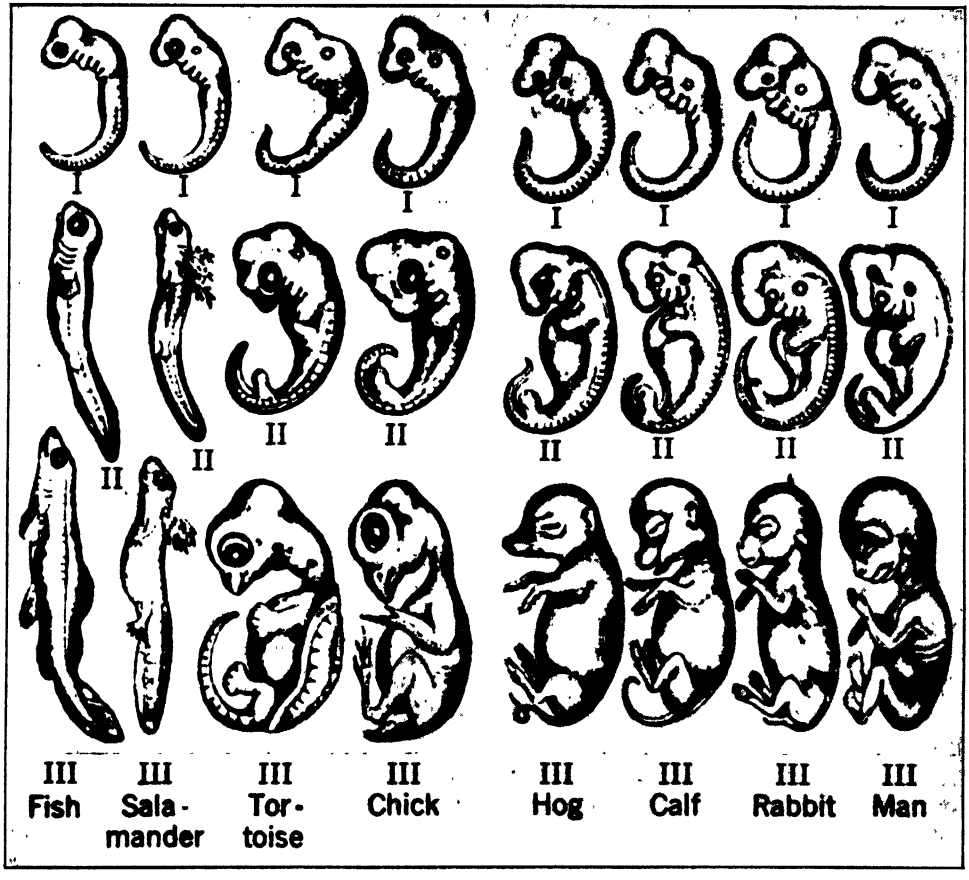

FIGURE 1. A series of drawings constructed to emphasize similarities in structure in various embryos at three comparable and progressive stages of development (marked I, II, and III). (From *Darwin, and After Darwin.* Vol. I. *The Darwinian Theory,* by G. J. Romanes. Chicago: Open Court, 1896, 152–153. By permission of the publisher.) This old diagram is presented here as a schematic device only. Research since it was drawn has made some alteration in the relationships demonstrated here.

lization. Slow rotary movements characterize the early behavior of many fish embryos. Fillipi is quoted by Preyer as finding in *Alosa finta* such movements soon after fertilization. In a species of trout Preyer found movement of trunk at a definite number of days subsequent to fertiliza-

getic movements of the whole tiny fish body may be observed. After the liberation of such organisms from their egg coverings, it is found that pressure stimulation on the body surface is followed by responses involving apparently the entire musculature of the trunk. Preyer points

out that these movements involve fully developed reflexes (p. 397). He makes this conclusion because the movements described consist in the total organism's drawing together of the head and tail. This same response occurs no matter what the locus may be of the point of pressure stimulation. As growth goes on, however, the strength of movement increases, and the movements become more and more regular and specific in relation to the exact locus of the area stimulated. Preyer gives quantitative tables of the increase in rapidity of the movements of the heart and the gills as development progresses (pp. 398–399).

Paton (1907, 1911) more recently studied the development of behavior in selachian embryos. He demonstrated the possibility of movement in fish embryos only nine or ten millimeters in length. For a study of teleost morphogenesis, see Oppenheimer (1934).

White (1915) describes the development of behavior in brook trout embryos. His observations cover the period from hatching until the yolk sac is absorbed. He notes that "the hatching is initiated by movements starting at the head and later extending through the whole length of the body . . ." (p. 46). After hatching, the swimming reaction is gradually made more nearly perfect. Touch and mechanical jars are effective stimuli immediately after hatching, and, interestingly enough, at this time the head is found to be the region least sensitive to pressure stimuli. Rheotropism, or response to water flow in currents, negative phototaxis, or the avoidance of light, and photokinetic responses, or responses initiated but not necessarily directed by light, are also present at this time. Excess carbon dioxide in the water in which fish are studied is activating up to a point, and then depressing on bodily functions. The dependence of the fish upon the chemical make-up of its external watery environment presents many analogies with the dependence of the higher animal upon the chemical make-up of the liquid internal environment of its own blood stream in which its own central nervous system maintains itself. Or, to put this in another way, the internal environment of the fish embryo is seen to be most closely related to its external environment. Before the nourishment-supplying yolk sac disappears at about two months, the reaction of the fish to stimuli seems to be away from the point of contact. After this, the fish embryo becomes quite suddenly exploratory and aggressive, and hence it moves toward the point stimulated (Preyer, 1885, p. 59). This striking observation may remind the reader that an intimate relationship exists between the degree of maturation of an organism and the "drive" which the organism shows in relation to external stimulation. Nicholas (1927) has applied experimental methods to the development of *Fundulus* embryos.

From the general standpoint of the development of behavior, however, the work of Tracy (1926) is especially worthy of study. This investigator has studied fish embryos, especially those of the toadfish. He has carefully observed and recorded the growth of activity in this form from its first movement to a final free-swimming condition. The first activity of the embryo in this form as in so many others is what may be termed in Parker's sense the preneural and "independent effector" action of the heart (Parker, 1919, pp. 53–63). The first behavioral movement of the fish is the bending of the trunk in the anterior region. At times this movement is to the right, at times to the left. It is probable that the afferent proprioceptor or muscle-sense system is not functional at first. At an early point a spontaneous flutter movement develops. This movement probably is important in freeing the organism from

the remaining egg membranes. In general, toadfish larvae when hatched lie at the bottom of the containing vessel in a quiescent state. Then suddenly they move. On the basis of careful study, Tracy concludes that this "spontaneous" behavior is related to cumulative changes in the blood of the organism such that at a certain point the central nervous system is directly stimulated or the threshold of the central nervous system is so altered that previously inoperative sensory impulses break over into motor outlets. Thus he concludes that spontaneous movements are the result of metabolites and oxygen deficiency in the blood stream (p. 345). Soon after the onset of such responses, the organism becomes very sensitive to exteroceptive stimuli. The mucous membrane area about the mouth is the first to be sensitized. In general, the spread of sensitivity is from this point toward the tail or possibly to the region that has just become most active. The "cephalocaudal progression" of sensory and motor development which some writers propose as a law is certainly far from regular in this organism, as will be seen in Figure 2. Receptors for light, vibration, chemicals, and body movement (proprioceptors) soon become effective. The behavior initiated by stimulation of these receptors involves jaw movements, trunk movements, and, interestingly enough, rotational and postrotational nystagmus of the eyes.

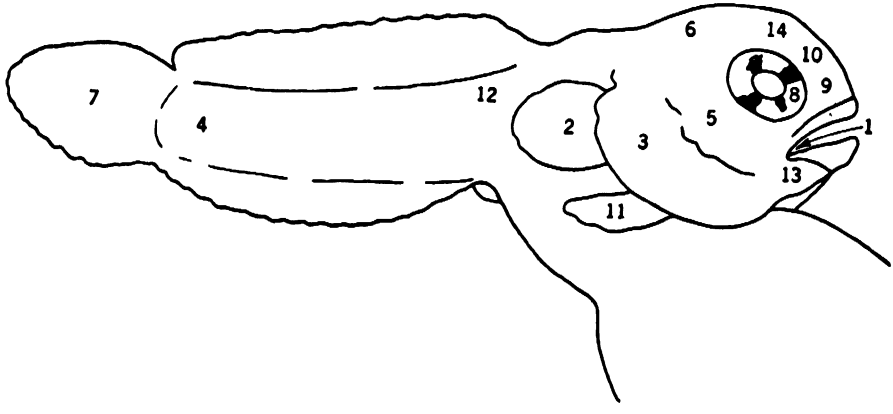

FIGURE 2. Diagram of toadfish larva to show by numbered areas the approximate temporal order of development of tactile reactions from various regions. (From "The Development of Motility and Behavior Reactions in the Toadfish [*Opsanus tau*]," by H. C. Tracy. *Journal of Comparative Neurology*, 1926, *40*, 295. By permission of the Wistar Institute, publisher.) It will be noted that, with some exceptions, this course of development of sensitivity is cephalocaudal, that is, from the head to the tail.

Tracy draws some fundamental conclusions from these studies. He holds that if external conditions could be kept constant the activities of the organism would be determined by its own life processes or metabolism. This would mean that all behavior would be rhythmic, like that of an excised muscle in a balanced salt solution (p. 345). At a later point we shall note that T. G. Brown (1915) holds that early mammalian reflexes may be of this nature. In conclusion, Tracy says: "From the beginning, and more or less continuously during its whole existence, the animal is driven through its environment as a result of stimuli which arise periodically in connec-

tion with its metabolic processes" (p. 345). The nature of later behavior may be thought of, he further suggests, as dependent upon neural development and the interference in the intrinsic rhythms of behavior brought about by the stimulation of the special exteroceptors of the organism by external energies. The basic relevance of this observation even for adult human behavior has been considered elsewhere (Carmichael, 1947).

We now turn to the study of the development of behavior in amphibians. Swammerdam, in his *Bibel der Natur* (1752), written before 1685, makes observations on the behavior of frog embryos five days after fertilization and at other periods (Preyer, 1885, p. 392; Swammerdam, edited, 1907). Swammerdam has also recorded observations concerning the development of behavior in snails and other invertebrates. Leeuwenhoek (1697, p. 792) made observations in this same field. Among other early students of behavior in invertebrates may be mentioned Stiebel (1815), Grant (1827), and Home (1827). Bischoff (1842) published a confirmation of the description of movements previously observed by Swammerdam in amphibians. He added a notation of the fact that the rate of these movements is a function of the temperature of the water in which the animals are maintaining themselves. Preyer (1885, pp. 392 ff.) reviewed all this work as well as that of Perschir and Cramer on the amphibian embryo. Preyer himself made elaborate observations on the early movements of frog and salamander embryos. He noted that stimulating the embryo led first to a slight twitch in the anterior portion of the organism. Following this movement in time he noted that the body was bent so as to bring the head and tail nearer together. Reference to Preyer's original drawings, reproduced as Figure 3, as well as to the text of his book, shows that he considered these C or reverse C movements very important. It is also clear from his drawings that he observed the fundamental S or sigmoid form of reaction. The importance of this S movement in freeing the organism from the egg is pointed out. That this movement is also related to the activity of swimming is an important consideration (pp. 393–394).

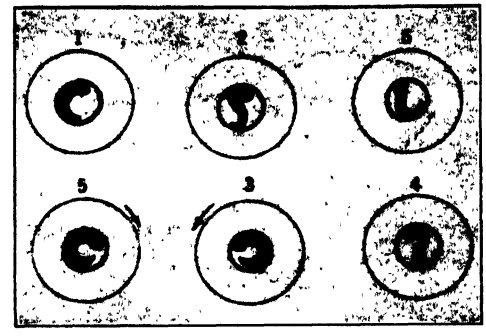

FIGURE 3. Diagram of various positions of frog embryos (*Rana temporaria*) just before emergence from the egg. Note especially the C and S reactions. (From *Specielle Physiologie des Embryo. Untersuchungen über die Lebenserscheinungen vor der Geburt*, by W. Preyer. Leipzig: Grieben, 1885.)

Other students have worked on the relationship between temperature and embryonic movements in larval amphibians (Preyer, 1885, p. 395). Many others have used this convenient laboratory type in work in experimental embryology. Much of this experimental embryology has direct bearing on the problems of this chapter. (See Detwiler, 1920, 1921, 1922, 1923*a*, 1923*b*, and the bibliographies given by him.)

If Preyer may be called the father of the scientific study of the development of behavior, the late G. E. Coghill (see references in the bibliography) must always be remembered as the investigator who first charted the relationship between the detailed growth of the nervous system and

the consequent alterations which occur in behavior. This investigator is notable also because of the completeness of his work on the salamander *Amblystoma*, as well as on other types. The life of Coghill with his complete bibliography by C. J. Herrick (1949) ably discusses the fundamental contributions of this original scientist to the study of behavior. Coghill's first paper in this field was written in 1902, and from that time until his death in 1941 he published a most important series of papers on the development of behavior in relation to the anatomy of structure. In the course of his many papers, Coghill reported detailed studies of the neural mechanism underlying the first movement and the later sequences of movements as they develop in *Amblystoma*. The first response results from the contraction of muscles just behind the head. As the embryo advances in age, this contraction becomes, after a period of gradual transition lasting for about 36 hours, one which involves the whole animal. The result of this reaction, as pointed out by Coghill, is that the organism assumes a position which may be described as that of a tight coil. This C or exaggerated C coil is sometimes oriented to the right and sometimes to the left. It may reverse instantly. At this point in development, all behavioral activities are initiated in the head region and progress toward the tail.

In commenting upon this sequence, Coghill (1929*a*) notes that at this time: "Nothing really new has yet been introduced into the behaviour pattern of the animal since its first movement was performed, and the coil reaction gives the animal no locomotor power. Nevertheless the coil has in it the primary locomotor factor: cephalocaudal progression of muscular contraction" (p. 6). The transition from this behavioral level to the S reaction is amazingly simple. One C contraction begins, for example, on the left, but before it has reached the tail another contraction to the right begins.

The components of this movement may be made clearer by consulting Figure 4. As this reaction gains speed, its performance exerts pressure upon the water and thus drives the organism forward. Thus the S reaction becomes the basis of swimming or aquatic locomotion. This fundamental pattern of behavior may well be a peculiarly significant stage in many other types of growing organisms. This same stage is seen clearly in the swimming of the lower vertebrates. It is somewhat obscured in the four-legged mammals and still more obscured in man, but that this S reaction plays its part in the growth of behavior in these higher organisms seems to be an established fact. Five stages in the development of this basic swimming activity have been made out by Coghill (1929*a*, p. 9). They may be presented as follows: (1) the nonmotile stage, in which direct muscle stimulation by mechanical or electrical means leads to muscular contraction and hence to externally observable response; (2) the early C flexure stage, in which light touch on the skin of any portion of the body leads to a response; (3) the tight-coil stage, in which the contractions noted in stage 2 become more pronounced and the extent of the contraction greater; (4) the S reaction, which is characterized by a reversal of flexure before the previous flexure has been completely executed as a coil, thus leading to the sinuous behavior of the total organism; (5) the speeding-up of the S reaction so as to produce the typical swimming movement of the amphibian larva.

Youngstrom (1937) in studies upon *Anura* (frogs, toads, etc.) concludes that the Coghillian sequence of developing behavior applies with only slight variations to the *Anura* studied. Wang and Lu (1940, 1941), too, have shown that the stages

through which the frog passes are similar to those described by Coghill. These investigators have also shown that severance of the spinal cord arrests the development of swimming at about Coghill's stage 4.

As already noted, the salamander has, besides aquatic locomotion, other significant behavior systems. Of these, walking or terrestrial locomotion and feeding require special consideration. The *Amblys-*

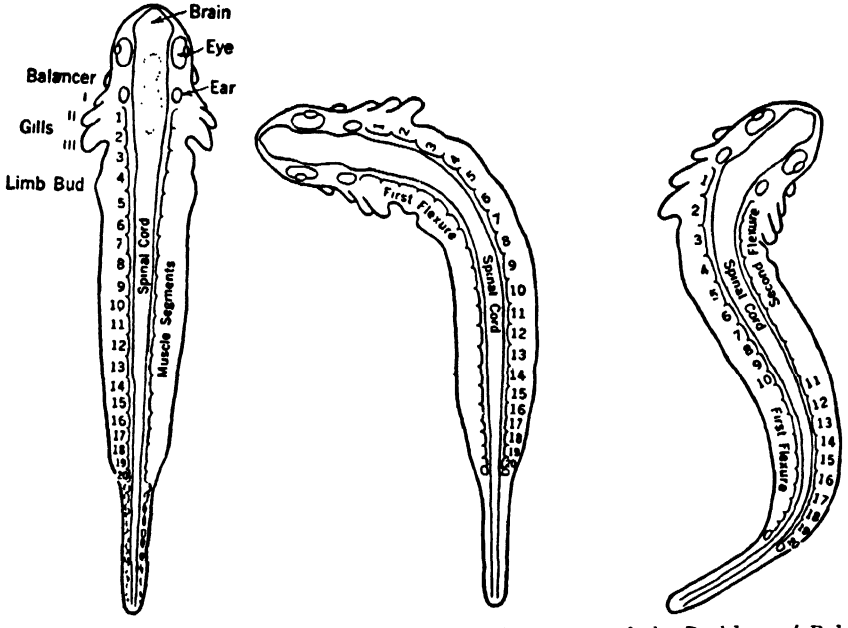

FIGURE 4. Three diagrams of *Amblystoma*. (From *Anatomy and the Problem of Behaviour*, by G. E. Coghill. Cambridge: University Press. New York: Macmillan, 1929, 7–8. By permission of The Macmillan Company.) The diagram at the left shows the organism in an early swimming stage but without indication of muscle contraction. The diagram in the middle illustrates the beginning of a swimming movement as a first flexure by contraction of a number of anterior muscle segments. The diagram on the right illustrates the swimming movement in which the first flexure has passed tailward and the second flexure is beginning in the anterior region.

Coghill studied in great detail the neural structure characteristic of the salamander in each of the five stages noted above. On the basis of these investigations he shows how the known structure of the nervous system may make possible the behavior which has previously been described. It is important to recognize that for the most part Coghill (1929*a*, p. 13) believed that in young organisms movement is typically away from the point of stimulation.

toma swims before its anatomical development has progressed to the point where it has true limbs. Structurally and functionally the forelimbs are in advance of the developing hindlimbs. In this organism, however, at first both sets of limbs, when they appear, move only in relation to the larger trunk movements described above as those of swimming. Coghill shows why this must be so because of the developing nervous system. Gradually, however, in-

dependence of limb action or *individuation* of limb behavior over the dominance of the trunk movements begins (1930*e*, p. 638). First the forelimbs gain a certain autonomy, and later the hindlimbs also. "It is obvious, therefore," observes Coghill (1929*a*), "that the first limb movement is an integral part of the total reaction of the animal, and that it is only later that the limb acquires an individuality of its own in behaviour" (p. 19). He then suggests that the forelimb itself may be considered to possess a pattern of development which is comparable to that of the total organism. At first, if movement occurs at all, the whole limb moves. Later, elbow flexion and wrist and digit movement in turn gain independence of the total member. It is important to recognize that during this developmental sequence the time relations of the swimming reaction may be considered as in a way superimposed upon limb activity. Thus one may, if he wishes to, think of the alternate movements of walking in a four-legged organism as a growth out of the basic trunk movements of swimming previously described. Coghill (1929*a*), indeed, says: "Movement of the trunk in walking is nothing more nor less than the swimming movement with greatly reduced speed" (p. 25). Gradually the sinuous movement of the trunk is reduced as walking becomes more independent, and eventually the characteristic land locomotion of the salamander appears.

The development of the feeding reaction in this same organism has been similarly studied by Coghill (1929*a*). This response begins with a movement of the trunk; then comes a reaction which involves a sudden lunge of the whole organism; after this there is a gradual correlation between this lunge movement and the activity of the jaws and the muscles of the esophagus. In summarizing this whole development, Coghill (1929*a*) says: "Behaviour develops from the beginning through the progressive expansion of a perfectly integrated total pattern and the individuation within it of partial patterns which acquire various degrees of discreteness" (p. 38). It should also be noted that as this development continues new senses become important in relation to behavior. Coghill (1930*a*) believes that "the individual acts on its environment before it reacts to its environment" (p. 345). In considering these beautifully elaborated generalizations of Coghill's, it is important to remember that a different sequence in the development of behavior may well characterize the growth of a mammal and a salamander. One should not forget also that even Coghill's own neurological studies point to specific relationships between the locus of stimulation and the muscles that are caused to respond (1929*a*, p. 12). In comparing the salamander and the guinea pig, for example, it may be noted that the limbs are quite fully formed before the first behavioral response or reflex takes place in the guinea pig, but in the salamander behavior begins before there is any real morphological forelimb at all.

In a series of papers Carmichael has presented the results of his studies of the development of behavior in *Amblystoma* and the frog under conditions such that experimental groups of animals were raised under unusual environmental circumstances (Carmichael, 1926*a*, 1927, 1928, 1929). A technique devised by Randolph (1900) and developed by Harrison (1904) was employed. For a consideration of the effect of the anesthetic chloretone on the organism in question, a paper by Matthews and Detwiler (1926) should be consulted. At a period before motility had begun, a large number of developing *Amblystoma* were divided into two groups. The first of these groups was used as a control. The second was used as an experimental group. The

experimental group was placed in water containing the anesthetic—a solution of chloretone. The control group was allowed to develop normally in water. Later, at a developmental point previously described by Herrick and Coghill (1915), vigorous responses began in the control group. At this time the experimental group showed morphological development but otherwise remained absolutely inert because of the action of the anesthetic. However, in a short time—often only a minute or two—after the drugged embryos were placed in fresh water, they began to swim well. "In fact, a number of the eighteen *Amblystoma* embryos swam so well in less than one half hour after they had shown the first sign of movement that they could with difficulty, if at all, be distinguished from the members of the control group who had been free swimmers for five days" (Carmichael, 1926*a*, p. 55).

In later experiments efforts were made to control stimulation in other ways (Carmichael, 1928). As a result of these investigations, the conclusion is drawn that the development of the neural and other mechanisms upon which behavior depends does take place in these organisms whether or not they are as individuals responding to external stimulation. This seems to have a negative implication concerning an extreme interpretation of Child's (1921) environmentalist theory of the causation of growth in the nervous system. Nothing in these experiments is to be taken, however, as invalidating the idea that the growth of the nervous system itself involves activity. Studies such as those of Burr (1932) and P. Weiss (1926, 1939) on this same organism emphasize the dynamic character of such growth processes. For a general consideration of the relationship between neural growth and the development of behavior see Hooker (1950).

Nicholas and a number of collaborators have studied the development of *Amblystoma*, especially in regard to the development of motility in relation to the nervous system. Some of their results show that the sensory component is exceedingly important in coordinating the activity of groups of muscles (Nicholas and Barron, 1935). Nicholas has also carried out a series of studies on limbs of amphibians developed after experimental embryological manipulations so that they have foreign innervation (1924, 1933*a*). Some of the results obtained in these studies are interpreted as dependent upon the coordination of nerve responses in the central nervous system rather than upon peripheral selection as suggested in the "resonance theory" of P. Weiss (1926, 1939). Nicholas (1929*a*) published an extensive study of the analysis of the responses of isolated parts of the amphibian nervous system. In this paper an excellent historical summary of the whole field of the innervation of the limbs in developing *Amblystoma* is presented.

In the reptile class comparatively little work has been done, although Preyer (1885, p. 404) reported some occasional observations on snakes. Tuge (1931) also did some very interesting work upon the growth of behavior in the turtle. In this work the sequence of Coghill is seen as modified by the existence of the shell which especially characterizes this form. Smith and Daniel (1947) have also made some interesting observations on the early responses of the turtle.

The Development of Behavior in the Embryos of Birds

From an evolutionary point of view, the bird may be thought of as presenting an interesting comparison with the lower vertebrate and the mammal. The amphibian

embryo provides unusually favorable material for developmental study. The growing salamander or frog embryo may be observed, without interference of any sort, through its translucent egg covering and in free life after leaving these coverings. Its egg yolk provides food during a long part of the early developmental period. On the other hand, the study of the development of behavior in the mammal involves relatively complex surgery and, at present at any rate, a certain disturbance of the normal environment of the growing organism. The bird embryo is harder to study than the amphibian but easier than the mammal. It may be studied in a relatively normal environment, but a special technique is necessary to render the development of the bird embryo continuously observable. Down through the years, however, the chicken's egg has been the subject of embryological study. Needham (1931) reviews the use that has been made of the hen's egg in embryology since earliest times. This writer describes the history of the artificial incubation of hens' eggs. He notes also the beginning of systematic observation of embryos taken from eggs in various periods of incubation at the time of Hippocrates (about 460 B.C.). From that time on, the hen's egg has been extensively used in morphological studies of development. Among those who have contributed to this development are Aristotle, Aelian, Pliny, Plutarch, Albertus Magnus, Leonardo da Vinci, Aldrovandus, Fabricius (who made beautiful illustrations of a series of chick embryos), Highmore, Sir Thomas Browne, Harvey, and Malpighi. Today the many admirable manuals on the embryology of the chick, such as those by Patten (1929) and F. R. Lillie (1919), present a large amount of evidence in regard to the structural development of the chick.

Preyer (1885), reviewing certain of these facts many years ago, noted that, whereas the structural development of the chick is comparatively well known, its behavioral development is not. Although advances have been made since that time, this observation is still true. A few casual observations on this development, nevertheless, were made at an early time. Harvey as long ago as 1651 noted that the chick in the sixth day of development showed a bending and stretching of the head (Preyer, 1885, p. 405). About a century later Béguelin noted the heart beat of the small embryo on the third day, and on the sixth day the oscillation of the whole body, and from that point on he records elaborate changes in movement. He records the fact that he was able to observe the development for fifteen days in the same living and developing embryo (Preyer, 1885, p. 405). Home, in 1822, was probably the first to note the movement of the extremities on the sixth day (Preyer, 1885, p. 405). Von Baer, in 1828, published rather extensive studies on the development of behavior in the chick, in which he noted the inception of the pendular movement of the whole embryo as a result of amnion contractions (Preyer, 1885, p. 405). Amnion contractions, he noted, were most marked on the eighth day and were successively less on the succeeding days. This same investigator reported general activity of the embryo on the eleventh, twelfth, and thirteenth days. The amnion contractions of the bird's egg have no complete parallel in other forms. The growing chick seems, as it were, to be tossed in a blanket as it grows. Von Baer also saw what he considered to be the beginning of breathing movements in the 14- to 16-day embryo. Several other investigators are quoted by Preyer as having also made observations upon the development of behavior in the chick. By far the most extensive study up to his time on the development of the bird embryo, however, was made by Preyer himself. The extent of his

study may be indicated by the fact that he used some 500 eggs in his experiments.

In this work Preyer gave much attention to the movements of the amnion which have been referred to above. Preyer pointed out that the rhythmic movement of the amnion when at its maximum extent, between the seventh and ninth days, leads to such an agitation of the fetus that no study of fetal activity can be made without taking these contractions into account. The amnion contractions are generally described as independent muscle reactions. They are non-neural. Preyer also describes the gradual development of behavior of the chick embryo from its earliest head movement to the behavior necessary for hatching (pp. 408–416, 555–585). Since the time of Preyer there have been a number of special studies on particular aspects of the fetal and hatching behavior of the bird, such as those by Breed (1911), W. Craig (1912), Clark and Clark (1914), and Patten and Kramer (1933). For the purposes of this chapter by far the most important work is Kuo's, which is presented in a series of papers (1932*a*, 1932*b*, 1932*c*, 1932*d*, 1932*e*, 1938, 1939*a*), and Orr and Windle's (1934).

To collect material for the study of the morphological development of the egg, it is necessary only to open the shells at known periods of incubation. Opening of eggs without special precaution leads to the early death of the embryo, but this is not important if the organism to be studied is placed at once in a fixative to prepare it for the histologist. A number of techniques, however, have been devised to open the shell and still allow the continuous observation of the early development of behavior in the bird. One of these methods, devised by Kuo (1932*a*), has yielded excellent results. Kuo's method makes possible an uninterrupted study of the developing fetus without interfering in any essential way with the natural membranes of the egg, or, more important, with respiration of the embryo. Kuo's operation may be described as follows: The shell of the blunt end of the egg is cut off with a fine pair of scissors as far as the inner membrane. The whole inner membrane, however, is allowed to remain intact. A very small amount of melted petrolatum is immediately and rapidly applied to this membrane with a Chinese writing brush. At the temperature of the incubator the petrolatum remains liquid but, when applied by an expert, does not spread. This treatment produces a transparent membranous window through which the embryo and the extraembryonic structures and functions can be observed. This technique renders the membrane so transparent that it is almost as satisfactory as removing the membrane. In the course of observations Kuo uses three incubators, one in which the eggs are kept before they are experimented upon, another in which the operation is performed, and the third a special observation incubator fitted with appropriate glass plates through which a microscope may be used. For a criticism of Kuo's technique, see Becker (1940, 1942).

Kuo has also devised a transparent dial graded in fractions of a millimeter which may be put over the cut end of the egg, thus making the quantitative measurement of fetal movements possible. The writer has collaborated with Kuo in making a moving-picture film of the typical stages of development of the chick embryo. For the most part these pictures were taken through the membrane treated as described above. This procedure has been described (Kuo and Carmichael, 1937). In connection with this technique a consideration of the air space of the hen's egg and its changes during incubation is interesting. (See Romijn and Roos, 1938.)

Using his special technique, Kuo has studied many thousands of eggs, and on

the basis of this study he has made definite statements in regard to the developmental sequence of behavior in the chick embryo. This work deserves special consideration in this chapter because it is the work of a scientist who is interested in the psychological significance of behavior and because it places emphasis on the part played by the environment in the determination of the course of behavioral development. The results are also presented in such a way that they are peculiarly applicable to psychological problems.

Kuo has traced the chronology and general nature of behavior in the chick embryo (1932*a*), the mechanical factors in the various stages leading to hatching (1932*b*), the influence of prenatal behavior upon postnatal life (1932*d*), and many other special topics such as the relationship between acetylcholine and the onset of behavior (1939*a*). In the last-named study Kuo shows that the first true neurally determined responses do not appear until after this substance may be detected. This suggests that there may be a chemical mediation of the first response of the chick. For a review of the general importance of acetylcholine, see Cannon and Rosenblueth (1937). A reference to Figure 1 will show that at one typical stage the embryo of the chick is very similar to the fetus of the reptile and, indeed, to the fetus of man. It must, however, be remembered that the arrangement of the embryo of the bird in relation to its extrafetal membranes is, as suggested above, in a number of ways peculiar. A description of this anatomical relationship may be found in Patten (1929).

Kuo's work on the chick may possibly best be given in summary by indicating briefly something of the observed movement and the time at which the movement was *first* observed. It should be noticed that the writer, by using the time at which the movement was first observed, may do an injustice in certain cases to the facts as presented by Kuo, because that investigator shows that in many cases the movement does not, on the average, arise until some hours or even days after it was first observed in peculiarly favorable specimens. A summary of the commencement of the passive and active movements characterizing the developmental behavior of the chick may, however, give the best generalized picture of the development of the chick that is possible in the compass of this chapter. The following activities are among those noted: heartbeat, at 36 hours; head vibration, 66 hours; body vibration, 66 hours; head lifting, 68 hours; head bending, 70 hours; trunk movement, 84 hours; amnion contraction, 86 hours; yolk sac movement, 86 hours; swinging, 86 hours; head turning, 90 hours; movement of forelimbs, 90 hours; movement of hindlimbs, 90 hours; movement of tail, 92 hours; movement of toes, 5 days; response to electricity (in an embryo removed from the shell and placed in a physiological salt solution), 6 days; eyelid movement, 6 days; response to pressure, 6 days; movement of eyeball, 7 days; swallowing, 8 days; leg folding, 9 days; fixation of body position, 9 days; bill clapping, 9 days; response to touch (in physiological salt solution), 9 days; first wriggling, 11 days; turning of body, 12 days; protrusion of neck, 16 days; respiratory movement, 16 days; response to rotation, 17 days; tearing of membrane, 17 days; peeping, 17 days; response to light, 17 days; response to sound, 18 days; response to vibration, 18 days; hatching, 19 days. Final leaving of the shell does not typically occur, however, until the twentieth or the twenty-first day (Kuo, 1932*a*).

Kuo has not been content with a mere passive description of the movements indicated above in their time sequences, but in every case he has attempted to give a description of the mechanical and environ-

mental factors which are important in determining the special movements and the special modifications of movements that he notes. Thus, for example, he points out that the beating of the heart leads to a general rhythmic vibration of the inert fetal body which starts the head into passive mechanical movement. In connection with the heart beat of the chick, it may be noted that the structural and functional change of this organ during growth has been intensively studied by Patten and Kramer (1933). Almost from the first appearance of the cells which are to form the organ, beating may be noted. This passive mechanical movement continues until at length it gives place on the fourth or fifth day to a true active movement. Head movement in the chick begins as an up-and-down bowing. Gradually, as a result of the change of the weight of the head and of associated structures in the egg, this up-and-down movement is changed to a sidewise movement, which is eventually inhibited by the altered relationship between the fetus and the yolk sac.

Kuo makes similar observations in regard to the movement of the appendages and to other special behavioral functions. He notes that during the period of the most forceful amnion activity, from the seventh to the ninth day, the mechanical movement of the fetus so stimulates it that there is a large increase in the active movements of the embryo. These movements are considered significant in the development of further movement. It is also observed that an active movement originating in the embryo may incite further activity of contraction in the temporarily relatively quiescent amnion. Indeed, possibly as a result of this reciprocal activation during the period of vigorous amnion contractions, the movements of the developing chick in this period are almost ceaseless. It thus comes about that every part of the musculature of the embryo has been exercised before half its incubation period is over. This fact led Kuo (1932*b*) to point out that any correlation which it is desired to make between the development of behavior and the development of the nervous system in the chick must take into especial consideration the changing conditions of response due to morphological growth and increase in weight of the body parts themselves and especially to the changing relationships between these growing body parts and the environment in which the growth is taking place.

It is interesting to note that the specialized movements of the eye and of the eyeball occur as early as the eighth or ninth day but that the first light response of the organism does not ordinarily appear until the seventeenth to the nineteenth day under experimental conditions. Thus the eye reflexes are present in the absence of effective visual stimuli. These early eye movements, indeed, have been found by Kuo to occur in conjunction with movement of the body in space instead of in response to visual stimuli. A similar temporal sequence in mammals and its probable mechanisms as worked out by the writer will be discussed below. Only in the later periods of development do the eyes begin to acquire a relative degree of independence from the rest of the organism. Kuo reports that in general the responses to touch, pressure, and electricity, which may be elicited from at least the tenth day onward, are similar to the normally excited responses which he has observed. In conclusion, Kuo asserts that practically every physiological effector mechanism is thus shown to be in a functional condition long before hatching. Thus the organs begin to function in many cases before they reach adult form; indeed, many function in rudimentary form. He feels that, as is true in the development of structure, too much stress cannot be laid on the

fact that the development of behavior is gradual and continual. In Kuo's opinion, the early embryonic movements may be thought of as the elements out of which every later response of the adult bird is built. In this connection he points out that certain of the typical postural attitudes of the adult fowl are but returns to the tonus condition of the attitudes of prehatching life (1932*d*, p. 113). This same observation, incidentally, although too infrequently presented, can be made in respect to mammals and man, and as such will do much to explain the maturation of many allegedly saltatory behavior patterns of postnatal life.

In the carrier pigeon Tuge (1934) has shown that active movements as opposed to passive movements begin at about 105 hours after the beginning of incubation. The first movements observed are extensions and flexions of the head. In 10 additional hours muscles of the neck, trunk, rump, and tail are also involved. "Spontaneous" movements begin before response to chemical or tactile stimuli can be evoked. At about 125 hours in the incubation period the first flexion of the head and neck to tactile stimulation is called out. The reflexogenous zone spreads from the cephalic to the caudal region as development proceeds. Local reflexes of the wings and legs appear at about 155 hours.

Orr and Windle and their collaborators (Orr and Windle, 1934; Windle and Orr, 1934*a*; Windle and Barcroft, 1938; Windle and Nelson, 1938; Windle, Scharpenberg, and Steele, 1938) have studied in detail the development of the bird. In 1934 Orr and Windle reported that the first response to a blunt vegetable fiber needle takes place in the embryonic chick at 6½ to 7 days after the onset of incubation. This first response is a quick movement of the wing away from the trunk, a lateral flipperlike extension. This movement remains localized. The local reflexes of the embryo do not seem to develop from a generalized behavior pattern but rather arise independently. In another paper (Windle and Orr, 1934*a*) these two investigators show that the flexion of the chick fetus which takes place on the fifth day is of a sort which cannot be explained by the spinal cord structure at that time. Probably the mechanism which sets off this behavior is chemical in nature. The motor and sensory sides of the nervous system develop in independence of each other, and the motor side is functional first. For a detailed report of the neural structure of the chick as its behavior develops, the reader should consult Windle and Orr's paper (1934*a*). Windle and his collaborators (Windle and Barcroft, 1938; Windle and Nelson, 1938; Windle, Scharpenberg, and Steele, 1938) have also published a series of papers upon the initiation of respiration and the development of respiration in the duck and the chick.

Kuo has also developed an elaborate theory of the growth of behavior in relation to environmental factors. He points out that the intensity of stimulation must be controlled if one is to make any statement concerning the generality or specificity of an organism's response. In a more recent study (1938) he has pointed out that the physiological *and* behavioral growth of the organism may be summarized in ten stages: (1) cardiac movement, (2) active head movement, (3) trunk movement and response to electric currents, (4) first limb and tail movements and first amnion contraction, (5) head turning and lateral flexion, (6) the hyperactive period from 6 to 9 days, (7) reduction of bodily activities, (8) period of relative quiet (15 to 18 days), (9) prehatching stage, (10) hatching behavior. This is a descriptive procedure much to be preferred to any too easy generalization attempting to summarize the

whole course of behavioral growth. Kuo (1939*b*, 1939*c*) has also given an interesting review of the whole question of which comes first, total patterns or local reflexes.

As suggested above, the possible importance of chemical mediation in the determination of the onset of behavior requires study. Kuo (1939*a*) published a paper summarizing his investigations in this field. He found that acetylcholine, the chemical whose presence would most likely be correlated with the onset of activity, was detectable in the embryonic tissues as early as 2½ days after the onset of incubation. Between the fourth and the twelfth days the production of acetylcholine produced per gram of body tissue fluctuates. This substance thus appears before any synapses are present, and it is present in easily detectable quantities before any somatic movement occurs. Kuo has not found any relationship between the acetylcholine development and the development of reflexes.

In considering chemical mediation, it is important not to lose sight of the parallel development of the nervous elements themselves. Windle and Austin (1936) showed in some detail the anatomical growth of the central nervous system of the chick up to five days' incubation.

The Development of Prenatal Behavior in the Infrahuman Mammal

The development of behavior in the infrahuman mammal is in a number of respects more significant for one who would understand the growth of behavior and psychological functions in man than is the consideration of the amphibian or bird presented above. There are peculiar difficulties, however, in studying the development of fetal behavior in mammals. These difficulties can be made clear only by a brief review of the bodily structures and functions involved in the prenatal development of typical placental mammals, including man. In barest outline, disregarding many differences between various species of such mammals and many consequent qualifications, this process of development may be reviewed as follows:

The tiny fertilized mammalian egg is not at first attached but, probably as a result of ciliary action and the muscular contraction of the tubes, moves from the oviduct where it has been fertilized to the uterus. Parker (1931) has summarized the evidence in this field. During the process of movement, which occupies 4 to 10 days, depending on the type of mammal under consideration, the processes of development have begun which are to form the embryo and its membranes. Two embryonic folds are early formed which join to make up the then enclosing amniotic sac. This sac gradually enlarges. It is filled with a special liquid, the so-called amniotic fluid, which has a very definite chemical make-up and a specific gravity of 1006–1081 (Feldman, 1920, p. 139). The specific gravity of this liquid is thus not far from that of the developing embryo, a fact of great importance in understanding the mechanics of certain forms of receptor–nervous-system–effector action in the fetus at a later period. As growth continues, the sac more and more completely surrounds the embryo.

The embryo thus immersed and supported is relatively independent of most direct mechanical surface contacts. Coincident with this development the other fetal sacs are formed. One of these, the vitelline sac, corresponds to the yolk sac of lower forms, although of course in the higher mammalian types it contains virtually no yolk. In later development of the fetus this sac is relatively much reduced in size, and at the time of birth is known as the umbilical vesicle.

The allantois also makes its appearance as an outgrowth of the developing digestive

tract of the embryo. This saclike structure comes in contact with the previously formed primitive chorion, with which it fuses to make up the true chorion. This doubly derived chorion now rapidly becomes a completely enclosing membranous wall outside the amniotic sac. The chorion continues to be attached to the embryo proper, however, by means of the allantoic stalk, which comes to conduct as well the two allantoic arteries and the two allantoic veins.

As this development has progressed, therefore, the egg has become attached to the wall of the maternal uterus. As the very complex morphological changes, some of which have been suggested above, take place, the circulatory system of the fetus and its membranes continues to develop. This fetal circulatory system is mechanically completely separated from the maternal blood system, but the separation is, in certain areas, only that of a cell wall. By interchange through living membranes, therefore, oxygen and food materials pass from the maternal blood system into the independent embryonic blood system; similarly, carbon dioxide and other metabolites pass in the opposite direction into the maternal blood stream. Typically, in the higher mammals only part of the chorion is thus directly attached to the maternal uterus. This area of attachment is called the placenta. As noted later in the chapter, the exchange of endocrines through the placenta is important. The placenta may best be thought of as involving two parts, one of which is derived from the embryo and the other from the maternal uterus. The part derived from the maternal uterus becomes larger and larger, eventually encapsulating the developing embryo and its membranes, which have just been described. This true maternal membrane, as distinguished from the previously considered fetal membranes, is called the *decidua capsularis*.

In human development, as the fetus grows this decidua capsularis comes to be in contact with the mucous membrane lining of the rest of the uterine cavity, the so-called *decidua vera*. Thus as it grows the fetus is enveloped in an elaborate series of membranes. Figure 5 shows these relationships in very schematic form in the human organism. These developed membranes serve an important function. They provide within the mother's body a strong, many-layered sac in which is maintained an aquatic environment of very constant temperature and remarkably constant physical and chemical constitution. Hsu (1948) has shown that in white rats increasing the temperatures somewhat above normal affects pregnancy. The results suggest that with elevated temperatures the percentage of pregnancies affected is greater when the heat treatment is earlier. This result emphasizes the importance of constant and normal conditions of the uterus during pregnancy.

For an elaborate consideration of fetal development made clear by excellent diagrams, see Spee (1915). See also Barclay, Franklin, and Prichard (1946, 1947) for a consideration of changes in fetal circulation at birth.

By means of the association at the placenta, as just noted, the independently developing embryo is able, parasitically as it were, to receive food materials, oxygen, and other needful substances from the maternal blood supply and to send back into that system the waste products of its own organic life. The extremely important and technical topic of fetal respiration has been intensively studied by Barcroft and his associates and by many other workers. For a review of this literature see Barcroft (1938, 1946), and Windle (1940). The mechanism of the fetal membranes, therefore, makes possible fetal respiration, nu-

trition, and excretion. It is in a physical world of this sort that we must consider the fetal mammal as developing and in its later stages as actively responding. The nature of this very special environment must not be forgotten in considering every evidence of sensory or behavioral life which the fetus

Birth consists in the rupture of the fetal membranes, often produced by the contractions of the muscular walls of the uterus. The physiology of birth is complex and important. (See Barron, 1940.) A short time after the birth of the young mammal or the child there follows the expulsion of the

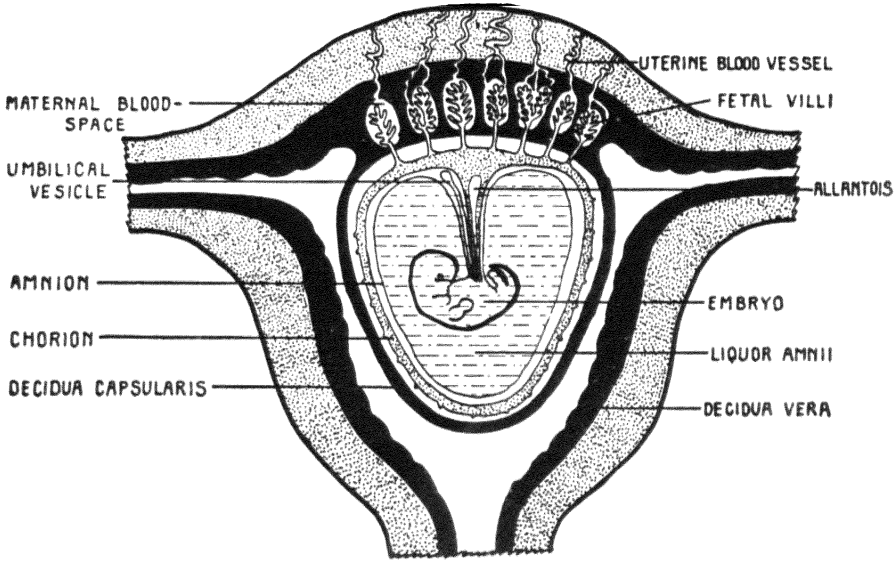

FIGURE 5. Diagram representing the relationship between the uterus, the membranes, and the embryo during early pregnancy. (From "Origin and Prenatal Growth of Behavior," by L. Carmichael. In C. Murchison [Ed.], *A Handbook of Child Psychology*. 2d ed., rev. Worcester: Clark University Press, 1933. 50. By permission of the publisher.)

shows. It must be emphasized, however, that there are great differences in detail in the relationship between fetus and maternal organism in different mammals. As Windle (1940) has pointed out, "Time and again in the study of prenatal physiology it will appear that species variations in the intimacy between maternal and fetal blood streams may explain differences in experimental results" (p. 5).

The relationship between blood flow in the umbilical cord and the rate of fetal growth in the sheep and guinea pig has been studied by Greenfield, Shepherd, and Whelan (1951).

now discarded enveloping membranes. This "afterbirth" consists largely of the remains of the decidua, the chorion, and the amnion. In infrahuman mammals this afterbirth is customarily eaten by the mother (Tinklepaugh and Hartman, 1930). This is an interesting response to be considered in relation to the problem of the special hungers and patterned "instincts" of the organism.

From what has been said, it is obvious that the developing mammal is so well protected that it is difficult to study its growth at different periods, and nearly impossible —although the "impossible" has been ac-

complished, as will be pointed out below—to observe continuously the development of the same mammalian fetus. A whole series of papers by Nicholas (1925, 1926, 1927, 1929*a*) demonstrates the possibility of experimental manipulation of the mammalian egg and growing embryo. This work has fundamental implications not only for the "new" embryology but for the whole study of the growth of behavior.

It may still be said that it is "impossible" to study the mammalian fetus under as nearly normal conditions as those under which Kuo has studied the chick. There is real danger in generalizing upon the nature of fetal development on the basis of observations made under abnormal conditions, as Kuo himself (1932*c*, p. 265) has said. Observations on the mammalian fetus must be abnormal because the protection which is provided by the fetal membranes just considered must be destroyed if direct observation is to be possible.

It will, of course, be unnecessary here to give an account of the development of behavior in all classes and orders of mammals. Indeed, no special studies have been made of most mammalian forms. For example, so far as the writer is aware, no special study has been made of the development of behavior in the fetal monotremes. The study of the development of behavior in these primitive Australian egg-laying mammals would probably provide fundamentally significant facts that might be applied to higher, truly viviparous forms. In both the ornithorhynchus and the echidna, eggs with soft shells, rich in yolk, undergo segmentation in the uterus and are then laid and incubated. The incubation by the ornithorhynchus is in a nest; by the echidna, in a pouch. When hatched, the young of this subclass are nourished by the secretion of great glands possibly more like sweat glands than like the true mammary structures of higher mammals. But a detailed description of behavioral growth in these forms is not, so far as the writer can discover, available.

Study of the development of behavior in what is generally considered the next higher subclass above the monotremes—namely, the marsupials—has been carried on. Indeed, the marsupials are found to be very favorable material for developmental studies. The young of animals in this subclass are born in a condition which can be considered only that of a relatively immature fetus (Langworthy, 1928). In the marsupials, although early development occurs in the maternal uterus, and although the fetus is nourished by secretions from the uterine wall, no true placenta is formed. Possibly for this reason these true mammalian fetuses are born while still at an early period of development and are as yet open to easy continual external observation during most of the important growth stages in which behavior change may be noted. This fact has made this form a favorite one for studies of neurological development by such students as Weed and Langworthy (1925*a*, 1925*b*) and Langworthy (1928). After birth the young are cared for by the mother for many weeks in a pouch, the marsupium, into which the mammary nipples open (Hartman, 1920). In certain of the marsupials, indeed, the once independent fetus again becomes functionally but not structurally attached to the mother, as for a long period after the maternal nipple is taken into the mouth the nipple is never removed until the animal is ready to enter upon truly free life (Hartman, 1920, p. 260).

From the standpoint of the student of the development of behavior, the most adequately studied form of this subclass is the Virginia opossum. In a series of complete and brilliant papers, Hartman (1916*a*, 1916*b*, 1919*a*, 1919*b*, 1920) has brought together the knowledge in regard to the de-

velopment of the fetus in the opossum and related types. Until his own work was begun, Hartman points out that the birth of the opossum and the behaviorally significant journey of the newborn organisms to the pouch had been observed and described by but one man, Middleton Michel. Michel's observations, which are reprinted by Hartman (1920, p. 252), led to a belief that the mother transferred the newborn animals to the pouch. Hartman's work, however, has shown that the newborn organisms travel directly from the vulva to the maternal pouch without the aid of the mother. He says:

> Unerringly the embryo traveled by its own efforts; without any assistance on the mother's part, other than to free it of liquid on its first emergence into the world, this ten-day-old embryo, in appearance more like a worm than a mammal, is able, immediately upon release from its liquid medium, to crawl a full three inches over a difficult terrain. Indeed, it can do more: after it has arrived at the pouch it is able to find the nipple amid a forest of hair. This it must find—or perish [p. 255].

Hartman has further shown that this essential journey is to be considered a negative geotropism, because under experimental conditions embryos can be made to travel away from the pouch if only the skin upon which they are moving is tilted upward. The locomotion of the embryo is described as a kind of overhand swimming stroke in which the head sways as far as possible to the side opposite the hand which is taking the propelling stroke. It is further noted that "With each turn of the head the snout is touched to the mother's skin . . . and if the teat is touched, the embryo stops and at once takes hold" (p. 256).

The conclusion may be suggested, therefore, that this young mammalian organism, less than 2 weeks removed from an unfertilized ovum, has already developed to a point of independent ability so far as air respiration, alimentary canal digestion, and the receptor-neuromuscular mechanism of geotropically orientated simple progression are concerned. McCrady (1938) has devoted a book to the description of the development of the opossum, a notable book in many respects but especially because of its beautiful drawings.

McCrady, Wever, and Bray (1937) have studied the electrical responses from the cochlea of the pouch-young opossum. These investigations have correlated reflex startle responses and the electrical output of the ear. The first responses of a startle type were found at 50 days. Nine days later the electrical output showed that the sensitivity of the ear was in about the mid-audible range with 2000 cycles as the maximum. At 82 days the maximum had shifted to 7000 cycles. A linear relationship between intensity of stimulus and electrical response was found. This suggests that these young organisms have a very efficient electrical-acoustical apparatus.

Goerling, in an article also reprinted by Hartman (1920, p. 259), gives an account of the birth of the kangaroo, an animal of the same subclass as the opossum. It has been observed that in the kangaroo the young animal moves through the fur from the opening of the urogenital canal to the pouch. The following observation is recorded in regard to the fetus: "It moved about slowly, very slowly, through the fur upwards, using the arms in its progress, and continually moving the head from side to side . . ." (Hartman, 1920, p. 260). Thirty minutes were required for the passage, but during this time the mother gave no assistance whatsoever. Goerling further notes that the arms of the newborn kangaroo are strongly developed. The small hands open and close like a cat's paws. He says: "By these strong little arms and

hands the young one is enabled to labour its way to the pouch, the place of safety and nourishment" (Hartman, 1920, p. 260). It is further pointed out that, so far as the sucking reflex is concerned, once a young kangaroo is removed from the teat which it has taken in its mouth it is apparently unable to reattach itself. Figure 6 shows

FIGURE 6 A so-called mammary fetus of the kangaroo attached to the maternal teat (From *A Text-Book of Zoology*, by T. J. Parker and W. A. Haswell. London: Macmillan, 1921. Vol. II. 577. By permission of The Macmillan Company.)

the early fetal appearance of the pouch-young kangaroo (Parker and Haswell, 1921, p. 577).

In the series of papers referred to above, Hartman reports his studies of the early embryology of the opossum but without any detailed reference to the onset and development of behavior before the early motility stage in which it is found at birth. It is interesting to note, however, on the basis of the evidence given above, that in the marsupials young organisms which might even still be called embryos are born in what is in many respects a very early fetal condition. Their behavior, as indicated above, is significant at any rate in a number of ways for the general student of the development of response. Once in the pouch these organisms can be studied without the usual difficulties of disturbed respiration and digestion of higher mammalian fetuses of comparable developmental age which still depend upon the placental circulation. The reports just given suggest that in this organism there is a general conformity with the pattern of development of the amphibian larvae considered above. As in the case of *Amblystoma*, the young opossum moves with a wriggling movement which from the description, "the head swaying as far as possible to the side opposite the hand which is taking the propelling stroke" (Hartman, 1920, p. 256), suggests the double S movement elaborated by Coghill and others as a characteristic of the onset of aquatic locomotion in larval amphibians. It is also significant to note that it is the forelimbs, both in the opossum and even in that characteristically hind-limbed organism, the kangaroo, which are mentioned as the first effective agents of locomotion.

This again at least does not contradict the view that behavior typically develops from the anterior to the posterior segments of the organism. This generalization may be said to be essentially true of behavior growth in invertebrates, amphibians, and bird embryos. Moreover, there is nothing in the development of the feeding reaction which is presented that shows its essential sequence to be different from that already noted in lower types. Langworthy (1925, 1928) and Weed and Langworthy (1925*a*, 1925*b*) have studied the development of progression and body posture in pouch-young opossums. They find that decerebration of young opossums does not lead to decerebrate rigidity, but rather to an increase in progression movements. This suggests that at this period the cortex has as yet established little dominance over the other neural determinants of behavior.

Similarly, they note, after giving a complete review of the work on the nervous system of the opossum, that electrical stimulation of the brains of pouch-young opossums gives contralateral leg responses but no other responses for over 50 developmental days (Weed and Langworthy, 1925*b*, p. 23). These observations are important in regard to the part played by myelinization of the nervous system in behavior and, incidentally, seem to confirm the priority of forelimb progression in the early behavioral repertory of this form. Larsell, McCrady, and Zimmerman (1935) have studied the morphological and functional development of the membranous labyrinth of the inner ear of the opossum. Nerve endings are present around the receptor "hair cells" before the ear is functional. Vestibular reflexes appear at about 43 days after insemination; acoustic reflexes appear at 50 days. Myelin appears on the vestibular nerve fibers at the time reflexes first appear. It increases as the reflexes become more pronounced.

Of all orders of infrahuman mammals, the rodents have probably been most completely studied, so far as the development of behavior is concerned. It is difficult to say when the study of behavioral growth in rodent fetuses began. They are convenient animals to work with, and it is highly probable that some member of this order was used by the classic embryologists, whose work will be historically reviewed below when a discussion of the specific development of behavior in man is given. It is known, at any rate, that the dead embryos of typical rodents—namely, the rabbit, guinea pig, and mouse—besides many other animal forms, were discussed by Hieronymus Fabricius in his monumental work *De Formato Foetu* in 1604 (Needham, 1931, p. 115). It is highly probable that this writer or some of the other great embryologists of the Renaissance observed the behavior of fetal rodents, because at this time embryology was still much concerned with the Aristotelian problem of the development of the vegetable, sensible, and rational souls in all the forms which were studied.

The first important experimental studies of the development of behavior in this order, however, that the writer has been able to find are those of Bichat (1819, 1827). This eminent early experimental physiologist studied the living embryos of a number of animals, particularly investigating the relationship between the blood stream of the mother and of the fetus. In this work he used the guinea pig extensively. As a result of his studies, Bichat came to a number of interesting, although to some extent unsound, conclusions in regard to the development of behavior in the fetus. He presents a generalized thesis, possibly growing out of the speculations of the Renaissance, that the organism at all stages combines what he calls two lives, one of which is that of sensibility, involving the brain and the senses, and the other that of the vegetative life, involving digestion, circulation, and the like. On the basis of his researches on fetal behavior he concludes that the life of sensibility does not begin before birth, although surprisingly enough he notes and describes in some detail the nature of fetal movements. He alleges that the fetus must be thought of as living in a world virtually devoid of stimulation, as he holds, correctly enough, that an energy, in order to be a stimulus, must change. As the fetus is held in a liquid of constant temperature and properties, he contends that it is virtually unstimulated. He does admit that the sense of touch may be stimulated before birth, but it is not, he further contends, really touch, as every true sensation supposes a comparison between a present and a past state of being.

For this conclusion he is roundly criticized by another eminent French physiologist, Magendie, who later edited Bichat's work. Magendie says in a footnote to Bichat's statements on the sense of touch: "Whatever Bichat may say, it exists in the fetus before birth." Bichat himself (1827), however, points out that touch is to be considered as the most fundamental of the senses and suggests that "philosophers say it is the only one of the senses which always is the agent of truth" (p. 136). Against this sweeping generalization, Magendie, in another footnote, quotes the old experiment of Aristotle upon the illusory localization of the crossed fingers (p. 137). Partly on the basis of his work on guinea pigs, Bichat concludes that the responses of the fetal organism develop continuously from zero to a point of greatest activity just before birth. He supports this conclusion by much anatomical evidence, which includes a discussion of the musculature of the limbs, the brain, the nerves, and the sense organs. He then attempts, it almost seems, to explain away the observations which he has just made, in the light of his own theory. For he at once asserts that the existence of the fetus is not that of an animal but virtually that of a vegetable. This conclusion is based upon the dichotomy which he attempts to establish even in the adult life of man between movements which are dependent upon the will, and hence "animal," as contrasted with such movements as those occurring in sleep, which he alleges are not animal but merely "living."

It is a long step from these early theories and observations to the present knowledge of the development of behavior in rodents, and indeed this step was not taken in a single jump. In 1818 Emmert, an embryologist, published certain incidental observations on the behavioral activity of field mouse embryos (Emmert and Burgätzy, 1818). Zuntz (1877) used fetal rodent material in a series of scientific observations. His work was devoted for the most part to a consideration of the chest movements of the newborn fetus of the rabbit, which was used in part of his study of the development of fetal respiration in mammals.

It was not, however, until Preyer began his series of experiments on fetal guinea pigs and other animals that the modern period of the study of the behavioral growth of the rodent began. In his great summarizing work of 1885, Preyer gives an elaborate history of the study of the development of behavior in each form which he considers. Significantly enough, however, in this treatise, when he deals with the development of mammalian behavior, he begins almost without historical references.

Preyer (1885, pp. 416–428), in his own experiments, however, used a number of different types of mammals and a number of different techniques in his study of the development of behavior. His most significant work was done on the guinea pig. In studying this rodent he used at least six methods:

1. The animal was placed on its back, and the movements of the external abdominal wall of the pregnant mother were observed without interference. He also made such observations on pregnant females on which so-called animal hypnosis or tonic immobility had been induced by an appropriate posture and pressure manipulation. As a result of these types of direct observation he concluded that there are periods of quiescence, lasting sometimes for more than an hour, interspersed with periods of great activity in fetal behavior, at least during the latter part of the pregnancy.

2. In another experiment he placed a long, thin needle directly through the abdominal wall and the fetal sacs of the pregnant female and pressed it into the fetus. This needle was inserted so that, when the

fetus moved, the needle, forming a sort of lever, could be observed to change its position. As a result of these investigations, the frequency of fetal activity was noted. It is all too clear to the modern investigator accustomed to the use of anesthetics in animal experiments that the fetus and the mother could hardly be considered "normal" during these studies.

3. He listened to the fetal movements through a stethoscope and recorded that in the later stages of pregnancy they made a peculiar *Knistern* and *Knacken*.

4. By operation he found it possible to allow a single limb to extrude from the sac in such a way that its movement could be observed.

5. By experimental surgery it proved possible to observe the movements of the fetus still in the mother's body. In this situation he was able to note the effect of changing the blood supply upon fetal behavior and to come to the conclusion that, although deprivation of oxygen did at times lead to general fetal movements, such deprivation was not an essential cause of such movements.

6. He also removed guinea pig fetuses in the air-breathing stage and studied them when supported by blood-warm physiological salt solution and in a warm chamber. In observing the movements of such fetuses he characterized their responses as *"sehr manigfaltig, ungeregelt, asymmetrisch, arhythmisch"* (p. 418).

It is interesting to note below that these are virtually the same words used by Minkowski and many others later in describing early human fetal movements. Preyer also observed certain movements of stretching and of reflex contraction and extension which would be difficult for the fetus while confined in the sac. This phenomenon has been seen many times by the writer, who knows of no evidence that Preyer used any anesthetics in employing any of the methods noted above. The criticism of the more painless work of later investigators, that possibly the fetal material was anesthetized, cannot therefore be urged against this pioneer work of Preyer, which may, however, be criticized on humane grounds.

In one case Preyer (1882) notes that, when his observations were made on a guinea pig in the still intact sac, touching the skin of the face led to a localized brushing movement on the part of the forelimb of the fetus as if to wipe away the offending stimulus which was touching the pad of the vibrissae (p. 212). We shall see that the study of the development of this ability in the fetus may throw light upon certain aspects of the old question as to whether or not the perception of space is natively or empirically determined.

Preyer gives a rather general description of development in the fetal guinea pig. In a fetus 20 to 21 mm. in length no movement was seen, but he adds that this may not be interpreted as assurance that no movement had previously occurred while the organism was in the uterus. In one of 81 to 83 mm., however, opened under blood-warm salt solution, the heart was seen to beat strongly and chest movements were noted. In much larger fetuses, 105 to 111 mm. long, a complete repertory of action almost like that seen in the adult animal was recorded. Many other observations are given on fetuses the lengths of which are not recorded. On the basis of these observations on fetuses, often approximately dated by statements in regard to the hair and teeth condition of the organism, it is possible to say that Preyer noted in the development of behavior in the guinea pig a gradual change in response with growth. The very early movements changed by gradual development until elaborate adaptive responses appeared. Concerning a series of carefully weighed litters in later stages he gives a

detailed account of definite responses. These activities include the pinna reflex to sound, now often called *Preyer's reflex,* the pupillary reflex to light, and even the cerebral inhibition of reflexes as a result of antagonistic stimuli (1885, pp. 587–595). He points out that in a 173-gram guinea pig the teeth of the organism were so well developed that they bit his fingernail sharply (p. 423). On the basis of all this observational and experimental work, Preyer turns to his consideration of the development of behavior in the human fetus, to which reference is made below.

The first systematic study of the development of fetal behavior in guinea pigs, from the point of view of genetic psychology, is Avery's (1928), carried out in the Psychological Laboratory of Stanford University. As a background for the study of prenatal development, Avery carefully investigated the responses to stimulation shown by newborn guinea pigs. As contrasted with the naked and almost helpless neonatal marsupials described above, the guinea pig is at birth in many respects structurally and functionally a mature animal. It is born with a sleek coat of fur. Its teeth are well erupted. Its eyes and ears are open. Its heart pulsations and breathing may be quite continuous and regular. It is able to roll from back to side, side to back, and side to haunches. It can crawl, stand, and walk.

> To the pinch stimulus applied to the foot it responds by kick or withdrawal of foot. The electrical stimulus elicits a muscular twitch, respiratory gasp, and jump. It can execute the scratch reflex spontaneously or when stimulated in the facial region. Although muscular weakness is evident the patterns of response show good coordination [Avery, 1928, p. 264].

The sensory control of behavior, this investigator points out, has also progressed to a remarkable degree. Lid and pupillary reflexes are present. The newborn animal avoids objects without touching them as it moves about. The ears are functional, and total bodily movements and pinna twitches are elicited by appropriate auditory stimulation. Needle pricks and heated objects lead to quick response. Olfactory stimuli evoke movement of the head. The complex movements of swallowing are well developed. So far as more integrated behavior is concerned, Avery reports that the young run together when separated from each other and run to the mother when separated from her. Somewhat similar observations were also made by Preyer (1882, p. 93). The young lick themselves, swim when placed in deep water, chew shavings, and attempt to disengage a foot held by an observer. No retreat responses were noticed when young guinea pigs were placed with an adult white rat. The prenatal development of behavior of this Minerva-like organism is therefore peculiarly interesting because it is such a complete story.

Avery's work on prenatal development must be strictly evaluated, however, in terms of the rather special conditions which he employed in his experimental study. Abandoning the techniques used by some of the earlier investigators in mammalian behavioral development, Avery removed from the mother each fetus that he studied. He thus, of course, intercepted placental circulation and therefore brought about all the changes which have been found to result from oxygen deprivation and an increasing concentration of metabolites in the fetal blood stream. That is, he often worked with dying fetuses. Thus his work is strictly comparable to most of the work on human fetuses reviewed below. Observations were most often made on a large metal tray placed on a well-lighted observation table. "An electric heater, re-

fetus could be made to respond by direct electrical stimulation. . . .

noted in the study may be characterized, at its first appearance, as a pattern of behavior, which involves a relationship between neck flexion and forelimb movement. . . .

8. Many of the points indicated . . . when stimulated, release behavior from the

first which in spite of very great variability could always be considered as a special "pattern of behavior." . . .

9. Each behavior pattern released by the stimulation of a particular area may be said to undergo a series of changes during fetal life. . . .

10. Photic stimulation of the eye may lead to motor responses of the limbs, etc., before the eyes are normally open in the fetus, when such stimulation is made possible by an operative exposure of the eye. . . .

11. Auditory stimuli released behavior in a 63-day fetus after the liquid had been removed from the external meatus. . . .

12. Needle stimulation ("pain stimuli") in general released responses which were quite comparable to responses released by pressure stimuli rather than to the vigorous responses characteristic of the adult animal when subjected to pain stimulation. . . .

13. Temperature stimuli well above and well below the temperature of the fetus, when applied to the skin, release behavior. . . .

14. In late fetuses compensatory movements during rotation and in the immediate post-rotational period were demonstrated. . . .

15. There is evidence that in late fetal life higher brain centers influence responses which are characteristically called "spinal reflexes." . . .

16. As development progresses, the amount of "motor diffusion resulting from specific receptor stimulation" decreases, at least in certain areas and under certain stimulus conditions. . . .

17. The study does not confirm in detail the specific laws of development, alleging that development is in all respects cephalo-caudal, proximo-distal. or from "fundamental" to "accessory" muscles. . . .

18. It is possible to view most of the typical patterns of behavior released by the stimulation of given areas as capable of securing some end or ends, which during fetal life itself or during subsequent independent life may serve adaptive needs of the organism. . . .

19. The present study does not give unqualified support to any of the more general theories of the development of behavior, such as those summarized by the words "individuation" or "integration," but suggests rather that the formulation of such generalizations is at present premature. . . .

After this general study it became apparent that a more detailed study of certain aspects of fetal behavior in the guinea pig was important. Bridgman and Carmichael (1935) studied 47 fetal litters *at just about the time that behavior first begins.* As a result of this study the following conclusions were drawn (pp. 262–265):

1. Prior to the onset of behavior in the fetal guinea-pig, myogenic contractions can be elicited from certain muscles. That these early responses are truly myogenic, and not sensory-motor responses, there is little doubt, because of their character, particularly as compared to later movements.

2. Active behavior in the fetal guinea pig begins in the last hours of the twenty-fifth day. Previous observers had placed the onset at least 1 day later than this.

3. True behavior, that is, response that results from stimulation, and which is secondarily induced by nervous discharge, can be elicited 10 to 14 hours before "spontaneous" behavior appears. These stimulated responses are of a sufficiently different character from the earlier myogenic contractions to be classified as active; i.e., involving neural activity. . . .

4. The first active responses of the fetal guinea pig are definite in character, and involve movements of the head, brought about by contraction of the neck muscles, and of the fore leg. The evidence is as yet inconclusive concerning which of these components arises first.

5. It is seen that, from the earliest period, the neck and limb responses occur

sometimes together, and sometimes independently, and that throughout the developmental period studied, independent elements of behavior are present at all times. That is, no gradual progressive "individuation" of the specific responses out of a total pattern is seen. . . .

6. Because of the simple and specific nature of much of the earliest behavior of the fetal guinea pig, it is thought that these responses may advantageously be described as reflexes. Moreover, no need to use such words as "generalized," "totally integrated," or "non-specific" in the description of this behavior has arisen. . . .

The development of temperature sensitivity in the fetal guinea pig has been studied by Carmichael and Lehner (1937). The results of this study are summarized in Figure 8. This figure shows that in fetuses of all ages there is an increase in released behavior as stimuli (drops of water) are used which are either warmer or cooler than the physiological zero (about 37.5° C.) of the organism. The conclusions of this study (pp. 224–226) may be summarized in the following statements:

1. Temperature stimuli . . . are effective in releasing responses during most of the motile fetal period of the guinea pig.

2. At each of three fetal development periods, as these periods were established for the purposes of this study—young, mid, and old—the greater the difference between the temperature of the stimulus and the physiological zero of the organism, the greater the relative number of responses released by that stimulus.

3. At the youngest ages studied, there appears to be a slight tendency for cold stimuli to be relatively more effective than warm stimuli if certain assumptions of equality are made concerning units of measurement.

4. During the "young" period of fetal life, as defined above, there appears to be development of temperature sensitivity. Sensitivity is greater, that is, in the mid period studied than in the initial period. There is no corresponding increase during the other periods studied. In the last period, the growth of the insulating hair coat unquestionably modifies the effectiveness of the stimuli as applied in this investigation.

5. There is no great change in the percentage of specific and general responses

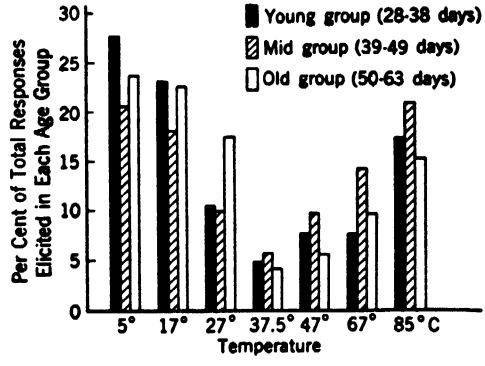

FIGURE 8. Responses of guinea pig fetuses to thermal stimuli. (From "The Development of Temperature Sensitivity during the Fetal Period," by L. Carmichael and G. F. J. Lehner. *Journal of Genetic Psychology*, 1937, *50*, 222. By permission of the publisher.)

released by the stimuli used at any of the three periods studied, nor does the effective intensity of stimulation (as measured by the greater degree of difference from physiological zero) change in a definite manner as development progresses in its efficacy in releasing either general or specific responses. There is a slight preponderance of specific over general responses, as these two words are defined in this paper in each period, but this finding can hardly be considered as statistically significant.

6. There is some shift in the relative sensitivity of the six areas stimulated during fetal development. These data may be considered as supporting the generalization made by previous investigators that the development of sensitivity spreads from the cephalic to the caudal regions of

the body and from the proximal to the distal region of limbs.

Bonardi (1946) has also made observations on the stimulation of the nose with cold and hot water at various fetal ages. At the temperatures used cold water was

(10) Point in medial palmar surface of one forepaw.

more effective than hot water in releasing behavior.

Hooker (1944) and other investigators have emphasized the importance of the use of quantified pressure stimuli in working upon fetal material. Carmichael and Smith (1939) attempted to study this question in detail. (See also Carmichael, 1937.) First they decided to use certain well-established reflexogenous zones as shown in Figure 9. They then prepared a series of calibrated von Frey esthesiometers. In each case the lightest esthesiometer that would elicit a response was used, as well as one 7 to 9 points higher in the scale of esthesiometers. The quantitative conclusions of this study are shown in Figure 10. An example of the difference in response to the light and heavy stimuli is shown in Figure 11. In summary of this study it may be said that pressure stimuli are like

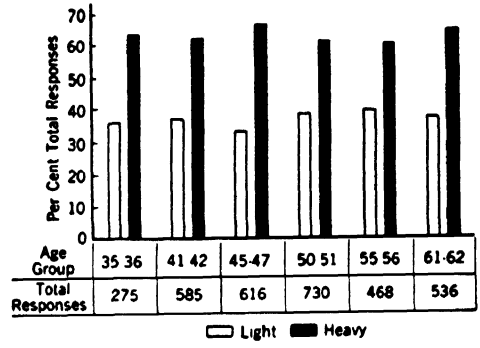

FIGURE 10. Percentage of responses at each fetal age group studied. (Normal gestation period is 68 days.) temperature stimuli in the importance of intensity upon resulting response.

Moreover, the present results show that the same relative proportion of general and specific responses seems to be released at all of the typical fetal ages studied. This

finding adds further confirmation to the view that specific responses are early developed in fetal life. Thus it becomes more than ever clear that the widely accepted formula that all specific behavior develops from the individuation of previously more general patterns of behavior needs revision. Such revision can come only from continued study of fetal behavior as released by stimuli of quantitatively known character [Carmichael and Smith, 1939, p. 434].

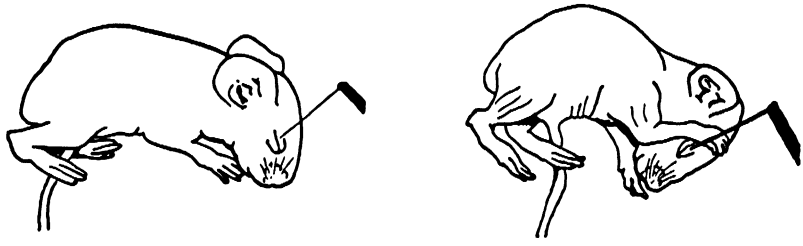

FIGURE 11. Outline tracings from moving-picture film of two postures of 51-day guinea pig fetus. (From "Quantified Pressure Stimulation and the Specificity and Generality of Response in Fetal Life," by L. Carmichael and M. F. Smith. *Journal of Genetic Psychology*, 1939, *54*, 432. By permission of the publisher.) Picture at left shows resting posture of the fetus as stimulated with light esthesiometer. Only response in this case was an eye wink. Picture at right shows one phase of movement elicited by a heavier esthesiometer. In this case, the entire trunk and all limbs are involved in the reaction. Note the precise localization of the stimulated spot by the forepaw.

Jasper, Bridgman, and Carmichael (1937) have studied the electrical brain potentials of the fetal guinea pig. Their conclusions (pp. 70–71) are:

1. The brain potentials of the guinea pig first appear when the age of 48–56 days of gestation has been attained.
2. No quantitative ontogenetic trend in the characteristic frequency of potential variation, nor in the total range of frequencies, has been discovered. The appearance of secondary groupings of characteristic frequencies is found more often as age increases.
3. The average amplitude of the characteristic frequencies at any age shows an irregular yet definite increase with age.
4. Definite though not invariable effects of stimulation on the character of the cortical electrogram have been noted, occurring as early as the 60th day of gestation.
5. The guinea pig brain first exhibits electrical activity at a time when behavioral indications also point to maturation of higher nervous centers.

In connection with this study it was noted that tying off the umbilical cord abolished most cortical activity but did not for some time abolish the lower reflexes of the fetus.

In another study, using high-gain electrical amplification of bioelectric phenomena in the fetal guinea pig, Rawdon-Smith, Carmichael, and Wellman (1938) have demonstrated that the cochlear electrical response (the so-called Wever-Bray effect) is present in a guinea pig fetus of 52 post-insemination days. The electrical response secured at 52 days had a peak voltage of 1 to 2 microvolts to a stimulus of 600 cycles per second at an intensity of 100 decibels above human threshold. Declining responses were noted to tones below this and above 2000 cycles per second. The rise in electrical output was rapid as de-

velopment progressed, for by 62 days 100 microvolts was recorded. It is interesting to note that the time of onset of the electrical response of the fetal ear—namely, 52 days—is exactly the same time at which the first overt behavior released by auditory stimuli can be observed in the fetal guinea pig.

Of all rodents, however, not the guinea pig but the white rat seems to be the most generally studied laboratory mammal. It is not surprising, therefore, that in recent years an increasing amount of attention has been given to the prenatal development of behavior in this convenient organism. One of the most elaborate studies of this sort is reported in an unpublished thesis by Swenson (1926). The experimental work for this thesis was done under the direction of Coghill. The thesis is entitled *The Development of Movement of the Albino Rat before Birth.* The operation by which the female is rendered immobile is described by Swenson in a special article (1925). The mother is deeply anesthetized, the neck is opened, and the carotid arteries are ligated as close to their origin as possible. The large left and right external jugular veins are also secured and ligated. Ether is now discontinued, and the skin incision is closed. After the anesthesia has been allowed to pass off, the mother is immersed in physiological salt solution. Each fetus is then in turn shelled out and studied.

Swenson's observation began with fetuses showing absolutely no movement save heart beat and continued at convenient stages to birth. It is difficult to generalize about any such developmental sequence because the omission of any of the details of the onset of behavior is likely to give a prejudiced picture of the total process. It is possible in review here, however, to give a few of the salient points of the growth of behavior in the rat as found by Swenson. The first movement noticed was a slight lateral bending of the head. This same movement, differently interpreted, may be characterized as a slight cephalic trunk-bending movement. From this early action to the precise adaptive movements of tongue and paws in late fetuses, there is found a continuous quantitative and qualitative change in the movements as observed in litters of increasing gestation age. In the general theoretical discussion of the causal factors concerned in the development of behavior, we shall again refer to the work of Swenson, particularly to the observations which he made upon fetuses with clamped umbilical cords. Clamping of the cord he found to lead to an increase of metabolites in the fetal system and certain characteristic behavioral changes. Abstracts of the thesis noted above, and additional observations, have been published by Swenson (1928*b*. 1929).

Angulo y González (see references in bibliography), also associated with Coghill, has published some very important studies of the development of behavior in the fetal albino rat. He used much the same technique as Swenson in operating on the mother rat and in preparing the fetal material for observation. He selected his material with unusual care. Of the 643 fetuses used in one study, all came from healthy female rats of known stock 110 to 190 days of age, his previous work having indicated that these precautions were necessary in order to obtain scientifically comparable results at various gestation ages. In his work moving-picture records were taken to supplement the written protocols. Angulo y González in his experimental report gives the percentages of fetuses showing each movement at each age. For these detailed conclusions the reader is advised to consult the original papers (1929*a*, 1930*b*, 1932*a*, 1939). This same author, after using the drug *curare*, which alters

the physiological relationship of motor nerves and muscles, was able to stimulate muscles directly in young fetuses. This indicates that the first responses of the rat fetus may be purely myogenic.

It is interesting to note that both Swenson and Angulo y González independently first observed movement in the rat fetus in the three hundred and seventy-eighth hour after insemination. Angulo y González' general description of the developmental process, particularly so far as the process of "individuation" of behavior is concerned, may best be given in his own words:

> During the early stages of development the appendages move only with the trunk. Thus, upon stimulation of the snout the reaction more frequently obtained is a total mass reaction which involves the trunk and appendages. This total mass reaction we called a total pattern. This total-pattern reaction consists of a primary or basic movement, lateral flexion of the trunk, and a series of secondary movements. Similarly, there develops later a total pattern consisting of a basic movement of head extension and a series of secondary movements. The basic movements, during the early period of behavioral development, assert their sovereignty upon the secondary movements. During the later period of the development of fetal behavior, we find a number of specific reflexes showing what at first seems to be a breaking up of the total patterns into individual and specific reflexes. But close study has convinced me that the process by means of which the individuation and specificity of certain reflexes is attained is not a disintegration or breaking up of the established pattern, but, rather, is due to an inhibitory action by means of which the primary or basic movements are in a large measure arrested. In other words, the total-pattern reaction is never abolished completely, nor is the dominance of the primary over the secondary movements lost [1932*a*, p. 442].

This same investigator (1933*a*) has suggested that there are three phases in the development of somatic activity in albino rat fetuses: (1) a myogenic phase in which behavior can be elicited only by direct muscle stimulation; (2) a neuromotor stage in which internal stimuli acting upon the nervous system initiate behavior; (3) a sensory-motor phase in which true reflex action begins.

Angulo y González (1934*a*) has also shown that the dissolution of the behavioral systems of the fetal rat is in inverse order to its evolution, which is in general cephalocaudal and proximodistal. The relationship of this observation to Hughlings Jackson's generalizations (1884) should be noted. Angulo y González (1934*b*, 1939, 1940) has studied in detail the change in neural mechanisms which are correlated with behavioral development.

Besides these studies of the whole developmental sequence in the rat there have been a number of investigations devoted to certain aspects of the growth of the activity of the response mechanism in the rat. Lane (1917) has studied the development of the correlation between structure and function of the special senses in the white rat. His method of preparing fetal material consisted in killing the pregnant mother and studying the excised fetuses in a warm chamber. This method is open to the limitations pointed out in the evaluation of Avery's work given above. During the observation period the fetus was bathed in a warm physiological salt solution.

Lane's (1917) observations on the development of the senses in the white rat may be summarized as follows:

Touch. He found no evidence of this sense in 7½-mm. embryos, which are generally agreed to be immobile. Neurolog-

ically, at this stage he found both sensory and motor fibers developed. The sensory fibers, however, had not as yet reached the periphery. In 16-mm. embryos, that is, in organisms approximately 17 gestation days old, the tactual sense is reported as present on the flanks and snout, as evidenced by motor response to needle pricks. Lane reports no response to stimulation with a sable brush at this time. This is contrary to the findings of all subsequent investigators and is probably a function of the special condition of the embryos used. In 23- to 28-mm. embryos, that is, embryos approximately 19 to 20 gestation days old, he reports response to stimulation with a fine sable brush as well as with a needle prick. The snout region is most sensitive, although stimulation about the shoulder, upper arm, hip, rump, and thighs also evokes motor responses. He reports that there is a noticeable increase in the number of vibrissae as well as a greater complexity in the neural fiber basket of the vibrissae follicle. In very late fetuses and newborn rats a still better development of the tactual sense is found, responses being elicited by stimulation of any point on the entire body, including the tail. Pain as the result of needle stimulation is at this period shown by squeaks. The fibrillae baskets in the vibrissae follicles are now elongated cylinders, from the base of which neural fibrils in comparatively large bundles are seen to emerge, distad to the base of the follicle itself. In later stages there is no particular advance noted in tactual sensitivity, although the snout region continues to be superior to the rest of the surface in sensitivity.

Equilibrium. In regard to this sense, this investigator found in 7½-mm. embryos that stimulation leads to no behavioral trace whatsoever. Histologically, he reports the semicircular canals to be as yet undeveloped. In the 16-mm. embryo Lane again found no experimental evidence of the sense of equilibrium, although the semicircular canals are now well developed. In 23- to 28-mm. embryos, Lane still finds no experimental evidence of a sense of equilibrium. Histologically, the differentiation of the cells of the cristae is at this time further advanced than in the previous stage, although the sensory and supporting elements are not yet distinguishable. Slight indications of central connection with the cerebrum are noted. In a 35-mm. fetus the sense of equilibrium was first observed, as seen in the righting responses of the organism when in contact with a surface. Structurally, the semicircular canals are now virtually complete. On the first day after birth, however, the righting responses were better developed, as were the histological and neural connections seen in the semicircular canals. In later stages there was manifested a greater perfection of the sense of equilibrium accompanying an increasing power of coordinated movement. Lane makes no reference to the part possibly played by neck proprioceptors or by other receptor fields in determining these righting responses, nor is any reference made to the analysis of postural reactions suggested by the school of Magnus, to which reference will be made below.

Smell. Lane reports no satisfactory method of smell stimulation in rat embryos from 7½ mm. to 28 mm. in length. Histologically, he says: "During these stages the olfactory apparatus is being gradually laid down, both as regards its sensory and peripheral portions. The histological differentiation of the olfactory epithelium has not advanced sufficiently far to enable the sensory cells proper to be identified" (p. 51). Using a brush placed in an odoriferous substance, Lane obtained no certain response to olfactory stimuli in 35-mm. fetuses. Histological development, however, is noted as continuing. Small's work

(1899) on smell in the newborn rat is quoted, and the statement is made by Lane that "there is on the whole a gradual perfecting of the olfactory sense from day to day" (p. 52). No experimental proof is given of this statement, and it is hard to understand its basis in view of the difficulty reported by Liggett (1928) in dealing with this sense in the white rat.

Taste. In this sense, Lane reports that the 35-mm. fetuses were able to swallow, but neither in these nor in those of any preceding stage were any true evidences of a sense of taste discovered. At no time previous to birth could taste buds or other fully differentiated organs of taste be demonstrated. On the first day after birth, however, he notes that sugar solutions were received with less objection than salt or acid solutions. Lane again makes a generalized statement that in postnatal life this sense is gradually perfected, although no experimental evidence is given to support the view.

Hearing. Here Lane reports that "absolutely no response to sound was noted before the twelfth day after birth," and that "from that day to the sixteenth or seventeenth day there is a gradual increase in the ability to perceive sound" (p. 63). No evidence is given for this conclusion in the monograph, however, save that change is inferred from structure. In his conclusions he says:

> Previous to the twelfth day the portions of the ear concerned with the perception of sound have been undergoing a gradual development, but have not yet reached that degree of differentiation of the organ of Corti necessary for the perception of sound. By the twelfth or thirteenth day the organ of Corti is apparently differentiated for at least part of its extent, though the lumen of the external auditory meatus is not fully opened. The next few days witness the completion of the differentiation of the apparatus of hearing [p. 63].

For a study of the early growth of the inner ear of the rat, see Wada (1923).

Vision. As far as this sense is concerned, the report of Lane is: "Absolutely no response to light was obtained before the opening of the eyes on the sixteenth or seventeenth postnatal day" (p. 69). This was determined by the use of an electric flashlight. The objection may be raised, on the basis of a good deal of other experimental work, that this stimulus was possibly not strong enough to bring about response. No record is given of the pupillary response which might have been obtained had the eyelids been opened by operation. Histological evidence, however, is given to suggest that there is a neural and receptor development paralleling the reported functional development.

Lane's theoretical conclusions concerning the anatomical basis of early development in the rat fetus and the function of the receptor in the development of the reflex arc will be given at the close of this chapter.

From the report just given of Lane's work, as well as from the incidental observations in the work of Swenson and Angulo y González, it becomes obvious that, of all the sensory fields in the white rat, that of skin sensitivity is apparently earliest and most completely developed during prenatal life. The development of this sense in the fetal rat was quite extensively investigated by Raney, working with the writer (Raney and Carmichael, 1934). In this work the pregnant female was deeply anesthetized and the spinal cord completely transected between the sixth and seventh cervical vertebrae. The result of this operation was to provide an effectively immobilized and, so far as the field of the operation is concerned, a completely desensitized adult organism in which, how-

ever, circulation and respiration continue in a virtually normal condition. After a period of one and a half to two hours, the fetuses were shelled out, with placental circulation maintained, into physiological salt solution held at 37.5° C. by thermostatic control. Raney and Carmichael's work was conducted not only in an effort to study the effect of change of skin sensitivity at various fetal developmental ages, but also to consider the origin of what may be called "local sign," at least in so far as such local sign may be demonstrated in the progress of localizing movements of the limbs of the fetus resulting from punctiform stimulation.

Klemm (1914), in his history of space perception, referred to the development of the view that space is perceived in relation to body movement. James (1890, Vol. II, pp. 170–282) also considered the factors leading to this view, and Peterson's experimental work (1926) on local signs as orientation tendencies again emphasized this conception. Raney and Carmichael's work shows that with increasing gestation age the fetus first becomes sensitive to areal stimulation, as, for example, to stimulation with a camel's-hair brush approximately 5 mm. in diameter. Response to punctiform stimulation by a single light hair is observed to begin some time later. The first appearance of sensitivity is in the head region and is observed to pass gradually caudad (that is, toward the tail). The first responses to stimulation are slight movements of the trunk occurring during the sixteenth day, as noted by previous investigators. As development continues, stimulation at any sensitive point may elicit much more complicated behavior, often involving neck, trunk, forelimb, hindlimb, and other muscle movements. The peculiar sensitivity to tactual stimulation of the region from which the vibrissae issue is noted throughout this developmental sequence. The early function of this tactual organ, as it may be called, is particularly interesting in reference to the full innervation of this area as shown by Lane and in the behavioral observations on the function of the vibrissae in young rats by Small (1899), and especially in the special study of this receptor field by Vincent (1912).

Raney and Carmichael (1934) have found, however, where the mechanical possibility of movement is present, that is, where the limb may touch the surface, that the responses may gradually become more and more precisely related to the point of stimulation. Thus at an early gestation age stimulation of the region of the vibrissae may lead to slight trunk movements. Later such stimulation may lead to the movement of many muscle groups of the fetus, including the limbs. At a still later time, the principal response may be merely that of the forepaw moved ever so slightly toward the point stimulated. If the point touched is on the body wall, the movement may be toward that point. If it is on the nose, it may be toward that point. It must be noted, however, that, even at the best time for such differentiated response in late gestation periods, the stimulation of any point may also bring out very general activity. It is possible that such generalized response is due to interruption of some "spontaneous" movement, or that it is related to the strength of stimulation. The frequency of stimulation or the immediate past activity of the organism may also be important in inducing such activity. The significance of intensity of stimulation in this connection in the guinea pig fetus is explained above. This is not the place for a full consideration of the theoretical implications of Raney and Carmichael's study as it bears on space perception, but the results suggest a certain reformulation of one form of a modified genetic theory of the perception of exten-

sion as considered by Boring (1929, pp. 250–262).

Lincoln (1932), also working in collaboration with Carmichael, was able to show in the rat fetus something of the elaborate sensory and behavioral sequences which are antecedent to the sucking reflex as that reflex is seen at birth. The report of this investigation is recorded in library copies of a thesis. This work is especially interesting in relation to Lane's work on the correlation between structure and function in the nursing reflex of the young rat and guinea pig. In Lane's work (1924) especial attention is given to the development of the tongue both as a locus of taste receptors and as a prehensile organ. Further references to the sucking reflex are given below.

Angulo y González (1937) has shown that the sensory system follows the motor system in development. The earliest functional sensory endings develop in the region of the snout as tactile receptors. The receptors in the forelimbs, for example, are later in development than those in the snout. The total arc connections seem to be formed by the growth of collateral fibers which establish functional connections after the sensory and motor systems are complete.

Windle (1934*b*) has demonstrated that all the spinal reflex arcs are present at 11 mm. but they are incomplete because sensory collaterals are just beginning to enter the mantle layer of the spinal cord. The main difference between the nervous system of motile and nonmotile fetuses lies in the number and length of these elements.

Besides the special studies noted above, there have been a number of other investigations dealing with particular muscle groups or special behavioral characteristics of the white rat fetus. Corey (1931) has studied the causative factors of the initial inspiration of mammalian fetuses, using the white rat as material. In this study it is concluded that the initial respiration of the fetus is normally brought about by a change in the relationship between carbon dioxide and oxygen in the blood in cooperation with the stimulating effect of the drying of the skin. Blincoe (1928*a*, 1928*b*) has worked on the development of behavior in the motor system of the forelimb of the rat. He has elaborately studied the anatomy of the limb before the fifteenth day, that is, just before the onset of motility. An effort has also been made to present a correlation between this stage of development in the rat and in man. In the later study he points out that it seems that the arm of the rat shows "the stat e assembling of many bodily components which await some complementary addition to render them a dynamic whole" (1928*b*, p. 293). It is suggested that this addition is to be found in functional innervation. In this connection see also a paper by Barron (1934) on the results of his experiments on the peripheral anastomoses between the fore- and hindlimb nerves of albino rats.

Also working with the rat fetus, Windle, Minear, Austin, and Orr (1935) have shown that physiological muscular development may be summarized in the course which it takes. In general this development proceeds from the head to the tail region and distad and ventrad from the dorsal part of the trunk. (See also Windle and Baxter, 1935, 1936.)

Bors , (1925), Nicholas (1925, 1926, 1929*c*), Hooker and Nicholas (1927, 1930), Nicholas and Hooker (1928), and others have performed experimental operations on rat fetuses. Following a very elaborate technique, these students have been able to operate on mammalian fetuses without interrupting pregnancy. In the course of this work they have made a number of incidental observations on the development of motility, and Hooker and Nicholas

(1930) particularly have pointed out the fact that during intrauterine existence "movements are restricted to a large degree and there is also a greater degree of independence of the individual cord segments than is found in later postnatal stages" (p. 431). These observations are significant, for they were made under conditions more nearly approaching those of normal development than any other studies of the development of mammals.

Straus and Weddell (1940) have shown that the earliest visible contractions of the forelimb muscles of the rat appear during the latter half of the fifteenth or the first half of the sixteenth postinsemination day. The extensor muscles are more readily stimulated than the flexor muscles, and if a nerve trunk can be stimulated the response is greater than if the muscle must be directly stimulated. (See also Straus, 1939.)

Corey (1934) has shown that in the fetal rat the cortex is not extensively involved in the production of fetal movements.

A number of studies of special aspects of the development of behavior have been made on the rabbit, to a few of which reference has been made above. Preyer (1885, pp. 418 ff.) made some observations on fetal organisms of this type. Langworthy (1926) has worked on progression in very young rabbits. He points out that in such animals decerebration does not lead to extensor rigidity but to prolonged progression movements. In the more mature newborn guinea pig, however, rigidity follows decerebration. This difference is attributed to the degree of myelinization in the central nervous system. The importance of myelinization, or the formation of the myelin sheaths, on neurons is discussed below. Zuntz (1877) also used the rabbit fetus in his work on respiration. Richter (1925) has observed sucking movements in rabbit fetuses about 20 days old. Pankratz (1931*b*) has adapted Swenson's technique to the study of the rabbit. Mechanical stimulation of nose, head, and neck led to response of simple lateral flexion of neck and trunk in 15- to 16-day rabbit fetuses. In a 17-day fetus there was a marked ventrolateral flexion of head and upper trunk, with some movement of the forelimbs. In 20-day-old fetuses, opening and closing of the mouth, active movements of the forelimbs, flexion of the hindlimbs, and lateral flexion of the whole trunk were observed. As the gestation period advanced the movements became more complex.

The cat has proved itself to be an eminently suitable animal for the laboratory study of the development of fetal behavior. Its neuromuscular system is quite highly organized. Its gestation age of over sixty days allows for the development of an organism at birth that is relatively mature. Much is also known as a result of past research concerning its structural development (Hill and Tribe, 1924; Latimer, 1931; Latimer and Aikman, 1931), anatomy, and certain of its adult behavioral characteristics, such as the righting response (Camis, 1930). These factors combine to make the animal peculiarly satisfactory for research upon the development of fetal behavior. The general purposes of this chapter, therefore, demand a rather complete summary of the investigations of fetal behavior in the cat.

Windle and Griffin (1931) reported a study in which a large number of cat fetuses of precisely known or accurately estimated gestation age were experimentally studied. The technique employed by these investigators involved an operation on the brain of the mother cat such that later, without anesthesia, it was possible to study the fetal organisms under warm physiological salt solution with fully maintained placental circulation. The methods of studying the fetuses varied more or less

according to age. In all, 34 pregnant cats were used, giving 125 living embryos and fetuses for study. Of the litters of the 34 cats thus employed, 19 were of known age since copulation. The ages of the other fetuses were calculated from their body measurements, a procedure that is not in all respects satisfactory.

These investigators reported that no movement was seen in the 23-day stage or on any day previous to that. In later studies, however, it was established that movement does take place on the twenty-third day (Windle and Becker, 1940*a*). In the 24- and 25-day stage, what the reader may now begin to consider as the characteristic response of young fetuses, namely, the very slightest slow ventral lateral head flexion, was observed in a number of embryos. This was also independently confirmed by Windle (1930*a*). The earliest limb reflexes are well-localized movements occurring on the side of stimulation at the twenty-fourth day (Windle, 1934*a*). In the 26- to 27-day stage, movements were in general more complex and of greater amplitude or duration and strength than those noted previously. Generalized trunk undulations, however, still formed the permanent background of activity, but forelimb flexion had also begun. The investigators have pointed out that, at this stage, rotation of head and trunk appears to be coordinated with older components, but that this activity results in movements which strikingly resemble the righting reflexes seen in later fetal life. At this stage the fetuses seem unresponsive to brush or probe. At 28 days slight flexion of the hindlegs was noticed, and at this time also the first responses to touch, particularly in the head region, were observed. Stimulation of this sort was followed by typical apparently "random" head-trunk-limb undulations. At 30 days the activity recorded was still more complex. Active flexion of the hindlimbs was noted, and at the same time definite, although sluggish, mouth movements appeared. From this time until birth, continued and progressive increase in the specificity of behavior was noted by these observers.

So far as the development of sensory capacity in these animals is concerned, it has already been noted that no external response to stimulation is found in fetuses of less than 26 mm., that is, of approximately 28 gestation days. These investigators hold that there is evidence, however, of exteroceptive and proprioceptive function even in the first animals that show spontaneous movements. "The fact that the unilateral trunk or neck flexions seemed always to be executed toward the observer and away from the surface on which they rested may indicate that the earliest sensation is one of deep pressure" (Windle and Griffin, 1931, p. 175). So far as behavior at the 26-mm. stage is concerned, it is held that the activity noted may be the result of a "primitive type of proprioception" (p. 175). This would explain the spread of motor response, although there is some possibility that the wavelike progression of muscular contraction noted is due to the function of long association pathways in the central nervous system.

The first so-called cutaneous reflexogenous zone, that is, cutaneous area, in which stimulation can be shown to lead to response included the nose areas and in general most of the head. Pronounced response in the fetuses at 28 days followed stimulation of the nose. Gradually, as fetuses of later ages were considered, the area spread caudally to the neck, pectoral region, forelimbs, trunk, hindlimbs, and finally to the tail. Windle and Griffin point out: "It is interesting to note that spontaneous motor activity always involved a part of the body before responses could

be elicited either locally or at a distance from the point stimulated" (p. 175). The strength of stimulation was also reported as significant in determining the nature of response. Usually the light touch of a brush was found to be ineffective in specimens less than 60 mm. long. In a few fetuses a little longer than this a response was secured when the brush was applied to the nose. It was noticed that a light stimulus which caused no response if once applied was sometimes adequate if repeated several times. This effect of summation of stimuli is noted in many fetal forms under a variety of conditions. Very little difference could be observed between strong innocuous stimulation and stimulation producing observable protoplasmic damage. The authors believe that the primitive type of pressure-touch sensitivity, which they postulate as the characteristic state of the receptor surface of early fetuses, was not replaced by definite touch and pain until relatively late in fetal life. In fetuses of 75 to 80 mm. marked differences between the responses to light and to strong stimuli were observed, and pain responses were thought to be definitely present.

In the cat, vestibular function probably appears in prenatal life. No absolute evidence of its presence is found until very shortly before birth. It should be borne in mind in all considerations of this sense in fetal life that there are great difficulties in testing it accurately in a squirming fetus. In a later study, however, Windle and Fish (1932) demonstrated by the use of several techniques, including the operative interference with the vestibular apparatus, that the true vestibular righting reflex elicited in animals in contact with a surface probably appears in fetal kittens of 100- to 115-mm. crown-rump length, that is, on about the fifty-fourth day of gestation. These same investigators (Fish and Windle, 1932) considered the onset of rotary and postrotary nystagmus in the eyes of newborn cats.

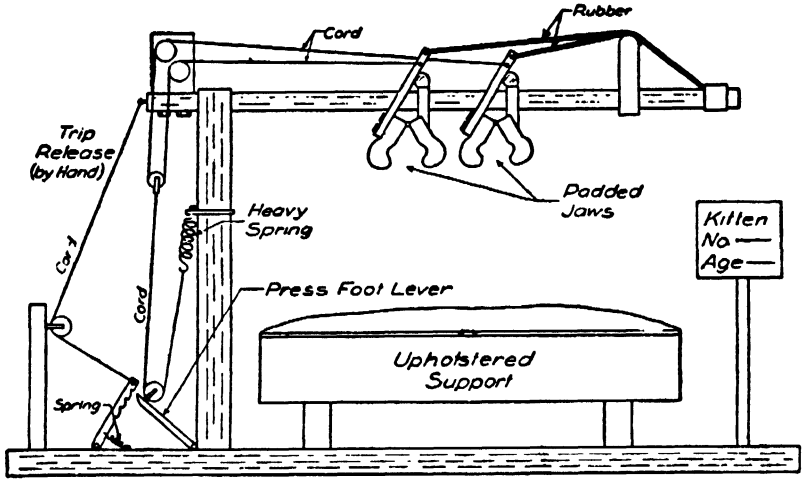

FIGURE 12. Apparatus used in the study of the development of the air-righting reflex in small mammals. (From "A Study of the Development of the Air-Righting Reflex in Cats and Rabbits," by J. Warkentin and L. Carmichael. *Journal of Genetic Psychology*, 1939, *55*, 68. By permission of the publisher.)

For an important early study of the developing of the "falling reflex," see Muller and Weed (1916). Carmichael (1934*b*) and later Warkentin and Carmichael (1939) studied the genetic development of the of the act. Thus an animal may be able to perform all the behavioral acts needed in air righting before the total pattern in time can be accomplished in the short period allowed by a free fall.

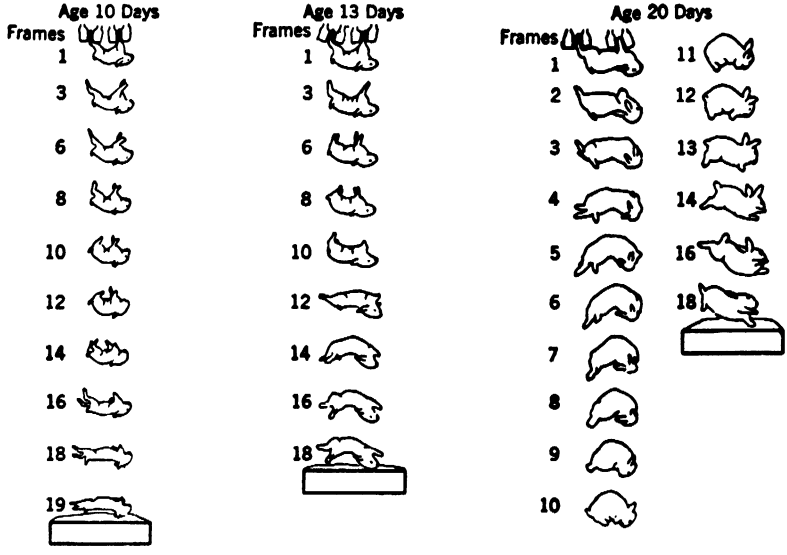

FIGURE 13. Diagrams of movement sequences during falling in a young rabbit at three different ages—10 days, 13 days, 20 days. (From "A Study of the Development of the Air-Righting Reflex in Cats and Rabbits," by J. Warkentin and L. Carmichael. *Journal of Genetic Psychology*, 1939, *55*, 77. By permission of the publisher.) Not every frame is shown. The frames represented are numbered at the left of each diagram, the numbering for each falling sequence beginning with "Frame 1" as the last frame before the jaws opened. Since the film was photographed at the rate of 64 frames per second, and the exposure per frame was about 2 sigma, the time interval from one frame to the next was roughly 15 sigma. All the diagrams are drawn to the same scale; hence the animal is larger at the later ages because of normal gain in size and weight during the days represented.

kitten's capacity to right itself when falling through the air. Rabbits were also used in the second study. The apparatus used to release the animals is shown in Figure 12, and a typical sequence as drawn from high-speed moving-picture films is shown in Figure 13. These studies were correlated with studies on the development of vision in kittens (Warkentin, 1938). They show that there is a genetic relationship between the time sequence of the partial responses making up air righting and the performance

From study of the vestibular sense, Windle and Griffin (1931) turn to a consideration of the development of posture and progression in general. In this study they follow in part the analysis of Hinsey, Ranson, and McNattin (1930). Walking can be shown to require the coordination of several behavioral patterns, including the ability to maintain an erect posture. In this connection the analysis of Magnus (1924, pp. 357 ff.), which shows that posture may depend on impulses from the

various receptor groups of the nonauditory labyrinth, from the proprioceptors of the muscles and associated structures, and from the exteroceptors including touch and the distance receptors, is distinctly relevant. In view of the facts it becomes obvious that the maintenance of erect posture may demand quite elaborate stimulation and the establishment of postural tonus by the proper neurological balance between flexor and extensor muscle groups. This complex mechanism makes possible successful opposition to gravity and behavioral acts dependent upon such opposition. For an illuminating evaluation of the effect of gravity on the development of behavior in mammals, the reader should consult a treatment of this subject by Holt (1931, pp. 62–72). Windle and Griffin (1931) further show that the essential receptor and effector mechanisms necessary for progression involve an added condition, by means of which alternate and rhythmic changes in the limbs are brought about. This last component is necessary if balance is to be changed in such a way that stepping movements may be accomplished.

Windle and Griffin report that these mechanisms, which are essential to locomotion, develop at different times during fetal growth. The onset of the righting reflex has just been reviewed. The first positive evidence of rhythmic movement of the forelimbs, involving flexion and extension movements, was seen in a 58- to 60-mm. fetus. At this time the hindleg movements were less rhythmical. Occasionally in a 100-mm. fetus complete stepping movements were observed. In this connection the study of Laughton (1924) on the nervous mechanism of progression in mammals should also be consulted. It is further suggested by Windle and his associates that the unilateral rhythmic flexion-extension of the limb as seen in the scratching reflex may have a relationship to the occurrence of the alternate rhythms of locomotion. The first indication of the scratch phenomenon was thought to have been observed at the 75- to 80-mm. stage, following ear stimulation. These observations show that the walking movement even as seen in prenatal life involves a complex series of factors which are concerned with virtually the entire receptive field and the entire muscular system of the organism.

Besides this characteristic behavior pattern, these same investigators have also studied the development of the sucking reaction, a response which, like that of locomotion, is characteristic of early vertebrate behavior and to which reference has been made above. The first head raising and lowering of the jaw were noted in 27- to 28-mm. fetuses. This early prefeeding response was followed in the 45- to 50-mm. organisms by tongue reflexes which were so amplified in the 70- to 80-mm. organisms as possibly to be characterized as sucking. In the 95- to 103-mm. organisms, this response had developed so much farther that it was present in virtually its adult form (Windle and Griffin, 1931; Windle and Minear, 1934). Windle and Minear have also shown that the response to faradic shock given to the snout changes with age. At first the reaction is dominantly away from the stimulus (that is, on the opposite side); later, homolateral responses appear. Windle (1937) and his collaborators (Windle, O'Donnell, and Glasshagle, 1933) have also studied the detailed neurology related to the first forelimb responses. At 14 mm., or about 23 days, true reflexes are elicited. At this time the sensory collaterals of the cord are just complete. Windle emphasizes the fact that these responses are not part of a total mass reaction pattern when they first appear. He had previously (1935) shown that the simplest forms of reflex pathways are laid down in the central nervous system before higher integra-

tion systems are functional. (See also Windle, Orr, and Minear, 1934.) This same investigator (Windle, 1939) suggests that calcium and potassium deficiencies may account for certain delays observed in the onset of fetal movements.

Another elaborate study of the development of behavior in the fetal cat was undertaken in 1928 by Coronios, working in collaboration with Carmichael and other investigators (Coronios, 1930, 1931, 1933; Coronios, Schlosberg, and Carmichael, 1932). Unlike Windle and Griffin, Coronios used only fetuses from litters whose insemination age he knew accurately. In Coronios' work the pregnant female was prepared for observation under deep ether anesthesia. While the animal was anesthetized the carotid arteries were ligated, a cannula inserted in the trachea, and a complete midbrain section carefully performed. After this section, the anesthetic was immediately discontinued. The decerebrate adult cat was then allowed to remain quiet for 1½ or 2 hours before the fetuses were exposed for observation by an operative technique. Before the observations began, the cat was placed in a specially devised bath apparatus in which physiological salt solution was maintained thermostatically at 37.5° ± 0.5° C. Into this blood-warm liquid the fetuses were shelled out one by one. A summary of the behavior observed at various copulation ages may be found in Figure 14. In a supplement to this chart Coronios (1933) offers the following conclusions:

> In the early stages the behavior is diffuse, variable, relatively uncoordinated, and weak. With the increase in gestation age, the reactions become more vigorous, more regular in their appearance, less variable, individualized, and better coordinated. These qualitative changes do not occur abruptly but are continuously progressive modifications in the quality of the observed reactions. Moreover, these qualitative changes do not, as it were, "invade" the total organism at once. Rather they seem to follow a general course in their development, beginning at the head region and progressing toward the tail [p. 363].

It is interesting to note in this description of the development of behavior in a highly organized mammalian fetus a marked similarity to the description of the development of behavior noted in *Amblystoma* and virtually all other forms considered above. It must be emphasized, however, that there is danger in making too sweeping generalizations about fetal behavior, but it is impossible to deny that there are certain descriptive terms which accurately characterize the development of behavior in many forms.

As a conclusion to his work, Coronios (1933) makes the following points:

1. Before birth there is a rapid, progressive, and continuous development of behavior in the fetus of the cat.
2. The development of behavior progresses from a diffuse, massive, variable, relatively unorganized state to a condition where many of the reactions are more regular in their appearance, less variable, better organized, and relatively individualized.
3. In the early stages of prenatal development the behavior appears to be progressing along a cephalocaudal course.
4. The development of the sensitivity of the reflexogenous zones passes through a continuous and transitional development from a time when rather vigorous stimulation of any "spot" of the body within a large area serves to elicit variable, diffuse, uncoordinated patterns of behavior to a later time when a weak stimulus becomes adequate, within a much more circumscribed area for precise, well-coordinated, uniform, and less variable patterns of behavior. The direction of such development is cephalocaudal.
5. The "primitive" reactions of breathing, righting, locomotion, and feeding are

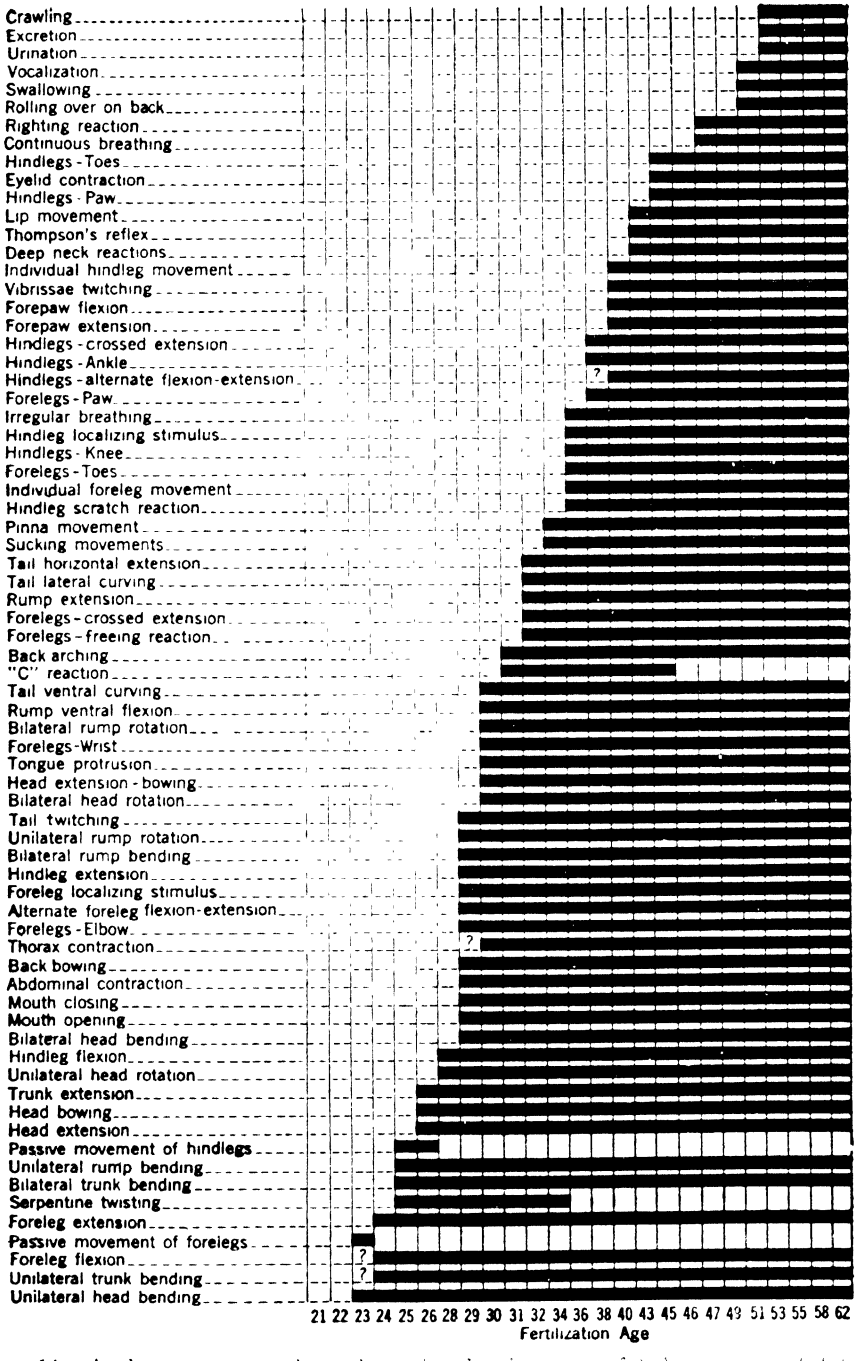

FIGURE 14 A chart constructed to show the development of behavior in cat fetuses of various gestation ages. (From "Development of Behavior in the Fetal Cat," by J. D. Coronios, *Genetic Psychology Monographs*, 1933, *14*, 362. By permission of the Journal Press, publisher.)

the products of a long and continuously progressive course of prenatal development.

6. Behavior development appears first in the gross musculature, and in the fine musculature later.

7. Behavior develops in each of the limbs from a proximal to a distal point; that is, the entire limb is first involved in the response and then gradually the more distal joints become, as it were, independent of the total movement [pp. 377–378].

Each of these generalizations is to be taken as a statement of a typical course of development and not as a specific formula that can be applied to other mammals or man in advance of observation. For example, from the time of Aristotle the anteroposterior course of development has been noted (Needham, 1931, p. 75). This apparently holds true in the primitive gradients of the organism and in the weight of different organs of its developing structure, as well as in the development of "individuated" behavior. This generalization must, of course, be considered descriptive and not explanatory. For further discussion, see Kingsbury (1924, 1926) and Child (1925).

Besides these two elaborate studies of the development of behavior in the fetal cat, there have been a number of incidental studies calculated to investigate some special problem in fetal behavioral growth. T. G. Brown (1914, 1915) reports an experiment on the development of the mechanism of progression in the fetal cat. He used four fetuses of unknown gestation age, the placental circulation being maintained and the observations made in a warm salt solution. The fetuses were studied both before and after decerebration. On the basis of this work he asserts that blood stimulation is very important in eliciting the rhythmic movements seen before birth. He concludes:

> It is possible that the "quickening" movements which are a symptom of human pregnancy may be due to similar progression movements in man; and if they are thus evoked by some such accidental asphyxia as that conditioned by pressure upon the umbilical cord they may tend, in an indiscriminate manner it is true, to relieve that pressure [1915, p. 214].

He also suggests on the basis of other observations a phylogenetic theory of the development of locomotion based on Sherrington's view of motor half-centers in the central nervous system.

Langworthy (1929) has also studied the development of behavior in the fetus of the cat. He reported a study on six fetuses near term and a number of kittens of varying ages after natural birth. In these fetuses after decerebration he found behavior that is characteristic of the late cat fetus, although less well-defined hindleg movements were observed than those reported by Brown. The behavior of the fetal and young organisms was then correlated with structural studies of the nervous system. He reported in summary of this work:

> Bilateral movements of the extremities begin to coordinate when the ventral commissural fibers of the cord receive their myelin sheath. The animals turn the body at a time when myelinated vestibular fibers reach the spinal cord. The hindleg movements become better coordinated when myelinization becomes marked in the lumbar portion of the cord [p. 169].

The general significance of this correlation of behavior and myelinization will be considered below.

Tilney has prepared a chart showing the stream of behavior reaction in the cat similar to the chart concerning the development of behavior in the guinea pig cited above (Woodworth, 1929, p. 204). In this chart many behavioral acts are shown as

appearing in postnatal life which the studies given above show in prenatal life. This is true of "primitive escape," "snatching," and, indeed, virtually all the reactions shown in the chart. The "sudden emergence" of some of these behavior patterns noted below the chart, as in most "saltatory maturation," may seem therefore to involve the reactivation under different environmental conditions of behavior which has had a prenatal developmental history. Similar facts of human fetal development are significant in interpreting the conclusions of Gesell (1929*b*) and Shirley (1931*a*, 1931*b*) concerning human behavioral maturation. Windle and Orr (1934*b*) have shown that when the fetus is dying there is likely to be a vermiform contraction. These general reactions may appear after the heart has ceased to beat.

A number of special studies have been made on other mammals. Erasmus Darwin (1796, p. 101) quotes an account from Galen of the fetal development of the goat. The fetus, after removal, got to its feet and walked, shook itself, scratched, smelled of objects, and then drank milk. Huggett (1927, 1930) has used this same ungulate in elaborate studies of the onset of breathing reflexes in the fetus, which will be considered below. He used animals 1 or 2 months before full term. The size of the animal made it convenient for operative purposes, but some difficulties which experimenters with small animals are spared may be noted, since a "domestic bath" had to be used to hold the saline solution into which the fetus was delivered (1927).

Scharpenberg and Windle (1938) have now shown that, in the sheep, myogenic responses precede neurogenic ones. Some sensory collateral fibers have grown out from the dorsal funiculus and have reached the internuncial neurones of the cord at the time the first true reflex arcs are established. The most elaborate studies of the fetus of the sheep, however, have been made by Barcroft and Barron (1939). These investigators outline the results of an elaborate series of studies upon this large fetus. In this animal the first spontaneous movements appear on the thirty-fifth day after insemination. These responses involve forelimb, neck, and trunk movements. By the thirty-eighth day the observed movements are more "definite" and the movements are larger and more numerous. Such spontaneous movements are quite transient. Even in a 40-day fetus they may last only 5 minutes after delivery. Maintained posture following movement is seen by the forty-second day. In their study of responses these investigators stimulated by various means the fields related to some of the important peripheral nerves of the body. As a conclusion of the study of the maxillary nerve, for example, they state that the motor response to specific stimulation is at first confined to a few muscles, then more muscles become involved, but at length only those are activated which respond in the adult sheep. Again, in regard to the sensory nerves distributed to the trunk and limbs they conclude that local muscular reactions are first evoked, but with increasing development more and more muscles may be brought into play.

Barcroft and Barron (1936) have also studied the genesis of respiratory movements in the fetus of the sheep. Barcroft, Barron, and Windle (1936) have shown in the same large embryo localized responses to mechanical and electrical stimulation. These writers conclude that behavior may be considered to have its genesis in localized patterns of response. This conclusion is qualified, however, in a later paper by Barcroft and Barron (1937*a*), in which a neurological distinction is drawn between reflexes and local contractions, for example, of the neck. These same investigators in

another paper (1937*b*) give an excellent description of the movements of the fetal sheep in midfetal life. Barcroft himself gives a more general description of this work in a paper entitled "The Mammal before and after Birth" (1935).

Barcroft's summary of much of this work appears in his excellent volume of Terry Lectures entitled *The Brain and Its Environment* (1938). In this volume brain activity in relation to its internal environment in fetal and neonatal life is brilliantly described. In all of Barcroft's work the importance of the changing internal environment of the fetus subjected to experimental study is emphasized. For a comprehensive evaluation of these problems see Barron (1950) and Windle (1950).

Bolk (1926) has made a comparative morphological study of fetuses of the gorilla, chimpanzee, and man in relation to a theory of development. Tinklepaugh, Hartman, and Squier (1930) have studied fetal heart rate in the monkey. Hines and Straus (1934) have studied the motor cortex of fetal and infant rhesus monkeys. The gestation period of the macaques used was taken as 168 days. Fetuses 85 days old showed good contralateral responses of shoulder and head on cortical stimulation. The fingers gained cortical representation during the first week after birth, as did also the facial areas and lower extremities. It seems that the muscles innervated by the dorsal strata of the limb plexus (extensor system) are the first muscles of the extremities to gain representation in the motor cortex.

Incidental observations on other animal fetuses are given by J. F. Craig (1930) in his revision of Fleming's *Veterinary Obstetrics*. Needham (1931, pp. 484–489) gives tables of the gestation times of hundreds of animals which are valuable for comparative purposes.

General Aspects of Human Fetal Development

Prescientific Study. From one point of view at any rate, all that has gone before in this chapter has been intended to prepare the reader for the consideration of the prenatal development of behavior in human beings. Behavioral development before birth has long been a subject of notice in the human race, but only comparatively recently has it been studied in a systematic and scientific manner.

That the fetus moves before birth is knowledge as old as mankind. Certainly there are references to this phenomenon in the folklore of primitive peoples (Ploss and Bartels, 1927). It is interesting to notice also, so far as the anthropomorphic theory of primitive deities is concerned, that the process of making gods in the image of man even included speculations about god embryos. For a consideration of this topic, see Briffault's work *The Mothers* (1927) and Witkowski (1887). There are references to prenatal development of behavior in Biblical literature and in ancient Indian and Chinese writings. The Egyptians early began the consideration of this matter, as is shown in a hymn to the sun god attributed to Amenophis IV (about 1400 B.C.):

Creator of the germ in woman,
Maker of seed in man,
Giving life to the son in the body of his mother,
Soothing him that he may not weep,
Nurse (even) in the womb.
Giver of breath to animate everyone that he maketh
When he cometh forth from the womb on the day of his birth.

[Needham, 1931, p. 49.] [1]

[1] For much of the historical material given in various parts of this chapter, including the quotation at the head of the chapter, the writer is indebted for actual references and for many interpretations to Needham's illuminating history of embryology (1931). The writer had begun the collection of material in

In pre-Socratic Greek antiquity, among the many who speculated on almost all aspects of nature were those who considered embryology and, apparently, also the beginnings of fetal activity. It was at this time, the very beginning of recorded scientific history, that some of the notions arose in what has been called "theological embryology" which have come down to our own period. At this time some held that the general form of the body is completed in males many days before it is completed in females (Needham, 1931, pp. 51–53). Similarly, Empedocles (about 450 B.C.) began the speculation, which was long to continue, as to whether or not the "life" of the embryo was like the "life" of the independent individual (Needham, p. 51). Plutarch says that Plato (circa 429–347 B.C.) directly asserts that the fetus is a living creature that moves and is fed within the body cavities of the mother (Needham, p. 60).

It was not, however, until the time of Aristotle (384–322 B.C.) that the life and soul of the embryo were considered in detail. In the third chapter of Aristotle's remarkable treatise on embryology, the entrance of the various souls into the embryo is considered. The views there expressed have possibly influenced the laws related to abortion which have appeared since Aristotle's time in canon and civil codes. In transmuted form these ideas appear in both patristic and scholastic philosophy. It is possible that this Aristotelian doctrine is basic to the rules of the church in regard to prenatal baptism, which is considered historically by Witkowski (1887, pp. 133–152). Aristotle taught that the vegetative or nutritive soul existed in the unfertilized material of the embryo. In summary, Aristotle, in the following quotation given by Needham (p. 69), says:

> . . . for nobody . . . would put down the unfertilised embryo as soulless or in every sense bereft of life (since both the semen and the embryo of an animal have every bit as much life as a plant). . . . As it develops it also acquires the sensitive soul in virtue of which an animal is an animal. . . . For first of all such embryos seem to live the life of a plant, and it is clear that we must be guided by this in speaking of the sensitive and the rational soul. For all three kinds of soul, not only the nutritive, must be possessed potentially before they are possessed actually.

During the third century B.C., Herophilus, according to Plutarch, attributes to newborn babies a natural movement, but not respiration. The sinews are the instrumental cause of this movement. Afterward the baby becomes a perfect living animal, and when it is taken forth from the mother's body it inhales air (Needham, pp. 78–80).

Galen is also credited with writing much between A.D. 150 and A.D. 180 upon the subject of developmental embryology. He has especially considered the question of whether the embryo may be described as an animal. A reference to Galen's observations on a goat fetus has already been made.

In the years sometimes called, because of the dominance of the church fathers, the Patristic Period, interest continued in the movements of the fetus. Tertullian (born A.D. 160) held that the soul was fully present in the embryo through uterine life. In his *De Anima* he says:

> Reply . . . O ye Mothers, and say whether you do not feel the movements of the child within you. How then can it have no soul? [Needham, 1931, p. 91.]

this field before Needham's book was published, but when it appeared it proved to be so fruitful in suggestion that it has been used extensively in this chapter. Whenever possible, specific references are given. For a study of the ideas of primitive peoples concerning generation as they have evolved into modern scientific understanding, the reader is urged to consult Meyer's *The Rise of Embryology* (1939).

Saint Augustine, Bishop of Hippo, apparently did not wholly agree with this, but held that the soul entered the fetus in the second gestation month and sex in the fourth month. Other church authorities followed Saint Augustine in this matter. The council of the church held at Byzantium in 692, however, declared that no distinction could be made so far as infanticide is concerned as to whether the fetus was "formed" or "unformed." Canon law for a time came to recognize the fortieth day for males and the eightieth day for females as the moment of animation, but later the fortieth day was accepted for both sexes (Goeckel, 1911, p. 5). The reader who may wish a modern view of sex differences in development as an exercise in contrasts may well consult Riddle (1927) and Willier (1939).

In the Talmudic writings of the learned Jews between the second and sixth centuries are found a number of views concerning the possibility of stimulating the fetus in the uterus. It is possible that the cutaneous sensitivity of the fetus was understood by these writers (Needham, p. 93). Needham gives a reproduction of a picture from the *Liber Scivias* of Saint Hildegard of Bingen, approximately A.D. 1150, which represents the soul passing down from heaven and entering the body of a pregnant woman and then entering the embryo (p. 96). It is not difficult to believe that the basis for this picture is to be found not only in such embryological knowledge as had come down to this time from antiquity, but also in the direct observations current in all times concerning the quickening of the embryo (Needham, p. 102). The greatest of the Schoolmen, however, Saint Thomas Aquinas (1227–1274), often called "the Angelic Doctor," developed a more elaborate theory of embryonic animation. Needham interprets his views as follows:

> He had a notion that the foetus was first endowed with a vegetative soul, which in due course perished, at which moment the embryo came into the possession of a sensitive soul, which died in its turn, only to be replaced by a rational soul provided directly by God [Needham, p. 104].

On the other hand, Duns Scotus (1266–1308), here as in so many other speculations a worthy opponent of Saint Thomas, considered that the embryo contained only a rational soul, which was infused directly into the organism. The views of both these scholastic teachers led to certain theological difficulties. It was difficult to say how the errors intrinsic in man since Adam's fall could be transmitted to each generation if the soul entered the fetus directly from heaven in each generation (Needham, p. 105). This really profound scholastic argument may in certain ways be considered the foreshadowing of some of the present-day arguments concerning the rôles of heredity and environment as determiners of development.

In Dante (1893 edition) it is interesting to note that a neurological theory of the animation of the fetus comes into play. He says:

> . . . but how from being an animal it becomes a child, thou seest not yet, moreover this is so difficult a point that formerly it led astray one more wise than thou . . . so that in his teaching he separated the active "intellect" from the soul because he could not see any organ definitely appropriated by it. Open thy heart to the truth and know that as soon as the brain of the foetus is perfectly organised, the Prime Mover, rejoicing in this display of skill on the part of Nature, turns him towards it and infuses a new spirit replete with power into it which subsumes into its own essence the active elements which it finds already there, and so forms one single soul which lives and feels and is conscious of its own existence [Needham, p. 106].

After the Renaissance, books on midwifery began to appear, and in these practical treatises there are a number of observations on fetal movements. For information on these views, see Spencer's *History of British Midwifery from 1650–1800* (1927).

The great William Harvey (Spencer, 1921) combined in himself a knowledge of classical Renaissance embryology, a practical knowledge of midwifery, and a truly scientific ability in observation. A combination of these various advantages makes his writing peculiarly important in this field. He says in one place, according to Needham (p. 139):

> I saw long since a foetus . . . the magnitude of a peasecod cut out of the uterus of a doe, which was complete in all its members & I showed this pretty spectacle to our late King and Queen. It did swim, trim and perfect, in such a kinde of white, most transparent and crystalline moysture . . . about the bignesse of a pigeon's egge. . . .

In all his work Harvey maintained that growth was a process of continual epigenetic development and not the unfolding of something preformed in the eggs of the organisms considered. Harvey also gave a rather elaborate picture of the activity of the human fetus in which he said, in a quotation from Spencer (1921, p. 35):

> For he swimmeth in a water and moveth himself to and fro, he stretcheth himself now this way, and now that, and so is variously inflected and tumbled up and down, in so much that sometimes, being entangled in his own navel string, he is strangely ensnared.

Harvey noted the fact that the mother can feel the kicks of the unborn child in such a way as to assure her that the fetus does not always lie in the same position.

In 1664, Gregorius Nymmanus wrote in support of the proposition that the fetus in the uterus lives a life of its own, evincing its own vital actions, and if the mother dies it not uncommonly survives for a certain period, so that it can sometimes be taken alive from the dead body of its mother. The fetus, he continued, prepared its own vital spirits and the instruments of its own soul, there being no nerve between it and the mother. This is demonstrated by the fact that the fetus *in utero* moves during the mother's sleep (Needham, p. 160).

In the citation just given is seen a combination of the old speculation and the new statement of observation that had become so characteristic of the rebirth of science. This combination of attitudes toward fetal development comes down almost to our own day, but increasingly as the years have passed the problems of embryology have become questions of observation and not of speculation. For a consideration of certain aspects of the triumph of science over surmise in these matters, see Spencer's lecture entitled *The Renaissance of Midwifery* (1924). In the opinion of the writer there is, however, real significance in the fact that during the long centuries of speculation concerning the "besouling" of the fetus, the point of quickening was often considered most important. There is good reason for this. The writer is as convinced as was Tertullian that the quickening of the fetus is significant in the story of the onset of man's most distinctive characteristic—his mental life. Common sense and vulgar tradition are not sure scientific guides, but the observational basis of nonscientific speculation sometimes points to a truth neglected.

One of the problems that grow out of the view that the fetus early comes to have an independent existence is the value placed upon human fetal life. This prob-

lem of evaluation is essentially ethical rather than scientific. As such, it continues down to the present time to be significant. It is not, however, a topic within the scope of this chapter. Among the numerous treatments of this topic, the monograph by Goeckel (1911) dealing with the changes that have taken place in the evaluation of the life of the unborn human fetus is important. In this monograph the author reviews primitive opinion and the statements of Roman and old Germanic law in regard to the fetus. He presents an excellent bibliography of Roman Catholic theological pronouncements and of civil legal opinions on the value of the life of the fetus. The legal aspect of prenatal life is also given especial consideration in a paper by Morache (1904). As already noticed, the earlier history of the evaluation of fetal life is fully considered in Witkowski's detailed *Histoire des accouchements chez tous les peuples* (1887). Much of this work, however, seems to be based upon Cangiamila's *Embryologia Sacra* of 1775, which the writer has not seen.

Modern thinking about the value of the fetus is reviewed in such papers as those of Hughes (1905), Arendt (1910), and Glenn (1911), which treat of various aspects of the ethics of dealing with the life of the unborn child.

From early times the belief has been current that the mother's thoughts and experiences directly influence the fetus. For many years, however, this view of prenatal influence has existed in the popular rather than in the scientific tradition. That "thought transference" or some mysterious nervous relationship exists between mother and fetus is not, in general, held today by scientific investigators. Save in the chemical interchange between the two blood streams or in mechanical or infectious transmissions, biology and psychology offer no basis for this view. Compayré (1896, pp. 32–33) gives a brief history of this superstition. He describes the now amusing assertions of Malebranche in regard to the complete intercerebral sharing of all mental processes between fetus and mother and then carries the subject on to the speculations current in nonscientific writings at the end of the nineteenth century. Compayré does not, however, refer to the remarkable assertions of the philosopher Hegel (1894, pp. 28–29) concerning psychological embryology, in which mother and fetus are said to be in undivided "psychic unity." This magic relationship is held to be of the nature of animal magnetism, by which the character and talent of the mother are communicated to the child.

That superstitious views of prenatal influence are still discussed may be discovered by reading articles by the following writers: Coughlin (1905), Walton (1910), Christenbery (1910–1911), Tompkins (1911–1912), Barham (1915–1916), and R. L. Brown (1918). An example of such an observation is the following case described by Morrison (1920). A mother of five healthy children had two teeth removed during pregnancy. She feared that the child would have a harelip. She became obsessed with the idea. The child was born with a harelip. It proved difficult to convince the mother that maternal impressions were not an accepted scientific cause. In this case just given, one is apparently dealing with an unusual coincidence which seems very like a causal connection to those who participate in it emotionally. To the parent such a conclusion may thus be psychologically if not scientifically pardoned. Until new evidence is presented, however, such cases cannot be considered as having scientific significance. We may still say with some assurance that "prenatal influence" in the sense discussed is a superstition.

Scientific Study. We must now turn back in our consideration to the scientific

study of the fetus in order to consider what is known about the actual behavioral development of the unborn child. For the purpose of understanding this prenatal development of human behavior some general idea of morphological development will be found to provide a useful baseline upon which to represent the changing continuum of behavior. Figure 15, taken from Keibel and Elze (1908), shows a selected series of human embryos and fetuses 2.1 mm. to 23 mm. in length. The length of each specimen is given in the legend below the figure.

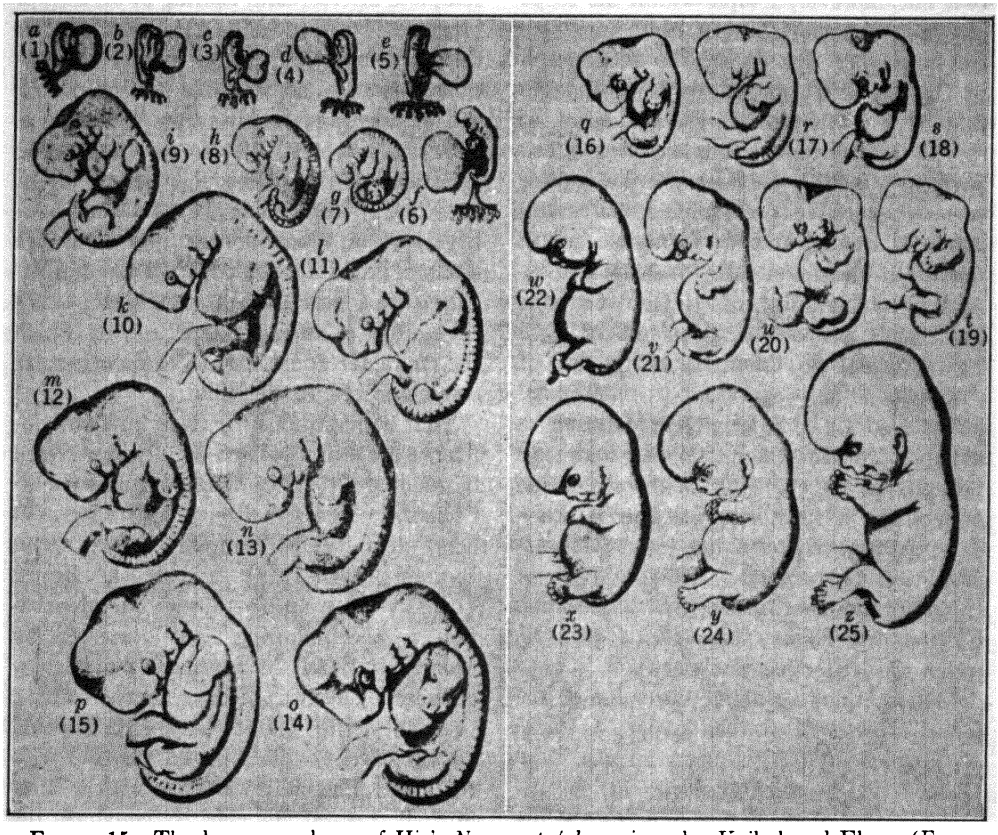

FIGURE 15. The human embryo of His's *Normentafel* as given by Keibel and Elze. (From *Normentafel zur Entwicklungsgeschichte des Menschen,* by F. Keibel and C. Elze. Jena: Fischer, 1908.) The letters designating each fetus, its size in millimeters, and its estimated age in days are: *a,* 2.1, 12–15; *b,* 2.12, 12–15; *c,* 2.15, 12–15; *d,* 2.2, 12–15; *e,* 2.6, 18–21; *f,* 4.2, 18–21; *g,* 4.0, 23; *h,* 5.5, 24–25; *i,* 7.5, 27–30; *k,* 10.0, 27–30; *l,* 9.1, 27–30; *m,* 9.1, 27–30; *n,* 10.5, 31–34; *o,* 11.0, 31–34; *p,* 11.5, 31–34; *q,* 12.5, 31–34; *r,* 13.7, 31–34; *s,* 13.8, about 35; *t,* 13.6, about 35; *u,* 14.5, about 37–38; *v,* 15.5, about 39–40; *w,* 16.0, about 42–45; *x,* 17.5, 47–51; *y,* 18.5, 52–54; *z,* 23.0, 60.

Many efforts have been made to compile a table from which the ages of fetal human organisms can be estimated on the basis of known physical measurements. Scammon (1927), indeed, estimated that there were 7500 titles on the growth and physical development of the fetus, infant, and child.

The construction of satisfactory norms of growth in prenatal life has proved to be a very hard scientific task because of the difficulties that must be overcome in evaluating the material to be measured. In the first place, even if organisms of truly known age were plentifully available, each age norm would necessarily be stated in terms of some statistical average, because of the many factors such as genetic stock, nourishment, and specific pathology which influence fetal size. For a consideration of some of these factors in infrahuman mammals, see the work of Bluhm (1929).

A greater stumbling block than this variability of size at any true age, however, is found in the fact that it is peculiarly difficult in the human individual to place correctly the starting point of development, even though, in the light of the discussion given at the beginning of this chapter, such point be taken as the moment of fusion of the nuclei of the two parent cells. As a matter of fact, this moment can never be absolutely accurately determined, and therefore many different ways of approximating the zero point of development have been used in the history of human embryology. Even now no complete agreement has been reached as to the most desirable procedure in arriving at this calculation. Of these methods the following are probably most important:

1. *Menstruation age.* In this scale the age of the fetus is calculated from the first day of the last period of menstruation prior to the onset of pregnancy (Mall, 1918).

2. *Mean menstruation age.* This age is similar to the above, except that it is based on the average calculated from many cases. Thus if 51 days is taken as a mean, there is a possible deviation from 40 to 62 days, so far as the relationship to morphological measurement is concerned (Mall, 1918).

3. *Conception age.* The age of the fetus is calculated from the last day of the last menstrual period prior to pregnancy. This is the age used by His and adopted by Minot (1892).

4. *Copulation, or insemination, age.* This age, based upon calculation and upon trustworthy cases of known copulation time, is found to be approximately 10 days shorter than the mean menstrual age defined above (Mall, 1918).

5. *Ovulation age.* This age is calculated from the time of ovulation. It is at present extremely difficult to determine directly the time of ovulation. Determinations are complicated by many factors, such as the observation that it is difficult to know how long spermatozoa may live after entering the female genital tract, and by many other considerations. A complete and critical study of the time of ovulation and the fertile period of the menstrual cycle is given by Hartman (1936) in a book devoted to a consideration of recent data and theories in this field.

6. *Fertilization, or true, age.* This age cannot at present be directly determined, but must be calculated from 1, 2, or 4 above. In general it may be said that the present evidence points to the fact that fertilization occurs in less than 48 hours after copulation (Mall, 1918).

A standard table of age-length equivalents during the prenatal period of development is still further complicated by the fact that the linear measurements of the specimens have been obtained by different methods. The measurements commonly used include the crown-rump length and crown-heel length or standing height. The second of these is really related to the first, that is, it is crown-rump length added to the rump-heel length (Minot, 1903). Besides these two usual measurements, there is the *Näckenlange* of His, that is, the length measured from a particular point in the caudal bend to a particular point in the neck band of the specimen (His, 1880, 1882, 1885).

Of there measurements the crown-rump measurement is possibly best for embryo-

logical purposes (Minot, 1903), but in most of the work on the development of behavior the crown-heel length has been employed (Minkowski, 1923, p. 477; 1928*a*, p. 531; cf. also Scammon and Calkins, 1929).

In a subject so full of possible divergences of opinion, therefore, it is little wonder that many apparently conflicting tables of age-length relationships have been produced. Among the tables frequently referred to are those of C. M. Jackson (1909), Preyer (and the other embryologists summarized by him) given in Minot (1892, p. 381), and the summarizing table from Keith (1913). Instead of giving all these tables and many others to which reference might be made, or of attempting any averaging of the results, it has seemed wise to present Mall's (1910) table, which seems to the writer to be based on excellent evidence. This table, based on Mall's own work and upon the collection of material by Issmer, is given as Table 1. Mall (1918) has reviewed his work subsequent to the publication of this table and finds the table still accurate. It should be noted, however, that particularly so far as the younger stages are concerned there is a possibility of great variability in judging age from such a table as that given. Weight is probably a better index but is seldom given (Minot, 1892, p. 381). Therefore, in all age determinations given in this chapter, it should be borne in mind that the word "approximate" should really be placed in front of almost any statement of fetal age. Streeter (1920) has prepared a series of growth curves of the human fetus based upon most carefully computed data. In his tables and graphs the relationships of weight, sitting height, head size, foot length, and menstrual age of the human embryo are presented. Hooker (1944) has suggested that length and weight provide a more useful index of behavioral development than does age. Gesell (1928, pp.

315 ff.) has considered the problem of human age in relation to infancy.

Arising immediately out of the relationship between growth and age of the fetus is a whole series of studies on the morphological development of the fetus, which of course cannot be reviewed in this chapter. Figure 16 shows graphically the significance of such knowledge for one who thinks of

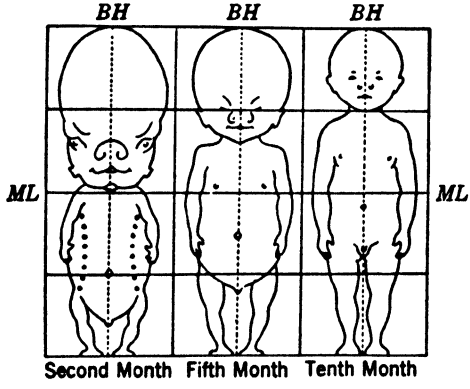

FIGURE 16. Changes in body proportions in fetal life. *BH*—body height; *ML*—midline. (From *Premature and Congenitally Diseased Infants*, by J. H. Hess. Philadelphia: Lea & Febiger, 1922, 36. By permission of the publisher.)

the fetus as a "smaller infant." The literature on general fetal development has several times been summarized, the early work having been brought together in an excellent summary by Pinard (1877). In this summary, the work on the morphology, physiology, and pathology of the fetus is treated separately. A bibliography of 870 titles is appended to this treatise. Next to Pinard's summary in importance is Wertheimer's (1904), which brings together the general literature on the fetus to 1904. Probably the most complete summary in English of the anatomical and physiological aspects of fetal development is Feldman's (1920), which, in spite of certain lacunae, should be read by all who are interested in the fetus. Noback and Robertson (1951) have studied the sequence of appearance of ossification centers in the human skeleton during the first 5 prenatal months and have summarized previous work on skeletal development of the human fetus.

As pointed out above, it may almost be said to be necessary, in order to understand the development of behavior, to have some reference line in terms of measurements of anatomical development. It has become a convention by following such a temporal line to divide the prenatal life of the human being into three periods (Feldman, 1920, p. 61; Williams, 1931, p. 163). The first period of 1 or sometimes 2 weeks is spoken of as the *germinal* period. From the third to fifth or sixth week is the *embryonic* period. From the sixth week to birth is the *fetal* period. The normal term of pregnancy is usually placed at 280 days (Williams, 1931, p. 163), although estimates varying between 270 and 284 days have been given by various investigators and summarized by Needham (1931, p. 486). It must be obvious, however, that such figures are meaningless unless the method of calculating true fertilization time is given. The normal length at birth is ordinarily given as 500 mm. in crown-heel, or 320 mm. in crown-rump, length. Sometimes, however, premature infants are born and successfully reared who have passed less than 180 days in the mother's body; but 180 or 181 days is usually taken as the average lower limit below which viability cannot be maintained (Hess, 1922). Claims have been made that much younger fetuses have been raised, but as, for example, in the case of Rodman's fetus which was alleged to have been but 4 months old, there is much doubt of the accuracy of the age estimation (Rodman, 1815; Baker, 1825).

At the other end of the scale the terminal point of postmaturity is also open to great

difficulty of estimate. In considering this matter, Ballantyne and Browne (1922) hold that no single index such as fetal length, weight, ossification of the skeleton, placental structure, or cord structural condition is sufficient to date the fetus. They state that the best estimate is obtained by combining a knowledge of the last menstrual period, the date of copulation, the date of the onset of morning sickness, the date of the quickening of the fetus, the size of the uterus, the difficulty of delivery, as well as the evidences of postmaturity such as measurements of length, weight, and ossification. Probably 334 days is the longest period legally considered during which a fetus may be thought possibly to have lived in the mother's body and still be delivered alive (Ballantyne and Browne, 1922, p. 198). Thus, from one point of view at any rate, the human fetal life span that will be dealt with in this chapter must be taken as lasting from fertilization until birth, a time which in the extremest possible cases may vary by as much as 154 days!

In this chapter most of the references to fetal behavior are made to unborn fetuses. It should be kept in mind, however, that the study of correctly dated premature infants may throw light upon the later fetal period. In interpreting the sensory ability or response activity of a prematurely born infant, it is not safe to attribute the same abilities to the unborn fetus of the same age. As suggested in the first part of this chapter, the greatest errors in genetic science are made by suggesting that because environmental conditions of one sort produce behavior of a particular kind in one individual, therefore these same abilities must be "implicit" in an organism living under wholly dissimilar conditions. A normal fetus of the same age as a successfully air-breathing premature infant may act in a very different way from the comparison organism. This is true not only because of mechanical differences of bodily make-up, such as the presence or absence of liquid in the ear, but because of the gross differences brought about by the change from placental respiration to pulmonary respiration and from placental nourishment to alimentary canal nourishment. The sheer mechanical change from life in a liquid with the specific gravity of the amniotic fluid to life in air is most important. Similarly, the effectiveness of external stimulation is vastly changed in the transition from a relatively constant stimulus world before birth to a continually changing and varied set of physical energies after birth. An excellent brief summary of the development of the fetus week by week is given by Williams (1931, p. 163). In the present chapter, save for the tables of fetal length and age, and save for the reproduction of the famous Keibel and Elze series of embryos and fetuses given above, no detailed consideration can be given to gross structural change which occurs during prenatal growth.

An interesting graphic representation of prenatal physical development is that in Figure 17, reproduced from Scammon and Calkins and redrawn by Needham (1931, p. 382), in which the age, height, or weight can, to the limits of accuracy of the original data, be read off if any one of these measurements is known. (See also Streeter, 1920.)

In a paper entitled "Physical Fitness in Terms of Physique, Development and Basal Metabolism" Wetzel (1941) presents a critique of a new method of evaluating individual progress from birth to maturity which suggests that there are types of physique which influence all growth tables. A similar observation could undoubtedly be made of fetal life as well. In this connection a study of body build by Sheldon and

his collaborators (Sheldon, Stevens, and Tucker, 1940) should be consulted. For a convenient graphic age conversion scale, see McCarthy (1936).

as possible will be given of the experimental studies on the development of behavior in operatively exposed human embryos. After these lines of evidence of fetal behav-

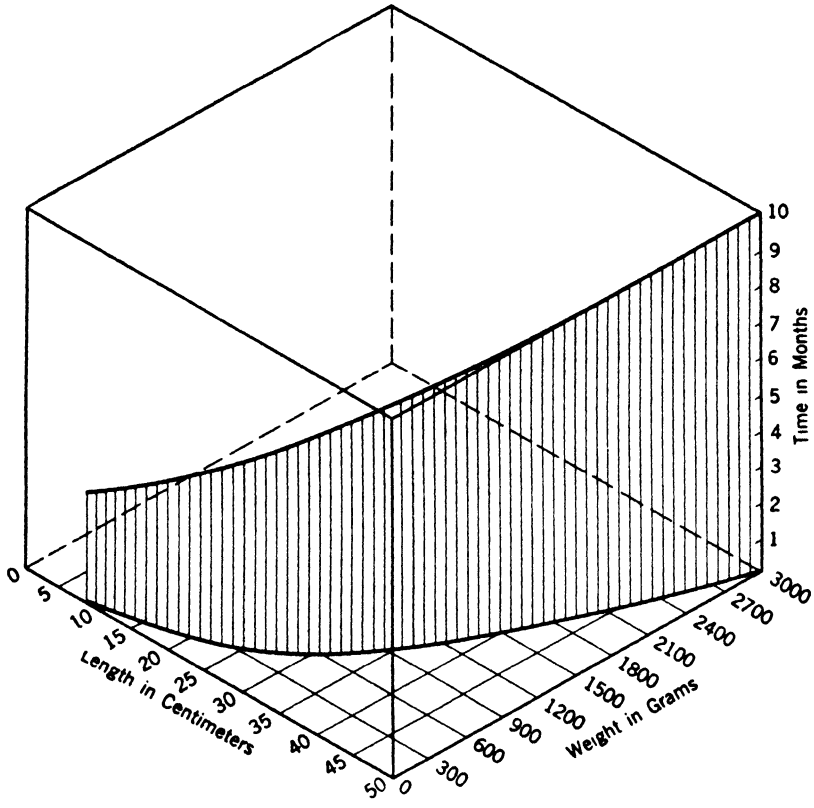

FIGURE 17. Three-dimensional isometric projection from which height, weight, and age of human embryos may be read off if one is known. (From "The Relation between the Body-Weight and Age of the Human Fetus," by R. E. Scammon and L. A. Calkins. *Proceedings of the Society for Experimental Biology and Medicine*, 1924, *22*, 157–161. By permission of the publisher.)

In the paragraphs below a review of the development of behavior in human fetal life without detailed reference to morphology is presented. In this presentation brief consideration will be given to clinical observations made on fetal movements without operation on the mother or the interruption of pregnancy. After this discussion, as accurate and complete a summary

ior have been summarized, a review of the knowledge concerning human fetal sensory life will be presented. A knowledge of sensory development will at once lead to a consideration of the theories that have been proposed to account for the development and control of fetal behavior, and an evaluation of all these observations for human psychology will then be presented.

Nonoperative Studies of Behavioral Development in the Human Fetus

A number of different methods have been used for the scientific study of the development of the human fetus without disturbing its normal course of development. The simplest of these methods involves the direct recording of reports of the mother concerning the movements of the fetus as she experiences such movements. A mother can sometimes perceive the "quickening of the fetus" by the seventeenth week (Feldman, 1920, p. 204). At times the physician may by the use of the stethoscope hear fetal movements as early as the fourteenth week (Mailliot, 1856, p. 258; Neu, 1915, p. 292). It is customary, however, to say that the first time at which such movements can be detected by the physician is in the fifteenth or sixteenth week (Feldman, p. 204). Feldman points out that in fetuses of 8 weeks the umbilical cord shows regular spiral twists (p. 204). Since such twists are not characteristic of animals that carry many young and therefore have little room for the fetus to turn in, it is assumed that the movements of the fetus even at such an early age determine the twisting of the cord. The writer, however, can see no reason why such twisting might not result from passive as well as from active movements.

In later periods of pregnancy, mothers give reports of movement involving part of the body. Sometimes the movements of the extremities or of the trunk alone are noted. Mermann (1887, p. 623), for example, reports a case of rhythmic movement of the fetal back palpated through the mother's abdominal wall in a fetus of 7 months. Whitehead (1867) gives an extended report of a case of violent convulsion of the fetus while still in the uterus. This convulsive condition occurred during the ninth month of pregnancy. The activity of the fetus caused the mother great pain. By palpation and by direct observation it was found that the fetus was in a state of marked hyperactivity. Both the head and limbs of the fetus were moved so violently as to cause active disturbances of the mother's body wall. The child, born 21 days later, was in all respects healthy and vigorous.

Palpation and various instruments for magnifying or recording various fetal movements observed through the intact body wall of the mother have long been in use. MacKeever (1833) pointed out that the stethoscope was a valuable instrument in this connection. The direct hearing and registering of fetal heart beat also have long been a subject that has attracted the attention of clinicians. Feldman (1920, p. 157) says that this phenomenon was discovered by a Swiss physician, but its importance was first brought out by de Kergaradec (1822, 1823). This student concluded that the fetal heart beat could be heard from the eighteenth week of pregnancy on. Mailliot (1856, p. 258) thought that it could be heard much earlier. Later, among others, DeLee (1927, 1928) and Hyman (1930) made special studies of the fetal heart beat, including such phenomena as irregularities in its rhythm.

In 1891 Pestalozza succeeded in taking a cardiograph of the second twin after the first twin had been born (Feldman, 1920, p. 159). In this he was more successful than Hicks (1880), who by the use of an instrument like a cardiograph obtained certain records which were, however, so badly obscured by the rhythmic activities of the mother that they could scarcely be identified. Krumbhaar and Jenks are reported by Feldman (1920, p. 162) as having obtained typical electrocardiographic tracings of the fetal heart. (See also Sachs, 1922.) Maekawa and Toyoshima (1930) have, by the use of amplifiers and a string galvanom-

eter with electrodes placed on the front abdominal wall of the mother, secured excellent electrographic tracings of the fetal heart. After birth the beat of the same heart is also recorded for purposes of comparison.

Stimulated by this work, Carmichael in 1935 attempted, with equivocal results, to record normal fetal heart activity by high-gain amplification. More recently, Mann and Bernstein (1941) and Geiger, Monroe, and Goodyer (1941) have published in this field, and the physiological psychologist D. B. Lindsley (1942) has published a most interesting paper on the heart and brain potentials of human fetuses *in utero*. In this paper a reliable method of recording maternal and fetal electrocardiograms is given. What is even more interesting, however, is the fact that this investigator has also been able to record fetal electroencephalograms. In the latter case, during the seventh and eighth months of human pregnancy electrodes were at times placed on the maternal abdominal wall over the palpated head of the fetus. By suitable amplification and recording, fetal electroencephalograms were secured by this means. The records were typical of those from the precentral region of the brain in the newborn. In all work upon fetal or neonatal heart rate the effect of asphyxia must be considered (Barcroft, 1938). A fall in heart rate that is nonvagal has been demonstrated in fetal rabbits by tying off the umbilical cord (Bauer, 1938).

Among the other early movements of the fetus which are often directly recorded are the so-called *Ahlfeld breathing movements*, or the rhythmic contractions of the fetal thorax felt through the mother's body. These movements should not be confused with uterine contractions occurring after the third month, sometimes called *Ahlfeld's sign*, which incidentally may have something to do with the onset of behavior, if an analogy with the amnion contraction of the chick noted above may be suggested (Kuo, 1932*c*, p. 263). In spite of the difficulty of the ancients concerning fetal respiration that involves the intake of no air into the lungs, it has of course long been understood, as Leonardo da Vinci knew, that the fetus does not breathe water (Needham, 1931, p. 108). The gaseous interchange of the mammalian fetus occurs in the placenta between the blood stream of the mother and that of the fetus. The general significance of this process and its detailed consideration have been studied by many physiologists. The history of the early advance of knowledge on this matter is summarized by Starling (1900), and the generally accepted facts about the fetus are brought together by Sarwey (1915) and more recently by Barcroft and Mason (1938). (See also Bylicki, 1921.)

The liquid environment, of course, completely precludes true lung breathing, but at least since 1798 movements of the chest and thorax of the fetus similar to breathing movements have been occasionally noticed. Béclard (1815) observed such movements in various mammalian embryos without removing the amniotic sac through which they were observed. Ahlfeld (1890) has developed a view on the nature and significance of certain irregular but vaguely rhythmic movements of the fetus which seem to be caused by the contraction of the same muscles which will make respiration possible in postnatal life. (See also Kouwer, 1919, and Kellogg, 1930.) Ahlfeld has made graphic records of these movements, which in typical cases vary from 38 to 76 per minute. C. A. Smith (1946) has presented an admirable summary of the fetal aspects of respiration. He discusses the experimental literature in this field. The point is made that respiratory movements of the fetus of animals studied cannot be considered as automatic, constant, and progres-

sive. His view is rather that here again, as in so many other aspects of fetal behavior, we see the setting off of a response pattern under certain conditions which otherwise, although acquired early, is normally held in abeyance for later use.

Teleologically, it has been suggested that these movements may be thought of as preparation for the act of breathing which comes at birth. In the fetus such movements are considered to lead only to the ebbing and flowing of the amniotic fluid in the trachea, but, as movements, they exercise and strengthen the neuromuscular mechanism of breathing. It is possible that this behavior is related to the functional establishment of the rhythmic action of the respiratory centers of the central nervous system. The theory has been proposed, therefore, that birth is not to be considered the point at which the onset of rhythmic respiration occurs. In carrying this idea further, it has been suggested that these prenatal chest movements are initiated, like adult breathing movements, by a change in the concentration of metabolites in the blood stream acting upon the breathing centers of the central nervous system (T. G. Brown, 1915).

In combining the views in regard to fetal breathing movements and their cause, it has been suggested that the active or passive general bodily movements of the fetus may occasionally be such as to impede circulation in the umbilical cord. This mechanical obstruction of the umbilical cord, therefore, leads to an increase in carbon dioxide tension in the blood. This in turn may lead to a facilitation of activity or the activation of appropriate centers in the brain and thus initiate movements whereby the mechanical relationship of fetus and cord is changed in such a manner as to reestablish placental circulation, T. G. Brown, 1915). It has been suggested even more speculatively that not only are the chest movements of the fetus part of the general movements which bring about a change in the position of the organism but also they act as a supplement to the fetal heart. They thus may act, it is suggested, as a sort of auxiliary pump brought into play as a result of a change in gas tension in the blood acting upon the breathing center (Walz, 1922, p. 334).

If these speculations are in any sense correct, therefore, the so-called first breath of the child may be considered to be just a change in the way in which the same neuromuscular mechanism determines the oxygenation of the blood (Walz, 1922, p. 341). For an excellent popular statement concerning the onset of breathing, see Henderson (1937).

Barcroft and Karvonen (1948) have studied the effects of carbon dioxide and of cyanide on fetal respiratory movements. They conclude that cutaneous sensory stimulation rather than asphyxia is responsible for the commencement of air breathing.

A number of investigators have severely criticized the Ahlfeld concept of prenatal breathing movements. Walz (1922) attributed these objections to the fact that the initial statement of Ahlfeld's view was unfavorably received by the two leading obstetricians of Germany at the time, and that the weight of authority long kept this phenomenon from being correctly evaluated. It should be noted, however, that Huggett (1930) in an experimental study of fetal respiratory reflexes referred to above says: "The exact mechanism suggested by Ahlfeld is not in every sense confirmed."

A good many speculations have been made as to the causes involved in the first intake of air breath. As noted above, many students have held that the increase of metabolites, and especially of carbon dioxide tension in the blood, is one of the essential causes of the first gasp (Corey,

1931). Cohnstein and Zuntz (1884) observed that in a fetal lamb clamping of the umbilical cord led to the first intake of air. Carmichael has noticed this same result in fetal cats, rats, and guinea pigs. Indeed, the procedure of clamping the umbilical cord to study the effect of the blood stimulus on general bodily movements has been part of the experimental technique of several investigators and notably so of Swenson (1926) in his study of the fetal rat. Angulo y González (1933*b*) reports that in fetuses of 19 postinsemination days in which tactile stimulation of the hindleg aroused no response there was immediate response after ligation of the umbilical cord. The general result of this procedure seems to be an increase in amount and vividness of activity for a time. Pflüger (1877), however, held that some external stimulus, such as cold air, was necessary besides blood change to bring about the first breathing act (cf. Huggett, 1930). Preyer (1885, p. 452) also suggested a relationship between cutaneous stimulation of some sort and the onset of breathing. Corey (1931) holds that an increase in the metabolites of the blood stream and some external stimulus, such as drying of the skin, seem usually to be antecedent to the initial respiratory gasp. It is suggested by Fender, Neff, and Binger (1946) that *asphyxia neonatorum* may play some part in the development of certain cases of epilepsy in human beings. For a general consideration of this problem see Windle (1950).

Snyder and Rosenfeld (1937) have made direct studies of the onset of respiratory movements. They have studied the fetuses of the cat, rabbit, guinea pig, and man. Rhythmic respiratory movements are initiated in all these types in the uterus. Oxygen and carbon dioxide affect fetal breathing movements; a certain level of carbon dioxide, for example, is essential to the maintenance of fetal respiration.

Windle, Monnier, and Steele (1938) and Abel and Windle (1939) show that there are no respiratory movements in cat fetuses less than 13 mm. in length. But in the middle third of the gestation period delicate and rapid rhythms of respiration may begin. Under certain conditions carbon dioxide breathed in by the mother starts such movements. There is no significant increase in blood volume at birth in the pulmonary system. There is a circulation in the lungs during the last part of pregnancy capable of caring for oxygenation when air breathing is established. For a more detailed consideration of the blood gases of the cat fetus, see Steele and Windle (1939), and for a consideration of the physiology and anatomy of the respiratory system in the fetus and newborn infant, see Windle (1941*b*). See also Potter and Bohlander (1941); Whitehead, Windle, and Becker (1942); and Zettleman (1946).

Besides "breathing movements" there are other movements of the fetus which are indirectly significant in behavior. The movements of the organs of the digestiv tract as seen in fetal organisms have been studied by a number of investigators. Yanase (1907*a*, 1907*b*) has studied peristaltic intestinal movements in fetal guinea pigs, cats, rabbits, and men. As a result of these studies, he concludes that peristaltic movements may begin long before birth. The status of gastrointestinal activity *in utero* has also been studied, especially in the cat and guinea pig, by Becker, Windle, Barth, and Schulz (1940); Becker (1941); and Becker and Windle (1941). In man such movements are possible in the seventh week. So far as hunger contractions are concerned, Patterson (1914) has shown that hunger contractions are practically continuous in young dogs. As age advances these contractions decrease in magnitude. Carlson and Ginsburg (1915), working on fetal dogs and newborn children, have writ-

ten: "The empty stomach at birth and in the prematurely born exhibits the typical periods of tonus and hunger contractions of the adult, the only difference between infant and adult being the greater frequency and relatively greater vigor of these periods in the young" (p. 29). For other aspects of the function of the stomach before birth, see Sutherland (1921).

Certainly, in view of the large amount of work on the "hunger drive" as a determiner of activity, part of which is summarized by Warden (1931), the possibility that these stomach and intestinal contractions are stimuli to "random" and "spontaneous" skeletal muscle movement, and indeed to much of the behavior of the premature or full-term infant, cannot be neglected by one who would understand fetal behavior. Such behavior initiated by internal stimulation may well be considered merely the setting into action of inborn neural mechanisms. In this connection, see De Snoo (1937).

The question has often been raised as to whether gross external fetal movements of the various sorts considered above have any part in the rearrangement of the fetus in the uterus in the normal position for delivery at birth. As so often happens when a phenomenon is difficult to explain, it has been alleged that the position of the fetus is governed by instinct (Dubois, 1833). Mechanical and physical explanations have been advanced by Paramore (1909), Barnum (1915), Griffith (1915), McIlroy and Leverkus (1924), and others. Possibly it may be said that no absolutely positive proof has been advanced to show that active fetal movements are essential in determining the normal position of the fetus at the time of delivery. Langreder (1949*a* and *b*) has considered the posture of the fetus in relation to fetal reflexes and position at birth.

In the study of the changes of fetal position before birth, much has been learned by the use of the X-ray. We have already seen that Avery attempted to study the changes in position of guinea pigs by the use of roentgenograms. This work of Avery's was directly adapted from human clinical procedures used in the study of the fetus. The use of the X-ray in the study of the fetus has given a new clue to the determination of fetal age by the study of the ossification of the fetal skeleton, although it is by no means an absolute clue. Hess (1918) has brought together much of the literature on this subject and suggests approximate norms of ossification at certain periods. (See also Mall, 1906, and Adair, 1918.) The study by Rudolph and Ivy (1933) on the rotation of the fetal head shows that uterine contractions and the movement of the fetus both contribute to this change in posture. Danforth and Ivy (1938) have shown that uterine activity is in part at any rate a function of calcium. Augmentation of uterine activity is brought about by increasing the calcium present; by decreasing the calcium the action is depressed. In this connection it is interesting to note that Good (1924) has shown that a patient may have the spinal cord completely severed and still give birth to a baby normally and painlessly.

A phenomenon of prenatal and immediately postnatal behavior which has long attracted attention is the first cry of the human organism. Kant (1799) found significance in the first sound uttered by the human infant. Preyer (1893, p. 213), indeed, quotes Kant as saying:

> The outcry that is heard from a child scarcely born has not the tone of lamentation, but of indignation and of aroused wrath; not because anything gives him pain, but because something frets him; presumably because he wants to move, and

feels his inability to do it as a fetter that deprives him of his freedom.

Both Preyer (1893, p. 213) and Compayré (1896, p. 89) have pointed out the futility of such verbal fancies. Such speculation, however, is not as yet entirely dead. An analytical psychiatrist who is quoted by Blanton (1917, p. 458) has written of the cry of the human infant at birth: "It is an expression of its overwhelming sense of inferiority on thus suddenly being confronted by reality, without ever having had to deal with its problems." By operative technique Minkowski (1922, p. 754) has found that crying occurs as early as the sixth month in the prematurely delivered fetus. In clinical practice many cases of *vagitus uterinus*, or fetal crying, have been reported. A typical case is that reported by M. Graham (1919), in which in a difficult delivery, the fetal sac having been ruptured by operative means to assist delivery, the crying of the still unborn fetus could be distinctly heard. Many such cases are reported, but they need not be reviewed here. (See also Feldman, 1920, p. 207.) Fetal hiccup has also been reported by a number of observers. These cases are summarized by DeLee (1928). See also a study by Norman (1942).

All cases of fetal crying reported above seem to be the result of appropriately activated muscles, which bring about the expulsion of air in such a way as to cause it to vibrate. There seems to be no reason to assume that this phonation has any greater mechanistic significance than many of the other random acts of the child. It catches the notice of the observer, however, because from such behavior language develops in later life. This function is, of course, one of the most important aspects of adult human behavior, and an aspect which will in itself come to be, at least in the subvocal stage of "verbal thought," peculiarly important even in strictly introspective psychology.

This concludes the consideration of human fetal behavior of the sort that can for the most part be studied during the normal course of development. In the next pages the study of the development of human fetal behavior in fetuses removed from the uterus before the end of the normal term of gestation will be considered.

The Study of Behavior in Operatively Removed Human Fetuses

Most of the living human fetuses to which reference will be made in the next paragraphs were removed while still alive from the mother's body because some disease of the mother rendered the artificial termination of pregnancy medically necessary. Minkowski's technique (1928*a*, pp 518–532) is typical. This investigator and a collaborator removed each fetus that was to be studied by a Caesarean section, usually performing the operation under a local anesthetic. The fetus, placenta, and amnion were removed. The fetus was then placed in a bath of physiological salt solution at normal blood temperature. This meant that such fetuses were cut off from their oxygen supply, and the movements which resulted must be thought of as the movements of increasingly asphyxiated organisms. This is important in the evaluation of the behavior reported, for, as pointed out above, increased metabolites in the blood at first lead to hyperactivity and then to hypoactivity.

The behavioral development of the human fetus as determined in operatively removed cases will be considered here in one series. This has its disadvantages because in certain reports estimated age is given; in others only measurements are presented; but certainly for an understanding of development it is most important to give esti-

mated age. The writer has attempted to make a summarizing table of human fetal development, but he does not feel that such a table gives a correct impression. One who wishes to see this material expressed as well as possible in tabular form should consult Coghill (1929*c*, pp. 993–996).

The development, then, of human fetal behavior as observed by various investigators in relation to estimated postinsemination age or menstrual age may be given as follows:

Fetuses Less than 9 Weeks Old. In very young human fetuses operatively removed from the mother, the first movement observed is of the beating heart. For several centuries there has been a scientific controversy as to whether the heart beat of the adult individual is to be thought of as primarily determined by direct muscle or by neural stimulation. It now seems that the early embryonic heart beat must be thought of as essentially an independent muscle contraction (Parker, 1919, pp. 50–63). Therefore, in most of the work on the development of behavior the beating of the heart is not considered to mark the onset of "true behavioral life." Pflüger (1877) has demonstrated the beginning of heart beat in the fetus as being in the third week, that is, in a fetus of approximately 4 mm. (See also Strassmann, 1903, p. 951.)

For a consideration of the mechanism of the initiation of contraction in different parts of the heart of a typical vertebrate, see Goss (1937, 1938, 1940) and Copenhaver (1939).

Williams (1931, p. 163) gives an excellent summary of development in this early period. The germinal stage of the human being may be considered to be the first week or two of life. The third week is thought of as the onset of the true embryonic period. At this period the medullary groove begins to be formed. A little later cell structures which make up the primitive heart are laid down and, as just noted, these cells begin the lifelong beat of the heart. At about this time, also, cerebral and optic vesicles begin to be differentiated and limb buds first appear. The muscles also develop rapidly in fine structure during this period.

In the second month there is continued morphological growth both in total height and weight and in the fine structure of the organs of the growing individual. Windle and Fitzgerald (1937) in a paper on the development of the spinal reflex show that all the elements needed for a reflex arc in the central nervous system are laid down during the sixth week but no spinal arcs are complete before the eighth week. Bolaffio and Artom (1924, p. 472) note in this period that isolated limbs torn during delivery can be stimulated directly.

Minkowski (1920*b*, p. 1202) reports that at the end of the second month cutaneous stimulation elicits response. This finding is not confirmed by Bolaffio and Artom (1924, p. 473), for they point out that at this time the skin is very thin and may involve in its stimulation the activation of receptors in underlying tissues.

Much is known of the structural and minute functional development of the receptors, nervous system, and effectors in this as in all later embryonic and fetal stages. It is not, however, until the fetus reaches the length of 15 mm., or is about 4 weeks old, so far as the writer can discover, that any direct statement can be made in regard to the activity of any part of the response mechanism, and this is a negative statement. In a fetus of this length, Minkowski (1928*b*, p. 66) reports that it was impossible to bring about muscular response even to an electric current of 40 milliamperes. He made observations on two fetuses of this length, with the same conclusion.

This finding is not entirely unexpected, as Hewer (1927) has shown that histologically the musculature of the fetus develops at uneven rates, the unstriped musculature, which is the first to develop, being clearly formed in an embryo 1 mm. in length. Striped musculature could not be detected in a fetus smaller than 2.5 mm. long, and it did not take on its definitive characteristics in fetuses less than 22 weeks old. Special changes of structure are also noted by this same investigator in regard to heart musculature.

Possibly the youngest human fetus to be observed to move is one reported by Yanase (1907*b*) in his studies of the development of intestinal movement noted above. In a fetus 20 mm. long and of an estimated age of 6 weeks, one movement involving the right arm is rather casually noted (p. 455). The next youngest human fetus to be reported moving is a fetus 22 mm. long and probably about 6 weeks old described by Strassmann (1903) in a case of extrauterine pregnancy. He observed through a rupture in the tube wall slow movements, backward and forward, of the arms and legs of the fetus (p. 963). In evaluating this observation it should be noted that Strassmann's report is given in such a manner as possibly to lead to a questioning of his observations, since apparently the fetus was observed in such a way that rhythmic mechanical movement of the adult body was possible. Certainly all observers of fetal behavior have had difficulty in deciding whether or not they were seeing something which was not the result of passive external mechanical movement. It should be borne in mind, therefore, that possibly these two earliest observations should be substantiated before they are finally accepted. In a fetus of 30 mm., or an estimated age of 8 weeks, Minkowski (1923, p. 477) observed a wormlike movement of the arms, legs, and trunk.

In Hooker's (1939*b*) description of his carefully controlled work the statement is made that no response to tactile stimulation has been observed before the eighth week of menstrual age (p. 8). In a 25-mm. fetus of a menstrual age of 8 to 8½ weeks, however, response to tactile stimulation has been recorded. This same investigator has repeated this observation on two other fetuses of approximately the same age. At this stage tactile stimulation is effective only in the area over the mouth and immediately adjacent to that supplied by the mandibular and maxillary divisions of the fifth nerve (p. 9). Hogg (1941) points out that the cutaneous nerves and nerve endings are very immature when responses are first elicited. No encapsulated endings are seen. Excitation is probably dependent upon deformation of the growing tips of the fibers by displacement of the surrounding tissue at this time, according to this author. Stimulation in this area in a fetus of this age led to contraction of the long muscles of the body and neck to produce body flexion. Limb girdle muscles related to both upper extremities were also activated. Rotation of the rump, caused by activation of the pelvic girdle muscles, was observed in very slight degree. Hooker notes that at this period a hair capable of exerting a pressure greater than 25 mg. may cause direct mechanical stimulation. Faradic stimulation at this time is also effective. No spontaneous movements were noted by Hooker at or before this age.

Fitzgerald and Windle (1942) report that in a study of fifteen fetuses 7 weeks to a little over 8 weeks old, fetal movement was seen in only three organisms. These responses were individual reflexes of trunk, arms, or legs when oxygenated blood was still supplied to them. For an excellent summary of the early development of human behavior, see Hooker (1943).

Fetuses 9 Through 12 Weeks Old. In a fetus of 35 mm. (estimated age 8 or 9 weeks) Minkowski (1928*b*, p. 65) reports muscle contraction to galvanic current. Minkowski's work shows that fetuses of 40 to 50 mm. (9 to 10 weeks) sometimes still show this characteristic muscle response possibly without neural activation. This observation coincides with the observations noted above on the fetuses of lower mammals, in which the musculature comes to respond to direct stimulation before true neuromuscular action begins. The most elaborate studies of this sort of muscular response have been made by Wintrebert (1904, 1920). (See also Minkowski, 1924, p. 244.)

Among the many significant observations that might be made at this period, it is interesting to note that the vestibular apparatus seems to be anatomically developed to its full (Minkowski, 1922, p. 753).

A fetus of 42 mm. was removed under operation by Woyciechowski (1928) to interrupt a pathological pregnancy. At the operation a mass was removed from the uterus. As soon as the mass was taken out, a fetus of 42 mm. dropped from the excised sphere of tissue. This fetus, estimated by the operator to be of approximately 2 months' gestation age, was seen to move both arms and legs spontaneously. When it was touched by a finger an energetic "protective movement" began which involved a much stronger moving of the arms and hands and the opening of the mouth. The observations made upon the movement of this fetus were checked by another observer. In spite of cooling, the movements of the fetus lasted in an active form for more than 5 minutes (p. 410).

In fetuses of the 9- to 10-week age period, Minkowski (1921*b*, p. 148; 1922, p. 753) noticed slow, asymmetrical, arrhythmic, noncoordinated movements. He also noted (1922, p. 753) that at this time neurologically the elements of the spinal reflex arc are developed anatomically.

Bolaffio and Artom (1924) studied a fetus of about this same age. They report that dropping the fetus from a height of a few centimeters to a table led to active contractions of the flexor muscles of the limbs. Further, they noted that tapping the table lightly with the fingers elicited responses of energetic movements involving the elevation of the scapulas, movement of the arms, and flexion of the thighs and legs. These movements were elicited for about 3 minutes, after which time they rapidly diminished in intensity and ceased. During the active period, stimulation by a blunt metal rod of the skin of the breast and of the abdomen led to no response. After the cessation of activity, direct brain stimulation led to no muscle response (p. 465).

In a fetus less than 8 weeks old, Minkowski (1922) reports that percussion of the patellar tendon resulted in contraction of the quadriceps muscle. After this contraction had taken place, irradiation followed to other muscles. In this fetus the heart beat was relatively constant at 80 beats per minute, but covering the fetus with normal salt solution at 40° C. led to an increase in the beat of the heart from a basal beat of 80 to 100 beats per minute (p. 752). Extirpation of the cerebral hemispheres in this fetus did not change the reflexes described. Sectioning the medulla just above the cord region, however, abolished the reflexes due to change in the position of the body. In a fetus about 9½ weeks old Hooker (1944) notes that stretch of limb muscles is effective in stimulating proprioceptive organs and initiating response.

In a fetus about 2 months old, Bolaffio and Artom report that stroking and tapping elicited slow local contractions of all the muscles of the limbs. For example, if these stimuli were applied to the palm of

the hand, adduction and internal rotation of the corresponding arm were noted; if to the leg, flexion of the corresponding thigh. These investigators state, moreover, that mechanical stimulation of the cortex in this fetus gave a constant movement of elevation of the left shoulder, but no contraction of either of the lower limbs or of the right shoulder. After this same fetus was decerebrated they note a greater vividness (*vivacitá*) of the local contractions referred to above and the reappearance of diffusion of movement at a distance from the stimuli which had ceased. In this experiment mechanical stimulation of the medulla led to respiratory movements. They further suggest that even in a fetus of this age removal of the cerebral cortex does remove some inhibition from the lower reflexes. It is interesting to note that during this period the neural and muscular mechanisms basic to sucking are developed so that they may function. A study of the evolution of this mechanism throughout the rest of the fetal period is instructive. For suggestions, see Feldman (1920, pp. 448 ff.) and, for the later period, Irwin (1930).

Bolaffio and Artom report in regard to another fetus about 2 months of age that gentle stimulation of the skin of the whole body was followed by no response, but percussion led to definite responses. Definite percussion blows on the forearm sometimes led to flexion, adduction, and slight internal rotation of the arm. Percussion on any part of the lower limb led to flexion and adduction of the thighs with slight flexion of the legs. If the percussion is rather light, the contractions are limited to the homolateral limbs; if somewhat more energetic, contractions also of the heterolateral limbs are reported. Percussion on the breast and abdomen gave homolateral responses about the pectoral muscles and bilateral responses about the abdominal muscles (pp. 465–466). Hooker (1944, p. 22) reports that in fetuses of about 8 weeks the reflexogenous zone of the cutaneous surface of the infant spreads from a very localized area, including part of the upper lip and the skin about the nostrils, to the whole upper lip, chin, and part of the neck. The responses made at this time are stereotyped and mechanical in nature. That the fetuses are ready for such responses is shown by Windle and Fitzgerald (1937). These workers demonstrate that the elements of the reflex arc are laid down by the sixth week. Spinal cord arcs do not seem to be complete before the eighth week. It should be emphasized that Hooker (1944, p. 25) says in commenting on this stage that "each stimulation in the reflexogenous area evokes a response which, within the limits of ordinary biological variation, is identical with every other one secured."

It is generally thought that even during the third month the cerebral cortex has as yet assumed no functions in relation to the general bodily activity. Bolaffio and Artom, however, report that removal of the cortex in a fetus of this age seems to remove inhibition from the reflexes of the lower limbs. This result is difficult for the writer to interpret. During this period sucking is theoretically possible; that is, the neuromuscular mechanisms necessary to bring about this response have probably already been determined. The reader who wishes a complete consideration of this earliest feeding reaction of the human individual should read the specific references given above to this reaction and then should refer to the summary of the knowledge of the reaction given by Feldman (1920, pp. 448–455). (See also Irwin, 1930.)

After superficial and deep stimulation of numerous points on the body of a decerebrate fetus of 90 mm., Bolaffio and Artom at first recorded very vivid contractions of apparently all muscles. After about 3 minutes, however, the contractions were still

bilateral, but limited now to segments and homologous regions of the body. As time passed, the contractions became more and more circumscribed, and after about 3 minutes they were limited to the muscles corresponding to the stimulated point. After 15 minutes every reaction had ceased (p. 466).

During the third month Minkowski (1922, p. 724; 1928*a*, p. 565) reports labyrinthine reflexes, but Bolaffio and Artom (1924, p. 471), obtaining the same responses that Minkowski reports, interpret them rather as responses elicited as the result of the stimulation of proprioceptors in the neck. Minkowski (1922, p. 723) reports tendon reflexes at this age, but Bolaffio and Artom (p. 473) do not find them until the sixth month. Here once more the decision must be a very difficult one to make, if the writer may judge from his own observations on infrahuman fetuses. Stimulation at the locus of a tendon may lead to a response, but this may be due to several possible forms of stimuli, such as (1) cutaneous stimulation, (2) direct muscle stimulation, or (3) a true tendon-stretch muscle stimulation. Mere observation of the response makes very difficult the decision as to which of these forms of stimulation has been effective. Bolaffio and Artom's careful work, however, seems to indicate that at first muscle sensitivity dominates when the tendons are stimulated, but in later fetuses true tendon reflexes begin gradually to arise.

Hooker (1939*a*) in summarizing development during this period says that by 9½ weeks of menstrual age responses include rotation of rump and body flexion. The neck-trunk reactions are usually contralateral. At this period "spontaneous" human responses were first observed. This same investigator notes that from 9½ to 12 weeks a "total pattern" of response is dominant. At 11 weeks palmar stimulation causes a quick but incomplete finger closure which marks the onset of the grasping reflex. Hooker (1938) studied the development of this reflex in great detail. He (1939*a*) further noted the onset of the plantar reflex during this period. Hooker (1944, p. 27) also noted that by 11 weeks stimulable cutaneous reflexogenous zones have spread over the whole upper extremity, and the sole of the foot has also become stimulable. Patterned eye movements seem to begin at this time.

Fetuses 13 through 16 Weeks Old. By 13 weeks the top and back of the head alone remain insensitive (Hooker, 1944). Minkowski (1922), studying a fetus in the early part of this period (110 mm.), recorded the fact that touching the lower lip or tongue with a blunt probe led to a closing of the mouth, brought about through the lowering and lifting of the jaw (p. 273). He also noticed in the same fetus that reflexes of the trunk and extremities were seen prominently, but after the transection of the cord in the dorsal region the lower reflexes were discontinued at once. This seemed to prove that conduction of activation in this case, at any rate, was through the cord. After this operation, moreover, he noticed that the short reflexes remained unchanged but were themselves abolished after total extirpation of the cord. Destruction of the lumbar and sacral cord abolished the hindlimb reflexes, whereas similar destruction of the cervical cord abolished those of the forelimbs.

The so-called spontaneous movements observed by Hooker at 14 weeks include the activity of most body parts as well as of the "organism as a whole." For the first time these movements, like those at about the same period elicited by tactual stimulation, may be characterized as "graceful" and "delicate." Hooker (1944) points out that by this period, except for movements of respiration and vocalization and the true grasping reflex, the fetus already

shows most of the responses that can be elicited in the neonate.

In a fetus of 135 mm. Minkowski (1922, p. 723) notes that a touch on the skin, using a blunt stimulus, led to reactions of diverse parts of the body. Characteristic of such stimulation were the flexion of both arms, the repeated opening and closing of the mouth, and simultaneous retraction of the head. He notes that at this stage of fetal development every part of the skin can act as a reflexogenous zone for various reactions. These reactions, however, tend to spread more or less over the entire fetal organism. Direct muscle excitability still remained at this stage 1 hour after the cord had been extirpated. Total removal of the cerebral cortex did not change the observable responses noted above. Transection at the midbrain, however, seemed to weaken the responses, although they still continued.

In a fetus 160 mm. long Minkowski (1922, p. 723) reports spontaneous dorsal flexion of the great toe, although he could secure no direct response to the touch of the sole of the foot. Distinct contractions of the abdominal walls were evoked in this fetus by brushing. Touching the closed eyelid in this fetus evoked a contraction of the orbicularis muscle.

Erbkam (1837) reports a study of a fetus, accidentally delivered, approximately 170 mm. long. He noted the contraction of both arms and legs and the movement of the head from side to side, "as if to breathe." In this fetus the heart beat for 10 minutes. After that time the water in which the fetus was lying became cool and the heart beat became slower. When more warm water was poured in, however, the heart beat became lively. The eyes of this fetus were closed. The great physiologist Johannes Müller saw the fetus and agreed with the author that it was of approximately 4 months' fetal age.

In a fetus of 180 mm. Minkowski (1923) noted spontaneous movements of all the extremities and the head. These were noted before the umbilical cord was ligated. In this fetus, touching the sole just at the time of delivery led to the dorsal extension of the big toe, the Babinski reflex. Later the plantar flexion followed (1923, p. 486; 1928*a*, p. 551).

In a fetus 190 mm. long Minkowski (1924, p. 250) obtained definite indication of reciprocal muscle innervation. He also reports at this stage that diagonal reflexes were established; that is, stimulating one foot of the fetus would lead to the movement of the arm on the opposite side. In certain instances the stimulation of the sole of the foot on one side even led to the movement of one finger, the little finger, on the hand of the opposite side of the body. These diagonal reflexes are considered by Minkowski (1922, p. 723) as significant in relation to the trotting reflex noted by a number of students of the genetic development of locomotion.

During this period the sole of the foot reflexes are thought by Minkowski (1928*a*) to have their connection in the spinal cord and the tegmentum. In terms of response this involves the domination of the response of extension over flexion (p. 551). (See also Dewey, 1935.) For a photographic sequence of the foot reflexes of a 14-week fetus, see Figure 18, from Hooker (1939*b*). Liesch (1946) has described the stimulation of mucous membrane areas and other cutaneous areas in a fetus 200 mm. in length and of an estimated age of 4 months.

Fetuses from 17 Weeks to Normal Birth Time. In experiments previously referred to, Barcroft (1938) has shown that after about one-third of the normal fetal period has passed in the sheep a remarkable change takes place. At this point the organism which has already developed most

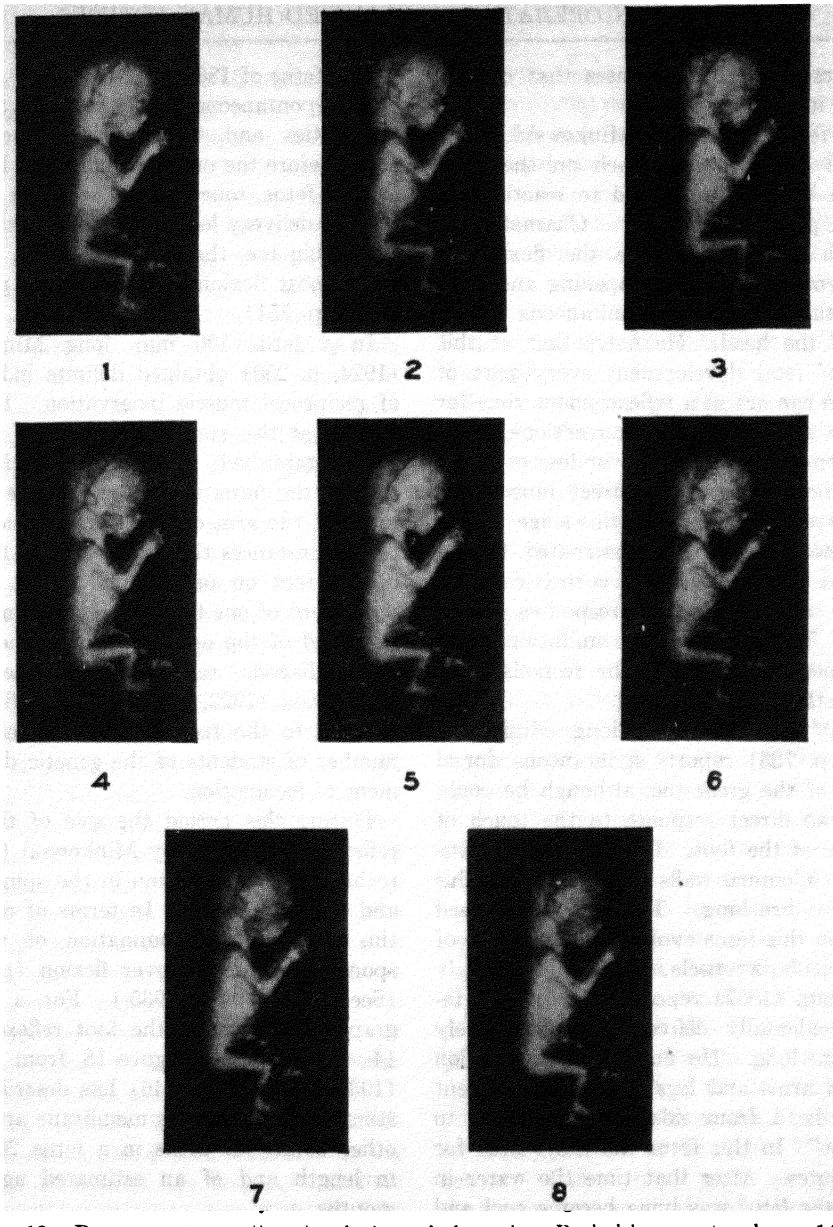

FIGURE 18. Response to tactile stimulation of the sole. Probable menstrual age 14 weeks. (From *A Preliminary Atlas of Early Human Fetal Activity*, by D. Hooker. Privately published, 1939, 91. By permission of the author.) Stimulation was applied by stroking the sole of the right foot with a 2-gram hair (1). The response consisted of the following elements: (*a*) Extreme dorsiflexion of the hallux (2 to 4) and "fanning" of the other toes (3 to 6). The toes, other than the hallux, ultimately show slight plantar flexion (6 and 7). (*b*) Flexion at the hip (2 to 4), slight flexion at the knee (3 to 5), and slight dorsiflexion of the foot (2 to 4). (*c*) Return to normal posture (5 to 8).

of the basic patterns of behavior becomes more quiescent. Spontaneous movements decrease. This is due to the fact that at this time a less adequate supply of oxygen is provided for the fetal central nervous system. At about the sixteenth week Hooker (1944) notes that a similar sluggishness begins in the human fetus. This again gives emphasis to the fact that in the study of the fetus positive evidence that such and such a response can be elicited is much more important than a negative finding when one is seeking for the neurological correlates of behavior.

In several fetuses approximately 200 mm. long, that is, about 17 weeks old, Minkowski found that brushing the sole of the foot led to plantar flexion of the toes, except the big toe, which did not move. This was directly related to Minkowski's elaborate study of the reflexes of the sole of the foot. (See 1922, p. 723; 1923, pp. 478–480; 1928*a*, pp. 550–556.) Direct mechanical stimulation of the motor roots of the spinal nerve at this stage showed that intersegmental spinal conduction is well established (1922, p. 752). Mechanical stimulation of the cranial nerves at the level of the medulla led to the opening and closing of the mouth. It is presumed by Minkowski that this reaction resulted from the direct stimulation of the facial nerve (p. 752). At this period direct stimulation of the cortex does not lead to response (Bolaffio and Artom, 1924, p. 477), but breathing changes do result from stimulation of the medulla.

In a fetus of 210 mm. Minkowski (1922, p. 723) observed opening and closing of the mouth accompanied by arm movements. The duration of such movements at this period was limited. Maximum responsiveness seldom lasted more than 1 minute at the most. In a fetus of 230 mm. Minkowski (p. 723) noted for the first time continued rhythmic contractions of the sort often described as Ahlfeld's breathing movements.

In a fetus of this same length Bolaffio and Artom (1924) noted that by employing superficial stimulation they were able to elicit localized muscular contractions in the limbs and other specialized muscle groups. By using strong and deep stimulation on a single segment of one limb, it is possible to elicit flexion of the whole contralateral limb. They also noted that stroking the ridge of the tibia gave vivid adduction of the homolateral thigh. In regard to the development of cortical dominance at this time it is interesting to note that mechanical stimulation of the Rolandic zone of the brain, either through the cranial cap or after its removal, did not call forth any reaction. Nevertheless, removal of the hemispheres did lead to more vivid local responses than in preceding excitations when the brain was intact. Stroking the pectoral muscles called forth adduction of the contralateral limb. In this case also these investigators reported that, if the intensity of the stimuli was increased somewhat, they got contraction of the whole corresponding limb. By stimulating the medulla they were able to call forth violent respiratory movements with active participation of the cervical, thoracic, and abdominal muscles, and those of the diaphragm. These movements were so violent they also led to elevation of the shoulder and adduction of the arms. It is further significant to realize that these investigators found, after repeated successive experiments and as the vitality of the fetus became less, that the muscular contractions disappeared first in the lower limbs and then later in the upper limbs (p. 466).

In a fetus of 240 mm. Krabbe (1912) reported slow movement of the limbs and contraction of the muscles as the result of percussion. He also obtained strong abdominal reflexes as the result of light blows.

The plantar reflex occurred without involving the participation of the big toe. In the fetus which he investigated the heart beat was strong and he was able to elicit a number of reflexes, the abdominal reflex being especially strong. The fetus was a female, but he was unable to elicit the female cremasteric reflex. He felt that both bone and tendon reflexes were present and was able to demonstrate that direct muscle stimulation was possible (p. 434).

In a fetus of 260 mm. Bolaffio and Artom (1924) attempted certain specific neurological experiments. By means of appropriate electric stimuli they explored the cortex but did not obtain any reaction even with intense stimulation. By operation the internal capsule and peduncles of the brain were exposed, but still electric stimulation gave no response. When they reached the pons, however, they got ready and synchronous responses from the muscles innervated by the facial nerve. Finally, stimulation of the medulla gave energetic respiratory movements. Stimulation of the cervical cord led to energetic movements of elevation of the shoulder with flexion of the upper limbs, and stimulation of the lumbar cord gave movements of the lower limbs (p. 466).

In a fetus 270 mm. long Minkowski (1922) noted that from the first the plantar flexion of the toes was present to stimulation of the sole of the foot. Minkowski is of the opinion that at this age the plantar flexion must still be considered as a pure spinal reflex (p. 754).

In a fetus of 280 mm. Minkowski was able to bring about rather elaborate but quite well-differentiated muscular responses to a single electric stimulus. For example, the muscles of the eyelid could be activated with great specificity. After exposure in air this fetus is reported to have made faint sounds (p. 754). These sounds are possibly the earliest observed in a human organism. They may be taken by those who are interested in zero points as the onset of functional activity in the great mechanism which makes human speech possible.

In a fetus of the same length Bolaffio and Artom (1924) observed that every muscle reacted even to quite energetic stimulation, such as percussion, by local contraction. This specificity is more marked in the head region than in the leg region of the fetus. Percussion in front of the ear led to a movement of closing of the eye with elevation of the angle of the mouth and chin. Strangely enough, however, it seems that the deep reflexes are not easily obtained at this age in the arms. Stimulation of the legs shows that the patellar reflex can be called forth bilaterally and the Achilles tendon reflex on one side. No plantar reflex was elicited in one fetus at this age (p. 467).

In a fetus of 310 mm. Bolaffio and Artom further reported the observation of periodic respiration. Breathing was "by fits and starts." The heart beat was regular. At this period all the muscles of the limbs can be excited one by one with percussion, obtaining vivid reaction. Appropriate local stimulation serves to bring out most of the typical percussion reflexes, including minor responses of the fingers, of the toes, and of the sole of the foot. The plantar reflex, however, and some of the others still seem to be absent (p. 467).

In general in the sixth month there is an increased tendency of various receptor-neuromuscular mechanisms to act independently, and this independent contraction is part of the greater quickness of response which characterizes this period as contrasted with earlier periods. Bolaffio and Artom (p. 472) find this month for the first time tendon reflexes which seem to be assuredly not the result of cutaneous or muscle stimulation. Their judgment on

this matter is based on the facts that the specific responses given at this period are not found before this time but continue to increase in strength during the later fetal periods, and that they are the same responses which are elicited in early infancy as true tendon reflexes. Direct stimulation of the mouth and tongue at this age elicited the sucking reflex, according to Bolaffio and Artom. In older fetuses stimulation of the lips alone leads to sucking movements which may or may not be accompanied by the protrusion of the tongue (p. 477). As noted above, Minkowski found this reflex at an earlier period.

These same investigators, using a slightly larger fetus (330 mm.), again reported superficial respiratory movements. These breathing reactions ceased after a minute or two. They reappeared when pressure and percussion of the thorax were used. In this fetus they noted also that with percussion the muscles gave powerful and localized contractions. The tendon reflexes which could be elicited included those of the biceps and triceps and the Achilles reflex. Direct stimulation of the cortex still brought no response. In this fetus it seems that no true cutaneous reflexes could be called forth either before or after the removal of the brain. In another fetus of exactly the same size these same investigators report that the fetus cried weakly and moved about spontaneously but with less strong movements than those characteristic of a fetus at term (p. 468). When death seemed imminent in this fetus the top of the skull was removed and the cortex directly stimulated electrically. All the various zones of the cerebral cortex were stimulated with negative results. Stimulation of lower brain centers, however, led to specific results such as increased breathing rate, shoulder, arm, and finger movements.

Bolaffio and Artom also reported the behavior of a fetus of 340 mm. which appeared to be slightly undernourished. This fetus made weak crying sounds and breathed weakly. After about 2 hours it stopped breathing. During the period before breathing stopped they elicited contractions by tapping one by one the muscles and groups of muscles of the body. In this specimen by stroking the sole of the foot the plantar flexion of the toes was brought out. All these reactions became more vivid just before the death of the fetus (p. 469). This suggests a change in the higher brain centers as a result of a lack of oxygen.

Certain responses noted in the seventh month, while definite, nevertheless are seen to involve synergic muscle groups (Bolaffio and Artom, 1924, p. 481). This finding must be taken into consideration in evaluating statements given in regard to the randomness of activity in the newborn child. It may well be that much of the apparent "mass activity" of the newborn child (Irwin and Weiss, 1930) is not truly diffuse response of the sort found in the early fetus, but rather the activation of groups of synergic muscles in the sense of the term as used by Sherrington and his associates (Creed, Denny-Brown, Eccles, Liddell, and Sherrington, 1932, p. 129). Krabbe, Minkowski, and Bolaffio and Artom all report abdominal reflexes at this period. A number of other specific reflexes are also clearly brought out at this time. The knee jerk is definitely elicited. The plantar reflex, according to Minkowski, now probably involves not only the centers concerned during previous months but also part of the lenticular nucleus and the red nucleus. Bolaffio and Artom feel that at this period the plantar reflex in its typical form is much like that of adult life but that it is still much more variable than it will be at a later period. This leads them

to be critical of statistical work on reflexes, such as that of De Angelis (1922). (Cf. also Cesana, 1911.) The corneal reflexes are seen in the seventh month. Direct stimulation of the cornea of the eye leads from this time on to an increasingly strong response. Decerebration in this month was found to lead to increased vividness of most reflexes, but also to a tendency to reflex spread.

In a still larger fetus Bolaffio and Artom reported that with slight percussion of all the muscles of the limbs they observed vivid responses not limited to single muscles. Such responses spread to synergic muscle groups. With percussion of the pectoral muscles they obtained adduction and internal rotation of the arm and flexion of the forearm. They obtained bilaterally the patellar reflex and an extension of the leg, sometimes associated with flexion of the thigh. Associated with this pattern of response was the dorsal flexion of the foot. The Achilles tendon reflexes, however, were not always obtained even in a fetus as old as this one. These investigators also failed to get abdominal reflexes in fetuses of this age. However, the slight excitation of the sole called forth a definite unified toe phenomenon, and then a more energetic stimulation called forth flexion of the toes. The sucking reflex was secured only by stimulating the tongue. They reported that the movement of grasping which they got by applying pressure to the palms of the hand was energetic. These same investigators reported that from the seventh month to birth they investigated 13 fetuses of 7 months, 3 of 8 months, and a large number of mature fetuses. In this study they have not considered protocols of any fetuses which, because of condition of nutrition or on account of the presence of disease, did not present normal situations. They assert that from the end of the sixth month the movements of the fetus became so powerful and complex as to render very difficult and sometimes impossible detailed and specific report of behavior (pp. 470–487).

During the last 2 months of pregnancy the muscular reflexes decreasingly tend to prevail over the tendon reflexes, according to Bolaffio and Artom (p. 472). By the end of the ninth month the tendon reflexes are so well established that they prevail over special muscular reflexes. All the tendon reflexes are found to be present during this period of fetal life, with the exception of those of certain of the upper limbs which are elicited with difficulty because of the small size of the member. Contralateral adductor reflexes are sometimes called out in this period. Even in the fetuses nearest term, the cremasteric reflex was difficult to elicit (Bolaffio and Artom, 1924, p. 474).

At any prenatal age, including this last period, however, it is noticed that very light stimulation of the hand gives variable and inconstant movements, whereas strong stimulation, possibly involving the muscle or other underlying tissue, leads uniformly to grasping (Bolaffio and Artom, 1924, p. 476). Bolaffio and Artom, therefore, believe that the grasping reflex is not to be thought of as a purely cutaneous reflex in prenatal life. Minkowski (1928*a*, p. 545) finds this reflex at an earlier period. Iris reflexes are present during the prenatal period (Bolaffio and Artom, 1924, p. 477). The reaction of the iris, however, is slow, and very strong light is needed to call out the response. (See also Minkowski, 1928*a*, p. 558.) It is difficult to say when the response would begin if stimuli as strong as direct sunlight could always be used. Bolaffio and Artom do not note the fact, but it seems obvious that, with such strong stimulation as they recommend, the danger of independent muscle effector action of the

sort described by Parker (1919, p. 53) must be guarded against.

There is some evidence that the cerebral cortex is directly stimulable at this period, although as yet the evidence is not conclusive (Bolaffio and Artom, 1924, p. 480), as will be pointed out below in considering the possibility of fetal learning.

It is possible to add to this consideration of month-by-month fetal development, therefore, some general statements that have been made by those who have been most directly concerned in these investigations. Thus Minkowski holds that one may say that every part of the skin can, as its receptivity is progressively established, serve as a reflexogenous zone for quite variable reactions which tend to spread more or less over the whole fetal organism. In the whole developmental process the gradual acquisition of postural responses and muscle tone is peculiarly important. The development of these responses will be considered below in the section in which the origin and development of the proprioceptive and static senses are considered. Minkowski offers in part explanation of the spread of reflexes during the early periods the fact that the spinal cord tracts as well as the nerve trunks have no medullary sheaths before the fourth month of fetal life. Illustrations of Minkowski's anatomical work on the nervous system are given in several places (1921*a*, 1928*a*). There is a suggestion that from this time onward there is an anatomical increase in specificity correlated with the differentiation of the nervous elements in ways possibly involving the nature of protoplasm, neurofibrils, medullary sheaths, synapses, long conduction paths, and other cell changes (Minkowski, 1922, p. 753). These gradual alterations in the nervous system, it is suggested, lead progressively to the possibility of more and more circumscribed and definite response. Compared with the diffuse character of early fetal response, therefore, in the late fetus, Minkowski (1920*a*) feels that all the well-known special reflexes have more or less been established. The discussion above, however, has shown that the process of development of these reflexes is a complex one and that later in adult life injury to the nervous system may bring about reactions which were characteristic of a previous period, even of a fetal period (Minkowski, 1922, p. 754). For the historical breaking of ground in this connection, see H. Jackson's essay (1884) on the evolution and dissolution of the nervous system.

It must be impossible to read what has gone before in this chapter without realizing that there is a general relationship in sequence of development of behavioral capacities from fish to man. It must be noted, however, that there are peculiar dangers in generalizing from, for example, the amphibian development of behavior, or even the rodent or cat development of behavior, to the growth of adaptive actions in man. For example, it has been shown clearly that in fish, amphibians, and lower mammals the first responses involve a unilateral bending of the trunk. This stage may or may not exist in the human individual, but at any rate no observations have so far been made in which trunk movements unaccompanied by arm movements are observed in early fetuses.

The basic pattern for the development of locomotion and other "individuated" responses, as suggested by Coghill and his students, may be seen in a less typical form in human development than might be supposed, although Coghill (1929*c*, p. 1009) himself has called attention to the attractive possibilities of the analogy. Little evidence of rhythm in the limbs of the human fetus has been determined. It may well be, therefore, that locomotorlike movements of the limbs do not appear

until very late in the human fetal period. Windle and Griffin (1931) have summarized this comparative evidence, and they suggest that the movements observed in the kitten fetuses with which they have worked possibly should not be compared directly to human fetal movements because of the differences between the two in the type of adult locomotion. In a similar way the locomotor mechanisms in fish and amphibians which require a high degree of trunk-muscle integration may be difficult to compare with the conditions obtaining in a mammal that stands erect. Such considerations as this bring up the old problem of the recapitulation in ontogeny of the phylogeny of behavior. This problem is as old as Aristotle (Needham, 1931, p. 69), and yet there seems to be nothing in the present evidence to make this view seem anything but a generalized, and in many details an inaccurate, description, and certainly not an explanation, of development. (See Davidson, 1914; Needham, 1931, pp. 1632–1638.)

Too much emphasis cannot be placed upon the fact that easy generalizations, such as the assertion that all behavioral development occurs from a generalized total pattern of the organism to the specific responses of adult life, must be taken with great caution. While this description may be true in many respects, particularly if the word "pattern" is given an unambiguous meaning, it seems certain on the basis of the specific responses considered above that it cannot be indiscriminately applied. Before generalizations can be made with assurance, there must be a large amount of accurate measurement and the determination of a series of statistical norms in regard to the development of each of the specific developmental stages in each form considered. Typical cross-sections in development in every form and in all responses from significant receptor surfaces must be considered before such a generalization can be made. Certainly the late fetus has an elaborately organized and in some respects quite specific response mechanism. To some stimuli the relatively early fetus makes quite definite responses.

It seems hard to believe that anyone who knows anything of the structure and function of the tracts and centers of the central nervous system can read the report of fetal activity at various developmental levels given above and still feel that there is much to be gained by saying that before birth the organism reacts as a whole, as certain psychologists, possibly under the influence of one form of the *Gestalttheorie*, have suggested. Much of the nervous system may, in some sense, be involved in any partial activity of the system, but this does not mean that the system is not in many respects sharply differentiated. Certain essential relationships between diffuseness and specificity and between individuation and integration of behavior will become clearer after the parts played by the specific senses in fetal life have been considered.

The account presented above from the reports of several investigators gives a picture of the development of behavior in human fetal organisms of estimated ages. No effort has been made to include all known fetuses but only those in which behavior significant for the general problem of this chapter was noted. Minkowski (1923, pp. 486–489) refers to at least 11 fetuses not considered here in which primarily the only reflexes studied were those released by stimulation of the sole of the foot. In the study of this response Bersot (1918, 1919; 1920, 1921) has also considered fetal activity in detail in relation to a study of the development of the clinically significant plantar reflex. This same response has been considered from a scientific and theoretical point of view by

Feldman (1922) and by Minkowski (1926) in work that has been referred to above. For an account of a fetus investigated by Winterstein, see Minkowski (1928*a*, p. 517).

Hooker has given permission to refer to his *Preliminary Atlas of Early Human Fetal Activity* (1939*b*), which was first issued for restricted use only. Reference has been made above to this work, but the author wishes to call especial attention to it because it contains very beautiful reproductions of photographs of human fetal material 8½ to 14 weeks of menstrual age. A careful study of this atlas may give a more adequate picture of early human fetal behavior than any other single reference.

The Special Senses in Human Prenatal Life

Historically there has been much speculation in regard to the rôle of the senses before birth. In earlier psychology these speculations centered largely about the question of whether or not some sort of dim conscious awareness exists in the infant before birth. More recently this essentially nonexperimental question has given place to one that may be studied. The question now asked is: How and when does the stimulus control of fetal behavior determined by the activation of the various receptor systems begin before birth, and how do behavior capacities develop? Objective techniques for study of the senses in the premature or newborn infant have been devised, of which those of Canestrini (1913) and A. P. Weiss (1929) are significant examples. These techniques have not only made quantitative study of the senses possible in a new way, but they have also added to the general knowledge of the part that stimulation plays in the subtle alterations of bodily activity. In this chapter, therefore, the various specific senses will be considered in turn in relation to fetal behavioral or mental life when such behavioral or mental life is considered as including not only experience but also specific receptor-controlled behavior.

After each of the senses has been treated, some generalizations will be made by the author on the significance for psychology of receptor-aroused activity in the fetus. The reader should be reminded that the material presented above on the development of the senses in lower animals and especially the elaborate work on the guinea pig has much relevance in a consideration of the growth of the human senses. In this section, however, the whole emphasis is placed upon human development except where specific reference to infrahuman forms is considered necessary for strictly comparative purposes.

The cutaneous receptors

In a consideration of the senses of touch, an effort is made to suggest such differences as have been noted in fetal life between light and deep pressure, temperature, and cutaneous pain. The development of skin in the human fetus has been anatomically described by a number of writers. This work is summarized by Feldman (1920, pp. 233–236). In appearance the skin of the late fetus or early premature infant is very red, owing to the visibility of the vascular system just beneath it. At 2 or 3 months before birth the skin is still quite thin and is covered with *lanugo hairs*, which appear at about the fifth month of pregnancy. The skin of the fetus during midpregnancy is typically much wrinkled, because of the comparative absence of subcutaneous fat. The hair on the scalp at this period is short and poorly pigmented. The nails grow gradually during late fetal life (Hess, 1922, pp. 74–77).

There has been much speculation on the skin as a sensory surface during the uterine

life of the fetus. Cabanis is quoted by Genzmer (1882, p. 10) as holding the skin to be a peculiarly important receptor field at this period. Bichat (1827, p. 137) and Magendie, as noted above, discussed the skin sensibility of the fetus. Some casual observations are also reported in relation to the material summarized on a previous page of this chapter concerning the possibility of stimulating the fetus by pressing on the abdominal wall of the mother. Of course, stimulation of this sort may well activate the deep-lying proprioceptors as well as the true tactile receptors. In the review of the literature in the experimental study of the development of fetal behavior in infrahuman organisms, many references have already been made to tactual stimulation. In the human field alone, Minkowski, Bolaffio and Artom, Krabbe, Hooker, and others have considered fetal responses that are released by cutaneous stimulation as indicated above. Hooker has been especially careful to use quantified stimuli. The part played by the sense of touch in animals and man in discrimination and even in responses of equilibration is considered by Kidd (1907).

A. Pressure. In summarizing the work that has been done on human and infrahuman fetuses, the following factors may possibly be isolated as important in a consideration of the pressure sense before birth:

1. *Place stimulated.* In general, cutaneous sensitivity seems to begin in the oral-nasal region, that is, the region involving the mucous membrane of the nostrils and the red of the lips (Genzmer, 1882, p. 6; Windle and Griffin, 1931, p. 179; Hooker, 1944, p. 22). In rodents the pads of the vibrissae also very early become sensitive (Lane, 1917, p. 34; Raney and Carmichael, 1934; Carmichael, 1934*a*), and in many animals the regions about the eyes and the openings of the ears are also very early sensitive, as is the anal region (Coronios, 1931). In the human infant Kussmaul (1859, p. 23) found the eyelashes very sensitive, but this was not confirmed by Genzmer (1882, p. 6). Most studies seem to suggest that, with individual variations, skin sensitivity develops by spreading out over the face region and then progressively over the surface of the body. In this development in certain organisms, such as the toadfish, the salamander, the rat, and the cat, a fairly well-worked-out course of temporal difference in the arrival of sensitivity in increasingly caudal segments of the body may be observed. In animals with tails this even goes on out to the end of the tail.

In this general course of development, however, certain exceptions have been made out, as noted above by the writer in a study of the development of the receptive zones of the fetal guinea pig. Sensory development in general has been treated by Minkowski and other investigators as the spreading of what they have termed reflexogenous zones. This term has much to recommend it because at present almost the only method used in the study of fetal sensory capacity on the skin is the recognition of behavior correlated with the experimental stimulation. Windle and Griffin (1931, p. 175) suggest in general that motility precedes the ability of a part to be stimulated. In his consideration of the "reflex circle," Holt (1931, pp. 37–43) has suggested the large part that self-stimulation may possibly play in the development of specific forms of behavior as organisms develop. Certainly no one who has watched an active mammalian fetus can help being struck by the fact that in its movements it stimulates almost its entire body surface by its own moving paws and head. It is peculiarly striking to watch a 48-day guinea pig fetus, for example, stimulate its head and face by appropriately cupped "hands." These scrubbing movements, performed not

once but over and over again, are such that the surface must certainly be irritated by the friction.

2. *Areal versus punctiform stimuli.* Minkowski (1922, p. 723), Coronios (1931), Windle and Griffin (1931, p. 175), Carmichael (1934*a*), Raney and Carmichael (1934), and Hooker (1936) have all apparently noticed that stroking produces stimulation when single punctate stimulation does not bring about response. Following this suggestion, Raney has been able to show that stimulation of a point on the skin by a single hair may not bring about response, but stimulating the same area immediately around such a point with a brush made up of comparable hairs will sometimes do so. (In this connection, see also Kuo, 1932*e*, p. 507.)

3. *Summation of stimuli.* Carmichael (1934*a*) and others have noted that a single touch with a light hair may fail to bring out response, but several touches apparently of the same intensity at the same point may be effective in eliciting response.

4. *Weak and strong stimulation.* Genzmer (1882, p. 10) long ago noted that in a premature infant entirely different responses might be elicited to weak and strong cutaneous stimulation. The distinction in terms of the strength of cutaneous pressure is one that has too infrequently been made in studies of fetal development. Thus, as noted above, Bolaffio and Artom disagree with Minkowski as to the point at which cutaneous reflexes begin in the developing fetus. This disagreement may be based on the fact that Bolaffio and Artom (1924, p. 473) indicate the possibility that Minkowski was unwittingly stimulating the underlying musculature and thus that the massive responses which he reports in young fetuses are not cutaneous but are due to the stimulation of deep receptors. The possibility of direct muscle stimulation in such cases must also be remembered. Holt (1931, pp. 40–43) considers that the distinction between strong and weak stimulation is a peculiarly important one in the development of the functional activity of the growing organism. He believes that light stimulation will usually lead to response moving toward the stimulus, or *adiently*, whereas only secondarily does strong stimulation of the same receptor field lead to *abient*, or withdrawal and avoidance, responses. Richter (1925) and others have confirmed this observation. Indeed, Coronios, Schlosberg, and Carmichael (1932) have been able to take moving pictures showing exactly this response as the result of stimulating the paw of a fetal kitten.

Under other circumstances, however, observations have not been such as to confirm this generalization. Thus Coghill (1929*a*, p. 13) asserts that the first responses of *Amblystoma* are all away from the region stimulated. Windle and Griffin (1931, p. 175) point out that the unilateral trunk or neck flexions of the earliest fetuses seem to be executed toward the observer and away from the surface on which the animal is resting. Kuo (1932*e*, p. 507) also uses the strength of the stimulus as a peculiarly important part of the theory of development which he has proposed. It seems possible that in responses in which apparently the same receptor field is stimulated first lightly and then more strongly two distinct neural mechanisms may sometimes be brought into play. It might be suggested speculatively that the facts behind the differentiation between the allegedly developmental epicritic and protopathic sensitivity, as proposed by Head and Rivers and especially as explained by Boring (1916) and later by Sharpey-Schäfer (1928), will ultimately provide some clue in the explanation of this diversity of response to different stimulus intensity.

Windle and Griffin (1931, p. 176) also discuss a developmental system of cutaneous receptor mechanisms. The difference in responses to light and heavy tactile stimulation makes peculiarly uncertain the interpretation of results of investigators who do not indicate that they have considered the strength of the stimulus as important in describing the fetal responses which they have elicited in experimental work. It is all the more peculiar that this distinction should not have been continuously made, because of the statement in regard to the difference in responses to weak and strong stimuli made, as noted above, many years ago by Genzmer. As previously reported, Smith and the writer (Carmichael and Smith, 1939) have demonstrated a quantitative relationship between the extent and spread of response and the intensity of punctiform stimulation when calibrated esthesiometers were used.

5. *Localization.* Preyer (1882, p. 110) believes that the first localization response to tactile stimuli is the seeking of the nipple by means of the cutaneous stimulation of the lips. Many specific references have been given above to the motor responses of various fetuses set off by tactual stimulation. It has been suggested in connection with the work of Raney and Carmichael (1934) that such responses possibly develop greater accuracy in localization as age progresses.

6. *Cutaneous reflexes.* As suggested in the preceding paragraphs, the skin may be thought of as a mosaic of points, each spot of which is the locus of stimulation for a more or less specific behavioral response. Many writers have discussed the significance of cutaneous reflexes in adult life. Givler (1921) has suggested the wide significance of the development of one such reflex, that of grasping. Hooker's (1938) careful observations on the grasping reflex show that it develops during fetal life in two phases: finger closing, and gripping. Finger closing appears as a quick flexion of the digits except the thumb at about 11 weeks of menstrual age. Gripping is first observed in the eighteenth week. It is still weak in the twenty-fifth week of menstrual age. In the first 25 weeks of fetal life the thumb seems to play no rôle in fetal grasping.

Minkowski, as noted above, considers in detail the variations in the pattern of the reflexes elicited by the stimulation of the skin of the sole of the foot. Sucking, in its later stages, is possibly conditioned by a number of exteroceptive and interoceptive stimuli, such as the stomach contraction of hunger, but it is in essentials always a cutaneous and mucous membrane reflex. The cremasteric reflex and certain of the abdominal reflexes also result from stimulation of the cutaneous field.

In general, then, it may be pointed out that many of the specific acts of the fetus are induced by stimulation of cutaneous pressure receptors Mucous membrane reflexes (Minkowski, 1928*a*, pp. 556–558) are also probably best thought of as involving receptor mechanisms, so far as pressure is concerned, that are similar to cutaneous reflexes. Peiper (1928, p. 92) has tabulated the cutaneous responses seen in newborn children. The writer must here again emphasize his belief that, given a stimulus just above the lower threshold and a quiescent fetus in a standard posture, there is typically *one behavior act* or *reflex* set off by the stimulation of each cutaneous area. These cutaneous "push buttons" are remarkably specific in their behavioral relations when the complexity of the central nervous system is considered.

B. Temperature. Warmth is one of the skin senses attributed by the philosopher John Locke (1849 edition) to the fetus. In spite of this early sanction it is difficult to understand how marked differences in

temperature can normally be present in prenatal life. In the study of the temperature sense in the prematurely delivered infant the matter is further complicated by the great variability of body temperature which characterizes the premature infant (Hess, 1922, p. 151; Evensen, 1931, pp. 11–15). Currently accepted views in regard to the mechanism of temperature stimulation start with the assumption that the temperature to which the skin is adapted must be taken as the physiological zero point. From this zero other stimuli are to be considered as above or below; therefore quantified work in regard to temperature in the premature infant is rendered difficult when only absolute temperatures of stimuli are recorded.

Some indications, however, of responses to both warm and cool stimuli in premature infants are given by both Kussmaul (1859, p. 23) and Genzmer (1882, p. 11). For the most part these observations agree with those of the following investigators of the temperature sense of newborn children: Preyer (1882, pp. 111–116), Canestrini (1913, pp. 76–85), Blanton (1917), and Peiper (1928, pp. 28–29). These opinions are criticized by Pratt, Nelson, and Sun (1930, pp. 144–167), who also add their own controlled experimental observations. These three collaborators report that newborn infants react much less strongly to stimuli warmer than the body than to stimuli that are cooler. The writer has described above a study of fetal temperature sensitivity (Carmichael and Lehner, 1937) in which some observations on the temperature responses of guinea pigs were made. In this study unmistakable reactions to temperature both of warm and cool stimuli were obtained under controlled conditions. Drops of blood-warm water call out no response save as they arouse tactile receptors, but cold- or hot-water drops do call out such activities. This sensitivity has appeared by approximately the middle of the gestation period. Here again the "more intense" stimulus (warm *or* cold) calls out more active responses than the "less intense" stimulus.

C. Pain. Locke (1849 edition) also attributed the experience of pain to the fetus. Since his speculation there has been little direct experimentation upon the fetal pain sense. A number of casual observations show, however, that the application of stimuli that must have caused gross destruction of skin and protoplasm has not called out very pronounced movements on the part of the fetus. Genzmer (1882, p. 12), on the basis of such observations, holds that the pain sense is very poorly developed in the fetus. On the first day of a premature infant's neonatal life he stimulated it until blood came and got no response. It is certainly true that increase in pressure over that necessary to bring out the typical responses to deep pressure does not always seem in the guinea pig fetus, at any rate, to increase the extent or intensity of response. Thus in certain cases the light pressure of a fine hair may lead to extension and stronger pressure of a heavier hair to retraction, but very strong and even obviously destructive stimulation of the same point may or may not make any observable difference in the elicited response over that noted to strong pressure stimulation. Similar observations have been made on the cat fetus (Windle and Griffin, 1931, p. 176). There can be no doubt that protoplasm-destroying stimuli sometimes bring about violent responses in late fetuses, but even this reaction does not always occur. Speculations on the part played by pain in relation to unpleasantness and discomfort will be referred to in the consideration of the organic senses.

The foregoing paragraphs may be summarized by the statement that there is much evidence that the specialized skin

senses have developed to an active functional state long before birth and are able when appropriately stimulated to initiate the release of behavior that is typically precisely related to the point stimulated.

The proprioceptive senses

The neuromuscular spindles may be taken as typical of the many classes of proprioceptors. They are found in the fourth month of fetal life in practically all muscles, including the extrinsic muscles of the tongue and the external eye muscles (Elwyn, 1929, p. 248). Historically it was not until quite recently that the kinesthetic senses came to be distinguished at all from touch. Carmichael (1926*b*, pp. 204–209) has described the history of knowledge concerning the "muscle sense." Much that Bichat (1819) wrote about the active touch of the fetus probably referred to the proprioceptive rather than to the cutaneous sense. Kussmaul (1859, p. 32) and Genzmer (1882, p. 8) both refer to responses which must have involved muscle-sense stimulation. Preyer (1885, p. 547) makes similar references. Peterson and Rainey (1910) also hold that not only touch but also the activity of the muscles of the fetus must lay the foundation "under the threshold of consciousness for a sense of equilibrium and vague spatial relationships" (p. 122). In his study of the relationship between local reflexes and posture, Coghill (1929*a*) comes to the conclusion that ". . . the limb is able to respond very precisely to stimuli arising within the body (proprioceptive) as the result of a particular posture before it can respond to stimuli that arise exclusively from the outside world (exteroceptive) . . ." (p. 21).

In experimental work on operatively exposed human and infrahuman fetal material during the active period, the proprioceptive senses are always much in evidence. Indeed, in the responses in fetal rats both Swenson (1926) and Angulo y Gonzáles (1932*a*) find evidence of this sense in a 16-day fetus. Coronios (1933) and Windle and Griffin (1931, p. 177) deal with this sense in detail. (See also Windle, 1940.) As noted above in the consideration of the cutaneous senses, these investigators report activities that show that the posture of the cat fetus at the time of stimulation seems in certain cases to determine the response that will be elicited. This point is substantiated by many protocols of the experimental studies of fetal behavior that the present writer has recorded. It is possible that this fact alone may be taken as indicating an early onset of proprioceptive control of behavior.

In this connection one must remember the differential gravitational action on the limb and body in air and in the liquid of the amniotic sac. In one of the studies of a very young human fetus—by Strassmann (1903), noted above—it is recorded that the observer pressed against, in a manner which apparently means moved, the limb of the fetus. As a result of this stimulation the experimenter could feel the foot press down on his hand. The writer has noticed this same response in young guinea pig fetuses. Even when very gentle or even relatively strong tactual stimulation would not release a response in the forelimb of the fetus, it not infrequently has happened that a forcible movement of the limb itself by the experimenter gave a specific and direct response. As the skin was not anesthetized in the cases reported, this may not of course be thought of as a wholly proprioceptive stimulus, but, as cutaneous stimulation was ineffective in producing the same response, the facts seem to favor the view that the responses noted were proprioceptively aroused. This conclusion must be taken with reservations because the bending and stretching of the skin which result from

the bending of a limb are a very strong pressure stimulus.

There is still other evidence that the proprioceptors are effective very early in fetal development. Hooker and Nicholas (1930) have reported experiments on fetal rats in which the spinal cords were completely sectioned at various levels. After some of these experiments it was found that stimulation above or below the sectioned point of the cord might lead to responses in parts of the body innervated by segments of the cord above or below the cut. The question at once arose as to how these impulses were transmitted. As one of the possible explanations of this transmission, these investigators have suggested the following course of events. An exteroceptive stimulus leads to afferent conduction over peripheral nerves to the cord above the region of the section. From this still intact segment of the cord impulses pass out over efferent peripheral nerves to trunk muscles leading to this response. This response mechanically moves the adjoining musculature and thus directly stimulates the proprioceptors in it. These newly activated proprioceptors then initiate afferent impulses which pass into the cord below or above the region of the cut, as the case may be, and thus in turn activate arcs in the intact region of the cord above or below the section, which in turn lead to responses obviously innervated by connections in the cord beyond the section. (See also Hooker, 1911.)

Windle and Griffin (1931) report many evidences of movement that may be considered on the basis of the analysis of Sherrington and his school of reflex physiologists as at least in part proprioceptively innervated. These investigators report (p. 186) that a quiescent embryo held in the cramped condition of the sac will, on the cutting of the sac, sometimes at once assume an exaggeratedly stretched position. It seems as though it were attempting to exercise itself after the close confinement of its entire previous existence. It may be remarked that the writer has seen and photographed similar responses. These maintained "extensor thrusts" are in many respects similar to the tonus of decerebrate rigidity as seen in the adult animal and may possibly involve proprioceptive stimulation. The experiments of Weed (1917), Weed and Langworthy (1926), and Langworthy (1928, 1929) give very clear evidence of other reactions involving this receptor system. The writer has sometimes noted when dealing with a late guinea pig fetus that, if the fetus, still wholly immersed in the bath, is held by its own forepaws on a submerged projection, the animal will seem to try to crawl up onto the projection. Correlated movements are here used which seem, to superficial observation, similar to those employed by a swimmer lifting himself out of the water onto a diving raft. This well-integrated and apparently purposeful activity seems to involve complex proprioceptively directed responses.

Most students of the development of fetal behavior agree that locomotion, as, for example, in the first crawling movements of the fetal opossum considered above, sucking, and breathing are three of the earliest essential behavior systems of the newborn animal. It is interesting to note that each of these in its developed form may involve marked proprioceptive stimulation. The geotropic responses of the opossum fetus considered above, occurring less than 2 weeks after copulation, seem, in the light of Crozier's work (1929, pp. 83–98) on geotropism in the rodent, to represent a response in which proprioceptive stimulation plays a part. Hunter (1931) has pointed out in a similar study that the vestibular apparatus and other

stimulus factors are probably also important in determining such responses.

As noted above, Minkowski (1922, p. 723; 1928*a*, pp. 559–560) reports that there are true tendon reflexes in the early fetus. This is questioned, however, by Bolaffio and Artom (1924, p. 472). These latter observers suggest that the responses seen by Minkowski in very early fetuses may have been the result of other forms of stimulation. The mechanism of deep stimulation which they suggest and true tendon-stretch stimulation both involve proprioceptive activity. Indeed, it may be said that the whole study of prenatal behavior in man and in the lower mammals indicates that the proprioceptors in muscles and tendons, and possibly joints, are functional well before birth. By the time of birth these mechanisms have undergone such development that they are among the best-organized receptor fields so far as the initiation and control of behavior are concerned. Much of the "movement of the organism as a whole" which so many writers refer to seems to be the result of rather specific proprioceptive stimulation. Such stimulation often leads to the "spread" of what are really quite delicately timed families of specific responses which can easily be mistaken for "vague" or "diffuse" behavior.

The receptors in the nonauditory labyrinth

Adult posture, righting responses, and other reactions to gravity, tonus changes due to rotation, and other alterations of the body in space are often held to result from stimulation of receptors in the nonauditory labyrinth and associated receptor fields (Camis, 1930, pp. 262–268). As suggested above in a consideration of the development of behavior in the fetal cat, the change of body posture in space has been shown sometimes to involve various combinations of nonauditory labyrinthine, kinesthetic, and exteroceptive stimuli. In the fetus it is peculiarly difficult to isolate the part played by the body exteroceptors and muscle proprioceptors from the part played by the receptors in the nonauditory labyrinth. It should be noted that there is some evidence also that in certain types there is an auditory function subsumed by receptors in this *non*-auditory receptor complex.

Historically, comparatively little reference has been made to the static senses in connection with fetal mental life as this life was considered in the older speculative child psychology Some reference, however, has been made to the part played by these receptors in determining the position of the fetus in relation to gravity Lane (1917) has noted in his study of the development of the senses in the fetal rat considered above that there is an apparent correlation between the histological development of the semicircular canals and the acquisition of postural righting responses on the part of the fetus. In Lane's work, however, no effort to differentiate between proprioceptive and static stimuli is reported.

The development of the labyrinth has been considered by many writers, including Streeter (1906) and Larsell (1929). (Cf. also Bowen, 1932, and McCrady, Wever, and Bray, 1937.) Minkowski (1922, p. 753), as noted above, has demonstrated from neurological studies that the labyrinth is fully differentiated in a human fetus of 40 mm. As noted above also, Windle and Griffin (1931) report that in very early cat embryos of 26 or 27 days ". . . rotation of head and trunk appeared to be indefinitely coordinated with the older components, namely, lateral and ventral head and trunk flexion. This activity resulted in motions that strikingly resembled the righting reflexes seen in late fetal life" (p. 156). Windle and Fish (1932, p. 95)

show that in cat fetuses several days before normal birth true labyrinthine reflexes do appear. These reactions make possible what has been called the first "purposeful" movement of the cat, that is, successful locomotion (Windle and Griffin, 1931, p. 171). This complex behavior act, as already suggested, is held to be a combination of equilibration, body-righting responses, general postural tonus, and rhythmic movement of the limbs.

Coronios and Carmichael have both noticed that, in late cat and guinea pig fetuses, turning the animal over while it is completely immersed in the warm bath does not always lead to righting movements. If the cord is ligated and the same fetus is placed on its side on the experimental table, righting may begin at once. This is possibly to be interpreted as indicating that at this period righting still, at any rate, involves exteroceptive and proprioceptive as well as vestibular functions.

Similarly, Coronios and Carmichael have both been able to elicit typical Magnus reflexes of limb extension as the fetal mammal's neck is turned to the right or the left. These responses are strikingly similar to those of decerebrate mammals and tend to confirm the observation agreed upon by all other investigators that for the most part the young fetus is not under the active control of the cerebral hemispheres. Minkowski (1922, p. 724) reports labyrinthine reflexes in early human fetuses. He suggests that it is not only possible to elicit responses from general labyrinthine stimulation but also possible to distinguish between the reflexes attributed by Magnus and his colleagues to the utriculus-sacculus complex of receptors as contrasted with those attributed to the complex of semicircular-canal receptors. His analysis leads him to believe that most of the fetal responses to nonauditory labyrinthine stimulation are the result of semicircular-canal receptor action.

Minkowski (1922, p. 753) states further that in his opinion the early anatomical development and functional use of the vestibular apparatus in the fetus are probably related to the fact that the fetus is living in a fluid medium the specific gravity of which is almost equal to its own specific gravity. Therefore it is almost "weightless," a condition in which he believes the labyrinthine reflexes may be seen to operate to excellent advantage (p. 753). Minkowski (1928*a*, pp. 565–568) is careful, however, not to disregard the possibility that the phenomena noted as the basis for attributing labyrinthine function to the fetus may be the result of the stimulation of proprioceptors in the neck and related receptors. Magnus (1924, p. 113), in reviewing this work, seems to emphasize the part of the tonic neck reflexes in such activities.

There is some reason to believe that the first eye movements of the fetus are in response to changes of the bodily position of the fetus in space; that is, the first eye movements are occasioned not by retinal stimulation but as part of the general tonus changes of the body brought about by gross movements in space. This fact is brought out very clearly in Kuo's work (1932*a*, p 426). Early eye muscle movements, indeed, may be thought of as specific. These movements take place, however, at the same time that other responses are active and hence may be called part of the "generalized" pattern of responses. Later specific responses are observed which can then be said to differentiate themselves out of the more complex pattern (Minkowski, 1924, p. 253; 1928*a*, p. 568; Tracy, 1926, p. 283).

There is no reason to believe, however, that these early "postural" responses of the eye muscles are as definitely related to spe-

cific aspects of semicircular-canal stimulation as they are in the adult condition so well summarized by Maxwell (1923), Favill (1929), and Holsopple (1929).

Eye movements in adult life that are determined by vestibular function may be modified in various ways (Dodge, 1923). Wellman and Carmichael have made preliminary and as yet unpublished studies of the origin and development of eye movements in the fetal guinea pig. Although these results are still tentative, the following statements may be made, based upon the electrical recording of eye movements in living fetuses: (1) Vestibular stimulation brings about responses before light stimulation is effective in causing eye movements. (2) Optokinetic (that is, light-induced) responses can be called out in the fetal guinea pig which have some of the same characteristics as such responses in older animals. In these experiments a moving field of bars of light and shade gradients is passed near the eyes of the fetus. The resulting reactions show the slow and fast photic responses typical of such stimuli in adult animals.

In conclusion, then, it is difficult to say with assurance the exact part which the labyrinthine senses play in determining behavior before birth, but it is certain that the tonus adjustments of the body muscles in postural responses, including precise adjustments of eye muscles, are among significant prenatal activities. An understanding of these responses in fetal and adult life is important (Magnus, 1925). One of the points, however, at which a knowledge of the development of proprioceptive responses in the fetus is most important is the evaluation of the studies of postnatal life in which the alleged saltatory character of certain responses there noted is observed in the light of the knowledge of prenatal postural responses. Popularly speaking, the postural actions of the fetus may be considered a fundamental preparation for a diversity of actions in postnatal life. Walking and localizing responses of arms, trunk, and legs can take place only in an organism in which postural mechanisms are developed. It is almost as if these senses provide the essential "gyro-control" necessary before a reaction can be made, just as gyro-apparatus on a warship is necessary if the guns are to be pointed effectively in a heavy sea. In considering the part played by incoming nerve impulses which themselves result from motor reactions one should consider the whole nature of "feed-back" systems in biology as related to similar electronic systems (Wiener, 1948).

The organic senses

Historically there has been some speculation in regard to the organic senses in the fetus. Some have held that the fetus lives in a perfect world in which hunger, thirst, and all other needs are cared for before they arise (Bichat, 1827, p. 133). Locke (1849 edition), on the contrary, held at an early period in the total story of speculation about fetal life that the unborn child has "perhaps some faint ideas of hunger and thirst." Kussmaul (1859, p. 31) agrees with this view. As noted above, Yanase (1907*a*, 1907*b*) has studied the movement of the fetal intestines. In the rhythmic nature of these movements is found a basis for possible organic experience and, indeed, for the indirect activation of the skeletal musculature.

The work of Patterson (1914) and Carlson and Ginsburg (1915) on newborn infants and on dogs delivered before normal time indicates something of the nature of the tonus changes of the stomach which may occur in late fetal life. These changes in these organisms are found under appropriate conditions to be rapid and active. This coincides with the observations of

Preyer (1893, pp. 152–158) and of Peterson and Rainey (1910, p. 121) on the hunger of newborn full-term or even premature infants. Some suggestion of the developmental course of hunger activities and stimulation may be obtained from an observation of Hess (1922, pp. 177–180) that very early premature fetuses are much less able than later premature infants to show the usual signs of needing to be fed. Jensen (1932, pp. 368–375) notes the dependence in the infant of the reflex of sucking, a reflex incidentally too often considered merely tactual, on the concomitance of hunger stimuli and tactual stimuli. Preyer (1893, p. 153) notes the whole sequence of bodily changes, even including those of the eye muscles, which come to be related to the hunger activities of the newborn child.

The theory of "drive" or motivation held by some modern comparative psychologists, which correlates such activities to some extent with organic stimulation, finds support in the observations of the "random" activity of the fetus which is shown by Irwin (1930) and others to accompany hunger stimuli. As noted above, this activity may not be "random" in the ordinary sense of the word but rather the consecutive or concomitant release of a series of already described patterns of behavior. (See Carmichael, 1941.)

This concept of "drive" is closely related to phenomena considered by certain of the older descriptive psychologists as characterizing the motivating power of the affective processes. That is, "drive" is related to the bodily basis of pleasantness and unpleasantness. Thus Preyer (1882, pp. 140–176; 1885, pp. 486–487) and others have discussed reaction related to pleasantness and unpleasantness as apparent before birth or immediately after birth. These conclusions are inferences based on unaided observation of facial expression and on instrumentally recorded bodily changes, such as breathing and directly measured cerebral volume (Canestrini, 1913). Facial expression is reported by Minkowski as beginning in the relatively early weeks of active fetal life, and so it seems that this expressive pattern of so much significance in pleasant and unpleasant situations of later life has had ample opportunity for exercise during the prenatal period.

It may be noted in passing that the rate of fetal heart beat can be modified by external stimulation, thus possibly leading to vascular stimuli of the sort often considered to fall under the heading of "organic experience." The possibility of respiratory experiences, or "feelings of suffocation," is certainly present, so far as may be judged from a knowledge of stimulation and response. But there is, of course, no evidence that any introspective state actually follows such stimulation.

In conclusion, it may be said that there are possibly certain organic changes in the stomach, intestines, heart, and vascular and respiratory systems which occur before birth which may be important in receptor stimulation. It is possible that the stimulation of these receptor systems may lead to fetal activity which does not, of course, have any specific external end in view until, as a result of external stimulation and learning, such stimulation in postnatal life comes to initiate adaptive responses which some wish to characterize as "end-seeking." It may also be noted that no one who has worked with fetal material has failed to see that, after repeated responses, "fatigue" sets in, and for a time stimulation is difficult or impossible (Peiper, 1925).

The question whether fetal quiescence is to be considered as fetal sleep has also been debated (Preyer, 1885, p. 488).

Taste. The histological work on the development of the taste mechanism in the embryo is summarized by Keibel and Mall (1910). Taste buds are said by Parker

(1922) to begin to appear in man during the third fetal month. The taste receptors are also found to be much more widely distributed in fetal life than in adult life. Parker thus points out that there is evidence of a real retraction of the sensory field in man from the late fetal period to the adult state. At first, taste buds are found on the tonsils, hard palate, and parts of the esophagus. Later, functional taste cells are almost always limited to the tongue (1922, p. 110). Here is a striking example of a "reflexogenous" or receptor zone which changes as a function of developmental time.

Historically, there have been several different speculative opinions concerning this sense in prenatal life. The early opinions are summarized by Bichat (1827, p. 136). It is undoubtedly true that the amniotic fluid might serve as a taste stimulus As change is ordinarily thought of as essential to real external stimulation, however, the question may be debated as to whether or not the change in the amniotic fluid as pregnancy progresses is enough to make it at any point a taste stimulus (Feldman, 1920, p. 139). To the writer this seems unlikely. A safe conclusion seems to be that, although the mechanism for taste is present before birth, there is no adequate stimulation of this sense until after birth. Here again we have an illustration of what the present writer has called the law of *anticipatory morphological maturation.*

Experiments on the sense of taste in newborn children have been carried out by Kussmaul (1859, pp. 16–21), Genzmer (1882, p. 15), and Peterson and Rainey (1910, p. 120), using the method of general observation of facial expression after stimulation. The conclusion of these writers is that sweet is distinguished, even by premature infants, from salt, sour, and bitter. It is difficult to be sure, however, that salt, sour, and bitter are stimuli for behavior that is specific. Canestrini (1913) and Jensen (1932) have worked out a method of experimentally recording bodily changes which result from taste. Pratt, Nelson, and Sun (1930) find that under the conditions of their experiment, involving very dilute concentrations, there is not as strong evidence in regard to taste differentiation at birth as had previously been supposed. These later experimenters conclude that the stimulating efficiency of various sapid substances in early life is not only quantitatively but also qualitatively different from the condition in adult life (p. 124). (See Pfaffman, 1936, in this connection.)

In conclusion, it may be said that the receptors for taste are probably never normally activated before birth. The receptor-neuromuscular mechanism, however, has been shown, by work on premature infants, to be ready to function in late fetal life whenever appropriate stimulating conditions are brought to bear upon it. Most experimenters seem to conclude that sweet stands in a class by itself so far as the infant is concerned. Salt, sour, and bitter are apparently distinguishable with greater difficulty. References to the sense of taste in infrahuman fetuses have been given above.

Smell. Bedford and Disse and others quoted by Parker (1922, pp. 23–41) have considered the embryonic development of the receptor cells of the nervous fibers of the olfactory epithelium. Lane (1917, pp. 51–52), as noted above, has studied the development of the olfactory structures in the rat. Feldman (1920, p. 237) points out that the olfactory and tactual parts of the brain were found by Flechsig to be the earliest to be myelinated in the fetus. Historically, save where taste and smell have been grouped together, there seems to have been general agreement, in the early period at least, that while the nasal cavity is filled with the amniotic liquid there can

be no *adequate* olfactory stimulation. Preyer (1885, p. 478) specifically defends this conclusion, basing his statement on Weber's assertion (1847) that substances that could be smelled when vaporized were quite unable to arouse the sense of smell when introduced into the nose as liquids.

A great deal of relevant work in this field has been critically summarized by Parker (1922). This work shows that there is excellent reason to believe "that the olfactory organs of an air-inhabiting vertebrate can be stimulated by ordinary solutions, though this form of stimulation cannot be looked upon as normal" (p. 59). Even though this is true, however, the same difficulty as that met with in the sense of taste must be remembered to exist. Even though the amniotic fluid may be an effective inadequate stimulus for the olfactory receptors, there is little reason to suppose that there would be sufficient change in the liquid to effect significant stimulation during prenatal life.

In this sense field, therefore, the study of smell reactions of prematurely delivered infants will again be very significant in any determination of how the functional development of the olfactory mechanism progresses during late fetal life. Kussmaul (1859, p. 23) found that asafetida and certain other odors, but not irritating substances, led to responses in a 1-month premature infant. He is not sure that he was able to secure responses in earlier premature infants. Peterson and Rainey (1910, p. 121) also found smell reactions in premature infants.

Historically, there has long been a belief that the newborn child could distinguish odors effectively. Feldman (1920, p. 237) asserts that the Jewish sages in the time of the Talmud believed that a blind baby could tell his mother's milk by smell and taste. Rousseau also commented on the sense of smell in newborn infants (Feldman, 1920, p. 237). Preyer (1882, p. 134) reports that an 18-day infant refused a breast nipple on which kerosene had been placed but eagerly took the other odorless breast immediately after the refusal. Preyer (1882, p. 134) also demonstrated that newborn guinea pigs apparently select their food by the sense of smell. He asserted, moreover, that in young animals, including man, the sense of smell in general is most important in determining behavior. Indeed, in infrahuman animals it is suggested that this significant aspect of behavior determination by smell does not come to be neglected to the extent that it is by civilized man.

Experimental work on the sense of smell in newborn infants, which is probably also in general applicable to late premature infants, has been summarized by Canestrini (1913, pp. 86–87), Peiper (1928, p. 27), and Pratt, Nelson, and Sun (1930, p. 143). Canestrini concludes that there has been some exaggeration in regard to the effectiveness of the sense of smell in young animals. He feels that most of the work on smell has been concerned with stimuli which act on the receptors related to the trigeminal cranial nerve components of the nasal receptor surfaces. These trigeminal components are probably best considered as the "common chemical sense" (Parker, 1922, pp. 103 ff.) and not in the usual sense of the term "tactual" as suggested by Pratt, Nelson, and Sun (1930, p. 127). Certainly the trigeminal endings are not "olfactory" in the ordinary sense. Stimulation of the common chemical sense receptors typically sets off violent reactions, such as sneezing. A characteristic irritant of this sort is ammonia. It is significant in this connection to notice that Pratt, Nelson, and Sun found ammonia to be a peculiarly effective "smell" stimulus. Probably the responses of a newborn infant to ammonia should be considered as responses to the common chemical

sense rather than to true olfactory stimulation.

In summary: The neural mechanism for olfaction—that is, the mechanism related to the so-called first cranial nerve—is developed before birth, and the possibility of inadequate stimulation exists before birth. It is probably true, however, that olfaction does not generally occur in its normal form until the nasal cavity comes to be filled with air. Premature infants, at least in the last month, are able to smell substances when air enters the olfactory cavity. Much work on smell, however, has probably been vitiated by the fact that the free nerve endings of the trigeminal nerve (the fifth cranial nerve), the receptors for the common chemical sense, have been stimulated rather than the true olfactory spindles.

Hearing. Anatomically the development of the ear in the individual has been extensively studied. This work is summarized by Keibel and Mall (1910, pp. 264–290). Hess (1922, p. 76) shows an original drawing of a section through the ear of a late fetus. Stevens and Davis (1938) have summarized much of the experimental work upon the adult auditory mechanism.

Historical opinion on the sense of hearing in the human fetus is probably best summarized in the words of Kussmaul (1859, p. 27): "Von allen Sinnen schlummert das Gehor am tiefsten." The history of experiment on the sound response of full-term and prematurely born infants is excellently summarized by Pratt, Nelson, and Sun (1930, pp. 78–85). The general conclusion of these authors is in harmony with that of the later investigators, that hearing becomes effective only in the very early part of postnatal life.

Most of the early investigators of the development of audition concluded that the auditory mechanism was developed to a point at which it could be functional before birth but that the infant remained deaf until by breathing, crying, and possibly yawning the Eustachian tube was opened. Only in this way, they suggested, could the somewhat gelatinous liquid of the fetal middle ear be drained out (Preyer, 1882, pp. 72–96). Peterson and Rainey (1910, p. 118) specifically secured evidence of auditory response in a prematurely delivered infant as soon as there had been an opportunity for the draining of the middle ear. More modern work seems to have offered no reason to differ with this conclusion so far as stimuli of normal intensity are concerned. Preyer (1882, p. 92) also reports that newborn guinea pigs are deaf for ½ hour after birth and are then sensitive to tonal stimuli of a great variety of frequencies (C of third octave to E of eighth). Avery (1928, p. 265) has secured comparable results on late guinea pig fetuses prematurely delivered, as noted above. The experiment of Rawdon-Smith, Carmichael, and Wellman (1938), which shows by electrical methods of recording the onset of functional activity in the cochlea, has already been referred to. This experiment shows that the guinea pig fetus can hear before birth, judging by both electrical and behavioral criteria.

Although there has been some speculation on the fact that the sounds inside the mother's body might act as sound stimuli to the fetus, little evidence has been brought forward to make this seem certain (Preyer, 1885, p. 480). There are experimental findings which suggest that loud auditory stimuli may activate the human fetus. Peiper (1925, p. 237) was led to this study because he noted that in six neonates, very soon after birth, changes in the breathing curve were found in response to a special sound stimulus. The change in the breathing curve is reported as marked. He therefore decided to try to find out whether or not any indication of hearing before birth could

be secured. It had been discovered that auditory and other sudden stimuli give two sorts of responses in the newborn—one, a change in breathing rhythm, and the second, a change in the level of general movements. Peiper felt that there was no sure reason to believe that the unborn child would respond differently if it could be stimulated in its auditory receptors. The breathing center in the brain is open to stimulation before birth. He therefore thought of the possibility of using the prenatal "breathing movements" of Ahlfeld as an indicator of sound response. The disadvantage was found, however, that these movements were not always present, and so the number of subjects was limited. But with proper recording apparatus he was able to take records of the general movement of the fetus through the body wall of the mother.

It was obvious that sounds would be much muffled on their way to the fetus. Therefore a very loud sound was chosen as a stimulus, an automobile horn being used. The experimenter waited until the fetus was absolutely quiet and the mother had been prepared so that she would not herself respond to the stimulus. Incidentally, it proved impossible to train all mothers in this way. The stimulus was given in a quiescent interval. In more than a third of the subjects studied, definite fetal reactions were secured to stimulation of this sort. There were, however, individual differences in responsiveness. Sometimes the response was given on one day and not on the next. The movements which the fetus made in response to the stimuli also showed individual differences. Most often, however, the fetus seemed to draw its whole body together. Peiper (1925) comments that it might seem to one who had not been present at the experiments that the movement was a response of the mother and not of the fetus. He is certain, however, that one who had actually observed the experiment would be convinced that the response was fetal and not maternal. As an additional safeguard, a pneumograph was placed on the mother's chest and her breathing curve taken during the experiment. After a good deal of practice it was possible to train some mothers so that they made practically no response, and thus the fetal response could be recorded. Continued stimulation led to a diminution of the effect. This corresponds to a frequently observed phenomenon of fetuses and neonates, namely, that their responses are easily fatigued or exhausted. Peiper even goes so far as to suggest that this change in response may be thought of as a simple kind of attention. He also states that one mother remarked that she had noticed definite movements of the fetus while attending a concert.

Forbes and Forbes (1927, pp. 353–355) have reported a case of apparent fetal hearing. Thirty-one days before her baby was born a pregnant woman was lying in a metal bathtub full of warm water. A 2-year-old child was playing on the floor beside the tub. Accidentally the child struck the side of the tub with a small glass jar, and at once a sudden jump of the fetus was felt by the mother, which gave a sensation quite unlike the usual kicks or limb movements. A few days later an observer struck the side of the tub below the water line a quick rap with a small metallic object, meanwhile watching the mother's abdomen. A fraction of a second after the rap, a single quick rise of the anterior abdominal wall was clearly visible. The mother at this moment felt the same jump inside her abdomen as previously reported. Her own muscles were entirely relaxed, and she was not at all startled by the noise, nor was she conscious of perceiving any vibration through the skin. The mother's tactual sense later

tested showed that the same intensity of vibration could be perceived only by those portions of the skin coming in contact with the tub. In the infant in question, 8 days after birth, it is interesting to note that while the baby was nursing an auditory stimulus occurred which resulted in the flattening of the baby's ear against the side of the head for a few seconds, after which the ear relaxed again. These same investigators also report another case in which concerts attended toward the end of pregnancy resulted in troublesome activity on the part of the fetus. The conclusion of these writers (1927, p. 355) is:

> Good evidence exists that the human fetus 4 or 5 weeks before birth can respond with sudden movements to a loud sound originating outside the body of the mother. It seems probable that this is a true auditory-muscular reflex but the possibility of reception through tactile organs in the skin cannot be excluded.

The response of the fetus to auditory stimulation has been made the basis of several studies of fetal learning, to which reference is made below.

In summary: It may be said that the auditory mechanism seems to be well developed structurally during later fetal life, but in general, possibly because of the closure of the external ear or because of the gelatinous liquid which fills the middle ear, the fetus is probably deaf to sounds of normal intensity before birth and during a short period immediately after birth. Strong sounds, however, especially those which can directly pass through the mechanical blocks noted, seem to be able to bring about auditory stimulation before birth, although it is still possible that such responses are tactual rather than truly auditory.

Vision. The specific morphological cellular changes which are the essential antecedents to the development of the function of the human eye begin in the second or third week of development of the embryonic period, and from that time on an elaborate series of events occurs until, in the normal human individual, binocular convergence and the diverse activities associated with visual space perception and stereoperception develop in the young child. The anatomical aspects of this growth have been summarized by Keibel and Mall (1910, pp. 218–258) and by Mann (1928). Hess (1922, p. 75) has described in some detail the eye of an early premature infant.

So far as the function of sight in normal prenatal life is concerned, there has been general agreement that the absence of radiation of the sort that typically activates the retina makes true sight all but impossible in prenatal life (Preyer, 1885, p. 483). The possibility does exist that under very strong light stimulation, if the head were in just the right place, radiation falling on the mother's abdomen might stimulate the fetal retina, but this seems most unlikely. There is evidence, however, given by Kussmaul (1859, p. 26) that pronounced differences between light and dark bring about specific reactions in an infant born 2 months before term. Peterson and Rainey (1910, p. 118) also found light reactions in premature infants. Genzmer (1882, p. 21) does not confirm this observation. Preyer (1885, p. 485) agrees that adequate stimuli are impossible during fetal life, but he considers the possibility that inadequate stimuli of pressure similar to the stimuli which bring about phosphenes might be effective in prenatal life.

There is evidence that even at normal birth the optic nerve and related structures have not fully developed anatomically (Pratt, Nelson, and Sun, 1930, pp. 44–51). This knowledge has led to speculation in regard to the neural basis of the develop-

ment of eye muscle function in neonatal life. This whole question has been considered by Preyer (1882, p. 71) in relation to the nativistic and empiristic theories of the visual spatial world, with the conclusion that the evidence is conflicting.

The writer has taken a few records of the eye movements of human babies, using the electrical recording method. These movements were induced by placing the baby's head in a large rotating drum on which there were striations. The results of these experiments showed that it was possible to elicit optokinetic nystagmus in early infants. This technique may also be used as an objective means of determining lower brightness and color vision thresholds in normal or premature newborn infants. For a description of this technique especially as applied to recording of eye wink and eyeball movements see Carmichael and Dearborn (1947).

One of the best indices of the sensitivity of the fetus to light, although possibly not to the full neural mechanism involved in true visual responses, is thought to be the onset of the light-stimulated pupillary reflex. Portal (1818) alleged that responses of the iris diaphragm did not appear during fetal life. Hess (1922, p. 75) and others, however, have shown that in premature infants strong light stimulus leads to contraction of the pupil, followed in 2 or 3 seconds by dilation again. Bolaffio and Artom (1924, p. 476) and Minkowski (1928*a*, p. 558), as noted above, have been unable to make unequivocal statements about light reflexes in late fetuses. As pointed out in another part of this chapter, care must be exercised, especially when strong light is used, not to confuse the independent non-neurally determined muscular response of the iris to light with the true iris reflex. The development of the pupillary response in postnatal life has been summarized by Peiper (1928, pp. 11–13).

Much of the evidence in regard to the general muscular movements of the eyes in the first days of life has been summarized by Pratt, Nelson, and Sun (1930, pp. 44 ff.). Early eye movements have been carefully studied in the newborn child by Sherman and Sherman (1925). As already noted above, however, there is excellent evidence to show that during fetal life eye movements occur as part of the general tonus change of the body musculature resulting from the spatial reorientation of the entire fetal body. (See Carmichael, 1940*b*.) Preyer (1882) and many students since his time have discussed the development of function in the auxiliary musculature of the eye, including the mechanism of winking. In general, great differences are noted in the tonus and general behavior of the lids in the newborn child as contrasted with those of the older child. Some hints of the beginning of this development are to be found in the reports on fetal development given by Minkowski. In a fetus of only 160 mm. he found that touching the closed eyelid led to a contraction of the orbicularis muscle (1922, p. 723).

So far as infrahuman organisms are concerned, there is the greatest divergence from type to type in respect to the time of the opening of the eyes. The subject was early investigated, Emmert, one of the first students of fetal mammals, having studied this phenomenon in the mouse (Emmert and Burgätzy, 1818). Certainly no generalizations can be made from form to form in regard to eyelid activities at the time of birth. The guinea pig is born with eyes open and apparently in an adult functional condition, whereas the lids of the rat do not gain their adult condition until the sixteenth or seventeenth postnatal day (Lane, 1917, p. 69). Warkentin and Smith (1937) and Warkentin (1938) have studied the development of a number of visual functions by various techniques in developing ani-

mals. (See also Mowrer, 1936, for a general consideration of learning versus maturation in this field.)

In conclusion: Concerning vision in the fetus it can be said that the specific morphological changes that lie behind the development of the visual mechanism occur from possibly the second week after fertilization until well after birth. Light stimuli at intense levels ordinarily do not affect the retina before birth, but in premature infants it can be shown that the eye is probably sufficiently structurally developed before birth to make possible the light or iris reflex and the differentiation between light and dark. The functional development of the neuromuscular apparatus of the eye is also gradual. Indications have been obtained in regard to the relationship between vestibular stimulation and eye movements before birth which suggest that vestibular control is more primitive than visual control. Eyelid reactions are also found to undergo a progressive series of changes before normal birth.

The Senses in General Relationship to the Onset of Mental Life in the Prenatal Period

For the psychologist there are at least two major problems connected with the study of the senses. The first of these is the classic problem of the relationship between the senses and what the philosophers have long called conscious experience. The second is the relationship between receptor activity and the initiation, modification, and control of behavior. As noted above, this control must be considered in certain cases to include a continuous "feed-back" relationship with existing continuous or periodic activity (Wiener, 1948). Many psychologists, on the basis of some excellent reasons, hold that ultimately these two problems reduce to one, as Langfeld (1931) and others have urged in the interpretation of consciousness in terms of response. Historically, however, and indeed at the present time, the two problems are ordinarily treated as separate, or at any rate as separable. Some prefer to say that consciousness and behavior are aspects of the total functional description of the relationship between the adult (or immature) human organism and its environment. Here, although no attempt will be made to find an ultimate answer to the question whether these problems are really one or two, they will be treated as independent.

A study of the fetal senses contributes little to our knowledge of the so-called introspective psychology of consciousness. There has been some speculation concerning sensory experience before birth, but little of scientific validity has been written. As incidentally noted above, several of the empiristic philosophers concerned themselves with prenatal life. John Locke (1849 edition) did not neglect the possibility that some dim ideas were present before birth. Cabanis (Genzmer, 1882) held that quite elaborate sensory experiences were present in the fetus, even to the consciousness of self. (Cf. Compayré, 1896, p. 40.) Kussmaul (1859, p. 36) held that the child came into the world with a dim perception of an outer world. Preyer (1882, p. 177) also attributed experience of a sort to the fetus. Peterson and Rainey (1910, p. 121) say, "The newborn comes into the world with a small store of experience and associated feelings and a shadowy consciousness."

Such observations could be added to by other excerpts from early psychologists, but on the whole they seem profitless. Compayré (1896, p. 44), more than fifty years ago, summarized the scientific arguments against such speculations as well as against the fancies of the Neo-Platonists that "our birth is but a sleep and a forgetting." The

gist of his argument is that there can be no evidence on the matter. With this point of view the writer is in accord.

James (1890) and, more recently, Koffka (1924) and his associates made much of the fact that in early postnatal life specific experiences, like specific acts of behavior, become individuated out of totalities rather than at first synthesized out of discrete elements. Thus James (1890, Vol. I, p. 488) says: "The baby, assailed by eyes, ears, nose, skin, and entrails at once, feels it all as one great blooming, buzzing confusion." And again (p. 487): "Our original sensible totals are, on the one hand, subdivided by discriminative attention, and, on the other, united with other totals." Koffka (1924, p. 131) similarly asserts: "From an unlimited and ill-defined background there has arisen a limited and somewhat definite phenomenon, a quality." Certainly if these descriptions are adequate to the experiential life of the neonate, there is no reason to suppose that they may not also be adequate, although possibly in a still vaguer form, to conscious fetal life. If the writer were asked to make a guess in regard to the matter, he would say that he feels that the description given above by Koffka is probably relatively adequate as a description of the development of fetal conscious experience. It may be pointed out that such experience may parallel reactions to many different and quite specific types of receptor stimuli.

It must be noted, however, that so far as the writer is able to determine, there is no way to prove or disprove the general surmise about "fetal experience" given above. Consciousness of a particular sort must in such cases be assumed from the external observation of the structure and function of an organism in a particular setting. The fetus is of course quite unable itself to give linguistic introspective reports. The general method of introspection as a scientific tool has been severely criticized in the years since the 1920's, and certainly, if the general method is open to objection, the so-called method of indirect introspection is even more vulnerable. But it is only the latter method which may be used in fetal life. As Washburn (1926), one of the ablest exponents of the use of indirect introspection in animal psychology, has said:

> We know not where consciousness begins in the animal world. We know where it surely resides—in ourselves; we know where it exists beyond a reasonable doubt —in those animals of structure resembling ourselves which rapidly adapt themselves to the lessons of experience. Beyond this point, for all we know, it may exist in simpler and simpler forms until we reach the very lowest of living beings [p. 33].

So far as the present writer is concerned, there is no objection to applying to ontogeny, that is, growth in the individual, a point of view similar to that expressed above in regard to the growth of consciousness in the development of the animal series. Such judgments must be treated as complex inferences, however, and not as facts of observation. The writer further points out that a scientific definition of the word "consciousness" as commonly used has not yet been presented in a form to win general acceptance.

The second large problem which concerns the psychologist in relation to receptor activity has grown out of the approach to the study of mental life which deals explicitly with the processes of behavior. The problem of the receptor or, possibly better, of stimulus control of behavior is, however, much older than the so-called school of behaviorism. Kussmaul (1859, p. 6) explicitly defended this view in undertaking his study of premature and normal newborn infants. It is related to a much more general position, as is the view ex-

pressed by Forel and quoted by Canestrini (1913, p. 100): "Das wahre Baumateriel der Organismen liefern die Reize der Aussenwelt."

It seems more and more certain that, whatever else scientific psychology may do, it must concern itself increasingly with the relationship between the environment external to the receptors, be they extroceptors, interoceptors, or proprioceptors, and to the responses of the organism to such stimulation. In any consideration of fetal psychology, therefore, especial attention should be given to the facts of the stimulus control of behavior. In order to understand this relationship, it will be necessary to review the current status of fact and theory in regard to the causes underlying the beginning and differentiation of activity in the fetal organism. This consideration may well serve as a conclusion to this chapter, because any such discussion will necessarily involve a review of many of those processes of fetal life which are even inferentially significant for general psychology. For an excellent consideration of this general field see Hooker (1942).

In the beginning of this chapter, something was said of the early processes of morphogenesis in the developing organism. It was suggested that the point should be kept continually in view by one who is interested in behavioral development, that the general growth of structure and function always occurs in an organism that is in an environment. Organisms do not live or grow in a physical or biological vacuum. From the first cell division in the developing individual, each process of structural and functional modification is, moreover, to be considered as a complex resultant of activities. Some of these determinants are intrinsic in the cell and are, indeed, in the correct sense of the term hereditary, but such intrinsic determinants always act in a dynamic system which is also subjected to extrinsic influences. Development is apparently always a resultant of these two sets of forces working *interdependently*. For some of the evidence on this matter, see earlier papers by Carmichael (1925, 1938). Sharp (1926) summarizes this point of view when he says in his consideration of general cytology:

> The cell should not be thought of as a static . . . structure. It is rather a dynamic system in a constantly changing state of molecular flux, its constitution at any given moment being dependent upon antecedent states and upon environmental conditions [p. 58].

If space permitted a review of the present status of that part of scientific embryology which is devoted to developmental mechanics, it would become apparent that the process of growth in the organism involves a most complex series of energy relationships, some of which, it seems probable, have as yet only begun to be unraveled. It is certainly true, however, that, at least since the work in the latter part of the last century by Roux (1896), the older static view of development based on the study of dead histological material has gradually given way to the modern notion of an *Entwicklungsmechanik*. For an evaluation of this change, consult Morgan (1927) and Holt (1931, pp. 8–23). As suggested above in regard to the cell, this study has shown that the process of development in one sense, at any rate, must apparently be considered a dynamic organization of a system of energies. This view of the development of an active organism makes it apparent that growth is not to be thought of as a mere unfolding of preformed materials, but rather as the construction of a new pattern of organized systems and subsystems in protoplasm. Each such system is to be understood only in its particular environment. As Durken

(1929, pp. 109–113) has well said: "Die Entwicklung ist keine einfache Entfaltung, sondern eine wirkliche Neubildung." And again: "Kurz gesagt, ist daher an der Allgemeingültigkeit des epigenetischen Charakters des Entwicklungsprozesses nicht zu zweifeln." See also Howells (1945).

Many similar statements, and the elaborate evidence upon which they are based, could be found in the rich experimental work of the modern students of developmental mechanics. In such a view, however, it is of course possible, starting with the energy relationships between the organism and its environment, to go beyond the established facts. Whether or not this has been done by Child is difficult for the writer to judge. The following quotation from that student of the physiological development of the nervous system, however, indicates that it is possible for an experimental biologist to consider the external energy relationships of the organism as of the greatest significance in determining development. Child (1921) makes this very definite when he says:

> The organism represents an order and unity in protoplasm which is related at every point to the external world. The development and evolution of organismic integration are essentially the evolution of mechanisms and methods of response and adjustment to environmental conditions [p. 7].

This investigator has developed, on the basis of much experimental work, a concept of various sorts of gradients in the living and developing organism. In certain respects these gradients may in the last analysis be thought of as energy relationships, which are embryologically often precursors of definite organ systems. In so far as the nervous system is concerned, he says:

> . . . the reflex strictly speaking is a specialized behavior pattern depending on the presence of certain morphological mechanisms; but it is physiologically a development from the primary organismic behavior mechanism, the excitation gradient [1924, p. 235].

It may well be, of course, that the relationships between the series of events occurring in the organism and the series of events occurring outside the organism are more elaborate than would be suggested by a relationship "at every point"; that is, that some such view as the "organizer" of Spemann (1927) may supplement the simple intrinsic-extrinsic relationship by what may be essentially a chemical process or other process occurring in time and intrinsic in the organism. Whatever the details of this development may be, however, it seems relatively sure, as the work of many investigators seems to demonstrate, that there is, antecedent to the possibility of functional action in the differentiated nervous system, an elaborate series of processes in the organism some of which involve what are, to the elements of the system, environmental forces. A hypothesis concerning the relationship between a primitive gradient of activity and the beginning and development of true nervous structures and functions has been made especially clear by Coghill (1929*a*, pp. 39–78). This point of view emphasizes, as Burnham (1917) has well pointed out, that environmental stimulation which is basic in an understanding of adult psychological phenomena is itself in certain respects, at any rate, significant in determining the mechanisms which make such adult responses possible.

In this connection the work of Kappers (1917) and Bok (1917) on the functional activity of neuroblasts in the development of the elements and the relationships of the central nervous system may be mentioned. The theory of neurobiotaxis developed by these writers, which suggests that

the growth and arrangements of the nervous components are tropistically determined responses of the elements of the nervous system, has proved to be one of the valuable hypotheses in describing the experimental embryology of the nervous system. The contributions of Ingvar (1920) and others to this point of view are summarized by Child (1921, 1924) and Herrick (1924, pp. 111–112). The brilliant work of Detwiler (1920, 1921, 1922, 1923*a*, 1923*b*) and other experimental embryologists on the morphology and energetics of neural development also presents specific evidence on the relationship between external and intrinsic factors in the development of the functional nervous system. (See Sperry, 1951.) For a whole picture of cell activity in the living organism, the reader should consult Gerard (1940).

There seems, therefore, to be excellent evidence for the view elsewhere discussed by the writer (1925) at greater length that, from the moment that growth has begun in the fertilized ovum until senescence or death, development consists in the alteration of existing structures and functions in an organism living in a continually changing environment. It cannot be overemphasized that there is both an external and an internal environment. As elsewhere noted in this chapter, the alterations which take place in the chemistry of the blood stream which supplies the central nervous system are fundamental in altering the way in which this system responds to the afferent neural impulses which come in from its receptors.

In the question of behavior change, it is not possible save for pragmatic reasons to say at any point that growth has stopped and learning has begun, but that the environment plays a part in all "maturation," and maturation plays a part in all learning. The course of this development, however, is apparently almost infinitely complex. It cannot be summarized by any catchword phrase. It does seem, however, that the suggestion made in the introduction to this chapter that even the first receptor-neuromuscular response of the organism is not to be considered in all respects a novel event follows directly from the knowledge that the organism develops in relation to an environment of energies. The processes which have gone on in the organism in order that the first response can occur apparently themselves involve elaborate stimulus-response relationships in narrower environments. Thorndike (1931) has picturesquely said that the life processes of a neuron include (1) eating, (2) excreting waste, (3) growing, (4) being sensitive, conducting, and discharging, and (5) movement. "The neuron thus lives much as would an amoeba or paramecium which had been differentiated to make conduction its special trade and which had become fixed immovably save for a few extremities here and there" (p. 57).

A similar portrait could be drawn of the other cells of the developing response mechanism. Thus it seems probable that the first activity of the total neural arc must be thought of as both old and new. The processes of change that are involved are similar to the processes of its growth in certain respects, but when total activity results, new time relations, if not new polarities, are involved. Thus in a sense an "organismic" response emerges from more discrete and primitive activities. But the function is to be understood completely only if described in terms of the past history of the total mechanism concerned and of the present stimulating situation.

This distinction between *part function* and *total function* which causes so much confusion in biology and psychology is clearly illustrated in the known facts of peripheral nerve regeneration. Sherrington (1922) points out that, when a previously

cut nerve is regenerated, what is developed in the nerve, so far as the adaptive function of the total arc is concerned, is useless until total regeneration and end organ attachment are completed. But of course the processes of development are themselves functions of the growing cells and the specific environment of these regenerating cells. Thus the eventual emergence of the so-called property of total arc conduction is in one sense not a saltatory change. So far as the functions of the protoplasmic patterns are concerned, it may be said that they involve a novel temporal and spatial organization of processes that have occurred in other energy relationships during previously described stages, but, from another point of view, with the completed nerve comes a most important and wholly novel emergence of total function. For a suggestion of some of the many factors involved in such development, see Goldstein (1904, 1939).

It seems to the writer, therefore, that the fact that cells and tissues do not develop in isolation, as Irwin (1932*b*, p. 194) points out in an excellent summary of the so-called *organismic hypothesis* of development, does not necessarily mean, as the same writer asserts, that the "nervous system is a complex dynamic organization which operates as a whole." On the contrary, it seems to suggest that the story of the development of behavior must be written not in any generalized formulae but in terms of the development of minute specific processes, no matter how diffuse or particularized, occurring in individual organisms under definitely described environmental conditions.

The discussion in the last few paragraphs has been presented to prepare the way for the consideration of the psychological aspects of the stimulus control of behavior. In the course of the study of the onset of receptor-neuroeffector behavior, many suggestions have been made for the cause of these first acts. The writer can see no reason to believe that all the diverse causal factors suggested are necessarily mutually exclusive, in spite of some assertions to that effect. Indeed, it seems that, so far as the onset of behavior in the fetus is concerned, the *fallacy of the single cause* has been peculiarly in evidence. As Jennings (1930) well says:

> This fallacy is the commonest error of science, making unsound a considerable proportion of its conclusions Everywhere there is a search for "the" cause of this or that phenomenon; the investigator is not content until he has found "it." Yet natural phenomena—and most emphatically is this true of biological phenomena—merely arise out of the complex situation in which they occur. Many elements of that situation affect them; and all that experimental science can do is to determine what difference is made by altering one or more of these elements; none is "the" cause to the exclusion of the others [p. 208].

In this chapter, therefore, an effort is made to summarize some of the many scientific facts and some of the theories which relate to the onset and development of early behavior in organisms. Here no attempt is made to arrive at one single conclusion, unless that conclusion is that the onset of behavior is most complexly determined.

Fundamental in the writings of most students who have concerned themselves with early development of behavior is the view that the nervous system is basic to the observed responses of the organism. As we have seen above, this view was implicit even in Dante's speculation on the onset of behavior in the fetus. Each advance in the knowledge of the true function of the nervous system has indirectly influenced the thought of those who are concerned with

the early development of function in the fetus.

The details of the specific neural changes necessary for the onset and development of behavior have, however, been diversely dealt with. Some students, like Coghill, although not neglecting other factors, emphasize above all else the anatomical relationships in the nervous system of the organisms under consideration as the determiner of behavior. The following quotation from Coghill (1929*a*) in regard to the neural basis of behavior in *Amblystoma* may be considered typical of this anatomical tendency. It also gives a fair picture of what is at once one of the simplest and one of the most adequately studied of all the neural mechanisms subtending behavior:

> There are therefore in this non-motile *Amblystoma* both sensory and motor nerves in contact with their respective organs, the sensory field on the one hand and the muscles on the other, but the anatomical relations between these systems are such that an excitation cannot pass from the sensory to the motor mechanism. The muscles, while contracting in response to a mechanical stimulus applied directly to them, do not respond to stimuli from the skin, either tactile or chemical. Even when dropped into slowly acting fixing solution, embryos of this stage do not give any evidence of muscular excitation.
>
> With the ability to respond to tactile or chemical stimulation of the skin there appears a third series of cells. They bridge the gap between the sensory system of one side and the motor system of the other. . . . Their bodies lie in the floor plate of the medulla oblongata and upper part of the spinal cord. . . . In the non-motile stage these cells are unipolar. The one pole of the cell extends either to the right or to the left into close relation with the motor tract on one side only. When they become bipolar they complete the path from the sensory field to the muscle; and this path leads to the muscles of the opposite side from the stimulus because the conductors from the sensory field pass across the motor path of the same side to establish synapses with the dendrites of the commissural cells in the floor plate . . . [pp. 11–13].

A similar but usually much less completely worked out neural picture could be presented for many of the organisms the development of whose behavior has been considered above. For example, the anatomy of the nervous system of the fetal rat in relation to its behavior has been studied in quite elaborate detail by Angulo y González (1927, 1928, 1929*b*, 1930*c*), and this type and many others by Windle (1940) and his associates. But the development of neural structure alone may not explain fully the onset of behavior in any type.

Minkowski (1923; 1928*a*, pp. 548–556), himself primarily a neurologist, has given in great detail the neural mechanisms which he believes underlie the changes he has observed in the clinically significant reflexes initiated in human fetuses by the stimulation of the sole of the foot.

Although there is almost complete agreement that the nervous system is significant in the onset and development of mammalian behavior, it must be admitted that there is not complete agreement as to the detailed factors of this development. One of the most commonly held views in regard to the basis of functional activity in the nervous system asserts that there is a differing threshold at the synaptic junctures existing between neurons. Sherrington and his associates (Creed, Denny-Brown, Eccles, Liddell, and Sherrington, 1932, pp. 14–15) have reviewed the evidence for such a view, and both Herrick (1924, pp. 103–111) and R. S. Lillie (1932) have dealt with special phenomena basic to an understanding of the synapse. Holt (1931, pp. 24–29) has shown that, in his view at any

rate, this theory is adequate, when correctly understood, to explain the complexities of neural-embryonic development, particularly when it is supported by a correct understanding of the functional development summarized in the theory of neurobiotaxis. Lashley (1924) and Irwin (1932*a*), on the contrary, have raised a number of objections to the synapse, particularly as *the* one and only explanatory factor in the change of behavior. Certainly one must always remember that, in attributing anything to the synapse, one is referring to a *concept* which has been elaborated in part from behavioral data. The danger of a circular argument in "explaining" behavior by the synapse should be remembered. Other views, such as that of nerve fiber density in the spinal gray matter in relation to behavior, have been suggested. (See Windle, 1930*b*.)

Since the time of Flechsig, there has been a tendency on the part of many neuroanatomists to link myelinogeny, that is, the development of the myelin sheath of neurons, with the onset of differentiated behavior. Flechsig in his later publications even attempted to correlate the degree of myelinization with increase in the complexity of behavior and indeed with psychic life. Tilney and Casamajor (1924), Langworthy (1929), and other students have attempted to show the correlation between myelinization in the central nervous system and the onset of behavior in the newborn and fetal cat, opossum, and other forms. For the most part these investigators point out that this theory must be taken as specific to the particular function and to the particular type considered. Tilney, however, once made the statement in very general terms: "I think there can be no doubt as to the coincidence in the time of myelinization and the establishment of function." (See also Tilney and Kubie, 1931.)

There is, however, evidence of exceptions to this generalization. Probably it is no longer safe, however, to say of this "myelinogenetic law," as Thorndike did (1913, p. 229) on the basis of the experiments of Watson (1903) and others, that it seems "gratuitous and improbable." The evidence for the relationship of myelin and function does not show it as the only cause of the onset of behavior. As Angulo y González (1929*a*) has shown: "From the point of view of myelinogeny, our studies have proved that myelination is not necessary for function, since all the movements described by Doctor Swenson and by myself in the rat fetus occur many days before myelination could be observed" (p. 461). This same author objects to the observations on behavior made by Tilney and Casamajor, believing that the movements which they observed were really established long before the time at which they were described and hence well before the myelinization which they report. Angulo y González (1929*a*), moreover, finds that a rat fetus, 19 days after insemination, is capable of discrete reflexes and of showing the inhibitory action of higher centers.

> These discrete reflexes, which are specific to a given stimulation, demonstrate a selectivity in the conducting mechanism. Since myelination does not take place until several days after birth, this observation proves that physiological insulation of the conduction path occurs without myelination, and, therefore, that myelination is not a criterion of functional insulation [p. 461].

Windle, Fish, and O'Donnell (1934) have studied the relationship between myelinogeny and the onset of behavior in cat fetuses. They conclude that myelinization in the animals studied is not correlated with function. Myelinization may be considered a consequence of the order of appearance of neurons in the embryo. (See also Lang-

worthy, 1927, 1932.) There are other theories of development besides that of myelinization. For example, following the lead of Paton (1907, 1911) and other investigators, Lane (1917, pp. 15–21) held that the onset of behavior is specifically related to the anatomical development of the neurofibrillae. This investigator advances an elaborate series of arguments to show that the neurofibrillae are possibly to be thought of as the essential basis of functional activity in the nervous system.

> If therefore an absolutely conclusive answer cannot now be given to the question of the function of the neurofibrillae, it is most probable, in the light of our present knowledge in this field, that the power of conducting nerve-impulses lies rather in the neurofibrillae than elsewhere. At any rate, the presence of neurofibrillae may be taken as an indicator, a criterion of the functional state of the neurons . . . [p. 21].

After definitely accepting this view, Lane explains the fact that after the neurofibrillae have developed, before the arc can become functional, it is necessary that the receptor develop (pp. 14, 79). In each of the senses he believes that function must wait for the development of the end organ, and that this is the last link to be connected up in the chain between effective environmental stimulation and response. In all the explanations which he offers for the development of this system, he emphasizes intrinsic rather than extrinsic factors (p. 84). In this he is seconded by Avery (1928), who concludes, without further explaining the matter, that fetal behavior is, in part at any rate, caused by and dependent upon "certain response mechanisms which are definitely congenital or innate" (p. 324). Certainly in the general sense of these terms few today will disagree with this conclusion, but it is not an observation which advances "functional knowledge."

Windle (1930*a*), in studying the spinal cord development of cat embryos 17.5 mm. to 18.5 mm. long in which the first movement—"wormlike, total waves proceeding caudad from an indefinite point in the neck region"—had been observed, notes:

> Pyridine-silver preparations of these embryos demonstrate the neurofibrillar structure of the central nervous system. Primitive reflex arcs are distinguishable, afferent, association, commissural, and efferent neurons appearing in proper relationship to each other. . . .
>
> The earliest movements appear in regions where primitive reflex arcs were first distinguishable and not until some time after these have formed [p. 249].

(See also Windle, 1931, 1932.) Herrick (1924), in referring to neurofibrils, says: "They are commonly regarded as the essential conductors of the nervous impulse, but of this there is no direct evidence" (p. 108).

Certain physiologists assert that neural functions and indeed the capacities of the adult organism are related primarily to the time relationships of the neuron (Lapicque, (1926). Or, even more generally, it has been suggested that the facts of the activity of the peripheral nerve fiber, as developed by Adrian, his predecessors, and his associates, may be basic to some aspects of the differentiation and specificity of behavior. For a brilliant exposition of this view, see Erlanger and Gasser (1937). Forbes wrote an article, "The Interpretation of Spinal Reflexes in Terms of Present Knowledge of Nerve Conduction" (1922), in which the suggestion is tentatively made that specificity of behavior and "the evolution of the dominant activities of man" (p. 414) may be thought of as being determined in a system the essential characteristics of which are to be found in a knowledge of the facts of the nervous im-

pulse as it is seen in peripheral nerve fibers. P. Weiss (1926) has studied this relationship from a different and more revolutionary physiological point of view which may well contain within it basic suggestions concerning the onset of those neural activities which make behavior possible.

It is clear that the increasingly detailed knowledge of the specific structure and function of the receptors, the peripheral nervous system, and the various levels of the central nervous system, particularly in regard to the relationships between these processes as brought out by Sherrington and his pupils (Creed, Denny-Brown, Eccles, Liddell, and Sherrington, 1932), must be ultimately taken into consideration in an explanation of the onset and early development of behavior. As indicated many times above, however, this view is almost certainly to be considered in relation to the changes of the chemical make-up of the whole internal environment of the organism.

The function of the endocrines in fetal life is still imperfectly understood. The substances elaborated by the endocrine glands of the body are concerned with growth and metabolism rather than with overt behavior as such.

The principal endocrine function of the pancreas is found in the cells of the islets of Langerhans. There has been much discussion of the part played by this secretion, which is called fetal insulin, in prenatal life. As noted in a previous paragraph some endocrines can pass the placental barrier, and therefore it is difficult to determine what is, for example, fetal insulin and what is maternal insulin in the fetus itself. Windle (1940) has discussed this and related problems. The suprarenals have an interesting history in the fetus. At birth they are about 0.02 per cent of total body weight. In the adult they are only about 0.01 per cent.

Pankratz (1930) has suggested that the onset of behavior is in time, at any rate, related to the beginning of functional action of the secretion of the suprarenal medulla, which possibly causes "an increase in the irritability of the muscular or neuromuscular system, and thus facilitates the beginning of foetal movements" (p. 235). He (1931*a*) believes that he has experimentally demonstrated in newborn organisms, including man, that there is a temporal correlation between the onset of functional activity in this gland and the first responses of the growing organism.

Willier (1939) has summarized the development of the sex-related hormones in the fetus. Male gonads produce male sex hormones in fetal life. In man this production probably begins about the seventh week. By the eighth week the female ovary is histologically recognizable. The conflict or interrelation between the female sex hormone of the mother and the female or male sex hormone of the fetus, as the case may be, has been the subject of study and speculation.

Wells and Fralick (1951) have studied the production of androgen by the testes of fetal rats. These investigators seem to have demonstrated that the testes of fetal rats produce an andogenic hormone which stimulates the prenatal growth of the accessory reproductive organs of males. Davis and Potter (1948) show that under specific conditions the administration of testosterone propionate to mothers during early pregnancy did not produce demonstrable changes in gonads or genital organs of male fetuses.

Possibly more fundamental than this speculation is the now widely accepted view of the chemical mediation of nerve impulses. Certain aspects of this work have been summarized by Cannon and Rosenblueth (1937). According to this point of view, synaptic function may in

certain reflex systems be mediated by acetylcholine or in other systems by an adrenaline-like substance. Kuo (1939*a*) has demonstrated the presence of acetylcholine in the chick embryo at the time of the onset of motility, and others have also suggested its significance in the mammalian fetus. Nachmansohn (1940) has shown that in the sheep high concentration of choline esterase appears in different parts of the central nervous system at different periods of development. Choline esterase is an enzyme which rapidly alters acetylcholine. Choline esterase is present in the spinal cord in high concentrations between the sixtieth and the eightieth days of gestation, but at that time its concentration in the brain is low. It rises rapidly in the higher centers just before birth, however. These results are in agreement with the activity of the centers involved. Youngstrom (1941) has determined the acetylcholine esterase concentration in typical fetal organisms. This study shows a significant relationship between developing motility and the concentration of choline esterase. A fully satisfactory explanation has not yet, however, been found for the occurrence of greater concentrations of choline esterase in fetal than in adult tissues.

The results just referred to are but a few indications of the modern emphasis on various forms of internal environmental change as related to the onset of activity in the organism. It has become obvious to many investigators that the movements of respiration, as well as other rhythmic movements known to be brought about or facilitated by a "blood stimulus," are important in a total understanding of behavior. For example, it has been reported that the asphyxia of the mother brought about definite movements in a very early fetus (Kussmaul, 1859, p. 31). Preyer (1885) was before his time in considering this problem, as in so many other ways. He considers the importance of the blood condition in connection with fetal movements on the basis of experiments in which he interfered with the normal respiration of the adult animal (p. 417). As already indicated, Ahlfeld and most of the other students of premature breathing movements have considered the "blood stimulus" to be significant. This sort of activation is also especially considered in the work of Zuntz (1877), T. G. Brown (1915), E. A. Graham (1913–1915), Walz (1922), and Tracy (1926), most of which has been previously reviewed.

Tracy (1926), as explained above, well combines the views of the importance of stimulation and the importance of the development of the nervous system in the determination of the onset of behavior in larval organisms. Thus he says:

> . . . The behavior reactions displayed by embryos and larvae of different species at different stages of development are dependent upon the relative time at which efficient connections are established between the various elements of the early nervous system (primitive bilateral motor system, commissural elements, spinal-ganglion cells, Rohn-Beard cells, and receptors) [p. 357].

But he also points out, as noted above, that:

> From the beginning and more or less continuously during its whole existence, the animal is driven through its environment as a result of stimuli which arise periodically in connection with its metabolic processes [p. 345].

Barcroft (1938) shows on the basis of elaborate experimental work that, as Claude Bernard said, the constancy of the internal environment is the condition of the free life. The work of Barcroft and his school, indeed, throws doubt upon many experiments in fetal behavior which have been

done without continually checking the oxygen tension and other characteristics of the fetal blood. In spite of this vast store of information upon the nature of fetal and maternal blood, it is interesting to note that Barcroft does not make a final judgment concerning the part played by the internal environment in the initiation of behavior (1936). He points out that in a typical reflex the external stimulus is important, and because of the changing cortical oxygenation of blood the center is also important. Thus the two sets of factors should be considered together. Barcroft (1938) does point out, however, that:

> The higher centers await investigation on modern lines; at present there is nothing to be said about them except what is rather obvious, namely, that the foetus of the sheep even up to birth presents few if any signs of consciousness. Within a few minutes of birth . . . the lamb lifts its head and tries to get up. It is plainly awake, and may be sent to sleep once more either by cold or by reducing the amount of oxygen in the blood. These matters must await further investigation; but it is evident that the higher faculties need a higher tension oxygen supply than those of a more vegetative nature [p. 67].

Changes in temperature, oxygen, carbon dioxide, glucose, water, sodium, calcium, and other substances are known as they alter the internal environment to have a part in the changes which result in behavior. These all no doubt contribute to alterations in fetal behavior. (See Carmichael, 1940*a*, p. 136, and Barcroft and Mason, 1938.)

Sontag (1941) has suggested some important considerations on the significance of fetal environmental differences. He believes that drugs used by women during pregnancy, their nutrition, endocrine status, and even emotional life, may be important in the postnatal life of the children they bear.

Newbery, Pyle, and Champney (1943) have attempted a quantitative study of the ability of mothers to rate the fetal environment in respect to thirteen factors during pregnancy.

Besides such students as Barcroft, who emphasize both the internal and external environment, there are some who emphasize the rôle of the intensity of external stimulation in the onset and development of behavior without much reference to the neural basis of such behavior. Kuo is in certain respects an exponent of such a view. He says:

> . . . As has been previously stated, I am inclined to think that to explain the total behavior pattern in terms of neural anatomy (that is, in terms of certain special connections between neurons) seems unnecessary or far-fetched, since all the neurons in the nervous system are interconnected in some way, and since body parts without direct neural connections may also move together, as in the case of the synchronous movement of the tail with the beak and eyes [1932*e*, p. 511].

The neurological-minded reader of the above paragraph is probably struck at first by the question of how, if the assertion is true, the observed differentiation in behavior is to be explained. Kuo offers the explanation that local reflexes are determined in part by external environmental influences. In the case of the chick he has ingeniously made many observations, some of which have been presented above, to show that in the fetal organism, growing in a rigidly shell-defined environment, certain mechanical influences interfere with the ease of general movement. For example, as development goes on, head movements come to be interfered with mechanically by the yolk sac, and thus he explains the fact that partial head movements, such

as those of the beak, occur in the head region. Kuo (1939*a*, 1939*b*) has, as noted above, more recently emphasized other concomitant functions such as the part of acetylcholine in the onset and early development of behavior.

On the basis of elaborate experiments, Lashley (1929) and his predecessors have shown that there was much misunderstanding in regard to the absolute specificity of central nervous system elements which subtend behavior, particularly in the higher centers. (See also bibliography cited by Lashley, 1929.) Lashley's work and the work of many other students make clear that no single brain neuron is probably ever functionally absolutely isolated and that the reflex arc is never so simple as the elementary textbooks a generation ago showed it to be. Indeed, Lashley's brilliant experimental work has revolutionized many of the older conceptions of the specificity of the arcs in the higher centers of mammals.

From these discoveries, however, there is much question whether such writers as Irwin (1932*b*) are justified in suggesting that "the early form of activity, with its lack of mature specificity and the presence of so few effective coordinations or reaction patterns, probably points to an organismic rather than to a reflex chain theory of behavior." The writer has no wish to disagree with this statement, save only to point out that the "cell theory" and the "reflex theory" that are usually attacked by "organismic" writers are in most such criticisms truly "men of straw." All that has gone before in this chapter seems to suggest that the explanation of behavior will hardly be advanced by saying that the nervous system "operates as a whole." Unquestionably, in the human fetus as in the human adult there are functions which can never be understood in isolation, but only by looking at the *totality* of processes; but totality alone does not explain the specific long, short, homolateral, and heterolateral skin reflexes, the face, hand, and foot reflexes, the mucous membrane and tendon reflexes, the proprioceptor and static reflexes, and the many other specific responses of the fetus. The fact that an early concept of the reflex arc was inadequate is no reason to assert that there is no truth in the general view that behavior involves discoverable relationships both temporal and anatomical between stimulation and response. Some such responses are more variable and some are more specific than others, but still there are specific patterns of behavior in the growing organism. As Skinner (1931) has effectively said in summary of a paper in which he criticizes current attacks upon the reflex hypothesis:

> The essence of the description of behavior is held to be the determination of functional laws describing the relationship between the forces acting upon, and the movement of, a given system. The reflex is, by definition, the precise instrument for this description [p. 455].

From the paragraphs just given, it is clear that there have been many efforts to explain in simple terms the mechanism which makes the onset of behavior possible. External stimulation is not *alone* important in the development of behavior; nor probably is the change in the synapses, the onset of acetylcholine, or any other factor *alone* the one determinant of all new responses in all organisms at all times. It does seem at present, nevertheless, that so far as the fetus is concerned there can be little doubt that an adequate explanation of its behavior at every stage in its development must be given in terms of the dynamics of its organization in each specific environment. Such dynamics, however, can be expressed only in terms of as detailed a knowledge of the structures and

functions of the organism as possible. Any response can be understood only if it is recognized that it may not be the result alone of the most obvious stimulus that is apparently calling it out, but rather that it may be a resultant of the total interoceptive, proprioceptive, and exteroceptive stimulation of the moment in an organism the chemistry of whose internal environment is known in its often rapidly changing characteristics.

In a final understanding of the sensory control of behavior in fetal life, as complete a knowledge of all such relevant factors as possible is important. Seldom apparently during late fetal life can an exteroceptor be stimulated so as to bring about a response that may not be conditioned also by other internal stimuli which may at the same time be tending to drive the organism "at random." This is particularly true of fetuses such as those studied by Minkowski, Bolaffio and Artom, and Hooker, which during observation are always undergoing more and more complete asphyxiation. As suggested above, it must not be forgotten that it may be that at certain periods of development and in certain physiological states the exteroceptors are best thought of as interrupting and directing behavior that is internally aroused. At such times the "drive" of the fetus may be said to be more important than its "knowledge of the external world." In this connection see Minkowski (1947–1948, p. 88). In any case, in a situation of this sort, gradually more and more adaptive behavior develops, which means that the exteroceptors play an increasingly important rôle.

Coghill's well-known formula for behavioral growth is possibly an adaptation of Spencer's famous definition which held evolution to be a passage from "a relatively indefinite incoherent homogeneity to a relatively definite coherent heterogeneity." Coghill taught that his formula has wide if not universal application in the development of behavior in all vertebrates. He (1929*c*) states it as follows:

> The behavior pattern from the beginning expands throughout the growing normal animal as a perfectly integrated unit, whereas partial patterns arise within the total patterns and, by a process of individuation, acquire secondarily varying degrees of independence. . . . Complexity of behavior is not derived by progressive integration of more and more originally discrete units [p. 989].

On the basis of what has gone before in this chapter, it seems that this process of *individuation* is certainly *one* important means of describing the process of development, but not the only means of describing such development. On the other hand, concomitantly but not necessarily temporally concomitantly, *integration* has long been recognized as a mechanism of behavior development. As Pavlov (1932) has put it in another context, one must consider the "initial decomposition of the whole into its parts or units, and then the gradual reconstruction of the whole from these units or elements" (p. 102).

In terms of a very broad generalization, the writer believes that an excellent case can be made out for the view that *individuation* is the pattern of all development, including all learning, but certainly in the experimental situation the concept of the *integration* or the combination of responses also provides, at times, a convenient working hypothesis. James (1890, Vol. I, p. 487) said that "psychology must be writ *both* in synthetic and in analytic terms." To the writer this seems to give a satisfactory clue to the expedient way of considering the changes in behavior that occur as fetal and neonatal behavior progresses. As we have seen above, certain responses are

early individuated, while others are still quite nonspecific.

New relationships between specific responses, as in the development of the plantar reflex, begin to develop before specification has gone far in certain other bodily acts. Each process must be considered at each level if a false generalization is to be avoided. Hooker (1937) has recently analyzed this problem and suggested three possible sequences of development: (1) At first reflexes are nonspecific. (2) At first reflexes are specific. (3) Specific and total reflexes develop simultaneously He urges the detailed study of behavior to answer these questions. This chapter suggests that all three are possible descriptions of certain responses, but the writer's own experimental work leads him to believe that (2) above should be emphasized much more than has been "fashionable." For a consideration of a generalized story of functional development of mammalian neuromuscular mechanisms, see Barron (1941).

Genzmer (1882, p. 28), after reviewing the debated question whether the newborn child has intelligence, suggests that the observed movements of the early infant are not the result of intelligence but are rather the material out of which the later intelligence is to be built. If the process of development is one of sheer individuation out of a totality, it would seem that statistical studies of early infancy might well show a high degree of what Spearman calls a "general factor." If the techniques used in the studies of Furfey, Bonham, and Sargent (1930) are satisfactory, however, it seems that the opposite is true. In a study of seventeen responses, such as the plantar and grasping reflexes in newborn children, corrected intercorrelations proved to be zero. These investigators conclude: "These results suggest that there is no mental integration in the newborn child. Integration takes place during the first postnatal month. . . ." Although technical questions may be raised in regard to this study, it certainly seems that, with the use of the same techniques, there is no reason to suppose that the responses of the fetus would show a more general factor than would those of the newborn child.

Minkowski (1924) has considered the part played by the conditioning of reflexes in later development, and certainly the question of the relationship between individuation and integration will be made clearer when it can be said at what ontogenetic level of development true conditioning of responses is possible. Ray (1932) has attempted to condition fetal responses. Spelt (1938), using the auditory response of the fetus described above, has worked on the conditioning of human responses. Marquis (1931), however, has brought about in the newborn child conditioning of the food-taking reaction to the sound of a buzzer. She holds that this may be conditioning at the subcortical level, but in any case it involves what is commonly considered combination rather than individuation of responses. Wenger (1936) and Wickens and Wickens (1939) have also worked in this field. Carmichael (1936) has elsewhere reviewed the work that has been done on early learning in young animals. Here the work of Kasatkin and Levikova (1935*a*, 1935*b*) on early conditioning and other studies are reviewed. It is possibly true that at a verbal level all conditioning can be described as individuation, but in such a formulation a generalization of the concept of individuation beyond the point at which it is pragmatically most useful seems required.

It may even be suggested that so-called learning itself always depends upon *maturation* or *growth*. In a trial-and-error sequence the animal must always be able to perform the successful act before learning, that is, the later elimination of mal-

adaptive acts, begins. This same view may even be applied, but less directly, to so-called conditioned response learning. In this connection, see Guthrie (1942). The phenomena of "refractory period" following previous stimulation and the "summation of stimuli" can be demonstrated in fetal organisms (Carmichael, 1934*a*; Carmichael and Smith, 1939). Both these phenomena show the influence of past activity on present capacity.

In general conclusion, then, in regard to the sensory control of behavior in the fetus and in regard to the related processes of the individuation and integration of behavior, it seems that as yet, at any rate, it is better to record as unambiguously as possible the responses that can be made by a fetus at any stage rather than to attempt to fit all developmental change into one formula. It seems to the writer, nevertheless, that the actually recorded facts of this development of behavior in infrahuman and human fetuses have been shown to throw important light upon certain of the insistent problems of psychology. It has been impossible to consider each of these processes in detail in this chapter. It seems, however, that in the later chapters of this book when, in postnatal life, problems of the development of behavior patterns, heredity and environment, the nature of instinct, the development of perception, the continuity or saltatoriness of development, and the nature of learning are considered, it will be obvious that the facts presented in this chapter will always have a bearing on certain aspects of the answers that are given to such problems. As Tracy (1926, p. 253) has suggested, a study of adult behavior without a consideration of its origin before birth is as incomplete as would be the at present unthinkable study of adult anatomy without reference to the embryology of the structures considered.

The student who wishes further study in this field should consult, besides the detailed references given, papers by Hooker (1936, 1939*a*, 1942, 1943), which summarize much of the work in this field; the summary of the development of behavior by Dewey (1935); and the important book *Physiology of the Fetus: Origin and Extent of Function in Prenatal Life* by Windle (1940).

The late Sir Joseph Barcroft's important work, to which many references are given in this chapter, is also summarized in a book, *Researches on Pre-Natal Life* (1946). Early development in general is summarized in a chapter, "Ontogenetic Development," by Carmichael in the *Handbook of Experimental Psychology*, edited by S. S. Stevens, 1951.

This chapter may well end with a quotation from Oliver Wendell Holmes (noted by F. C. Irving in his foreword to C. A. Smith's excellent *The Physiology of the Newborn Infant*, 1946):

> So the stout fetus, kicking and alive,
> Leaps from the fundus for his final dive.
> Tired of the prison where his legs were curled
> He pants, like Rasselas, for a wider world.
> No more to him their wanted joys afford
> The fringed placenta and the knotted cord.

CHAPTER 3

ANIMAL INFANCY

RUTH M. CRUIKSHANK

Historical Introduction

The study of the genetic development of human behavior would not be complete without some reference to and comparison with the ontogeny of behavior in subhuman forms. Accordingly, this chapter has been included in this manual. An analysis of the development of young animals should show in clearly defined ways the general similarities and differences in the development of behavior in man and animals from which general principles can be drawn. Gesell (1928) has very tersely stated this:

> The study of infancy in its broadest sense must therefore be a comparative science. The more general laws of development in the very nature of things will be applicable to all vertebrates not excluding either fish or man. In spite of the bewildering diversity of the behavior traits of the young of widely varying species, it is not improbable that there are certain orders of emergence and sequences of pattern which are common to all. It is conceivable moreover that certain pervading correspondences may even yield to quantitative and qualitative gradations when the infancies of a large array of species are systematically studied from the standpoint of developmental economy [p. 336].

More than this, however, such studies make the contribution of supplying information on problems which may not be readily accessible or even possible for observational and experimental study in the human being. A survey of the preceding chapter by Carmichael as well as of this chapter will suffice to point out certain problems to which studies of the development of the young animal have contributed, or may in the future contribute, additional crucial data. Until complete descriptive accounts of the normal development of young animals have been made, however, progress in the studies whose aim is more than descriptive must remain limited.

Although the young of groups other than the mammals are of interest for any complete survey of this topic, this review is restricted to a consideration of mammalian infancy. Lack of space and, indeed, lack of sufficiently correlated detail make this limitation seem advisable at this time. However, the reader interested in the inclusion of other animals is referred to the accounts of Mitchell (1912) and Pycraft (1913).

That the young as well as the adult of a given species must be observed has probably been considered for some time, although careful and accurate observational studies of young animals in the field or laboratory have not been carried out until comparatively recent times. A statement by Rennie in 1838, quoted by Yerkes and Yerkes (1929), expresses this idea:

> The great interest attached to the chimpanzee, as approaching so nearly to ourselves in the scale of animal life, has induced us to dwell longer upon this part of his history than we had originally intended, but we hope without either wearying the

patience or exhausting the curiosity of our readers. A thorough acquaintance with the manners and intelligence of the young animal, as accurately observed and related by zoologists accustomed to such investigations, was besides necessary to enable us to form a just estimate of the habits and economy attributed to the adult in his native forests, and of the degree of credit to which the accounts of different travellers are entitled [p. 209].

John Fiske states the case for an understanding of animal infancy as it is probably most familiar to a student of genetic psychology. His essay, *The Meaning of Infancy*, written in 1883 and republished several times, brought attention to this problem, although post-Darwinian workers in biology, physiology, and psychology had already begun to investigate it. This is Fiske's informal report of how he became interested in the problem:

Well, in the spring of 1871, when Darwin's "Descent of Man" came out, just about the same time I happened to be reading Wallace's account of his experiences in the Malay Archipelago, and how at one time he caught a female orang-outang with a new-born baby, and the mother died, and Wallace brought up the baby orang-outang by hand; and this baby orang-outang had a kind of infancy which was a great deal longer than that of a cow or a sheep, but it was nothing compared to human infancy in length. This little orang-outang could not get up and march around, as mammals of less intelligence do, when he was first born, or within three or four days; but after three or four weeks or so he would get up, and begin taking hold of something and pushing it around, just as children push a chair; and he went through a period of staring at his hands, as human babies do, and altogether was a good deal slower in getting to the point where he could take care of himself. And while I was reading of that I thought, Dear me! if there is any one thing in which the human race is signally distinguished from other mammals, it is in the enormous duration of their infancy; but it is a point that I do not recollect ever seeing any naturalist so much as allude to [1911 ed., 25–26].

Although at this time a complete historical account of the early studies on the development of behavior in young animals will not be given, it might be well to mention just a few of the more important contributions which have led to our present interest in the subject.

One of the early studies of animal infancy was made by Spalding (1873, 1875), who stressed the necessity for an understanding of the development of young organisms in order to answer certain theoretical questions then prevalent. Spalding's observations were carried out to establish evidence regarding the existence of instincts in the young animal.

Preyer's work (1882) may be taken as pioneer in the experimental study of the psychological aspects of infancy considered in the broad comparative sense. Preyer refers to various behavior items of young animals, comparing them with those of the human infant. His work also includes observations of fetal behavior so that, notwithstanding the fact that his studies are among the first to treat of behavioral development, they do not fall into the error of considering it as a strictly postnatal phenomenon.

Mills (1898) likewise appears to be among the first to attempt a description of the behavior of young animals. Mills enlarges the significance of the study by pointing out the necessity of such a study as part of the total field of psychology. His position is clearly stated:

It must be equally clear to those who, guided by facts alone, untrammelled by tradition and dogma of every kind, com-

> pare the psychic status of the young with that of the mature animal, that psychogenesis is a fact; that the mind does unfold, evolve, develop equally with the body. And as with the body so with the mind, each stage in this development can only be understood in the light of all the previous stages.
>
> This truth is apparently as yet only dimly comprehended, for, till recently, studies on psychic history, development or psychogenesis have been all but unknown, and as yet, even in the case of man, are very few and confessedly imperfect [pp. 113–114].

The next important work concerning the young mammal is Small's (1899). Taking his lead from Mills, Small made a detailed study of the development of the white rat. Small, distinctly recognizing his problem as one in genetic psychology, introduced his study as follows:

> A study of the psychic development of any young animal needs no apology. Apart from the fascination and the self-education of watching the development of any form of life from its early protoplasmic simplicity into complex maturity, there is the solid scientific reason that Genetic Psychology has much to hope from minute and accurate records of the developmental periods of young animals of all species. It may never be possible to reconstruct a complete psychic organism from the evidence of a single trait—an ideal borrowed from morphology—but something surely may be accomplished towards a *comparative embryology* of the soul. What Preyer and others have done for the human infant, needs to be done also for the baby-animal of every species [p. 80].

In 1903, Watson published an experimental study of the psychological development of the white rat correlated with the growth of its nervous system. Watson did not repeat Small's work but, testing the rat in simple learning situations, endeavored to ascertain the age of psychological maturity for the rodent. This he placed at approximately 24 days, although the animal learned in simpler situations at an earlier age.

Allen's work (1904) on the behavior of the guinea pig was published the next year. Allen's study was comparable to Watson's in aim, an examination of another member of the rodent group.

Yerkes' work (1907) on the dancing mouse contains reference to the development of the young mouse, but it is primarily a study of the mature animal.

More recent work on the development of behavior in young animals is treated topically rather than chronologically in other sections of this chapter.

Behavior of the Newborn Animal

Several references to the behavior of the newborn animal are to be found in the literature. These studies derive their significance from the fact that birth represents a stage of transition from one type of environment to another. When such observations are interpreted in light of the longer developmental history of the organism, they offer valuable data; but when they are interpreted without reference to the preceding behavioral development of the animal, they are extremely misleading. When the literature on certain topics of psychological interest such as that of "instinct" is reviewed, the reader is indeed impressed with this fact.

The developmental levels which mammals have reached in intrauterine life have been reviewed for the reader in the preceding chapter by Carmichael. Descriptions of the functional development of the animal at birth are found in succeeding parts of this chapter. For further discussions of the development of specific animals at or soon after birth the reader is referred

to the accounts of: Small (1899), rat; Allen (1904), guinea pig; Goerling (1913), kangaroo; Lashley and Watson (1913), monkey; Blair (1920), chimpanzee; Hartman (1920, 1921, 1928*a*), opossum; Allesch (1921), chimpanzee; Tilney and Casamajor (1924), cat; Robinson (1925), gibbon; Shaw (1925), Columbian ground squirrel; Johnson (1927), prairie dog; Kao (1927), rabbit; Wade (1927), striped ground squirrel; Avery (1928), guinea pig; Hartman (1928*b*), monkey; Struthers (1928), Canadian porcupine; Fox (1929), chimpanzee and orangutan; Sturman-Hulbe and Stone (1929), rat; White (1929), chimpanzee; Brown (1930), chimpanzee; Kuroda (1930), monkey; Sherman (1930), bat; Windle (1930), cat; Enders (1931), agouti; Jacobsen, Jacobsen, and Yoshioka (1932), chimpanzee; Tinklepaugh (1932), chimpanzee; Tinklepaugh and Hartman (1932), monkey; Coolidge (1933), gibbon; Coronios (1933), cat; Huestis (1933), deermouse; Foley (1934), monkey; Svihla (1934), deermouse; Tomilin and Yerkes (1935), chimpanzee; Yerkes and Tomilin (1935), chimpanzee; Errington (1939), muskrat; Alcorn (1940), ground squirrel; Fisher (1940), sea otter; Murie (1940), sea otter; Yerkes (1940), chimpanzee; Britton (1941), sloth; Ingles (1941), Audubon cottontail rabbit; Tappe (1941), kangaroo rat; Barrington (1942), pocket gopher; Cooper (1942), lion; Orr (1942), brush rabbit; Richardson (1942*a*), ring-tailed cat; Hatt (1943), pine squirrel; Richardson (1943), wood rat; Shadle and Ploss (1943), porcupine; Sollberger (1943), eastern flying squirrel; Hamilton (1944), short-tailed shrew; Scheffer (1945), sea lion; Taber (1945), nine-banded armadillo; Smith (1946), bear; McBride and Hebb (1948), McBride and Kritzler (1951), bottle-nose dolphin; Scott and Marston (1950), dog; Tevis (1950), beaver; Liers (1951), river otter; and Pournelle (1952), cotton mouse.

Sensory Development of Young Animals

Vision. The ages at which certain visual responses are observed after birth can be seen by reference to Table 1. A survey of certain studies of the development of visual acuity is made by Warkentin and Smith (1937). They also report the best evidence concerning the development of visual acuity for the young kitten. They give average ages for eye opening (9 days), nystagmus (14 days), visual placing (25 days), acuity of 360-minute visual angle (14 days), acuity of 180-minute visual angle (16 days), acuity of 43-minute visual angle (21 days), and acuity of 11-minute visual angle (25 days). There was no relationship noted between the age of eye opening and the appearance of nystagmus, but a high degree of visual acuity preceded visual placing responses. Concerning the visual acuity of the young chimpanzee and the young child, the Kelloggs (1933) point out that the animal seems to possess very great acuity and notices many finer details than does the child (pp. 89–90). The point needs experimental study.

Turner (1935) has investigated the visual responses of young rats allowed to orient toward a black door in a brightly lighted field. Animals with eyes open perform more efficiently than animals with eyes still closed, and the older animals orient with a greater degree of accuracy, indicating some genetic development of this type of response. This development seems to be correlated with the increased efficiency of the eye mechanism and possibly also with increased learning in the situation. Food deprivation does not seem to have any large effect upon the young rat's orientation to light (Biel, 1939). For a discussion of phototropisms in rats, see Crozier and Pincus (1927*a*).

TABLE 1

TYPICAL RESULTS FROM OBSERVATIONS OF THE DEVELOPMENT OF BEHAVIOR IN YOUNG MAMMALS *

Response	Rat	Guinea Pig	Rabbit	Cat	Dog	Monkey	Chimpanzee

* The chart should be read with recognition of its many sources of error, including (1) observation of the neonatal animal without reference to the fetal animal, (2) casual rather than systematic observations, and (3) variability of developmental ages. Reference for more accurate data for animals whose fetal development has been studied should be made to the preceding chapter by Carmichael.

† Abbreviations: F—Foley (1934); HT—Tinklepaugh and Hartman (1932); JJY—Jacobsen, Jacobsen, and Yoshioka (1932); K—Kao (1927); LW—Lashley and Watson (1913); M—Mills (1898); P—Preyer (1882); S—Small (1899); TC—Tilney and Casamajor (1924); W—White (1929); Wi—Windle (1930).

Investigations of the genetic development of color vision in those mammals which might be expected to have such vision are practically nonexistent. There are to be found investigations of sensitivity to red in the rabbit (Washburn and Abbott, 1912) and in the calf (Kittredge, 1923), a few comments such as those of the Kelloggs (1933, p. 92) concerning the infant chimpanzee, and a study of methods suitable for such work by A. W. Yerkes (1935).

The development of distance perception in young animals, it would seem, might be investigated experimentally with profitable results. Foley (1934) comments that, during the early days for the young monkey he observed, "misjudged distances were the rule rather than the exception" (p. 76). The reactions of the older animal, however, were swift and accurate (Foley, 1935). Kuckuk (1936) reports a number of interesting observations of young bears' recognition of a familiar figure at a distance. In contrast with these observations are those of Lashley and Russell (1934), who found that adult rats reared in total darkness during their earlier life can, without training, discriminate distances and jump with a force well adapted to the distances involved.

We also have some evidence concerning the genetic development of such functions as pattern vision, size discrimination, and brightness discrimination. Hebb's experimental investigations (1937*a*, 1937*b*) of the adult rat's discrimination of these variables after being reared in darkness from the age of 6 or 8 days to maturity indicate that for this animal the proficiency of performance does not depend upon previous visual stimulation. When tested at maturity, pattern vision of rats from which the visual cortex had been removed in infancy is lost, according to Tsang (1937*b*), although discrimination of brightness and relative size persists as it does in adult operates. Tsang notes a few cases which he believes suggest a primitive type of pattern vision in young operates, which, however, is by no means as delicate as that of the normal animals.

The two chimpanzees reared in darkness to the age of 16 months about which Riesen (1947) reports showed good pupillary responses, startle reaction to sudden changes in intensity of light, and head and eye turning toward the source of light when they were first tested. Blinking at the approach of an object and fixation of an object were not immediately elicitable. Several days of experience in the light were needed before the animals showed visual recognition of an object like the feeding bottle, although this was familiar both tactually and kinesthetically.

Audition. Observational evidence concerning audition in young animals is given in Table 1. Data of this sort are subject to considerable error, but until further evidence is offered they must suffice. Pitch discrimination and intensity discrimination have not been satisfactorily tested. Biel (1939) notes that young animals deprived of food respond to sound stimulation at a significantly later age than do normally fed rats.

Interesting comparisons of auditory localization in the young chimpanzee and the child were obtained by the Kelloggs (1933), who required the blindfolded subject to find the experimenter, whose position could be determined only by his voice. The child at 16 to 17 months made an average error of 40.2 degrees in localizing the sound, whereas the chimpanzee at 13½ to 14½ months made an average error of 25.9 degrees. An 8-year-old child tested in the same way made an average error of 15 degrees. Observations by Kuckuk (1936) on auditory distance perception in young bears are of note.

Olfaction and Gustation. Evidence concerning olfactory and gustatory sensitivity

in young animals is given in Table 1 under the appropriate headings. Techniques adequate for measuring olfaction in young animals unable to make decisive motor responses have not been worked out. Pfaffman's technique (1936) for studying gustatory sensitivity in young animals deserves special mention. The number of sucking responses which a young animal makes to various solutions is recorded graphically. Using young kittens, Pfaffman reports differential sensitivity to salt and milk at 1 day. The 10-day-old animal discriminates solutions of salt and bitter and shows some sensitivity to solutions of sweet and sour. Comments upon the responses of the young chimpanzee to gustatory and olfactory stimuli are given by the Kelloggs (1933).

Touch, Pain, Temperature, and Kinesthesis. Since nearly all young animals observed seem to be sensitive to tactile stimulation (see Table 1), a study of the ontogeny of such responses must deal with the fetal organism. It is probable that thigmotactic responses play a large part in the huddling behavior of young animals. James (1952*a*, 1952*b*), for example, carefully observed newborn puppies and mechanically recorded their movements toward other puppies, the mother animal, and decoy objects. Tactile stimuli appeared to give direction to their movements.

Few references concerning tactual localization in the young animal appear in the literature. The Kelloggs' (1933) tests, in which a blunt pencil was applied to the body of a young chimpanzee at 10 months, show that the animal makes almost perfect localizing responses. The animal appeared to be very sensitive to tickling. A young chimpanzee which was raised from 4 weeks to 31 months by enclosing the limbs in cardboard cylinders showed, according to Nissen, Chow, and Semmes (1951) some deficiencies in tactual-motor coordination. The animal had difficulty in bringing the fingers to a stimulated region of the body such as the head. It also had difficulty learning to discriminate the position of two widely separated tactual pressure stimuli. In a visual discrimination problem on size, form, and depth, however, the animal performed about as well as a normal animal.

Young animals show definite response to pain stimulation. (See Table 1 and also Anderson and Patrick, 1934.) The chimpanzee examined by the Kelloggs (1933) gave evidence of ability to localize the source of pain when tested at 10 months (p. 118).

Numerous investigators report that they believe temperature variations play a dominant part in the activities of young animals. Huddling in young rats, for example, is considered by Small (1899) to be a manifestation of the need for warmth, and he suggests, as do others, that the need for warmth may be basic in socialization. That variations in temperature influence the amount of spontaneous activity of young animals has been shown by Stier (1930).

Orientation of young animals on an inclined plane has been studied in the rat by Crozier and Pincus (1926, 1927*b*, 1928, 1929*a*, 1929*b*, 1931*a*, 1931*b*, 1932*a*, 1932*b*, 1933) and by Pincus (1927); in mice by Crozier and Oxnard (1927); in the guinea pig by Upton (1930, 1932) and Elliott and Stavsky (1933); and in the kitten by Stavsky (1932).

Motor Development

A number of observations on the motor development of young animals are summarized in Table 1. For detailed descriptions of the motor development of specific animals the reader is referred to the investigations listed in the section on the behavior of the newborn animal. See also the description of reflexes in puppies

(Bahrs, 1927); other discussions of locomotion in young animals (Hatt, 1931; Kennard, 1938; Beach, 1939); placing reactions in young animals (Tang, 1935; Warkentin and Smith, 1937); air-righting reflexes (Carmichael, 1934; Anderson and Patrick, 1934; Warkentin and Carmichael, 1939); grasping in young animals (Richter, 1931); handedness in rats (Wentworth, 1938); general activity of young rats (Slonaker, 1907, 1912); and persistence of sucking behavior (Lashley, 1914; Richter, 1925; Courthial, 1929; Ross, 1951).

A comparison of the development of motor functions in the infant chimpanzee and the human infant may be made by referring to the table compiled by Shirley (1931), to which Jacobsen, Jacobsen, and Yoshioka (1932) have appended the age of appearance of the behavior item in question for the young chimpanzee they observed. The first number refers to the age of appearance for the human infant, and the second to the age for the chimpanzee. (See Table 2.)

The young chimpanzee raised by the Kelloggs (1933) had passed through the stages of locomotion noted by the Jacobsens and Yoshioka except the final one of erect walking when she was first observed by them at 7½ months of age (pp. 71 ff.). Further development of climbing, jumping, and skipping occurred, and from the descriptions of these activities it appears that they reached a high level of proficiency comparable with the maturation and strength of the young chimpanzee.

The observations of the Jacobsens and Yoshioka (1932) on the development of manipulation in the young chimpanzee are worthy of more elaborate description, for they present a direct comparison with one of the more complex motor developments of the human infant. The young chimpanzee shows reflex grasping at birth, continuation of the ability to hang by one arm

TABLE 2

MOTOR DEVELOPMENT OF HUMAN INFANT AND YOUNG CHIMPANZEE

(From Jacobsen, Jacobsen, and Yoshioka, 1932, as adapted from Shirley, 1931)

1. Progress toward creeping goes through the following stages:
   - *a.* Lifting the head, chin free, when on the stomach; (3/3).
   - *b.* Lifting the head, chest free, when on the stomach; (9/5).
   - *c.* Knee pushing or swimming; (25/7).
   - *d.* Rolling; (29/8–10).
   - *e.* Rocking, pivoting, worming along; method of making progress; (37/11).
   - *f.* Scooting backward by using the hands.*
   - *g.* Creeping forward.*
2. Progress assuming an upright posture goes through the following stages:
   - *a.* Lifting the head when lying on the back; (15/5).
   - *b.* Sitting alone momentarily; (25/12).
   - *c.* Sitting alone; (31/13).
   - *d.* Standing holding to furniture; (42/15).
   - *e.* Pulling self to standing position by means of furniture; (47/15).
   - *f.* Sitting from standing position.*
3. Progress toward walking goes through the following stages:
   - *a.* An early period of stepping.†
   - *b.* Standing with support of a person.†
   - *c.* Walking with help, led by a person; (45/17).
   - *d.* Standing alone; (62/20).
   - *e.* Walking alone; (64/25–29).

* Did not appear for the chimpanzee.
† Adequate tests not made for chimpanzee.

(in contrast with its waning in the human infant), reaching without grasp during the fifth week, hand play and thumb and toe sucking in the seventh week, reaching and grasping during the eighth week, and further development of reaching and grasping during the succeeding weeks. The animal's use of its mouth and its feet in reaching

and grasping is noted by the authors. The descriptions of these authors and the comments by the Kelloggs (1933) concerning the very fine manipulations made with the lips by the chimpanzee Gua (p. 59) and the loss of certain skills in foot grasping by Gua after she had worn shoes (p. 237) indicate that under normal conditions the use of these members is more persistent and reaches a higher level of development in the chimpanzee than in the child, although mouth grasping and foot reaching do occur in the human infant. Significant in the manipulations of the chimpanzee is the level of proficiency to which they attain so that the animal is able to perform such skilled acts as guiding a spoon to the mouth (twenty-first week), removing a lid from a small can (twenty-eighth week), holding a nursing-bottle in each hand (thirtieth week), and walking erectly while carrying two small objects (forty-fourth week).

In the series of tests with common objects which the Kelloggs used in comparing the prehension of the child and the chimpanzee, the child excelled the chimpanzee in all but the handling of the envelope, which they both were able to do satisfactorily (pp. 61–62).

Considerable interest has been attached to the development of motor reactions in young animals through correlative neurological studies. It is not intended to treat this topic in detail here, but a few of the studies will be mentioned.

The study of the "electrically excitable" motor areas of the cortex has led to some observations with regard to the correlation of excitability and genetic development of certain motor reactions. The reader is referred to Huber (1934) for an historical review of this problem in which reference is made to the work of Soltmann (1876), Tarchanoff (1878), Ferrier (1880), Paneth (1885), Mills (1898), Michailow (1910), Bechterew (1911), Weed and Langworthy (1925, 1926), and Langworthy (1927), among others. Most of these studies have indicated that excitability of the cortex occurs some days after birth with the areas associated with the hindlimbs and facial regions excitable later than those areas associated with the forelimbs. The conclusions listed below are ones to be found in the literature.

1. There is a tendency for the appearance of excitability of forelimb areas before hindlimb areas
2. There is an increase in the number of excitable points with age.
3. The threshold of excitability is higher for younger animals and decreases with age.
4. First movements so elicited are of the whole limb, and movement of discrete segments occurs later.
5. Correlation of development of function with "electrical excitability" of the cortex is difficult to appraise at present.

Although these conclusions probably hold in general, there is good reason to believe that some of the data upon which they are based will be found to be inexact. For example, Henry and Woolsey (1943) have repeated the work on the kitten, using 60-cycle sine-wave stimulation and exploring the cortex of the kitten in greater detail. They find, contrary to results of previous workers, that electrical stimulation elicits responses in the newborn animal from all the principal motor foci which are identifiable for the adult animal. It would seem that crucial data should be sought for the fetal animal. Kennard and McCulloch (1942) have examined the excitability of the cortex of a 3-week-old *Macaca mulatta*. Responses were more easily elicited in the face, less easily in the hand, and not at all in the leg. Relatively high voltages were required, and the responses were characterized as less discrete and slower

in execution and cessation than those of an adult animal.

Attempts at correlating behavioral development with the myelinization of the nervous system have not given conclusive results. Watson (1903) and Angulo y González (1929), for example, have not found such a correlation. Tilney and Casamajor (1924) and Langworthy (1929), on the other hand, suggest that myelinization occurs before the functional development of the parts.

Windle (1930) reports an increase in the density of nerve fibers in the spinal cord with increasing motor performance of the kitten.

Studies of the bioelectric phenomena of the central nervous system may in time give additional evidence concerning relationships between behavioral and neural development. Kornmüller's (1935) work and that of Jasper, Bridgman, and Carmichael (1937) are pioneer in this field.

Studies of the effect of brain lesions upon the behavior of the young animal and its subsequent behavior have extended the correlation between neurological and behavioral developments still further. Brooks and Peck (1940), removing the cortex of young rats during the first 5 days of postnatal life, found that ablation of the area of the cortex which for adult rats is the sensory motor area renders the placing and hopping reactions of these animals, when tested several months later, deficient to the same extent that it does those of the adult animal. Kennard (1936, 1938) has observed the effect of lesions made in the motor and premotor areas of the cortex in young monkeys upon their later motor performances. The age of the animal is one of the most important factors determining the deficiencies resulting from the lesion, inasmuch as the loss is not as severe in young animals.

Learning and Memory

As yet the work on the modifiability of response and the permanence of this change in the young animal is somewhat fragmentary, but there are a few problems such as the relationship of maze learning and age which have received more attention, although the results are not completely conclusive.

Incidental Observations. A number of incidental observations of learning in young animals can be found in the literature, but only a few items will be reported here. The feeding situation often provides interesting observations concerning the learning ability of young animals. Dove (1935) notes that the young of animals learn early in life to follow the mother and to eat the same type of food. Foley (1935) comments that, when he entered the laboratory in the morning before feeding time, the sound of his footsteps and the closing of the icebox door would elicit the "hunger-anticipation" cry of the young monkey he observed. The reader will profit from the discussions of the Kelloggs (1933) concerning the incidental learning of Gua in the human environment (pp. 188 ff.). The chimpanzee reared by the Hayeses (1951) since its birth grew up in an environment which, like that of the child, required considerable learning. The baby chimp learned early to grasp the thumb of the hand which held her feeding-bottle and thus pull the bottle toward herself. Later she learned to pull a string to which the bottle was attached. As she grew older, she learned such activities as playing peek-a-boo, imitating adults by blowing a whistle, clapping her hands, stringing a wooden bead on a string, and turning a key.

Maze Learning. There are a number of reports of maze-learning studies in animals of varying ages. Watson (1903) reports that young rats learn a maze more readily

than adult animals. Yerkes (1909) found that 1- to 2-month-old mice learned less readily than 10-month-old animals. Hubbert's (1915) results indicate that younger rats learn better than older animals. Liu's (1928) animals 30 and 45 days old made the poorest scores, whereas animals 75 days old made the best scores. Animals older than 75 days performed less well. Stone (1929*a*, 1929*b*) reports that young animals 30 to 75 days old make superior scores. Biel (1939, 1940) found in a study of maze learning in young rats 16 to 29 days old that the older animals' performance is significantly superior to that of the younger ones. In an unpublished study of the writer it was found that no large differences in the ability of guinea pigs to run a maze are correlated with age. The younger animals were more active than the older ones, but they did not make consistently superior performances.

Possibly some of the apparent discrepancies in these studies can be explained partially in terms of different motivation at different ages. The investigations of Margolin and Bunch (1940) on the relationship between age and strength of hunger motivation indicated that young rats (30 to 40 days of age) in an obstruction box apparatus crossed the grid a greater number of times than did the postpubescent or the adult animals.

Comparing the maze-learning ability of normal adult rats, adult rats hemidecorticated at 21 days of age, and animals decorticated in adulthood, Tsang (1937*a*) reports that greater deficiencies exist for the animals older at the time of operation than for the ones which were younger. He reports that a loss of less than 10 per cent of the cortex in the adult animal is as serious as a loss of 40 per cent in the young animal. Hemidecortication in which a diagonal decortication (that is, anterior and posterior quadrants of different hemispheres) was made had a greater detrimental effect than a unilateral decortication.

Other Problems. Golubeva (1939) was able to condition motor responses to acoustic stimuli in newborn guinea pigs. Fuller, Easler, and Banks (1950) were able to condition puppies of 18 to 21 days of age to light, sound, and odorous stimuli. On the basis of conditioned response reactions, they found that light is effective around 16 days, sound about 19 days, and odor and contact at birth.

Yerkes (1909) reports that young dancing mice 1 month old learn to make a white-black discrimination in fewer trials than do animals 4, 7, and 10 months old. Learning of a light-dark discrimination by kittens given differing amount of electrical shock for incorrect choice has been investigated by Dodson (1915). From his results it is indicated that the relationship of strength of stimulus to speed of learning depends upon the difficulty of the problem, so that with a difficult problem a medium shock is superior to a strong one, whereas with a simple problem a strong shock is definitely superior to a medium or a weak one.

Shuey (1932) found little evidence that kittens between 11 and 12 weeks old at the beginning of training can perform a simple alternation problem consisting of pressing two plates of the Jenkins problem box, although one of the nine animals tested seemed to have established a fairly consistent habit. All the kittens tested by Shuey (1931) in the Jenkins problem box learned three steps. A number of other steps were learned by some of the animals, but too few animals were used to show how significant the scores are.

For other observations of learning see Kinnaman (1902), Allen (1904), Hamilton (1911), and Kuckuk (1936).

Some reference is made in the literature to studies of immediate or delayed memory

in young animals. The Kelloggs (1933) carried out a delayed-reaction experiment with their son and the young chimpanzee when the subjects were at the approximate ages of 10½ to 12 months and 8 to 10 months, respectively. Under the circumstances of their test situation, they found that the child could delay for 5 minutes, but that at 10 minutes he made errors in about half the trials. The animal, on the other hand, satisfactorily responded to the shorter time intervals and responded correctly in 7 out of 10 trials for an interval of 30 minutes. It appears that the chimpanzee could delay longer than the child in these circumstances. It would be interesting to know the whole course of development for the animal and the child.

Jacobsen, Taylor, and Haslerud (1936) investigated the question of immediate recall after frontal lesions in young monkeys. They found this to be permanently abolished after lesions in the young animal as well as in the older animals.

Effect of Food Deprivation on Learning. The question whether food deprivation in the very young animal has any deleterious effects upon subsequent learning has been studied by several investigators. Biel (1938) examined the effects upon the maze-learning behavior of young animals of severe inanition brought about by subjecting them to reduced food intake. He found no deleterious effect in their learning of the Warden U-maze or the Stone multiple-T maze. Using a multiple-T water maze, he found that rats subjected to food deprivation performed less efficiently at a later age than normally fed rats (1939).

Deprivation of vitamin B is shown by several workers to be detrimental to subsequent maze learning (Maurer and Tsai, 1929, 1930; Bernhardt, 1934; Maurer, 1935*a*, Poe, Poe, and Muenzinger, 1936, 1937; and Bernhardt and Herbert, 1937). Vitamin B_1 deficiency beginning at 2 weeks gives less retardation than B_1 or B complex deficit according to Muenzinger, Poe, and Poe (1937), although Maurer (1935*b*) showed retardation when the deprivation is begun earlier than at 2 weeks of age. The animals show greater deprivation when they are given a diet lacking vitamin B during the nursing period than at a later age. O'Neill (1949) repeated the work on vitamin B deficiency, using controlled amounts of vitamin B_1. He found that larger amounts of thiamine led to improved performance in learning a water maze. If the rats received an excess of B_1, no further improvement was indicated by the addition of other elements of the vitamin B complex.

Biel and Wickens (1941) have shown that rats deprived of vitamin B_1 from approximately 1 week of age were when compared with normal animals at 7 to 10 weeks of age significantly poorer in the conditioning of eyelid responses.

Acute vitamin A shortage does not lead to as severe retardation in nursing rats as a vitamin B deficiency. The number of trials for learning a maze is not significantly different from the learning of normals, although the time scores are reliably different, indicating loss of speed (Maurer, 1935*c*).

The effects of several other types of food have been studied using young animals as subjects. The maze performance of young rats fed a diet of whole pasteurized cow's milk is not different from that of normally fed controls (Maurer, 1935*d*). Porter, Griffin, and Stone (1951) found that groups of rats, 29 days and older, fed diets which were chosen to affect glutamic acid metabolism did not show significant differences in performance on an 8-unit Warden water maze. Young albino rats fed a diet arranged to produce an amino acid deficiency learned a simple tunnel maze somewhat better but not significantly so than littermate controls (Bevan and Freeman, 1952). The control animals were fed a standard

diet restricted in weight to that of the experimental animals' previous day's diet. On relearning, the control group performed reliably better.

Effect of Electroconvulsive Shock on Learning. According to experiments by Eriksen, Porter, and Stone (1948), the learning of the Stone multiple-T maze by rats given one electroconvulsive shock daily during the age period from 20 to 30 days and trained after a 10- (or 20-) day post recovery period for 15 days on the maze was somewhat inferior to that of litter-mate controls which had received no shock treatment. Although no gross behavioral differences were noted, the differences were statistically significant when the data were analyzed. Animals similarly shocked at the same early age but given 74 to 90 days post-shock rest before being trained on the maze (Porter, Stone, and Eriksen, 1948) were inferior in performance to a control group. Whether the decrement is a function of the age of the animal at the time of shock has not been determined, but, as these investigators point out, the problem should be systematically studied.

Similar results were obtained by Bernberg (1951) with slightly older rats (35 to 44 days) at the time of receiving electroconvulsive shock or electronarcosis treatment. The animals which had undergone either the electroconvulsive shock or the electronarcosis treatment did not learn the Stone multiple-T maze as well as the control animals.

Effect of Anoxia on Learning. Studies on the effect of anoxia at birth or shortly thereafter upon the behavior of animals provide experimental evidence to consider along with clinical studies of human infants. Becker (1950) and Becker and Donnell (1952) found that guinea pigs asphyxiated at birth and tested in a simple alternation maze were less active than litter-mate controls and were inferior to them in learning ability and retentive capacity. Meier and Bunch (1950) investigated the effect of a 30-minute period of oxygen deprivation undergone within 3 hours of birth upon learning, relearning, and reversing a position habit. In initial learning and relearning when animals were between 75 and 100 days of age, the litter-mate controls performed better but the difference was not statistically reliable. In learning to reverse the position habit, the controls were superior at a 2-day interval, but the anoxic animals were superior in reversing the habit after an interval of 14 days. Armitage (1952) found that offspring of female rats which had been given varying dosages of barbiturates at the time of parturition were inferior in learning and reasoning tests to normal animals when tested at 90 days of age.

Infantile Experiences as Determinants of Adult Behavior. One of the important questions for which partial answers can be supplied from the behavior of animals is the effect of infantile experiences upon later adult behavior. The problem has its significance in that this basic psychoanalytic doctrine can be subjected to controlled experimental analysis. One specific experiment on the topic was carried out by Hunt and his co-workers (1941, 1947) on the effect of infantile feeding frustration upon adult hoarding in the albino rat. In these experiments young rats shortly after weaning were subjected for 15 days to feedings consisting of 10-minute group feedings of a wet mash at irregular intervals varying from 9 to 36 hours. Litter-mate controls had wet mash available to them continuously. After these 15 days the animals were given unlimited food. When the animals were about 7 months old, they were tested by allowing them to obtain and hoard food pellets for 30 minutes on each of 3 successive days. All the animals, including the experimental and the control

rats, were given a limited diet (adult feeding frustration situation) for 5 days, which was followed by 4 days of trials of 30 minutes in which they were allowed to hoard. The results showed that the animals hoarded little, even the ones that had been subjected to feeding frustration in infancy. After the adult feeding frustration, the experimental animals hoarded more than the control animals. Hunt (1941) interprets the results in terms of learning theory.

McKelvey and Marx (1951) did not corroborate the earlier results of Hunt. Their two groups of experimental animals, rats deprived of food or water for 15 days just after weaning, did not hoard significantly more than the control animals when they were tested during trial periods after they had reached 130 days of age. Food-deprived males did hoard significantly more on post-deprivation tests than did control males. In an effort to reconcile the conflicting results on infantile deprivation and hoarding, Marx (1952) further tested the hypothesis that increased adult food hoarding in animals deprived during infancy may come about as a result of an increased rate of eating. Significant differences in rate of eating between rats deprived in infancy and control rats were found for the first day of the adult hoarding trials, but by the end of the 7-day deprivation trial period the differences had disappeared. There were no differences in amount of hoarding.

In the experiments of Porter, Webster, and Licklider (1951) it was found that young post-weanling rats (26 and 33 days of age) hoarded very few pellets whereas these same animals after 2 days of food deprivation hoarded on an average almost 10 pellets per 30-minute test. Compared with the scores of older animals, both pre-deprivation and post-deprivation scores are much lower for the young animal. There is an increasing amount of hoarding as the rats are older when first tested.

In Kahn's (1951) experiment on the effect of severe defeat at various age levels on the aggressive behavior of mice, trained fighter mice were allowed to attack non-trained mice. Three groups of mice, 21, 35, and 60 or more days of age, were the experimental animals. Thirty days after the attacks by the fighter mice, both the experimental animal and its litter-mate control were subjected to a test for aggressiveness against another mouse. In general the study indicated that at maturity the aggressive behavior of the animals which were young at the time of the fighter attacks was less than that of the animals which were mature, suggesting that this type of early traumatic experience has more effect upon later behavior than a traumatic experience later in life or at maturity.

Another type of infantile experience and its relation to later behavior are reported by Hall and Whiteman (1951). They studied the effect of an intense sound stimulus administered to mice at the ages of 4 to 7 days by testing them in several different ways at a later age. In the first open-field test the control animals showed markedly fewer signs of emotional reaction than the experimental animals. In the stovepipe test the performance of the control animals was somewhat superior. Both experimental and control animals showed fewer emotional signs with more experience in the test situations. Griffiths and Stringer (1952), giving young rats in their experimental groups intense auditory stimulation, rapid rotation, extremes of temperature, or shock on an electric grid from the first day of life, found no statistically reliable differences between the experimental and control animals. They conclude that "subjection to intense stimulation during infancy does not measurably affect adult behavior in the rat" (p. 305).

Competition for food by adult mice which either had been trained to compete for food

when hungry for 7 one-a-day trials beginning at 29 days of age or allowed one single experience in competition at 33 days of age was studied by Fredericson (1951). He found that, when the animals were retested at 72 days of age, they competed over food even though they were not hungry. Littermate controls raised under conditions which did not allow competition for food did not compete for food on similar tests when not hungry.

The effect of early experience on learning and problem-solving behavior is shown in a number of studies which have concerned the effect of a varied or of a limited environment on the animal. Hebb (1947) in exploratory studies showed that animals raised in a limited environment performed more poorly in simple problem-solving tasks than animals raised as pets without as much cage restriction. Animals blinded late in life performed somewhat better in maze learning and problem solving than those blinded early in life. Bingham and Griffiths (1952) concluded that young rats reared in a richer environment (a room containing such items as tunnels and inclined planes) were superior in learning the Warner-Warden maze and an inclined-plane maze to animals reared in small "squeeze" boxes or regular laboratory cages. Forgays and Forgays (1952) likewise found that rats reared in a free-environmental situation from 26 days until about 90 days of age were distinctly superior to rats reared in mesh cages. Rats reared in a free environment which contained "playthings" in the form of simple wooden and metal structures were superior to other animals reared in a free environment. Hymovitch (1952) reported that rats reared in free-environment situations proved superior on a closed-field test given at maturity to animals reared in standard cages, small mesh cages, stovepipe cages, or activity wheels. These groups did not differ significantly in performance on a 10-unit enclosed T-maze. Furthermore, early free-environment experience proved superior to late free-environment experience. Although late-blinded rats performed better on a closed-field test than early-blinded rats, the differences in mean error scores between the groups were not significant.

In summary, the studies described here have confirmed the fact that infantile experiences may affect later behavior. However, this effect is not necessarily inevitable, and it is quite possible that the animal will react after initial readjustment in a manner similar to that of the nonstimulated animal.

Emotional Behavior

Evidence for the development of emotion in young animals will be limited in this review almost entirely to a discussion of emotional development in subhuman primates. Avoidance responses and aggressive responses are, of course, to be noted in other animals. Small (1899), for example, notes that fear in young rats develops considerably after the onset of visual and auditory functions, and he believes that the young give evidence of pleasurable emotions, for they "show signs of satisfaction when hunger and the desire for warmth are satisfied" (p. 98). Kellogg (1931), however, did not find evidence of fear of a moving stimulus in young rats (4 to 5 weeks old).

The aggressive behavior of cats toward rats has often been cited as an instance of instinctive behavior. Early observations showed that kittens do kill rats (Yerkes and Bloomfield, 1910), but more recent studies have shown certain variations in rat-killing behavior in young kittens. Rogers (1932) noted that the young kitten reacts differently to the rat, depending upon whether olfactory, visual, or tactual cues are dominant and whether or not the

animal is hungry. The 5-week-old kitten observed by McDougall and McDougall (1927) did kill wild mice, but it did not in the time of the observations kill several white rats with which it was caged from time to time. Kuo (1930) showed that animals reared in isolation killed less frequently than those reared with an adult in a rat-killing environment. Some animals which had previously not killed rats did so after they had seen this done, whereas animals reared with rats did not kill a rat like their cage-mate and, when allowed to watch another cat kill a rat, still failed to make frequent responses of this nature. Studies by Kuo (1938) show that, when kittens were reared together and with two cage-mate rats, they very seldom killed a cage-mate although they frequently ate a shaved rat or the young of the cage-mate rats (as did the adult rats themselves at times).

Young wood rats, according to observations of Richardson (1942*b*), when their eyes were yet unopened reacted toward snakes as inanimate objects. When the young were 26 days old (eyes open 11 days), they gave an alarm thump when confronted with the snake. Even older animals gave a more typical fear response, although they had had no previous experience with snakes.

The monkey observed by Lashley and Watson (1913) showed avoidance responses to such noises as rustling paper at 3 weeks of age. Tinklepaugh and Hartman (1932) observed that, as long as the young monkeys under 2 weeks of age were clinging to some object, loud noises or stimuli which might lead to fear behavior were not effective. If the animal was prevented from clinging or grasping, however, it showed some fear. Thwarting of the movement of the animal resulted in anger responses. Bingham (1927) reports that one young chimpanzee which he observed gave evidence of fear of the male parent by running to the female parent and clinging to her when the adult male was excited.

Several studies are reported from the Yale laboratories with regard to the development of emotional behavior in the chimpanzee. Jacobsen, Jacobsen, and Yoshioka (1932) report that patterns of fear, anger, mild fear, timidity, and mild excitement may be distinguished for the young chimpanzee. Patterns of fear and anger, although not well differentiated at first, could be observed from birth. The early fear responses were indicated by "clenching of feet and hands, drawing up of the arms and legs, and a tendency to cling to objects; by wrinkling of the face and retraction of the lips; and by a high-pitched crescendo scream" (p. 63). This behavior was elicited according to the authors in several situations: "(1) picking up the infant from the crib, a sudden light touch on various parts of the body, and sudden jarring of the crib; (2) complete removal of support when the infant was held in the arms; and (3) sudden intense noises" (p. 63). Some modifications of the response occurred during the first 3 months, and later, with the development of progression, the animal was able to retreat from the situation.

Anger as a response during the first 6 months was difficult to distinguish from fear. What the authors consider a clear-cut instance of anger was observed during the twelfth week when the animal rejected a nursing-bottle after she had eaten. Thereafter on several occasions the chimpanzee screamed angrily when left alone. Later, anger was often set up by some activity of the animal which was interrupted or forced upon her.

The Jacobsens and Yoshioka differentiate fear from mild fear in that:

> (1) Mild fear or timidity did not appear until the fourth or fifth month, when the infant showed marked disturbance if a stranger approached her crib or attempted

to handle her; (2) there was whimpering rather than screaming; (3) while the animal retreated under both conditions, in timidity the retreat was less rapid and less intense; the object was observed more or less continuously during withdrawal in contrast to the headlong flight in fear; (4) timidity was more readily overcome than fear [pp. 69–70].

Mild excitement is described by the Jacobsens and Yoshioka as indicated by

(1) approach toward or manipulation of the stimulating object or person, in contrast to withdrawal in timidity; (2) marked freedom of movement in contrast to the tension of fear and anger; and (3) usually vocalization of a distinctive type, namely, the soft bark which later was replaced upon occasion by rapid inspiration and expiration without laryngeal sound production [p. 70].

Yerkes and Yerkes (1936) observed the behavior of chimpanzees of different ages when a series of animate and inanimate objects were placed before them. The youngest chimpanzees, ranging in age from 1 to 2 years, were in general less responsive than slightly older or adult animals. These workers point out the importance of perceptual development and experience in the genesis of the avoidance response, and they suggest as possible stimulus characteristics predominant in the response: visual movement, intensity, suddenness, and rapidity of change in stimulus.

Haslerud's (1938) study of the effect of animate and inanimate objects in a food-securing situation upon the animals previously observed by Yerkes and Yerkes (1936) indicates that the younger animals showed less avoidance of an inanimate object than they did of an animate object, but the adults showed only slightly less avoidance of the inanimate object than of its animate counterpart.

McCulloch and Haslerud (1939) observed a chimpanzee, reared in isolation, in the food-approach situation. At the first test, at 7 months of age, it was found that only moving objects elicited avoidance responses. Definite avoidance responses were made to a live alligator and a bouncing ball. Some aggression was shown toward a bouncing ball, but on the whole very little response was of the aggressive type. Some months later, at the age of 15 months, the chimpanzee showed more avoidance behavior and more aggressive behavior to a wider range of stimuli. The animal no longer avoided objects on the basis of movement alone, however.

The emotional behavior of the infant ape, Gua, is described by the Kelloggs (1933) as being predominantly fear behavior, but including also evidence of anger, mild anger, jealousy, anxiety, and pleasant emotions. At first the principal conditions for eliciting fear behavior were loss of support and being alone, but later the suddenness or abruptness of occurrence of strange objects or persons presented visually, auditorially, or tactually called forth an avoidance response. Often the animal retreated toward the human person in her environment.

Yerkes and Tomilin (1935) report relatively little behavior of sexual significance on the part of infant chimpanzees. They state that "there are instances, but the surprising limitation in variety as well as in frequency suggests that they are exceptions" (p. 339).

Social Behavior

The study of the development of social behavior in young animals presents a very fertile field for investigations inasmuch as in mammals so many different patterns of adult social behavior seem to exist. To what extent these patterns are modifiable

is an interesting question. Since the possibility of many mammals' existing apart from the female adult during the neonatal period is very slight—although a large and well-developed animal such as the guinea pig might occasionally live [1]—complete isolation is not likely. Many mammalian young, however, can be almost completely isolated so that an exact study of the development of the animal under known conditions of social stimulation can be made.

The complexity of social relationships between young and adult animals varies considerably. There are some mammals where the main "social" factors seem to be need for warmth and food on the part of the young, the guinea pig representing this level of development. Still other animals are born in such a weak state that additional "social" factors must be sought in the behavior of the maternal animal, for the offspring are too immature to react in any fashion completely adequate for maintenance of life. On the other hand, some animals, such as the opossum, are extremely immature at birth but are able to make adequate adjustments without the aid of the adult (Hartman, 1920). At later ages the young too give evidence of reactions to the adult which are social in character, although, as soon as self-sufficiency is reached and weaning occurs, there may be no longer any special social bonds between the animals. Still other animals, extremely immature at birth, are cared for by the female until the young are weaned and sometimes longer, but reciprocal social relationships exist for a period of time after this. In contrast to the normal care of the newborn by the adult mother are the statements found from time to time in the literature that the adult mother often kills some or all of the newborn animals. See, for example, the study of Pearson and Bassett (1946). Instances of maternal care of the young in various species may be found in the surveys of Mitchell (1912), Lang (1925), Yerkes and Yerkes (1929), and Causey and Waters (1936), as well as in many of the references cited previously in the section on the behavior of the newborn animal.

For the typical laboratory animals a number of observations concerning maternal care of the young have been made. The adult female rat makes preparations in the form of nest building before parturition, collects the young into the nest, and hovers over them, allowing them to suckle (Kinder, 1927; Sturman-Hulbe and Stone, 1929; Wiesner and Sheard, 1933). Retrieving behavior occurs for a period of several weeks until the animals start crawling in and out of the nest at about 17 to 20 days of age (Sturman-Hulbe and Stone, 1929). Maternal behavior of rats with cortical lesions is inferior to that of normal animals, according to Beach (1938), but animals operated upon in infancy are usually superior to adult operates.

Other animals, such as the guinea pig, clean the young after birth in a more or less haphazard fashion, allow the young to suckle, but seem to make no attempts to gather the young about them although the young are usually to be found in the near vicinity of the adult. Seward and Seward (1940), in a study of the maternal drive of adult guinea pigs, found that the animal crosses to a litter in a shorter time just after parturition than it does several weeks later. Seward (1940), attempting to analyze more systematically the many factors which go to make up filial behavior in the guinea pig, found that the average time for crossing to the incentive compartment decreases after the animals are 1 week old with little difference in the number of crossings in a period of 10 minutes

[1] The writer has raised several guinea pigs in isolation without forced feedings of any sort, although food was left within the cage. Mortality is high.

for either the unfed or the fed group. The difference in time of running to an empty compartment and to the mother is in favor of the adult guinea pig as an incentive. Seward suggests two factors as playing the major part in filial behavior: (1) a biological factor, the need for warmth in addition to food, and (2) a social factor, the result of conditioning to the mother. Evidence fully supporting the theory is not given, but the study is a further step in applying adequate techniques to developmental problems.

Little behavior of the paternal sort has ordinarily been observed in accounts of social behavior, although occasionally observations such as those of Horner (1947) have been noted. But it must be remembered that many of our studies of those animals in which such behavior might be expected have been made under conditions of isolation or under laboratory conditions where natural groupings of the animals did not occur. It is well to remember these limitations in interpreting our knowledge of the normal social development of the young animal. For a discussion of the relationship between parent and offspring in which a wide survey of animal groups is made, see Mitchell (1912), and for a classification of social groupings see Alverdes (1927).

A detailed study of the development, especially social development, of puppies has been reported by Scott and Marston (1950). Seventy-three animals of seventeen litters and seven breeds were observed under very carefully controlled conditions of rearing. For four periods of development, neonatal until opening of eyes, transition until leaving of nest, period of socialization until weaning, and juvenile until maturity, they discuss social development under the general headings: (1) ingestive behavior, (2) eliminative behavior, (3) investigative behavior, (4) et-epimeletic behavior, (5) contactual behavior, and (6) agonistic or conflict behavior. Allelomimetic behavior and sexual behavior are also included in the last two developmental periods.

Other studies on special aspects of social behavior in puppies include examination of dominance-submission differences in a competitive feeding situation (James, 1949) and social facilitation of eating (Ross and Ross, 1949*a*, 1949*b*).

Scott's (1945) observations on the social behavior of a small flock of domestic sheep were made over a period of 4 years under conditions in which there was a minimum of human interference. The early forms of social behavior include such activities as eating-nursing, shelter-seeking, and investigating. Later the young lambs join other lambs in a play consisting largely of immature forms of adult behavior.

Most complete details concerning the social relationships of young and adult subhuman primates come from the work of the Yale laboratories (see, for example, Yerkes and Tomilin, 1935). Carpenter's (1934) observations of young and female howling monkeys in their native habitat show that the young animals cling to and climb upon the adult and that the adult orients the infant toward her and prevents it from climbing too far, retrieves the infant when it falls, and seems to give it a certain amount of tuition as it grows older. The young react fairly specifically to their mothers after they are a few days old. Carpenter suggests that the strength of the social bonds between the adult and young reach their maximum at about 8 to 10 months and decline thereafter. (See also, for descriptions of the young primate, Lashley and Watson, 1913; Allesch, 1921; Bingham, 1927; and Tinklepaugh and Hartman, 1932.)

Evidences of maternal tuition in certain activities of the infant, such as Carpenter (1934) mentions, have been cited by other

investigators. Yerkes and Tomilin (1935) comment with regard to this that "effects are achieved, whether or not intentionally, as result of example, request, command, prohibition, prevention" (p. 342).

Very little is known about the relationships among the adult male, adult female, juveniles, and young subhuman primates. Bingham (1927) observed a family of a male, a female, and an infant chimpanzee in its second year. He comments that the male animal neither interfered with the female and the child nor did he assume responsibility for the child. Carpenter's (1934) account of monkeys in their native habitat gives evidence of the concern of all animals in the group at the cries of a fallen young animal. (See also Yerkes, 1936.)

Likewise, little is known about the relationships of young animals to each other in a naturalistic situation. Carpenter (1934) comments upon the attempts of the juveniles in a group of howling monkeys to pull an infant away or to wedge themselves in a position near the adult. Tomilin and Yerkes (1935) report the activities of a pair of infant chimpanzee twins.

The social behavior of animals reared in isolation for a large part of their life is commented upon by Jaocbsen, Jacobsen, and Yoshioka (1932) and by Foley (1935).

Grooming behavior is probably very infrequent for the subhuman primate infant (Yerkes, 1933), but an instance of such is reported by the Jacobsens and Yoshioka (1932) for the chimpanzee in the thirty-ninth week.

Play. Considerable interest in the play of young animals has been evidenced since the publication in 1896 of Groos's *The Play of Animals.* General comments on the subject can be found in Mitchell (1912), Beach (1945), and Schlosberg (1947), and a number of observations are reported below. Many young animals give evidence of play behavior of the running, jumping, climbing, biting sort. (See, for example, Mills, 1898; Small, 1899; and Allen, 1904.) This type of activity becomes more easily identifiable in the more developed animals. Scott (1945) classifies various sorts of playful behavior in lambs as sexual, fighting, and allelomimetic such as running together, gamboling, and game playing. Foley (1935) reports play behavior in the young monkey consisting of running, jumping, and leaping upon objects. An increase in play behavior occurred after 18 months, when the animal was placed with other animals. Instead of a self-directed play which had previously seemed to be the rule, the animal's activity now seemed to be externally directed. There may be some question whether this transfer resulted from the termination of the isolation of the animal, for Lashley and Watson (1913) noted behavior which Foley considers comparable in a young monkey before 15 weeks.

Carpenter (1934), in his observations of young howling monkeys, notes that the young animals may play alone or with small objects and at a later age may play with other animals in wrestling or chasing types of play. The play activity "rises to a maximum by the time the animal is classed as a juvenile 1, and following a period of development there is a rather sharp decline in the amount of play" (p. 79).

The Jacobsens and Yoshioka (1932) suggest the following analysis of play behavior in the chimpanzee they observed. They note *exploration, manipulation, and simple play,* which occurred infrequently during the first 2 months and developed into a tactile examination of objects during the third month. *Organized play,* "in which the animal organized diverse activities in relationship to a central point" (p. 72), was observed first during the sixth month. A third type of play, *bodily activity as play,* seems to have developed with the

motor development of the animal. A fourth type, classed as *play and manipulation essentially social,* was evidenced in such behavior as the threatening and attacking responses with which the animal approached the human observers, a pet dog, and other infant chimpanzees.

Accounts of the play of the young chimpanzee reared in a human environment are given by the Kelloggs (1933) and C. Hayes (1951). The story of the play activities of the animal reared by the Kelloggs begins at the age of 7½ months and is illuminating with regard to the type of play entered into by a chimpanzee and a human child. The ape raised by the Hayeses grew up much as an "only" child in an environment as nearly like that provided for a human being as could be arranged. Both of these animals showed highly advanced play behavior, including physical activities like swinging, playing tag and peek-a-boo, and play with toys and objects appropriated for toys and the like.

For other descriptions of play activities, see Bingham (1927) and Yerkes and Tomilin (1935).

Vocalization. Most of the references to the behavior of young animals include some descriptions of the vocalizations of the animal—the birth cry, the cries of the young when not sucking, the cries occurring during play, startle cries, hunger cries, etc. Descriptions of the vocalizations of monkeys and chimpanzees, with some comment on the possible function of such vocalizations, are to be found in Jacobsen, Jacobsen, and Yoshioka (1932), Kellogg and Kellogg (1933), Carpenter (1934), Foley (1935), and Yerkes and Tomilin (1935). According to Yerkes and Tomilin, the infant chimpanzee's vocalizations include a shrill birth cry, cries of *uh-uh,* barks of *oo-oo,* whimpering, whining, shouting, and screaming. They believe the adult recognizes these cries not so much in terms of the kind of vocalization as in their pitch, volume, and abruptness. The young animal seems to learn very slowly to react to the sounds and gestures of the adult, but it finally responds differentially to a great many sounds. The observations of the Kelloggs agree with those of Yerkes and Tomilin. Their observations further indicate that the young ape gives no evidence of learning the vocalizations of human beings but that the animal does respond quite definitely to some of the words of the human being.

One of the main projects to which the Hayeses (1950, 1951) devoted their attention was the development of language in the chimpanzee. As a very young animal, the chimpanzee, Viki, brought up in their home seldom made any sounds. Unlike the human infant, she never cried but did make the sound of *oo-oo, oo-oo,* which could turn into a scream if the animal were under severe stress such as falling. At 1 week Viki said the sound *uh-uh-uh-uh,* and she gave a chimpanzee bark at 5 weeks of age. She used the sound described as a food bark at 14 weeks. She also made other combinations of sounds, but these did not compare in frequency or variety with the babblings of babies. At 5 months, training was begun to get Viki to vocalize to the command "speak." At 10 months she made the sound of *ahhh* and reached for food. This was the sound she used in "asking" situations. Later by manipulation of the lips of the animal she was taught three words, *ma ma, papa,* and *cup.*

While Viki's vocalizations of sounds like those of the human adults with whom she lived were very limited, her understanding of sounds advanced much further. To be sure, responses were sometimes dependent upon the situation and did not always occur, even though the animal had previously responded quite correctly. In general, language development in the chimpan-

zee is limited. Hayes (1950) believes that "the chimpanzee's failure to talk is not due to inadequate speech organs or general intelligence, but rather to a neurological condition similar to aphasia" (p. 276).

Effect of Isolation. In one study on the effect of isolation upon social behavior Bayroff (1936) reared rats in isolation from the twentieth day to approximately the one hundred and fifteenth day. Using a technique designed to test whether the animal displayed any behavior indicating social preference, he found none indicated in his results. The technique used, however, while allowing a response of a social nature, also permitted the establishment of a positional habit on the part of the animal. Accordingly, Bayroff (1940) used another technique which made it necessary for rats swimming under water to reach the escape compartment first in order to be released. No significant differences appeared in the speed of swimming of animals reared in isolation after weaning from that of animals reared together. The experimenter concludes that "the nature of the early life is not the principal determiner of success in the competition" (p. 306).

Descriptive accounts of young primates reared in isolation are given by Jacobsen, Jacobsen, and Yoshioka (1932) and by Foley (1934).

Need for Further Work

The reader who has followed the course of this chapter has probably been impressed by several facts: (1) the accumulation of observations regarding the ontogenetic development of behavior in numerous mammalian groups; (2) the incompleteness of data and possible inaccuracy of some conclusions; (3) the growing number of experimental studies involving the young animal; and (4) the importance of knowledge in this field for the ultimate solution of certain insistent problems in genetic psychology. Considerable work remains yet to be done. Descriptive studies are by no means complete, and experimental studies utilizing precise methods and satisfactory quantitative measurements are relatively few. Yet these basic studies must be made before problems dealing with larger aspects of genetic psychology can be treated successfully.

There have been in the past few years additions to the research on young animals. Some descriptive reports have been made on the genetic development of domestic and typical laboratory animals and also on the growth of animals in their native habitats. Furthermore, more experimental studies have been undertaken, many of these in new areas of investigation, as, for example, the effects of nutritive material on behavior, electroconvulsive shock on later learning, natal anoxia on learning, and early experiences of various sorts upon later behavior. Some of this research has been directly initiated in response to the need for experimental data on topics of great import in child development for which data other than clinical records are not likely to become readily available.

Probably most adequately treated up to now is the development of motor responses in young animals. Here the responses are less difficult to observe, and several groups of scientific workers other than psychologists have been interested in the problem. Relatively lacking in experimental work, but yet providing richly provocative material for research, is the analysis of the perceptual responses of the young animal. Additional work is needed on the problems of learning, memory, and intelligence; and an increased interest and the use of more adequate techniques for observation should contribute further work upon the problems of emotional and social development.

Chapter 4

THE NEONATE[1]

Karl C. Pratt

Birth

Nature and Significance. Birth is the term applied to the transfer of the developing child from the uterine environment to that of the external world. It is accomplished by contractions of the uterus which, by exerting pressure, rupture the fetal membranes and expel the child through the birth canal. This event severs the parasitic connections with the mother and necessitates an autonomy of vegetative functions if the child is to survive. The effects of birth on the infant may be inconsequential and transitory or they may greatly affect the course of subsequent development.

Organismic Changes. In the fetal environment the child leads a parasitic existence. It is dependent upon the maternal organism for external respiration, for digestion of food and the preparation of nutrient materials, for excretory functions, for thermal regulation, and for protection.

During the birth process the circulatory relations with the maternal organism (by way of the umbilical cord and the placenta) are at first disturbed and then broken off. At about this time the crucial vegetative function, external respiration, must appear or the child will be asphyxiated. Clifford (1941) found that over one-half of "live-born" infant deaths are caused by asphyxia.

Up to the onset of the birth cry the lungs have been uninflated and nonfunctional. Two major theories, according to Fernandez (1918) and Feldman (1920), have been advanced to account for the initiation of pulmonary respiration: (1) that the process is started by external stimuli; (2) that it is brought about by a critical concentration of CO_2 in the blood stream of the infant.

According to the first theory, cutaneous stimuli (contact and thermal) serve to bring about an innervation of the musculature of the thorax while atmospheric pressure inflates the lungs. Relaxation of the muscles produces exhalation. The process is repeated with succeeding inhalations brought about by neural discharges proceeding from the respiratory center. In support of the theory of the excitatory rôle of cutaneous stimuli it is pointed out that the attending physician employs still more intense cutaneous stimuli if the infant has not begun to breathe. The effects of thermal stimuli below physiological zero upon the breathing of newborn infants have been observed by Pratt, Nelson, and Sun (1930), and are a matter of common experience at later age periods.

According to the second theory, pulmonary respiration is started when the CO_2 content of the blood attains the critical concentration which acts directly upon the respiratory center to arouse it to activity. It is said that the birth process, by disturbing the circulatory relations between the maternal organism and the child, increases the CO_2 content of the child's

1 The writer is indebted to Dr. O. C. Irwin and to Dr. D. M. Trout for suggestions and for criticism in the preparation of this chapter.

blood stream and that breathing starts as soon as the respiratory center is activated. This theory accounts for the Ahlfeld "breathing movements" of the fetus. Doubtless both cutaneous stimuli and those provided by the blood stream cooperate in establishing pulmonary respiration.

Coincidental with the onset of breathing, valves in the heart operate to alter the circulation from the fetal to the natal type. Instead of passing to the placenta for aeration the blood now flows to the lungs.

The interruption and cessation of circulatory relations with the maternal organism mean that no more nutrient materials ready for assimilation are available to the child. Henceforth it must take food, digest it, excrete, egest, and maintain a relatively uniform body temperature despite variations in its thermal environment.

Environmental Changes. Birth transfers the developing child from an environment of relatively few to one of many stimuli; from one in which the conditions for learning are unfavorable, or restricted, to one presenting manifold possibilities; from one devoid of the social factor to one in which it is operative. From the observations of Bersot (1920, 1921) and Langworthy (1933) it seems probable that this postnatal environment not only provides richer opportunities for learning but also stimulates the continuing development of the nervous system.

Birth Trauma. The pressures produced in the birth process sometimes give rise to fractures of bones during passage through the birth canal, but the more common consequences are hemorrhages. They may be of slight extent and quickly absorbed; they may involve vital nerve centers and result in death; or they may permanently affect parts of the nervous system with consequent impairment of function.

In addition to their effects upon general intelligence, birth injuries have transitory or permanent consequences for sense organs such as the ear and the eye. Kutvirt (1912) and Vosz (1923) have correlated lack of auditory sensitivity with prolonged and difficult labor; Sicherer (1907) and Edgerton (1934) have discussed the effect of retinal hemorrhages and other optic disturbances in the neonate.

The psychoanalytical school postulates psychic trauma resulting from the rupture of the fetal relations with the mother. Rank (1929) holds that the primal anxiety state, whence all subsequent anxiety states stem, has its origin during the birth process. This concept is widely accepted as a fundamental facet of psychoanalytic doctrine. Rank, like Ribble (1944), ascribes its formulation to Freud himself. Despert (1946), however, considers it doubtful whether Freud ever regarded it as more than a dubious assumption, and Ruja (1948) asserts that Freud claimed there were no empirical checks by which Rank's thesis could be evaluated. Freud had suggested an investigation of the relation of the crying of newborn infants to the duration of labor of the mothers, but Ruja (1948) did not obtain statistically significant correlations.

Anderson (1948), in a very significant paper, has criticized the dogma, currently popular in psychoanalytic and allied circles, that childhood is a period of extreme susceptibility to trauma or shock. The attempts to locate the traumatic incident have led to a continual but vain regression through adolescence, childhood, infancy, and, finally, to birth. The ultimate, he hints, in such regression would be to place the initial trauma at conception. This, in fact, is where Sadger (1941) was led by his analyses, only to discover that the troubles of some of his patients dated from their *earlier* existence as spermatozoa and ova.

In general, psychoanalytic interpretations of the experience of the child at birth or before show a kinship with the antecedent literary and philosophical treatments of Lucretius, Kant, and others. Sterne, in *Tristram Shandy*, anticipates Sadger's views (1941) by remarking in the famous passage concerning the fate of the homunculus

> Now, dear Sir, what if any accident had befallen him in his way alone!—or that, through terror of it, natural to so young a traveller, my little Gentleman had got to his journey's end miserably spent;—his muscular strength and virility worn down to a thread;—his own animal spirits ruffled beyond description,—and that in this sad disordered state of nerves, he had lain down a prey to sudden starts, or a series of melancholy dreams and fancies, for nine long, long months together.—I tremble to think what a foundation had been laid for a thousand weaknesses both of body and mind, which no skill of the physician or the philosopher could ever afterwards have set thoroughly to rights.

Definitions

Derivation. The term *neonate* is a Graeco-Latin derivative. Its respective Italian, French, German, and English equivalents are *neonato, nouveau-né, Neugeborener,* and *newborn.* The Spanish *recién nacido* has a slightly different but scarcely less indefinite connotation.

Further ambiguity for indices and bibliographies is created by the use of such terms as *child, infant, Säugling, nourrisson, enfant, bambino, lattante,* without restricting adjectives or statements of the age range of the studies.

Duration of the Period. According to McGraw (1932), the child is not a *neonate* until the "umbilical cord is dressed and the baby is taken to the maternity nursery." Before this the just-born child for a period of "about the first 15 minutes of life" is a *partunate.* This is the period "during and immediately following parturition." In terms of the latter statement the time stated for this period must be grossly inaccurate. Furthermore, it would appear doubtful whether McGraw, in terms of her own definition, is actually reporting the behavior characteristics of *partunates.*

A few authorities hold that the neonatal period extends to approximately the end of the first postnatal week; for others it comprises the first 2 weeks. Still others extend the period to 1 month, with Vinay (1897) going further to an extreme of 3 months. Gundobin (1907) rejects a fixed chronological terminus and instead considers it as ending when complete regularity of assimilation indicates the general integrated functioning of all organs.

Valentine and Dockeray (1936) would differentiate between *newborn infant* ("the first 10 days of life") and *neonate* ("the first 30 days"). There is nothing, however, in the etymology of the terms or in historical usage to warrant such a distinction.

The prevailing usage in the field of infant behavior follows Feldman (1920) and Gesell (1925) in defining the *neonatal* period as extending from birth at full term to the end of the first postnatal month.

General Characteristics. The duration of the period is determined by physiological, medical, and psychological criteria. It is a period of adjustment and perfection of newly acquired vegetative functions. It is marked by the obsolescence of such structures as the ductus Botalli and the umbilical vein, and by the recovery from injuries such as asphyxia, umbilical infections, tetanus, obstetrical paralyses, and hemorrhages incurred during the birth process. It is likewise a period during which certain sensory-motor structures are first activated by adequate stimuli, such stimulation helping to bring about further maturation of the nervous system. This reactivity reveals

the effects of fetal maturation but in itself induces no pronounced developmental events, nor does it afford a basis for more than the mere beginnings of learning. In brief, the most important developmental events of the period appear to be those immediately consequent to the incident of birth which ushers in the period.

History of the Study of Neonate Behavior

The Longitudinal Approach. The first more or less systematic attempts to describe the behavior of the newborn infant appeared in the *baby biographies.* Of the fifty or more published during the preceding century and the first decade of this one, the following may be cited as outstanding in content or influence: Tiedemann (1787), Darwin (1877), Champneys (1881), Preyer (1882), Binet (1890), Hall (1891), Shinn (1893–1899), Lowden (1895), and Major (1906). Of these, the biographies by Preyer and by Shinn have had most significance and enduring value for child psychology. Dennis (1936) has compiled a bibliography of baby biographies, and Dennis and Dennis (1937) have made a tabular organization of the temporal incidence of the more important items of behavior as reported in forty such studies.

The serious limitations of the biographical approach to problems of development are well known: a paucity of cases, a probable nonrepresentative selection, and bias because of family ties. Furthermore, the lack of systematically introduced and controlled stimuli together with inadequate provisions for controlling the conditions of observation must result in the inevitable errors of the anecdotal method. The virtue of the "naturalness" of observation as opposed to the "artificiality' of experimentation has, however, been championed by Bridges (1935).

More recently the longitudinal approach to behavioral development has been revived, but with modifications which distinguish it in several respects from the biographical procedure. The investigator pursues the development of a number of children with respect to specific problems. The children are not related to the biographer and are probably not so select a population as that described in the early baby biographies. The observations may be made at fixed time intervals and frequently refer to the performance of children under specific *test* conditions. Notable among investigations of this type are those undertaken by Shirley (1931*a*, 1931*b*, 1933*a*, 1933*b*), Bayley (1933), Gesell, Thompson, and Amatruda (1938), and other collaborators.

McGraw (1935) and John Dewey, in the introduction to McGraw's account of the nonidentical twins Johnny and Jimmy, have been inclined to characterize all other studies as presenting merely a series of cross-sectional *achievements* and to claim that only her investigations are truly longitudinal. McGraw's conclusions in regard to normal development are, however, not supposed to rest solely upon observations of the one set of twins, but also to depend upon the results of an average of 38 examinations of 68 infants over a period of 2 years. It would thus appear that there is no fundamental distinction in respect to the frequency of sampling of behavioral development, aside from the twins, between McGraw's work and the studies which she has criticized. In a review of McGraw's book, the writer (1936*b*) has pointed out that all such studies of behavioral development represent time samplings of behavior and that the pursuit of a particular mode of behavior from time section to time section may be described as a longitudinal study, but such usage in no way alters the fact that the pursuit is discontinuous; and hence everything observed in a given time

sampling is an "achievement" at the moment regardless of the size of the interval separating the samples.

The Cross-sectional Approach. The ontogenetic progression of behavior may likewise be explored by investigating the response repertory in cross-sections of the population at successive age levels. Because it is difficult to pursue sequential development in a large constant population, most of the data of child development have been obtained from researches of the cross-sectional type, which provide more stable norms and more information regarding individual variation. Almost all investigations of the neonate represent this approach.

Population Controls in Experimentation. In longitudinal studies of development the same population is followed through succeeding age periods. The co-twin control method, devised by Gesell and Thompson (1929) to provide populations with the same hereditary potentialities for the purpose of contrasting the effects of exercise or learning with those due to maturation alone, has as yet not been employed during the neonatal stage. Instead, recourse has been had to the familiar device of control and experimental groups. This is illustrated in Marquis' (1931) attempt to establish conditioned sucking responses in the neonate to auditory stimuli.

In cross-sectional studies which aim to establish the effect of specific stimuli upon the behavior or activity of the infant, as in the researches of Pratt, Nelson, and Sun (1930) and Pratt (1934*b*), a populational control is in effect when the activity of a given infant is observed and measured not only during an experimental period in which specific stimuli are introduced but also during a control period in which there are no experimental stimuli.

The need for population controls is emphasized further by the fact that the character of a response is influenced by the physiological state of the infant at the time of stimulation. A sampling control may attempt to meet this by varying the position and the order of control and experimental periods. The effects of specific stimuli upon the child must be allowed to subside before other stimuli are applied. When all this is done, however, differences in physiological state remain which seem to necessitate the description and measurement of behavior according to differing physiological conditions. In the field of neonate study Pratt, Nelson, and Sun (1930), Pratt (1934*f*), Irwin and his students—Weiss (1934), Stubbs and Irwin (1934), and others—and Wagner (1937) have made beginnings in this direction.

Experimentation. Control and measurement are the essence of the experimental method, and they apply to the stimulating conditions, to the nature of the populations studied, and to the responses of the individual organisms.

The rudimentary beginnings of experimental methods may be seen in a few of the baby biographies, in the cross-sectional investigations of Kussmaul (1859), Genzmer (1873), and Kroner (1881) during the past century, and in the studies of Peterson and Rainey (1910) and of Blanton (1917) in the early years of this century. These sometimes involved sizable neonate populations and an extensive survey of the behavior equipment but comprised merely the introduction, without control or measurement, of experimental stimuli, and a more or less uncontrolled observation of the responses elicited. Studies of this type, but confined to some particular response, are illustrated by Engstler's (1905) observations of the plantar responses of 1000 children.

Bechterew (1908) was one of the first students of human behavior to urge that quantitative registration and measurement

of responses be substituted for qualitative observation and description. Canestrini (1913) realized this objective by using a pneumograph and a kymograph to register the effect of various stimuli upon respiration. In a similar fashion he recorded circulatory responses by employing a Marey pneumograph attached at the infant's fontanelle. He did not, however, achieve any appreciable control or measurement of his experimental stimuli, nor did he provide an expression, in quantitative terms, of his kymograph records so that central tendency and individual variation might be determined. At about the time of Canestrini's researches, Benedict and Talbot (1914) were using a crib-recorder to afford a continuous registration of the "spontaneous" movements of newborn infants, even for periods of 24 hours.

Peiper, whose researches encompass all aspects of early human behavior (see a partial list of his contributions in the bibliography), employed a modified Morse apparatus to measure reaction times (1925*b*, 1926*a*) and devised stimulus controls (1924*b*, 1926*a*) for the investigation of thermal and of pain sensitivity. Eckstein and Rominger (1921) measured respiration by means of a facial mask and pneumatic system; Eckstein (1927) improved the earlier crudely instrumentalized study of the sucking response; and Eckstein and Paffrath (1928) employed apparatus to measure the general activity of the neonate. Carlson and Ginsburg (1915) first measured the stomach contractions of the newborn infant.

The problem of emotional patterns of behavior was explored by Sherman (1927*a*) through the medium of motion-picture photography. At the Yale laboratory Gesell made use of the photographic dome in obtaining motion pictures from different angles, and the subsequent frame analysis of such records provided a remarkable normative series (1934). The production of instructional films of child development, likewise under his direction, is, as Beck's (1938, 1942) lists indicate, an outstanding contribution.

The comprehensive researches upon neonate behavior undertaken at Ohio State University by Doctor A. P. Weiss (1929) and his students established the groundwork in general technique for many subsequent studies. The activity of the newborn infant was recorded objectively and automatically by an adaptation of the stabilimeter-polygraph apparatus originally designed by Renshaw and Weiss (1926) for the study of postural responses in adults. Pratt, Nelson, and Sun (1930) designed and described an experimental cabinet [1] which would effect some control of the stimuli impinging upon the child. The work of Pratt, Nelson, and Sun likewise represented an advance in the direction of control and measurement or evaluation of many of the stimuli employed. Irwin (1930) made the most extensive studies of neonate activity through 24-hour periods so far attempted. Other major contributions by Weiss and his students are illustrated by Jensen's (1932) remarkably instrumentalized research upon the sucking response, and the first attempt by an American, Marquis (1931), to establish conditioned responses in newborn infants.

After the untimely death of Doctor Weiss the center of significant research upon neonate behavior shifted to Iowa State University, where Irwin and his students not only made the innovations already mentioned but also, in addition to undertaking the solution of new and important problems of neonate behavior, pressed

1 The Pratt experimental cabinet was first modified and improved by Irwin and his students with the introduction of facilities for motion-picture photography, including a "cold" light (1931). Dockeray and Valentine (1939) have redesigned it to meet the original aims more adequately as well as to incorporate the improvements introduced by Irwin.

steadily forward in the setting-up of the best control of all aspects of experimentation that has so far been attained in this field. With Richards (1936), Irwin has demonstrated that the era of uncritical reliance upon the "clinical method" in the investigation of behavioral development must come to an end with realization not only of the inadequacy but also of the personal distortion inherent in the purely observational recording of behavior.

A later research tool employed in investigating the responses of the newborn infant (Hunt, Clarke, and Hunt, 1936) was ultrarapid motion-picture photography as developed by Hunt and Landis (1936). Before their work ordinary motion pictures had been employed for record purposes, for frame analysis of some responses, and for a rough measurement of certain reaction times. With ultrafast motion pictures, however, Landis and Hunt were able to overcome the limitations of our sensory-motor mechanisms and to differentiate responses temporally which heretofore appeared to be overlapping and confused. As Landis and Hunt (1937) point out, what one observes depends in part upon the temporal relations of events, and hence it may become necessary in the future to state the temporal conditions of observation according to which the description of behavior applies.

In the statistical expression of data on infant behavior Bersot (1920, 1921) has been a pioneer. He stressed the need for noting and evaluating the variability of responses. Correlational procedures have been employed by the Shermans (1925) to follow maturational changes or improvement in responses with increasing age; by Furfey, Bonham, and Sargent (1930) to determine whether any general factor runs through all neonate responses; by Pratt (1930) to study the relation of activity to environmental temperatures; and by Irwin (1932*f*) to pursue the change in activity from one nursing period to another. The standard error of percentage has been employed by Richards and Irwin (1934*c*) to determine the prevailing type of toe movements in the plantar response.

Richards and Irwin (1934*a*) have written the best account of experimental methods in the investigation of neonate behavior, and reviews of the behavior repertory of the infant have been furnished by Peiper (1928, 1930, 1949), Pratt (1933), Hurlock (1933), Stirnimann (1933, 1940), Dennis (1934), Dewey (1935), Munn (1938), and Irwin (1946). A bibliography of the physiology and pathology of the newborn has been compiled by Antonov (1947).

Physiology

Circulation. With the beginning of pulmonary respiration the course of fetal circulation changes to the postnatal type. With increase in age the cardiac rhythm decreases while the blood pressure increases (according to Feldman, 1920, the blood pressure is 60 in the newborn infant and 120 in the adult). Sontag and Wallace (1935*a*) found that the heart rate averaged 144 beats per minute during the latter part of the fetal period. Murlin, Conklin, and Marsh (1925), as reported by Richards (1935), obtained a basal pulse rate of 117 per minute in the neonate. Halverson's (1941) most comprehensive investigation of the pulse rate under different situations indicates great variation. In *profound sleep* the mean rate was 123.5; during *crying* it was 94.7 beats greater. The velocity of the pulse wave is said by Rominger and Meyer (1932) to increase with age. Bernfeld (1931) has confirmed the Yllpö thesis that the capillary resistance is less at first, particularly among prematures, and that this may be related to a high incidence of hemorrhages during the birth process.

Both rate of heart beat and blood pressure are modified by the various stimuli acting upon the organism. Sontag and Wallace (1935*b*, 1936) have shown that in the last month before birth vibratory stimuli applied to the mother's abdomen increase the average heart rate by 14.3 ± 0.74 beats per minute. The effects are first demonstrated during the third month before birth. They have also shown that 8 to 12 minutes after the expectant mother begins smoking the fetal heart rate increases 5 ± 0.19 beats per minute.

Canestrini (1913) proved the sensitivity of the neonate to stimuli of different modalities by registering the changes in rate and volume of the pulsations at the fontanelle. Although differentiation of modalities in terms of brain curves is impossible, some stimuli result in a slower pulse rate and others in a faster rate. These are interpreted as indicating, respectively, pleasant and unpleasant feeling tones.

Respiration. According to one view, pulmonary respiration is initiated by intense cutaneous stimulation. Runge (1895) is an exponent of this view. A second theory states that breathing is precipitated by a critical concentration of CO_2 acting upon the respiratory center. Other writers believe that both factors are operative. Peiper (1933*a*) adheres to the second theory. For him the viability of the premature infant depends upon the level or critical maturation of the respiratory center. In a number of researches he (1933*a*) and collaborators such as Good (1934) have discovered that the breathing movements of prematures have the characteristics of those which are physiological rather than pathological in lower animals. Creutzfeldt and Peiper (1932) have shown that death from respiratory failure depends upon immaturity of the respiratory center rather than upon its impairment by hemorrhages.

According to Peiper (1933*a*, 1933*b*), among the types of breathing indicative of immaturity of the respiratory center are periodic breathing (Cheyne-Stokes), which is sometimes seen in the full-term infant and which is characteristic of the premature, and gasping respiration (*Schnappatmung*), which reveals a still greater immaturity. Breathing of the neonate is of the abdominal type with the thorax becoming more involved when the child assumes an upright posture and begins to walk.

According to Schmidt (1950) and Peiper (1951), observations and motion pictures demonstrate that gasping (*Schnappatmung*) rather than the birth cry is the first respiratory response of the neonate. Schmidt (1950) found gasping to have a duration of 13 to 45 seconds in normal full-term infants, up to 6½ minutes in eighth-month prematures, and up to 12 minutes in difficult births.

Ahlfeld (1905) registered "breathing movements" of the fetus *in utero* of a rate similar to that of the neonate. In the neonate Vormittag (1933) reports the average to be 35 per minute during the first week after birth, and 37.7 per minute during the remainder of the neonatal period. By the end of the first year it has declined to 27.8, and from 10 to 15 years, to 19.1 per minute. Murphy and Thorpe (1931) found an average of 43.1 per minute in the newborn infant, and Peiper (1933*a*) places it between 35 and 45 per minute. Halverson (1941) reported that the breathing rate alters markedly from one situation to another and from one infant to another. In *sleep before awakening* the mean rate was 32.3; in *crying* it was 133.3 respirations per minute.

Employing a Krogh spirometer, Murphy and Thorpe (1931) found an average minute volume of 721.4 cc. and a mean tidal air of 16.7 cc.

A number of responses deeply involve or are intimately associated with the respiratory mechanisms. Among them are sneezing and coughing, reported as occurring shortly after birth. The birth cry itself is interpreted as a concomitant of the initiation of pulmonary respiration. Peiper (1933*a*, 1933*b*) interprets yawning, found even in young prematures, as a breathing movement of a primitive type but having no pathological significance in its persistence. Peiper (1933*a*, 1939*b*) has also demonstrated that during the suckling period a relation exists between the respiratory, sucking, and swallowing centers which enables the child to suck, swallow, and breathe at the same time, an ability not possessed by the adult. The rhythm of the swallowing center influences that of the sucking center, and this in turn influences the rhythm of the breathing center. The ratio of swallowing, sucking and breathing movements is commonly 1:1:1, less frequently 2:2:1. Swallowing occurs during the pauses between phases of breathing, according to Peiper (1939*b*) and Halverson (1944). Halverson (1944, 1946) reported that sucking movements occur simultaneously with breathing movements except during strong sucking, when the strongest sucks come after thoracic inspiration. In general, strongest sucking is accompanied by costal rather than abdominal breathing. Good coordination may be obtained even in premature infants. Peiper (1933*a*, 1933*b*) considers crying to be a breathing response.

The rate and amplitude of breathing movements in the newborn are, as Canestrini (1913) proved, modifiable by stimuli of various types and manifest great differences according to the physiological state of the child. As in circulation, the effects of stimuli upon respiration are general and nondifferentiating. Slow and regular breathing movements following certain stimuli are interpreted as revealing a pleasant feeling tone, whereas the heightened respiratory activity consequent to other stimuli is said to indicate unpleasant feeling tones. The effects of specific stimuli are mentioned in other sections of this chapter. Peiper (1933*a*) emphasizes the contrast in respiratory activity and regularity between sleeping and waking states.

Alimentation. Before birth, nutrient materials ready for assimilation by the fetus are furnished by the maternal organism. The alimentary tract, whose function it is to ingest food, to undertake its digestion, and to egest the indigestible materials, is not functional in the accepted sense of the term. But this does not mean that it is wholly inactive. Bersot (1920, 1921) has emphasized that here, as in respiration, there is preliminary activity during the fetal period. Examination of the contents of the alimentary canal reveals the presence of amniotic fluid which has been swallowed.

From the nutritional point of view it is to be noted that the transition to autonomy in digestion is accompanied by a loss of birth weight until about the middle of the first week, when the child begins to increase in weight and achieves birth weight by the seventh to tenth day. Various and conflicting theories have been developed to account for this loss in birth weight. According to one theory it is caused by scanty milk production. As a general explanation this seems untenable because supplementary feeding does not prevent some loss. This leads to the supposition that imperfect assimilation is responsible. A part of the loss may be mechanical as, for example, a loss of water. Talbot (1917*a*), however, believes that it arises because colostrum does not meet the energy requirements of the newborn infant.

In most mammals the process of alimentation is served by mouth orientation responses which, elicited by tactual stimulation of the face and lip areas of the young,

operate to bring the opened mouth to the nipple. When contact or coupling is thus effected sucking starts, and ingestion of food follows. Salivation takes place and swallowing responses are coordinated with sucking and breathing. Gastric secretion likewise follows. When the stomach fills, the child ceases to nurse and contact is broken. Frequently there is regurgitation, often followed by hiccuping.

The stomach empties in 4 to 5 hours at most; the small intestines in 7 to 8 hours; and the large intestine within 2 to 14 hours. Kahn (1921) has noted that the young suckling differs most in this respect from the adult, who requires 20 to 40 hours for movement of materials through the colon. Proponents of self-demand feedings, such as Trainham and Montgomery (1946), assert that when cow's milk is used the passage through the stomach requires 3 to 4 hours but that with breast milk the duration is from 20 minutes to 1 hour.

Defecation or egestion completes the sequence of activities in the alimentary tract. Halverson (1940) has found that defecation occurs most frequently during the first half hour after feeding. On the basis of 8½ hours of daytime observation he places the median number of defecations in 24 hours at 4.7. Most of the defecations occurred during wakefulness, but, contrary to other observers, he reports that the infants are usually quiet during and after the act.

Aside from the fact that alimentation is a vital process, it is of interest to the student of behavior because it appears to be intimately associated with the two "drives" of "thirst" and "hunger." Simsarian and McLendon (1942, 1945) have stated that on a self-demand schedule of nursings infants were more variable as to frequencies, had a greater number of feedings, and spent more time nursing during the first 10 days after birth than infants under the customarily imposed schedules. Thereafter, although still highly variable, the infants' demands approached the 5–6 feedings per day which are characteristic of infant schedules in the culture. The relation of general activity or motility in the neonate to "hunger" has been the object of a number of investigations.

Having correlated the subjective "hunger" in adults with certain muscular contractions of the stomach, henceforth termed "hunger contractions," Carlson and Ginsburg (1915) have demonstrated their presence by means of the balloon technique in infants that have not yet nursed. These contractions differ from those of the adult only in the shortness of periods of quiescence between periods of contraction. According to these investigators, awakening and crying had some relation to the vigor of the contractions.

In more extensive studies R. Taylor (1917) found that the "hunger" contractions of the neonate were more vigorous than those of the adult. In the adult they may be inhibited when taste substances are introduced in the mouth; in the newborn infant no such effects follow. Small quantities of water or of milk introduced into the stomach, however, do produce temporary inhibition of the contractions.

Taylor (1917) describes the sequence of events as follows:

> The first contraction period is apt to be short. After a wait of perhaps twenty minutes a longer and more intense hunger period arrives; then another and another. The infant's sleep becomes lighter. He is more easily awakened by external stimuli or by gastric discomfort. He is put to the breast, nurses vigorously, becomes fatigued or experiences satiety from distention and again goes to sleep.

According to Taylor (1917), increase in reflex excitability is synchronous with the periods of these stomach contractions.

Often the contractions are accompanied by automatic sucking movements. In normal full-term infants "hunger" contractions begin about 2 hours and 50 minutes after nursing, during the first 2 weeks; from 2 to 8 weeks they start in about 3 hours and 40 minutes after nursing. This demonstrates that they arise before the stomach has emptied and are therefore not ascribable to an empty stomach. This particular study offered no evidence that "hunger" is the immediate cause of crying.

These studies, as well as those made of other animals, seemed to indicate that some of the general activity of such organisms is related to events in the alimentary tract. Pratt, Nelson, and Sun (1930) observed the difficulty of obtaining infants who were not crying and were not excessively active as a nursing period approached. They measured general activity in control periods set up to provide a basis for comparison of activity during periods of experimental stimulation.

The most thorough studies of general motility in the neonate are those made by Irwin (1930, 1932*c*, 1932*f*) and by Richards (1936*a*, 1936*b*). From his 24-hour studies of activity Irwin came to the following conclusion:

> The fact that activity usually is greatest toward the end of the observation period, that is, just before nursing, and usually is least at the beginning of the period, just after nursing, suggests that the activity is stimulated probably by hunger contractions. This inference is best illustrated by the exceptional rise of the curve during the long night period when the nursings were eight hours apart. Since the external stimuli were constant, the conclusion seems justified that the activity of these infants is due largely to internal factors, presumably of the alimentary canal.

In a later research involving 73 infants, but with sampling of activity from 2:30 to 5:45 P.M. only, Irwin (1932*e*) substantiated his earlier findings and demonstrated that there is a significant increase in motility by the fourth to fifth day. Irwin (1932*f*) also found that general motility correlates .97 ± .04 with lapse of time from one nursing period to another. Contrary to usual belief, he found that more infants were awake during the first 15 minutes than during the last 15 minutes and that more were asleep during the middle 15 minutes of the period. Activity during the first 15 minutes amounted to 17.0 oscillations per minute; during the last 15-minute period it soared to 45.0 oscillations per minute.

Pursuing these studies of motility, Irwin (1933*d*) found that general motility correlated −.13 ± .008 with Pirquet's index of nutritional status, and .007 ± .08 with Finlay's index. Irwin (1932*d*) likewise found no significant relations to exist between intestinal area and motility.

Richards (1936*c*) has attempted to review the evidence bearing upon the nature and origin of the stimuli producing general activity in the newborn infant. He (1936*a*, 1936*b*) has conducted experimental researches to determine the relations between motility and muscular activity of the stomach. From the results he has concluded that peristaltic activity increases with the time since feeding. Bodily activity increases similarly but does not result from peristalsis because there is no more bodily activity during strong peristalsis than during gastric quiescence. Furthermore, the presence of the balloon in the infant's stomach inhibits general activity but not peristalsis. This investigator's conclusion, "It is likely that in hunger gastric activity is a specific reaction to the general nutritional state of the organism as expressed, perhaps, by constituents of the blood," leaves the problem of the direct excitant of motility still unsolved.

Excretion. Halverson (1940), on the basis of 8½-hour periods of observation of male infants, has estimated the average number of voidings per 24 hours to be 18.6. The greatest number of micturitions occurred during the first hour after feeding. A wide variation (ranging from 5 to 285 minutes) in the intervals between micturitions was observed. Most voidings took place during wakefulness and while the infant was quiet. The relation of micturition to bathing and to auditory or to other external stimuli appears as yet to have had no systematic study.

Secretion: Duct Glands. Most of the duct glands are functional at birth, although secretion may be limited in amount and restricted to specific stimuli.

Jacobi and Demuth (1923) reported that salivary secretion is difficult to elicit, occurring only during the feeding act. Stirnimann (1936c) also has commented upon the infrequency of salivation of newborn infants to gustatory stimulation. When it does occur to the experimental stimuli he views it as a protective reflex. The ferment concentration of the saliva is greater in the full-term infant than in the adult, according to Hensel (1933).

Nothmann (1909) obtained gastric juice when infants that had not yet nursed were allowed to suck upon an empty bottle. This would seem to indicate innate reflex connections between the sucking act and gastric secretion, but Schmidt (1927) was unable to confirm Nothmann's findings. The premature, as compared with the full-term, infant has a less acid and less stable gastric secretion, according to Schmitt and Móritz (1933).

Sweat and tear glands secrete during the neonatal period, but tears are not an accompaniment of crying. In relation to the protective effects of tear gland secretion Ködding (1940) reported about two spontaneous winks per minute in the neonate as contrasted with six appearing at the end of childhood. The histological studies of Becker (1921) indicate increased tempo of development of the structures in the skin during the neonatal period.

Feldman (1920) accounts for obliteration of the meatus of the ear by the presence of numerous sebaceous glands.

Mammary secretion (witch's milk) of the neonate has long excited popular interest, and an extensive literature has developed on the subject. It is found, regardless of sex, in the majority of newborn infants and is regarded by most investigators as a part of the physiological picture commonly described as the "genital crisis of the newborn." A few, including Feldman (1920), view such secretion as a pathological phenomenon.

Apert (1914), Arteaga (1918), Hoeland (1927), Lorenz (1929), Joseph (1929), and others hold that it first makes its appearance 3 to 4 days after birth. Apert (1914) maintains that it begins to decrease from the eighth day; Jaroschka (1929) that it disappears between 30 and 100 days; and Joseph (1929) that it stops in 3 to 4 weeks. Apert (1914), Hoeland (1927), and Lorenz (1929) report that all stages from colostrum to milk resembling mother's milk are secreted by the mammary glands of the neonate. Apert (1914) has stated the view of those who hold that the phenomenon is produced by placental hormones, whereas Zaharescu-Karaman and Nastase (1931) have demonstrated that intramuscular injection of ovarian sex hormone in female infants is followed by hypertrophy of the mammary glands. Arteaga (1918) found no relation of the dropping-off of the umbilical cord to mammary secretion. Hoeland (1927) and Lorenz (1929) have noted that manual expression of secretion from the glands plays the same rôle in developing and prolonging the period of secretion as nursing does to the maternal breast.

Castro (1930) found such prolongation occurred in only one breast of the infant whom he studied. The hormonal stimulation of mammary secretion has been minimized and criticized by Lorenz (1929). He believes that the times of incidence and maximum secretion are not compatible with theories that such secretion is caused by the presence or by the disappearance of placental or ovarian hormones from the infant's system.

Secretion: Ductless Glands. Indirect evidence indicates the functioning of endocrine glands fairly early in the fetal period. The thymus has been termed the gland of infancy and is said to have an inhibitory effect upon growth, particularly upon sexual development.

The Genital Crisis. During the early part of the neonatal period the infant manifests phenomena which are considered characteristic of puberty. In addition to mammary secretion in both sexes, female infants have enlargement of the uterus, secretion from its mucous membrane, growing follicles and blood spots, according to Hartmann (1932) and other investigators. Hartmann (1932) and Moore (1936) found evidence of stimulation or enlargement of the prostate, and the former investigator reported activity in the testes of male infants. He also held that these phenomena are produced by ovarian hormones and by those of the hypophysis. Litzka (1933) demonstrated that in pregnant guinea pigs these hormones pass through the placenta.

The phenomena of the genital crisis are not, however, to be interpreted as having the sexual significance of puberty. Not only are they transitory but they are also not accompanied by differentiation of receptor organs to make the genital zones highly sensitive to external stimuli. The histological researches of Becker (1933) reveal a marked contrast to the richly endowed oral areas of the neonate.

Similarly, Halverson (1940) found tumescence of the penis in male infants neither to have a sexual significance nor to be ascribable to the factors producing the genital crisis. Studying the time and incidence of the response in relation to micturition and to defecation, he concluded that tumescence was caused by pressure stimulation of the bladder. It is accompanied usually by restlessness and has a frequency of 3 to 11 per day with durations ranging from ½ minute to 66 minutes.

Metabolism. Birth represents an increase in the rate of living of the infant. The neonate's metabolism, in terms of unit surface, is not, according to Carpenter and Murlin (1911), above that of the nursing mother but is above "that of a woman in complete sexual rest."

Talbot (1917*a*) affirms that the basal energy requirement increases with age from 44 calories per kilogram at 1½ to 6 days to 55 calories at 4 to 5 months. Talbot (1917*b*) estimates that to maintain normal activity and growth 100 calories per kilogram of body weight is needed as a *total* energy requirement.

Schlossman and Murschhauser (1933) report the basic exchange of newborn infants involves an oxygen consumption of 27.9 cc. per minute with a respiratory quotient of 0.828.

The interrelations of metabolic rates, heat production, body temperatures, pulse rate, specific food, etc., have all received attention.

Benedict and Talbot (1914, 1915) and Talbot (1917*a*, 1917*b*) attempted to determine the relation of metabolism and pulse rate and to ascertain what proportions of the food energy are expended to produce activity and growth of infants.

Benedict and Talbot's standards for determining basal metabolism in infants have been confirmed by Levine and Marples (1931), that referring to stature being most

reliable. In itself, age has slight relation to metabolism.

The creatinine coefficient is suggested by Paffrath and Ohm (1933) as an index of the level of muscular activity.

Rectal temperatures of newborn infants were discovered by Irwin (1933*c*) to range from 96 to 101.6° F. Correlation with activity expressed in stabilimeter oscillations per minute was $-.02 \pm .08$. Bayley and Stolz (1937) found a mean rectal temperature of 98.96 ($PE_m = .08$) at 1 month, and at 2 months one of 99.13 ($PE_m = .03$). Imperfect temperature regulatory mechanisms may make the infant slightly poikilothermic for a few hours, according to Herzfeld (1922). Talbot (1917*a*) maintains that healthy newborn infants tend to maintain their body temperature through increased muscular activity and crying. Levy (1928) indicates that temperature maintenance may be a serious problem in the premature infant.

In a critical survey of the relation of activity in the neonate to metabolic indices, Richards (1935) has concluded that no one index of physiological function correlates highly with bodily activity.

Neuromuscular Physiology. The first responses of the fetus, according to Minkowski (1928), may be idiomuscular rather than neurally aroused. The pioneer researches of Soltmann (1876, 1878), C. Westphal (1886), and A. Westphal (1894) showed that nerve and muscle tissues of newborn mammals are not as irritable as those of adult animals. This view as applied to human neonates is supported by Banu and Bourguignon (1921), by Banu, Bourguignon, and Laugier (1921), and by Rothe (1929). Rothe has stated that irritability is greater to mechanical than to electrical stimulation.

Banu and Bourguignon (1921), Banu, Bourguignon, and Laugier (1921), and Rothe (1929) found that muscle chronaxies in the newborn infant are greater (2 to 10 times) than those of the adult. In the adult the chronaxies of different muscle groups are sharply differentiated; in the neonate there is little differentiation. In the neonate, proximal chronaxies are greater than distal chronaxies. Banu, Bourguignon, and Laugier (1921) associate this with an alleged greater movement of distal segments of extremities. These observations of movement run counter to those of Irwin (1930) and Shirley (1931*a*) regarding the order of development of movement.

Muscle chronaxies of neonates differ more than nerve chronaxies from those of adults. Muscle chronaxies approach adult values in 7 to 20 months, nerve chronaxies in about 2 months.

Reaction times are stated in those sections of this chapter which deal with the different types of stimuli.

Hazard (1936) found the slowest reflex conduction rate for the patellar reflex in the newborn infant. The rate increases throughout childhood.

In Smith's (1938*a*, 1938*b*, 1939) electroencephalograms of the neonate the pattern derived from the occipital electrodes is a "straight line," but from either post- or precentral regions there are "recurrent, brief, ill-defined series of rhythmic waves of various frequencies." They are present only in sleep and disappear when the child wakes. Ellingson and Lindsley (1949) reported nonpersistent rhythms in the precentral or motor area during the waking state. Persistent alpha rhythms over the sensory zones do not appear until the second postnatal month and are slower than in the adult. Only about 10 per cent of neonates have the sleep spindle-pattern characteristic of adults.

Flechsig's myelinogenetic law, function following myelinization, has been widely accepted even to modern times, as represented by Tilney and Casamajor (1924).

Conel (1939, 1941), in his histological studies of the cortex of the neonate, has employed myelinization as one criterion of differentiation and development of neural tissue but has been careful to point out that it is not known whether the neurones of the cerebral cortex at 1 month after birth are functional in the sense of conducting impulses, nor is it possible to state when the cortex does begin to function. Among the workers in the field of infant development, Bersot (1920, 1921), Minkowski (1922), Peiper (1925*a*), and Langworthy (1933) have maintained that function may precede myelinization.

Conel (1939, 1941) has mapped the differentiation and development of cells in the cortical areas from birth to the age of 1 month. He has called attention to the fact that the region which shows greatest development, the anterior central gyrus, is the one from which Smith (1938*a*) first obtained encephalograms of rhythmic waves. Whether these are indicative of anything except metabolic activities is not known.

Reactions to Visual Stimuli

Sensitivity. The ready arousal of various visual reflexes has obviated any serious doubt regarding the existence of visual sensitivity in the newborn infant. The functioning of mechanisms essential to sensory discriminations and to perception is not granted so readily. Thus the presence of retinal hemorrhages, the shape of the eyeball, the alleged nonfunction of accommodatory mechanisms, and so on, would seem to preclude the focusing of clear images upon the retinae, whereas the relative lack of fixation and coordination of the eyes would likewise deprive the child of binocular criteria for depth perception.

Relation to Stimuli. For the adult, visual discriminations vary according to the wavelength, wave amplitude, wave composition, and the duration of the visual stimulus.

According to Munn (1938), there are no unequivocal data indicating the possession by the neonate of differential responses to the wavelength characteristic of visual stimuli. Peiper (1926*b*), after his discovery of an ocular-neck reflex which is dependent upon the intensity of the visual stimulus, was the first to attack the problem of color vision experimentally in premature infants. According to Peiper, the totally color-blind adult does not manifest the Purkinje phenomenon. Hence, if the infant under dark adaptation can be shown to have the Purkinje shift in brightness, there is good reason to believe that the child reacts differently to different wavelengths of the visual stimulus. From his study of the four prematures Peiper concluded that the Purkinje phenomenon is present at this stage of development, the brightness values of the hues corresponding to those of the adult and thus implying color vision in the young infant.

Smith (1936) showed that even after dark adaptation the long-wave end remained brighter than or as bright as the short-wave end of the spectrum for Peiper's subject. Hence the Purkinje shift of greatest brightness to the short-wave end is not demonstrated. In her own investigation of the brightness values of hues for 20 newborn infants Smith employed three hues (blue, green, and red) of equal energy as transmitted by Wratten filters. Before subjecting the infants to the 5-minute illumination period they were dark-adapted for 5 minutes. The respiration and the activity during the two periods were automatically registered, and observers recorded responses and crying. The percentage of immediate overt responses and the respiratory responses failed to discriminate between the hues. Activity and crying were inhibited most by blue and least by red. Whether

the infant's eyes were closed or open did not seem to affect this discrimination. In terms of the means, blue and green—but not red—inhibit crying and activity in males, whereas all three hues are effective for females. This student of the problem concludes that the reactions of the male infants conform to the picture presented by the totally color-blind adult, whereas those of female infants are compatible with dichromatic vision of the protanopic type. Hence the brightness values for hues of the same physical energy are not the same for infants as for adults with complete color vision.

Peiper (1937*b*), in commenting upon Smith's criticism, states that the Purkinje phenomenon refers to a change in brightness of the hues relative to each other rather than to white light. He likewise points out that Smith's subjects were not completely dark-adapted, and he questions whether a difference between the means for the sexes warrants the conclusion that *one* sex is color-blind and the *other* partially color-blind. Smith (1937), in reply, notes that the crux of the disagreement rests in conflicting interpretations of what constitutes the Purkinje phenomenon.

Chase (1937), employing a small moving spot of color within a larger field of another color but of the same luminosity value for the adult, found that infants as young as 15 days showed pursuit movements for all the hues studied but did not pursue a colorless spot within a colorless field of a different brightness. This is taken to mean that the infant has differential reactions to the wavelength characteristics of the visual stimulus.

Stirnimann (1944*a*) measured the duration of the newborn infant's gaze upon colored papers and found the longest staring to blue and green, the shortest to yellow. Red came in between. For him this is proof that the neonate discriminates hues by its feelings and that it therefore has color sensations. He has likewise reported color-contrast responses.

In regard to the Peiper-Smith controversy concerning color discriminations in newborn infants, Munn (1938) [1] maintains that the sex differences and brightness values for the different colors found by Smith are not statistically reliable, but that her criticism of the inadequacy of Peiper's data in demonstrating *equivalent* brightness values of hues for infants and adults is valid. He says:

> If the brightness value of hues is alike for infant and adult, the results of these experiments indicate color differentiation in very young infants. If the brightness value of the various hues is not the same for infant and adult, most of the data on color vision in infants are equivocal.

This fundamental difficulty in the investigation of color vision in infants had been anticipated by Pratt, Nelson, and Sun (1930) as follows:

> It seems that the structure and function of the adult eye must be regarded as one factor in our definition of luminosity. When we speak of the eye of the infant, the problem becomes more complex still.

Aside from the factor of duration, the visible and measurable activity of the neonate seems to depend primarily upon the intensity characteristic of the visual stimulus. Thus Peiper (1926*c*) determined the threshold for the ocular-neck response, whereas Sherman, Sherman, and Flory (1936) observed that the rapidity of the pupillary reflexes depends upon the intensity of the stimulus. Greater sensitivity with increase in age is shown by a de-

1 Munn, however, errs in saying that the differences under discussion are less than three times the PE. Some are less than three times the standard error of the difference, but one may well ask whether this is not primarily a reflection of the small size of the sample.

crease in the intensity required to elicit the responses. Irwin [1] has repeated certain aspects of Peiper's experiment showing the effects of different intensities of light upon the ocular-neck reflex. The percentage of infants responding and the percentage of responses to stimulation of brief duration (1 second) and ranging in intensity from 5 to 200 foot-candles were recorded. He concluded "that when a brief stimulus is used with a specific reflex the relation is directly proportional, but when a stimulus of continued duration is used with general activity, the effect is inverse."

Greater general activity, according to Irwin and Weiss (1934*c*), occurs neither under moderate intensities of visual stimulation nor in complete darkness, but under minimal light conditions (0.002 foot-candle). The same investigators, using three intensities of light stimulation (3.9, 0.02, and 0.002 foot-candle), found that activity was greatest under minimal and least under moderate light. Observational records of activity and of crying for the most part corroborated the polygraph recording of the stabilimeter oscillations. Weiss (1934), in the preliminary study of this series using the intensities mentioned, had found that the immediate effects, if any, were excitatory but nondifferential of different intensities. With prolongation of the illumination, however, activity decreased with increase in the intensity of the visual stimulus. The maximal inhibitory effects occurred 2 to 4 minutes after the onset of the stimulus. Maximum differentials occurred when the infants were not close to a feeding period or younger than the fourth day. Females appear to be more sensitive to differences in intensity than males. Irwin (1941*a*), employing visual stimuli of 5, 25, and 50 foot-candles, demonstrated that general activity is decreased by these higher intensities also. It was further shown that passage of the infant from an illumination period of 5 minutes' duration and at 5 foot-candles to a period of darkness is followed by an increase in activity.

The relation of intensity and adaptation is discussed in a subsequent section, and the effects upon activity of combining visual and auditory stimuli of some duration are reviewed in the section on the reactions to auditory stimuli.

With the demonstrated uncertainty regarding differential responses in the neonate to the wavelength characteristic of light, it is of course understandable that no investigations of possible reactions to wave composition have been undertaken.

Peiper (1926*c*), Pratt, Nelson, and Sun (1930), Pratt (1934*c*), and others have reported that visual stimuli of short duration evoke limited reflexes such as the palpebral and the pupillary, or more extensive responses such as the Moro or the "startle." Stimuli of longer duration, as Weiss (1934) has shown, may at the outset produce similar results, but as they persist activity and crying decrease under dim and moderate illuminations.

Infants under low illumination approaching deep twilight conditions do not manifest any appreciable increase in bodily activity during experimental periods of repeated visual stimulation furnished by flashes of light at various time intervals, as contrasted with the activity in control periods.

Visual spot illumination moving within the general visual field may elicit eye and head pursuit movements.

Relation to State of Organism. The general effect of a period of dark adaptation is to increase sensitivity to visual stimuli. Under these conditions Peiper (1926*b*) found that stimuli of an intensity inadequate for the light-adapted eye are effective

1 Personal communication to the writer upon the results of unpublished research.

in releasing the ocular-neck reflex. Similarly, according to Irwin and Weiss (1934c), there is decreased activity during periods of continuous dim or moderate stimulation, when such periods have been preceded by periods of darkness. Under subsequent minimal intensity of illumination, however, activity is increased. The dark adaptation process from beginning to final stages cannot be differentiated in terms of activity differences. Redfield (1937), employing dark adaptation periods of 1, 5, 10, and 20 minutes and intensities, in the later more extensive study (1939), of 0.5, 1.1, and 4.7 foot-candles in one series, and in another series of 0.04, 00.9, and 0.4 foot-candle, concluded that "increasing sensitivity to light after long as opposed to short periods of dark adaptation is indicated throughout the range of experimental intensities."

The possible alteration of the brightness values of hues and the question whether under dark adaptation the Purkinje phenomenon is produced have been considered in the review of the Peiper-Smith controversy.

In the activity differentials, from minimal to moderate intensities of visual stimulation, Weiss (1934) reported a greater decrease under waking conditions than when infants were asleep. Smith (1936), on the other hand, found no evidence of significant differences in the discrimination of the brightness of hues under these states of the infant.

The palpebral and most other overt responses are elicitable in both waking and sleeping states, but coordinated eye movements in pursuit of a moving light occur apparently only when the infant is awake.

Reaction Times. According to Canestrini (1913) the latent time of the circulatory and respiratory responses to visual stimulation is ½ to 2 seconds.

Types of Response. The responses range from the limited involvement of the accessory muscles of the visual sense organs to the greater involvement of the organism in circulatory and respiratory changes, in movements of the head and eyes, and more rarely of activity of most of the larger segments of the body. Inhibition of general activity appears when stimulation continues.

The *visuopalpebral reflex* (a closing of the eyes or a further tightening or twitch of the eyelids to a flash of light if they are already closed) had been described by Kroner (1881). Preyer (1882) was careful to distinguish this, as he termed it, innate blinking from the protective wink reflex to an approaching object, the latter not being elicitable until about the end of the second month. Pratt, Nelson, and Sun (1930) found that, in point of occurrence to discontinuous stimulation, the visuopalpebral response was the most invariable of those aroused by visual stimuli.

According to the early investigators, Kussmaul (1859), Genzmer (1873), and Kroner (1881), even premature babies manifest a lively *pupillary reflex*. Later investigators such as Guernsey (1929), Beasley (1933*b*), and Sherman, Sherman, and Flory (1936) seem to have demonstrated that the reflex, although sluggish at birth, rapidly perfects itself during the early part of the first postnatal week. Preyer (1882) and Feldman (1920) reported a consensual pupillary reflex. Gudden (1910) has noted that the pupil of the neonate is smaller than that of the adult during sleep and that there is no sudden dilatation to a maximum upon awakening. The continual play of movement of the margin of the iris, which increases upon external stimulation, was not found by Peiper (1926*d*) to occur in the neonate.

It is not known whether the ciliary muscle provides any *accommodation* in the early part of the neonatal period. The

diameter of the eye, however, according to Peiper (1928), makes it myopic, and retinal hemorrhages would make it even less likely that clear-cut images can be focused upon the retina. Ling (1942) has scrutinized the criteria of fixation and has concluded that neither the focusing of an image upon the retina nor the convergence of the eyes is applicable to newborn infants. For this age the principal criteria of fixation are the immobility of the eye and the inhibition of "spontaneous movements" in response to the stimulus object. Hence fixation may be monocular in type and although not present at birth develop rapidly during the neonatal period.

The convergence of the two eyes to produce *fixation* upon a bright light was observed by Genzmer (1873) and Preyer (1882) in infants shortly after birth. The Shermans (1925) and the Shermans and Flory (1936) find improvement in the response during the first 3 days. Even after coordination has been demonstrated, however, *strabismus* may be observed. Gutmann (1924) had obtained similar results. Peiper (1928) maintains that there is no real fixation during the neonatal period, and Guernsey (1929) states that it is lacking until well into the second month. Beasley (1933*b*), on the other hand, finds coordination in fixation rather than incoordination to be the general rule. According to Ling (1942), neither convergence nor binocular fixation occurs during the period of the newborn infant.

Kussmaul (1859), Kroner (1881), Preyer (1882), Blanton (1917), and later investigators had observed that a slowly moving light arouses *pursuit movements* of the eye and head. Jones (1926) did not obtain true visual pursuit movements until after the neonatal period. The most completely instrumentalized study of these responses was undertaken by McGinnis (1930). Moving visual stimuli were furnished by a rotating visual field, and motion pictures were made of the eye movements. Under these conditions, successful pursuit (eye movements in the same direction without frequent movements in the opposite direction and with head movements decreasing in frequency) appeared after the second week. Beasley (1933*a*) and Chase (1937) report that visual pursuit occurs within the first week. Beasley found that vertical and circular pursuit movements appear later than the horizontal, thus confirming the order though not the age of occurrence of these responses as stated by Jones (1926). Morgan and Morgan (1944) have likewise established the earlier appearance of horizontal pursuit movements. According to Beasley (1933*a*), the optimum rate of movement and distance of the moving light from the eyes varies from infant to infant. This, if confirmed, reveals methodological weaknesses in those experimental techniques wherein these factors were constant from infant to infant. Visual pursuit movements of eye and head are analogous to those observed in young kittens and termed by Tilney and Casamajor (1924) the "oculo-cephalo-gyric" response.

Conjugate deviation and *coordinate compensatory eye movements* were photographed by Ling (1942) as early as 32 hours after birth.

Optic nystagmus, of the same type found in adults, was observed by McGinnis (1930) to be present in infants a few hours after birth. Catel (1932) reports "physiological" nystagmus in the newborn infant, whereas Bartels (1932) holds that such eye movements resemble those of the blind.

The *ocular-neck reflex*, a bending backward of the head to a flash of light, was shown by Peiper (1926*c*) to depend upon the intensity of the visual stimulus.

A bright, intense flash of light may evoke, as Peiper (1926*c*) has noted, a response which some have designated *fear* and others

Moro's Umklammerungs reflex. From the tables of Pratt, Nelson, and Sun (1930) it seems that either this or the "startle" have a higher incidence during the first days of the neonatal period. Dupérié and Bargues (1932), however, were unable to elicit the Moro response by visual stimulation.

According to Canestrini (1913), the respiratory and circulatory responses of the neonate resemble those of the frightened adult.

Weiss (1934), Irwin and Weiss (1934*a*), and Richards (1936*b*) have demonstrated that, within certain intensity ranges, general activity decreases as the intensity of the visual stimulus increases.

Learning. According to Denisova and Figurin (1929), visual CR's[1] appear later than auditory CR's and are not set up within the neonatal period. Wenger (1936), pairing visual and electrotactual stimuli for two infants, found some indication of conditioning by the sixth day.

Technique of Investigation. The earlier investigators of the problem of color vision had little or no control over their stimuli and were in no position to determine which aspects of the visual stimulus were related to the observed responses of the infant. The later investigators, employing Wratten filters, have presented visual stimuli of known wavelengths, physical energy, and luminosity value for the human adult.

The problem of the presence or absence of color vision in newborn infants has been approached by attempting to discover whether, under dark adaptation, there is a Purkinje shift in the brightness values of the hues similar to that found in the adult with normal color vision. The differences in duration of fixation of the eyes upon different-colored papers have also been utilized as an approach to the problem. Another endeavor at solution consists in the movement of a colored spot within a visual field of the same luminosity for the adult, but of a different hue. The ocular-neck reflex has been used as an indicator of change in intensity to stimuli of short duration, and the effects of stimuli of long duration upon general activity have also been determined.

Pursuit movements have been studied in relation to manually produced moving visual stimuli and in relation to control of movement within a given plane.

Respiratory and circulatory responses have been recorded through pneumograph-kymograph systems, whereas general activity has been recorded through stabilimeter oscillations registered upon a polygraph or through electrical counters. Eye movements have been photographed.

Summary. The newborn infant reacts to light, but it is not certain whether any differential responses are made to the wavelength or to the complexity characteristic of visual stimuli. Responses do depend upon the duration and the intensity of the stimuli. Those which are sufficiently intense and of short duration release lid responses, circulatory and respiratory responses, the ocular-neck reflex, and probably the Moro and "startle" responses. If moving spot illumination within the visual field is provided there is some evidence of fixation, of pursuit movements, and of nystagmus. If the stimulus is of sufficient duration the pupillary reflex may be observed, and with continued illumination there is a decrease in general activity. Increasing the intensity, within certain limits, decreases the activity. The effect of a given stimulus intensity is profoundly influenced by the previous conditions of stimulation, that is, as in dark adaptation. Whether newborn infants manifest the Purkinje phenomenon is a matter of controversy.

[1] CR is here used as an abbreviation for conditioned reflexes (or responses).

Reactions to Auditory Stimuli

Sensitivity. From the earliest days of neonate study down to the present there has been a certain amount of controversy regarding the auditory sensitivity of newborn infants. Kussmaul (1859) was convinced that they were insensitive to auditory stimuli, whereas Genzmer (1873) claimed that not only did they possess such sensitivity on the first or second day after birth but that in all probability also the fetus received auditory stimulation from the heartbeats and aortic pulse and from the activities in the digestive tract of the maternal organism.

Kroner (1881) and Moldenhauer—according to Preyer (1882)—reported the early presence of sensitivity but commented upon its great variability. Moldenhauer observed the following reactions to auditory stimuli: quivering of the eyelids, wrinkling of the forehead, head movements, screaming, and awakening from sleep. Repetition of the stimulus either produced no effects or else was quietening. Poli (1893) and Sachs (1893) considered sensitivity to be evidenced by the palpebral reflex, and Sachs also noted the "fear" (*Schreck*) reaction.

Since these early investigations the existence of auditory sensitivity in the neonate has been confirmed by the researches of Koellreutter (1907); Peterson and Rainey (1910); Canestrini (1913); Blanton (1917); Waltan (1921); Peiper (1924*c*); Pratt, Nelson, and Sun (1930); Irwin (1932*g*); Pratt (1934*b*); Weiss (1934); Stubbs (1934); and Froeschels and Beebe (1946). A few writers during this period, namely, Feldman (1920), Löwenfeld (1927), Bryan (1930), and Haller (1932), maintain that there is relative insensitivity during the early postnatal days.

The discovery by Peiper (1924*c*), later confirmed by the observations and researches of Forbes and Forbes (1927), Ray (1932), Sontag and Wallace (1934, 1935*b*, 1936), and Bernard and Sontag (1947), that the fetus *in utero* reacts to vibratory stimuli of a rate affecting the auditory receptors of adults would seem to indicate a similar stimulation of the fetal auditory receptors. This may, however, take place through bone conduction, whereas postnatal insensitivity, if present, may depend upon the condition or state of structures normally responsive to air vibrations.

Various explanations have been offered for such alleged insensitivity: (1) mucus in the middle ear (Preyer, 1882); (2) occlusion of the external auditory meatus (Preyer, 1882; Feldman, 1920); (3) tympanic membrane not in a state to respond easily to air vibrations (Feldman, 1920); (4) fixity of auditory ossicles (Compayré, 1896); (5) transitory or permanent birth injuries (Kutvirt, 1912; Vosz, 1923); (6) imperfectly developed auditory nerve (Shinn, 1893–1899; Stern, 1914).

Relation to Stimuli. Auditory stimuli present certain variable characteristics of which the more important are frequency, amplitude, and complexity. As in other stimulus modalities, the duration of the stimulus is likewise of great significance.

There is no indubitable evidence that infants possess either differential responses to varying frequencies of vibration or the possibility of acquiring them during the neonatal period. Moldenhauer claimed that easily observed responses are more likely to occur to high-pitched sounds. This observation has been supported by Sachs (1893), who produced stimuli with tuning forks and Galton whistle; by Waltan (1921), who employed whistles and tuning forks; by Haller (1932), who used an audiometer; and by Muzio (1933) with tuning forks (according to this investigator females react quicker than males). In none of these investigations was there instrumentalized recording of responses.

Stubbs (1934) appears to have been the first to obtain adequate control of the auditory stimulus and at the same time to secure objective records of the responses of infants to it. The effects upon overt activity, recorded by the stabilimeter-polygraph unit, and upon implicit respiratory activity pneumographically registered, were compared when the stimuli were four different frequencies (128, 256, 1024, and 4096 cycles) produced by an audiometer at constant intensity levels in terms of sensation units and with a duration of 10 seconds. Observations were made by two observers, and their reliability was statistically determined. In this research the stabilimeter record disclosed no differences in overt responses to differences in frequency. Nor do the respiratory records reveal any effect of varying frequencies upon respiratory rate, but they do show significantly fewer cases of no response at the lowest as compared with the highest frequency. Of the responses observed, only eyelid opening and decrease in body activity appeared to occur more often at the lower than at the higher frequencies.

In view of Kasatkin and Levikova's (1935*a*) lack of success in establishing conditioned sucking responses to auditory stimuli before the first half of the second month, it seems unlikely that the conditioned reflex technique will demonstrate any capacity for pitch discrimination in the newborn infant.

The degree of organismic involvement in a response is related to the amplitude of the auditory stimulus. The correlation has been widely noted, but few have carefully investigated it. In the studies by Pratt, Nelson, and Sun (1930) the amount of measurable and observable activity of the neonate did not seem to correspond with the adult ratings of intensity or loudness of the experimental stimuli. The lack of control of the stimulus variables and the undetermined reliability of observations and of measurements render their evidence inadequate for determining the exact relationship of overt activity to the amplitude of auditory stimuli.

Stubbs (1934), who controlled the stimulus by means of audiometer and oscillator, found that with a 10-second duration for each frequency studied the percentage of responses increased as the stimulus intensities ranged upward from 30 through 50, 70 to 85 sensation units. The louder stimuli produced more bodily movements, greater frequency of eyelid closing and respiratory action, and a decrease in crying.

Weiss (1934) investigated the effects of two intensities (50 ± 5 and 75 ± 5 decibels) of a tone with a frequency of 420 cycles for durations of 5 minutes. She measured activity by stabilimeter oscillations and found that under sound-dark conditions the infant exhibited "a significant tendency toward lessened activity with increased sound intensity." In the sound-light experiment visual stimulation reinforced the auditory to bring about an even greater lessening of activity.

The possibility of variation of responses according to variation in the complexity of the auditory stimulus does not seem to have received any experimental study.

Early observations, such as those by Sachs (1893), and all later studies show that overt responses are greater if the stimulus duration is short (as in noises), whereas there may be inhibition of activity or complete lack of response if the stimulus is of longer duration (as in musical tones). These pacifying or inhibiting effects of stimuli of longer duration have been reported by Pratt, Nelson, and Sun (1930). These latter observations should be accepted with caution because the intensities of the stimuli employed were not adequately controlled. Haller (1932) reported that even with a stimulus duration

of only 10 seconds the response began with the onset of stimulation and declined or disappeared by the time the stimulus had ceased. Stubbs (1934) used durations of 1, 3, 5, and 15 seconds. The percentage of responses to the longest duration was significantly greater than to the shortest duration of the stimulus. The longer durations operated also to evoke greater bodily activity, increases in rate, and corresponding decreases in amplitude of respiratory responses. The longer durations, such as the 5-minute periods given by Weiss (1934), decrease bodily activity significantly as compared with periods during which no stimuli are presented.

These experiments seem to indicate that the auditory stimulus first releases certain overt responses and thereafter, if the stimulus persists, overt activity subsides and there is less movement than would occur in a period of no experimental stimulation. The continuous stimuli may inhibit the activity which ordinarily results from internal stimuli, or possibly the situation is analogous to the "listening" posture of the adult.

Discontinuous, repeated auditory stimuli produce rapid decreases in the circulatory and respiratory responses, according to the researches of Canestrini (1913). And Peiper (1924*c*) found that the "fear" response of the fetus *in utero* usually followed upon only the first stimulus. They ascribe this decline to inhibition rather than to fatigue. Pratt (1934*b*) used relatively constant but unmeasured auditory stimuli to demonstrate that during a period of discontinuous auditory stimulation activity is confined to movements following the discrete stimuli, that the response declines with successive repetitions of the stimuli, and that the amount of activity per stimulation decreases as their frequency is increased within a given period of time.

Relation to State of Organism. Aside from the transitory residual effects of previous stimulation it is known that the response evoked by a given stimulus is also dependent upon the physiological state of the organism. Poli (1893) observed that the cochlear-palpebral reflex (principally closing of the eyes if they are open or further tightening of the lids if they are closed) was most easily elicited during sleep but was most difficult to activate when the child was nursing. Canestrini (1913) noted that the nature of respiratory and circulatory responses depended somewhat upon whether the infant was asleep or awake. Peiper (1925*b*) obtained a longer reaction time for the "fear" reaction during sleep than during waking, and a number of investigators have affirmed that this "fear" response is best detected in the sleeping infant. That it is invariably followed by awakening is not supported by the data of Pratt, Nelson, and Sun (1930). Stubbs (1934) found that the smallest percentage of responses to auditory stimuli occurred when infants were crying, and the largest when they were awake and inactive.

Reaction Times. Peiper (1925*b*) reported a longer reaction time for premature infants than for a 2-month-old infant (0.25 second for the latter). Irwin (1932*g*), with an auditory stimulus of 581 cycles, a duration of 0.07 second, and a constant unmeasured intensity, found that the mean "body startle" reaction time of twelve infants, measured by stabilimeter-polygraph records, was 0.18 ± 0.03. The reaction time of respiratory responses was found by Stubbs and Irwin (1934) to be 0.09 second, with a standard error of the mean of 0.025.

Types of Responses. The overt responses elicited by discontinuous auditory stimuli, according to the intensity of the stimuli and the previous stimulating conditions, range from the minimum involvement of

the palpebral reflexes on through to the maximum involvement of most of the large behavior segments. When auditory stimuli are continuous for some appreciable duration, decrease in activity sets in after the initial overt responses.

The *cochlear-palpebral reflexes* may occur in relative isolation when the stimuli are of slight intensity or when the infant has been repeatedly stimulated, as Pratt (1933, 1934*b*) has shown. Moldenhauer was one of the first to observe these in the complex of responses, and Cemach (1920), who gave them particular attention, emphasized their persistence beyond the neonatal period. Irwin (1932*g*) has noted that they are more invariable in occurrence than the "body startle," whereas Landis and Hunt (1939) have maintained that blinking is a component of the "startle" pattern. Froeschels and Beebe (1946) also have reported acoustopalpebral reflexes as the most frequent reaction to auditory stimulation.

Bartels (1910) and Peiper (1928) state that auditory stimuli produce pupillary dilatation in newborn infants, but Peiper observes that there is great irregularity in its occurrence.

When infants are asleep, according to Canestrini (1913), auditory stimuli of some duration, such as musical tones, make breathing slower and shallower and decrease the pulse rate. If the stimuli are intense enough to wake the child the rates of respiration and pulse are increased. Intense stimuli of short duration (such as a pistol shot) result in an immediate increase in the amplitude of respiration, followed by irregular breathing. Stubbs (1934) found that increase in intensity and duration had measurable consequences in respiratory responses and that "respiratory responses were found less often to higher than lower pitches."

The earlier investigators of neonate behavior were impressed with the gross muscular response of the infant to auditory stimuli. Sachs (1893) was one of the first to term these reactions the "fear" (*Schreck*) response, and Watson (1919) made the alleged emotional pattern one of the cornerstones in his theory of three primary emotions. Peiper (1925*a*) was one of the first to liken the fear response, as elicited by auditory stimuli, to the "Moro" response, while granting that there was a difference in latent time. Schaltenbrand (1925) maintained that the Moro response was elicited by sudden sounds. Following these, Irwin (1932*g*), Pratt (1934*b*), Dennis (1934), Richards (1936*a*), and Wenger (1936) have held that the terms "fear," "body jerk," "body startle," etc., are merely different names for a general but variable response which may be elicited by stimuli of various modalities.

Other research workers have insisted that the fear response and the Moro response are distinct, for, according to Dupérié and Bargues (1932), the Moro cannot be evoked by auditory stimuli. They and Gordon (1929) maintain that the responses merely simulate each other, and they agree with Peiper (1925*a*) that in a given stimulus situation the fear reaction precedes the Moro.

Strauss (1929), as reported by Hunt, Clarke, and Hunt (1936), ascribed a "startle" response to intense auditory stimuli which differed not only in pattern but in age of appearance from the Moro response. According to this view, the Moro, but not the startle, is present during the neonatal period. In regard to arm movements, Hunt and Landis (1938) have stressed the extensor characteristic of the Moro as compared with the flexor characteristic of the startle.

Pratt (1937) viewed all these as variants of the Moro, and Wagner (1938*a*)

has proposed that they all be called "body jerks." Hunt and Landis (1938) and Hunt (1939) point out that the evidence from ultrarapid motion pictures reveals two patterns of response, one commonly known as the Moro and the other which they, following Strauss, call the startle. They (Landis and Hunt, 1939) assert that both patterns are clearly present at 6 weeks and that after a few months the Moro disappears but the startle remains. They cautiously favor the view that both responses may be present from birth, with the startle somewhat masked by the Moro (for segmental comparison of these see the section on the Moro and startle responses).

Pratt (1933) described variable plantar responses as part of the response to auditory stimuli, and Clarke, Hunt, and Hunt (1937) have photographed them. Pratt, using less intense stimuli than those employed by the three later investigators, noted that toe movements and the palpebral reflexes in many instances persist as other components of the response drop out with successive repetitions of the stimulus.

Waltan (1921), Froeschels and Beebe (1946), and others have claimed that some infants turn the eyes and head toward the source of auditory stimulation.

Learning. The conditioned reflex technique, as a means of studying auditory sensitivity, was suggested by Aldrich (1928). Kasatkin and Levikova (1935*a*), however, were unable to establish conditioned sucking responses during the neonatal period. Denisova and Figurin (1929), according to Razran (1933), established conditioned food-seeking responses to auditory stimuli during the second month, although natural as opposed to laboratory CR's appeared during the first month. Marquis (1931) stated that conditioned sucking and quietening to auditory stimuli were established during the first ten days after birth. Wenger (1936), despite some masking of the conditioning auditory stimulus by other auditory stimuli, obtained some indication of unstable leg withdrawal and respiratory "gasp" CR's with electrotactual unconditioned stimuli. The Wickenses (1940) attempted, with inconclusive results, to set up auditory-leg movement CR's, with electric shock as the unconditioned stimulus.

Technique of Investigation. Auditory stimuli have been produced with varying degrees of control by tuning forks, Galton and Urbantschitsch whistles, devices providing constant but unmeasured stimuli, and instruments of precise control such as the audiometer. Circulatory and respiratory responses to auditory stimuli have been recorded by means of pneumatic systems (pneumograph and tambour), the kymograph, and the polygraph. Gross movements and increase or decrease of bodily activity have been recorded by means of stabilimeter-polygraph systems or by stabilimeter oscillations through electrical counters. Reaction times have been measured by a modified Morse apparatus, by the stabilimeter-polygraph apparatus, and by ultrarapid motion-picture photography. The patterning of responses and the incidence of responses not registered by mechanical systems have been recorded by some observers and photographed by others.

Summary. The neonate is not deaf, but there is little evidence that it makes pitch discriminations or differential responses correlated with the complexity characteristic of auditory stimuli. Its responses are, however, modified according to the duration and the intensity of the stimuli. If they are of short duration and sufficiently intense, responses such as lid reflexes, circulatory and respiratory changes, and gross muscular patterns of response, such as the Moro and possibly the startle, appear. With successive repetitions of the auditory stimuli the gross muscular components decline in

extent of involvement and disappear, leaving the more invariant palpebral reflexes, and frequently responses of the toes. If the stimuli are of long duration their effect is to lessen the activity which would normally occur during the period, and the decrease becomes greater as the intensity of the stimulus is increased.

Reactions to Olfactory Stimuli

Sensitivity. The demonstration of the presence or absence of olfactory sensitivity in the neonate presents such methodological difficulties that the lack of agreement of different investigators is not surprising. Some have held that the sense of smell is important and well developed. Among them are Darwin (1877), Kroner (1881), and Peterson and Rainey (1910). Somewhat less certain of the importance and of the maturity of this sensory field are Ciurlo (1934) and Stirnimann (1936*b*, 1936*c*), whereas Disher (1934) is willing to grant that the neonate at least discriminates between odorous and nonodorous substances. Most of the workers in this field, however, have been extremely doubtful whether newborn infants react to olfactory stimuli. Kussmaul (1859), although subscribing to the view that the infant possesses olfactory sensitivity, was one of the first to note that ammonia and acetic acid fumes were most effective in eliciting reactions and to decide that such substances produce their effects as tactile rather than as olfactory stimuli. Preyer (1882) supported this view by saying that such substances irritate the mucous membrane of the nose. Canestrini (1913) found that only such substances affected respiration and circulation. He ascribed these effects to stimulation which set up impulses in the trigeminal nerve. Watson (1919) and Peiper (1928) accept this interpretation, and Tanner (1915), Blanton (1917), Drummond (1921), and Pratt, Nelson, and Sun (1930) likewise hold that olfactory sensitivity is not present or else is poorly developed.

Relation to Stimuli. In the first researches to introduce the principle of a nonodorous air control, a duration control by means of an olfactory pump, and a high degree of saturation of a given volume of air at room temperatures, Pratt, Nelson, and Sun (1930) used acetic acid, ammonia, oil of cloves, and valerian as stimuli. The observers noted the number of responses to stimuli, recorded in code the movements of different segments of the body, and afterward measured the stabilimeter-polygraph records of activity. Although they did not determine the statistical reliability of their observations and measurements, there seems little doubt that of the substances employed only ammonia and acetic acid, as evaluated by the air control, produced unquestionable results. Analysis of the percentage of specific movements of body segments in the responses that did occur to the different stimuli shows that with the air control the body extremities and eyes were most often involved, whereas there were scarcely any head or facial movements. Vocalizations and facial responses had greater incidence to ammonia and acetic acid. Sucking was more conspicuous in the responses to valerian. The infants reacted about as vigorously to acetic acid as to ammonia, whereas adults considered acetic acid much less irritating than the ammonia.

Disher (1934) devised a thermal control and used gas-collecting tubes for her reservoirs of odors. Three different degrees of saturation were obtained by drawing from these and from a pure air source by hypodermic syringes. Stimulation was effected by pushing on the plunger of the syringe while the experimenter counted to 25. Besides the nonodorous air control, odorous

substances following Henning's classification, such as violet, asafetida, sassafras, citronella, turpentine, pyridine, and lemon, were employed. Responses were recorded by two observers, and a set of motion-picture records was made. According to this investigator, newborn infants respond significantly in terms of percentage response to stimulation by the odor stimuli as compared with the percentage response to stimulation by pure air. Observation and segmental analysis of the responses, however, disclose no evidence of differential odor discriminations, and the pattern of responses to air alone, when there are responses, is apparently no different from that aroused by olfactory stimuli. Percentage of response and extent of organismic involvement appear to depend upon the degree of saturation of the olfactory stimulus.

Ciurlo (1934), using essence of lavender, valerian, and mint, which, it is supposed, do not stimulate the trigeminal nerve, is reported to have demonstrated by means of graphic records of respiration that the newborn infant differentiates odors as pleasant or unpleasant.

Stirnimann (1936*b*, 1936*c*) is of the opinion that volatile substances stimulate not only the olfactory and trigeminal nerves but also the glossopharyngeal nerve. The absence of the olfactory nerve does not lead to lack of response to stimuli which are ordinarily supposed to stimulate the olfactory nerve and to be pleasant. Hence the interpretation that the trigeminal, when activated, gives only unpleasant experiences is unwarranted. Stirnimann holds that differential responses to odorous stimuli are revealed by facial or mimetic responses.

Anise oil involves nasal taste (*gout nasale*) and gives rise to expressions of pleasure and to sucking and licking responses. Oil of chenopodium leads to grimaces of discontent; ammonium carbonate produces grimaces and pronounced turning-away of the head from the test tube containing the substance.

Types of Response. The overt responses elicited by ammonia, acetic acid, and so on consist of a throwing-back or turning-away of the head, wrinkling or grimacing of the face, squirming of the trunk, movements of the extremities, and frequently sneezing and crying. Such substances likewise affect respiration and circulation. Other substances, such as anise oil, essence of lavender, valerian, mint, and oil of chenopodium, generally held to be purely odorous stimuli, may give rise to *mimetic* and respiratory responses, supporting a classification into agreeable or disagreeable odors, according to Ciurlo (1934) and Stirnimann (1936*b*, 1936*c*). The "pleasant" odors may be accompanied by sucking and licking movements.

Technique of Investigation. The duration, saturation, and temperature of the air in which olfactory stimuli are presented have been controlled by various devices such as the olfactory pump, reservoirs of fully saturated vapor, and pure air source. Responses have been recorded by observers, photographed with the motion-picture camera, and registered by the stabilimeter-polygraph unit. Respiratory and circulatory responses have been graphically recorded by pneumograph-kymograph combinations.

Summary. It seems to be well established that newborn infants react vigorously to such stimuli as ammonia and acetic acid, but whether these rather general reactions of the body musculature are to be ascribed to the sense of smell or of pain is uncertain. According to some investigators, other substances, which are purely odorous for adults, are responded to by infants with mimetic responses indicating "pleasant" or "unpleasant" experiences. Some

stimuli lead to avoiding movements; others are followed by sucking and licking responses.

Reactions to Gustatory Stimuli

Sensitivity. Taste was considered by Kussmaul (1859), Preyer (1882), and Peterson and Rainey (1910) to be highly developed in the neonate. Shinn (1893–1899) believed it to be dormant, and Blanton (1917) maintained that taste, smell, and touch are not differentiated at this time. Canestrini (1913) obtained prompt circulatory and respiratory responses to gustatory stimuli but no reactions which would indicate differential responses or discrimination between "sour" and "bitter" stimuli. Pratt, Nelson, and Sun (1930) observed little differentiation, particularly when the percentage of responses evoked was compared with the percentage elicited by distilled water. With increase in age it appears that sucking responses to sugar solutions increase, whereas facial reactions become more pronounced to "salt," "sour," and "bitter" stimuli. Stirnimann (1936*b*, 1936*c*) holds that the neonate demonstrates taste discriminations of all four qualities, largely in terms of facial or mimetic reactions. Eckstein (1927) and Jensen (1932) have demonstrated that certain taste substances modify the sucking response.

Relation to Stimuli. The problem of taste sensitivity in the neonate resolves itself into several questions. Does the child make differential responses to taste substances? Are these of the same order or nature as those of the adult? Does the response alter as the strength of the stimulus is changed? The problem is complicated, as in the case of olfactory stimuli, by the fact that other than taste receptors are being stimulated. Also, the area of stimulation is not easily controlled. The arousal of a response may, again, depend upon the intensity rather than upon its specific modality. And, unfortunately, the effective strength of gustatory stimuli cannot be established in terms of equally concentrated solutions. Nor, as Pratt, Nelson, and Sun (1930) found, can it be said that the effective intensity of a taste substance is the same for the infant as for the adult.

Introduction of gustatory stimuli by means of applicator sticks dipped in solutions of salt, sugar, citric acid, and quinine in Pratt, Nelson, and Sun's investigation did not, when compared with similar introduction of distilled water, provide impressive evidence for taste differentiation in infants. Quinine and citric acid solutions appeared to be more effective than salt and sugar solutions. Jensen (1932), using the sucking reflex as an indicator, found differential responses (changes in the sucking response as compared with the control of mother's milk) to air and salt solutions. The approximate limen for the latter is a solution of 0.300 per cent. These differential reactions do not appear until the infant has sucked a few seconds, and therefore the reactions may depend upon the stimulation of other areas than those involved in experiments wherein the taste substance makes immediate contact with tongue areas.

Stirnimann (1936*b*, 1936*c*) applied taste solutions to the newborn infant's tongue by means of a nipple-shaped piece of cotton. In his opinion the neonate discriminates all four of the taste qualities, although there are no responses which may be said to be characteristic of each one. The differentiation is evidenced in part by differences in mimetic responses and in part by the sequential order of these in relation to responses of withdrawal, repulsion of the stimulating device, or in relation to sucking responses. The same investigator found that infants reacted more vigorously to a 7 per cent solution of saccharine than

to a 7 per cent lactose solution, and again more vigorously to a 16 per cent solution of the lactose solution than to the weaker solution of the same substance. No clear-cut differentiation was made between 0.9, 1.5, and 2.0 per cent salt solutions.

Relation to State of Organism. Jensen (1932) states that the "moderately full baby is a better discriminator than the very hungry infant."

Reaction Times. The responses to gustatory stimuli are varied in nature. From Canestrini's (1913) curves it seems that circulatory and respiratory responses follow quickly upon stimulation. Other responses apparently have a longer latent time.

Types of Response. According to Stirnimann (1936*b*, 1936*c*), taste as well as tactual stimuli frequently release a *vasomotor reflex* which produces a tumefaction of the inner surface of the lips. *Sucking responses*, as reported by Pratt, Nelson, and Sun (1930), occur to all taste stimuli. They are more pronounced to sugar solutions and become increasingly so with age. Stirnimann (1936*b*, 1936*c*) found these responses to be greatest to lactose, with citric acid a close second, but only of feeble occurrence to stimulation by quinine. Sonohara (1934*a*) found, as had Stirnimann, that saccharine arouses sucking responses. Jensen (1932) discovered that only salt solutions, among gustatory stimuli, impaired the sucking responses or caused them to cease. This confirms Canestrini's observation.

Movements of the tongue and lips, sometimes termed *defense* or *rejection*, have been observed by Pratt, Nelson, and Sun (1930) and by Stirnimann (1936*b*, 1936*c*). Stirnimann noted that muscles of the pharynx are innervated, as in vomiting. Allied to these responses are general activity and even crying. Sonohara (1934*b*) disagrees with most investigators, who hold that "bitter" stimuli evoke reactions of rejection.

Some have held that facial responses or mimetic reactions—the "wry" face, for example—are rather characteristic to "bitter" stimuli.

The *salivary reflex*, as Stirnimann (1936*b*, 1936*c*) and others have noted, is not well established in the neonate.

According to Canestrini (1913), "sweet" stimulation calms the child, salt solutions produce a slight disturbance, and "sour" and "bitter" solutions initiate pronounced irregularity of the *respiratory* and *circulatory* curves.

Technique of Investigation. In most of the investigations the concentrations of the taste solutions have been stated. Responses to these have been compared with those evoked by distilled water and mother's milk as controls. These substances have been introduced into the infant's mouth by applicator sticks or other devices, or have been sucked from a special nursing bottle. The mimetic and other responses have been recorded by observers, while circulatory, respiratory, and sucking responses have been automatically registered by kymographs and polygraphs.

Summary. It is uncertain whether the neonate differentiates all four taste qualities. It appears, however, that in terms of the sucking response salt solutions tend to break up the response, whereas sugar solutions elicit and maintain it. Acid solutions to a lesser extent evoke sucking; quinine solutions seldom do. Facial responses mimetic of "disagreeable" affects are conspicuous responses to the latter. In general, respiration and circulation are least influenced by "sweet," slightly disturbed by "salt," and considerably affected by "sour" and "bitter" solutions. Sucking mounts with age to sugar solutions as do facial responses to quinine. There is some evidence that, beyond the threshold point, responses

may be altered by differences in concentration of the taste solution.

Reactions to Thermal Stimuli

Sensitivity. The presence of thermal sensitivity in the newborn infant was noted by early experimenters, Genzmer and Kroner, and has not been questioned in subsequent studies.

The researches which have been undertaken involve either limited areal stimulations (but not punctiform exploration in newborn infants) or activity under different environmental temperatures. There has been no really systematic exploration of the cutaneous surface or other parts of the body to ascertain the differential sensitivity of the various areas. Canestrini (1913) demonstrated that "cold" stimuli applied to the forehead produced prompt and vigorous circulatory and respiratory responses. Pratt, Nelson, and Sun (1930), stimulating the same area with a temperature cylinder (50 sq. mm. application area) at an average temperature of 11 to 12° C., obtained observable responses to 73 per cent of the stimulations. Stirnimann (1939), applying water-filled glass tubes (18 mm. diameter) to the infant's cheeks, found 89 per cent response to temperatures of 43 to 45° C. and 96 per cent response to temperatures of 15 to 17° C. Peiper (1924*b*), holding constant the contact while changing the thermal stimulation, stimulated the chest with "cold" stimuli and obtained pronounced responses. Stirnimann (1939) stimulated hand areas (hollow of the hand or ball of the thumb) with the temperatures previously mentioned and received no response in 74 per cent of the cases. Application by Pratt, Nelson, and Sun (1930) of the temperature cylinder to the inner surface of the leg at the knee yielded reactions to 91 per cent of the stimulations. Crudden (1937), employing stimuli of ±5° C. or more from the initial neutral (33 to 34° C.) and applying them by Peiper's technique to the dorsal surface of the leg midway between foot and knee, reported some degree of response, as shown by examination of cinema records, to all stimulations. Stirnimann (1939) obtained 94 per cent response to stimulations of the sole of the foot by stimuli of 43 to 45° C., and 100 per cent to those of 15 to 17° C. Although the size of cutaneous areas stimulated and the duration of the stimulation vary in the researches mentioned, they suggest the possibility that leg and foot are more sensitive to thermal stimuli than hand and head areas.

Thermal sensitivity has likewise been demonstrated in the oral cavity. Pratt, Nelson, and Sun (1930) introduced small amounts of distilled water at temperatures ranging from 8 to 53° C. and observed the movements which were elicited. Jensen (1932) measured the alterations produced in the sucking response by milk at temperatures above and below 40° C.

Environmental temperatures likewise give evidence of the thermal sensitivity of the newborn infant. If they are atmospheric, activity tends, as Pratt (1930) has shown, to be negatively correlated with them. Excitatory effects of lowering the temperature of the bath have been noted by Preyer (1882). Exposure of the forehead or of the whole body, or stimulation of the arm by rapid evaporation, had no effect, according to Herlitz (1942–1943) upon pulse rate or blood pressure and produced no consensual skin capillary reactions, but the temperature both of the abdomen and of the rectum fell.

The thermal sensitivity of the neonate has not been compared with that of children in later developmental stages, nor are we able from the work of Peiper (1924*b*) and Stirnimann (1939) to compare with

any certainty the premature with the full-term infant.

Relation to the Stimuli. Temperatures present continuous series, but the "cold" spots respond when some critical point below physiological zero (skin or other body temperature) is reached and again, paradoxically, when a critical point above physiological zero is attained, whereas the "warm" spots respond only when a critical point above physiological zero is reached.

Physiological zero in infants has been given various values by different investigators and according to the area stimulated. It seems clear that oral and anal temperatures will differ from cutaneous temperatures. It is also evident that any thoroughgoing investigation of thermal sensitivity will require the determination of the skin or body area temperature for each neonate before the application of the thermal stimulus.

Pratt, Nelson, and Sun (1930) did not ascertain the temperatures of the areas stimulated. Stimulation of head and leg areas with the temperature cylinder at 33 to 45° C. did not seem to produce appreciable responses, whereas at 11 to 12° C. vigorous responses were aroused. Crudden (1937), on the basis of lack of response in preliminary trials, decided that 33 to 34° ±5° C. was neutral for the area of the leg which he studied.

To oral stimulation, by distilled water applied with a medicine dropper, Pratt, Nelson, and Sun (1930) observed least response at 43° C. among temperatures of 8, 13, 18, 23, 33, 48, and 53° C. From these studies it would appear that the point of least stimulation for this area must lie between 33 and 43° C. Jensen (1932) found no disturbances in the sucking response to mother's milk at 40° C. The higher thresholds or critical points ranged from 50 to 65° C. (median approximately 52° C.); the lower thresholds ranged from 23 to 5° C. (median approximately 19° C.). Physiological zero for mouth areas seems to be within the range 35 to 36° ± 16 tc 17° C., and Crudden's (1937) figures show it to be 33 to 34° ± 5° C. for leg areas.

Among early investigators, Preyer (1882), Canestrini (1913), and Peiper (1924*b*) were impressed with the potency of temperatures below physiological zero as compared with temperatures correspondingly higher. Pratt, Nelson, and Sun (1930) and Crudden (1937) have drawn similar conclusions. Jensen (1932), however, has pointed out that in terms of critical points for the sucking response the lower temperatures employed by Pratt, Nelson, and Sun represent greater deviations than the higher temperatures. Pratt, Nelson, and Sun and Jensen have reported that the incidence and extent of the response depend upon the degree of deviation from the critical thresholds. Crudden found no consistent relationship.

Purely thermal stimulation is difficult if not impossible to set up. In the case of stimuli applied through thermal conduction the only control available is to make the contact stimuli constant while varying the thermal. According to Peiper (1928), Sikorski (1908) reported a turning of the head toward the side stimulated by thermal radiation. Peiper (1928) was unable to confirm this, but Stirnimann (1939), using a *Goldscheiderlampe aus Rubinglas*, found reactions in 85 per cent of the stimulations, with movements toward the stimulus.

Relation to State of Organism. The effect of previous stimulation is illustrated by Crudden's (1937) demonstration of the setting-up of temporary neutral temperatures, in other words, the rapid onset of adaptation.

Pratt, Nelson, and Sun (1930) did not find any clear difference between thermal sensitivity during sleep and waking states,

but Crudden (1937) and Stirnimann (1939) are inclined to the view that the threshold is raised in sleep.

The enormous range between the high and low thresholds for thermal effects upon the sucking response, reported by Jensen (1932), may reflect the physiological state of the infant when nursing. Under different conditions the range of thermal neutrality might be considerably reduced.

Reaction Times. According to one of Canestrini's figures (1913), the reaction time of circulatory and respiratory responses to stimulation of the forehead with a cold piece of metal is not more than 0.5 second. Effects upon sucking are shown by Jensen (1932) to be delayed several seconds and to vary with the temperature deviation. Possibly this indicates the dominance of the stimuli producing the sucking response, or it may simply mean that changes in the sucking response await stimulation of other portions of the alimentary tract. With the capsule technique, Crudden (1937) reports reaction times of 2.5 to 11 seconds, with an average of 6.8 seconds to stimulation of the leg area.

Types of Response. Acceleration of breathing, throwing the head backward, gasping, shuddering, increase in brain volume, and irregular pulse follow the application of "cold" stimuli to the infant's forehead. Stimulation of the cheeks with temperatures of 15 to 17° C. leads to a turning-away of the head, whereas those of 43 to 45° C. generally evoke a turning-toward, seeking, or mouth orientation.

Stimulation of leg areas near the knee by the "cold" temperature cylinder produces most commonly flexion of the leg at the hip, with extension occurring only about one-third as often. Stimulation of the calf of the leg produces most frequently general patterns of response with most of the activity confined to the legs and with extension more frequent than flexion. Also, according to Crudden (1937), there is evidence of a "scratch"-localizing reflex.

Stirnimann (1939) reports that stimulation of the sole of the foot with "warm" stimuli leads to "seeking" movements of the other foot, whereas "cold" stimuli lead to withdrawal movements.

Thermal stimulation of the oral cavity elicits mimetic reactions, mouth movements, head movements, and squirming. It makes the sucking response irregular, and, with sufficient intensity, leads to disorganization and cessation of the response.

General environmental temperatures may give rise to shivering, as related by Blanton (1917), and general activity is correlated $-.205 \pm .024$ with temperature through a range of 74 to 88° F., according to Pratt (1930). Pilomotor reflexes (gooseflesh) to the normal combination of mechanical and thermal stimuli are very fleeting and slight in the newborn but are brought forth by adrenalin according to Hartmann-Karplus (1931).

Technique of Investigation. Cutaneous areas have been explored by thermal stimuli produced by temperature cylinders, evaporation of alcohol, etc. Tactual stimulation has been kept constant through use of a metal capsule attached to some portion of the body, the temperature being varied by changing the water in the capsule by means of inlet and outlet tubes. Radiant heat likewise makes possible a limited study of thermal sensitivity without any tactual accompaniment. The oral cavity has been stimulated with fixed amounts of distilled water at constant temperature, administered with medicine droppers, and by having the baby suck milk at different temperatures.

Jensen (1932) has used a manometer-polygraph combination to record the effects of thermal stimuli on sucking responses. Crudden (1937) has made cinema

records, and others have provided verbal descriptions of the responses.

Summary. The newborn infant is sensitive to temperatures that fall below the lower and above the higher thresholds, which appear to vary according to the part of the body stimulated and probably according to certain physiological states. They produce vigorous movements of the parts stimulated by the stimuli deviating most from the thresholds. Respiration and circulation are affected, and the sucking response becomes irregular or even ceases. The response involves more than the segment stimulated, although greatest frequency of reaction occurs in the stimulated member. There may be a localizing reflex of a "scratch" nature. Mild thermal stimuli above the higher threshold may lead to movement toward the stimulus, whereas those below the lower threshold lead to withdrawal movements.

Environmental temperatures appear to be correlated negatively with activity in the newborn infant.

Reactions to Contact or Pressure Stimuli

Sensitivity. A great variety of responses elicitable by contact or pressure stimuli upon the cutaneous areas or within the external cavities of the body leave, as Pratt (1937) has emphasized, no doubt regarding the presence and importance of such sensitivity in the neonate. Phylogenetically and ontogenetically, as Carmichael (1933) has pointed out, this type of sensitivity is the first to appear. It arises first in the oral-nasal region, but the sensitivity is widely distributed by the time the neonatal stage is attained.

There have been no systematic investigations of differences in tactual sensitivity of the cutaneous surfaces of the body. Genzmer (1873) and Preyer (1882), as reported by Peiper (1928), maintain that the face, the hand, and the sole of the foot have greatest sensitivity, whereas the shoulders, the breast, the abdomen, and the back have least sensitivity.

Differentiation of the effects of pressure or contact stimuli from the effects of other stimuli is difficult. The confusion with the effects of thermal, pain, gustatory, and other stimuli presents a difficult problem of control in studying the behavior of the newborn infant.

Another source of uncertainty arises from inadequate control of stimulus intensity so that cutaneous reflexes are confused with those due to deep pressure.

Stimuli which give rise to tickle in the older child produce no analogous vocalization, motility, or facial expression in the young infant, according to Nassau (1938). If it reacts at all it manifests expressions of "unpleasantness" and of withdrawal.

Hartmann-Karplus (1931) asserts that the position of itch as contrasted with pain, thermal, and tactual sensations is not clear. The stimuli producing it are such that perhaps it should be classified by itself, or with pain. Using a commercial itch powder composed of little plant hairs, this investigator reports that during the first 2 weeks there is little or no reaction. When a response does occur its reaction time is about 2 to 3 minutes compared with the 1 minute of older sucklings. The crying and restlessness which are elicited quickly subside. Neither at this time nor during most of the first 6 months is there evidence of localized scratching, although the general activity becomes more pronounced with age. This confirms the basic finding of Szymanski.

Watson (1919), the Shermans (1925, 1936), Peiper (1928), and Crudden (1937) have all reported "defense movements" to continued pressure upon certain body areas.

Relation to Stimuli. The responses evoked from a given body surface by tactual stimuli depend upon their intensity, duration, and whether they are of punctiform or stroking contact application. Summation effects have been noted.

Relation to State of Organism. The nature of the toe movements in the plantar response seems to be altered somewhat in sleep. The mouth orientation and sucking movements are not elicitable after the infant has completed nursing. The plantar response may vary according to postures, possibly determined by preceding stimulation. These are illustrative of various modifications of response which depend upon the condition of the infant at the time of stimulation.

Responses. They range from localized reflexes like the tactuopalpebral to responses which involve much of the body musculature. Many of the responses evoked are commonly described as defense movements. Some are viewed as withdrawal movements; others are supposed to localize and to ward off the stimuli which are being applied. Or they provide a fundamental orientation of the organism, as in the mouth orientation response to contact stimuli of certain facial areas (see section on responses for further description).

Summary. The newborn infant manifests widespread sensitivity to pressure or contact stimuli. The responses aroused constitute much of the neonate repertory and are interpreted by some writers as having a protective utility.

Reactions to Noxious (Pain) Stimuli

Sensitivity. The problem of pain sensitivity in the neonate is twofold: (1) the differences in sensitivity from one body area to another; (2) the degree of sensitivity as compared with later age periods.

In regard to the problem of differential areal sensitivity, Preyer (1882) considered the sole of the foot to be most sensitive, and the Shermans (1925) reported a differential between head and leg areas from birth on, the head areas being more sensitive to repeated needle jabs than the leg areas. Dockeray and Rice (1934), employing one needle jab with $\frac{1}{16}$ inch maximum penetration, found that in terms of vigor and quickness of response head areas were least sensitive, arm areas more sensitive than head areas, and leg areas most sensitive. The Shermans and Flory (1936) in further experiments with minimal intensities of stimuli have confirmed their earlier findings in regard to a cephalocaudal differential in sensitivity. They point out that sensitivity is shown by responsiveness of the organism and not by the amount of activity in the part stimulated.

Whether there is a marked pain insensitivity in the neonate, as compared with later periods, has long been an unsettled question. Genzmer (1873), applying needle pricks to the nose, lips, and hands of premature infants, reported little effect. Newborn infants on the first day manifested similar reactivity, with sensitivity slowly increasing during the first week. Canestrini (1913) noted relative insensitivity to needle pricks and also to faradic and galvanic stimulation. The Shermans (1925) found that an average of 6.5 needle jabs in the head areas was required to arouse a response at 0.5 to 5.5 hours, whereas at 35.5 to 40.5 hours 1.7 stimuli were needed, with 1 stimulation sufficing after 41 hours. The increase in the sensitivity of leg areas is shown by a decrease in necessary needle jabs from 10 at 0.5 to 5.5 hours to 2 at 70.5 to 75.5 hours, with only 1 stimulation required after 76 hours. Peiper (1926*a*), on the basis of controlled needle stimulation of arm areas, is convinced that there

is no marked insensitivity of the premature and the neonate as compared with older sucklings. The sensitivity of normal newborn infants as contrasted with the marked insensitivity of some idiots suggests pain insensitivity as a possible criterion of serious defect. Within the neonatal period Dockeray and Rice (1934) could discover no change in responses with increase in age. McGraw (1941*b*), on the other hand, found some "hypesthesia" during the first week or 10 days, the intensity of the responses increasing during the first month.

Relation to Stimuli. In studying this field of sensitivity the stimuli commonly employed have been pricks administered with a needle to different cutaneous areas of the body. Whether stimuli usually thought of as falling within some other field, such as those provided by application of ammonia or acetic acid fumes to the nostrils, should be classified as pain or noxious stimuli is not certain. Likewise, whether intense stimuli in such sensory fields as the thermal, the auditory, and the visual, or those involved in holding an infant's nose for a number of seconds, are to be interpreted as pain stimuli is also undetermined.

Relation to State of Organism. Wolowik (1927) observed in a 2-month-old infant that much more intense electrical stimulation was required to evoke crying during nursing than at other times.

Reaction Times. The reaction time (2 seconds) to stimulation of the sole of the foot is longer than that of adults, according to Preyer (1882). Peiper (1926*a*), applying needle jabs to the volar surface of the arm and measuring reaction times by a modified Morse apparatus, found the reaction time of body movements to range from 0.12 to 0.70 second, and of crying from 2 to 5 seconds.

Types of Response. In general, the responses, if the stimuli are not too intense, consist of withdrawal movements of the part stimulated and facial reflexes of "discomfort." Dockeray and Rice (1934), however, found only a general mass form of movements regardless of the area stimulated. Crying is a common feature of many of these responses.

Technique of Investigation. Needle jabs administered by the experimenter with more or less control of the penetration provide the stimuli in most investigations. Peiper (1926*a*) appears to have made this stimulation most constant and automatic. The responses have been recorded by observers, photographed, and their time relations obtained from the records of a Morse apparatus.

Summary. The presence in the neonate of sensitivity to pain stimuli has been demonstrated. Differential sensitivity of the cutaneous areas of the body has not been carefully explored, and there is disagreement regarding the relative sensitivity of the areas which have been investigated. Similarly, there is lack of agreement regarding the degree of pain sensitivity in the just-born infant as compared with that found at later age periods.

Reactions to Movement or Change in Position

Sensitivity. This sensitivity is demonstrated when spatial movements of the body stimulate the static receptors and thus give rise to postural responses. It is likewise manifested by responses aroused by active or passive movement of a part of the body. The sequences in coordinated movements are also said to illustrate the presence of sensitivity of this type.

Some have held that the generalized responses of newborn infants to stimuli may not be touched off directly by the experimental stimulus but that the part first re-

sponding produces kinesthetic stimuli which in turn evoke responses in other parts. Givler (1921) has suggested that learning in relation to kinesthetic and tactual stimuli during the fetal period may determine some of the characteristics of the grasping reflex.

Movements of hands and legs toward contact, or other stimuli upon the body, may include kinesthetic stimulation as an essential element in producing the necessary coordinations.

Relation to Stimuli. Peiper and Isbert (1927) and Peiper (1928) provided experimental stimuli by supporting the body in various positions. The postural and other consequences of such positions have also been studied by McGraw (1935). The movements of the infant's head when the child is placed in a prone position constitute the initial step in Shirley's (1931*a*) schema of sequential development. Jarring of the infant, used by Moro (1918), the withdrawal of support, mentioned by Watson (1919), and the vertical movements produced by Irwin (1932*h*) provide static stimuli. The effects of turning the head upon the body and limb postures, and of the body upon the head posture, have been investigated by Peiper and Isbert (1927). The effects of rotation upon eye movements (rotational nystagmus) and head movements, with the child in either a horizontal or vertical position, have been reviewed by Peiper (1928), as have the studies of caloric nystagmus. Baldenweck and Guy-Arnaud (1940) asserted that the vestibulary sensory apparatus of the neonate is completely developed. This is demonstrated by the nystagmus, aroused by rotation or by caloric stimulation, which is the same as that of the adult except for a lesser excitability. They relate this development to the active maintenance of equilibrar positions within the liquid environment of the fetus.

Relation to State of Organism. Information on this point is very casual or lacking in the studies reviewed.

Responses. According to Peiper and Isbert (1927) and Peiper (1928), support of the newborn infant at the abdomen only, or at the back on the buttocks, or at the side at the hip shows such complete dominance of gravity that the child is unable to hold its head and trunk upright or in alignment. When placed in a prone position on a table, however, the neonate partially lifts its head. This has also been confirmed by Bryan (1930) and Shirley (1931*a*).

McGraw (1935, 1941*d*) has described the process of falling over when the child is placed in a sitting position.

Peiper (1929) demonstrated that, when the newborn infant is held in an erect position with its feet resting upon a surface, alternate or "stepping" movements are made. Peiper made photographs of these and obtained footprint records. Possibly static and kinesthetic, as well as tactual, stimuli are involved in this response. McGraw (1932) has confirmed Peiper's findings.

Inverted suspension (holding the child by the feet, head downward) occasionally produces in the neonate a bending-back of the head as reported by Peiper and Isbert (1927). According to McGraw (1935, 1940*b*), a flexion of the legs at knee and hip occurs, resulting in an up-and-down movement of the body. Body and head are in general alignment in the vertical plane with arms maintained more or less in the usual flexed position. Irwin's (1936) motion pictures showed that inverted suspension produces in the neonate a momentary backward bending of the head. The reaction, occurring in the cervical region, is designated by him as opisthotonoid.

Jarring or the sudden dropping or raising of the infant evokes, as Irwin (1932*h*)

has shown, the *Moro's Umklammerungs reflex,* which is described in greater detail elsewhere in this chapter.

According to Peiper (1928), it is uncertain whether the *Brudzinski phenomenon* (a drawing-up of the legs when the head is bent forward) is a tonic neck reflex. Peiper and Isbert (1927) found it to be of rare occurrence in the neonatal period. Turning the infant's head to one side with a sudden jerk results in a "fencing" posture of the limbs. Other postural reflexes involving head and trunk consist of movements of the trunk if the head is moved and movements of the head if the body is moved. Mesina (1936) reports that, if one leg of a baby resting upon its back is flexed, the other automatically flexes.

Rotation of the body produces nystagmus and sometimes compensatory head movements arising from stimulation of the static rather than of the visual receptors. Bartels (1910) found that the head movements were in the opposite direction when the child was rotated in horizontal positions; Alexander (1911), that they were in the same direction during rotation, and in the opposite after rotation had ceased. The latter finds no rotation nystagmus, but an after-nystagmus for about 15 seconds. McGraw's (1941*a*) study appears to support Alexander rather than Bartels. Baldenweck and Guy-Arnaud (1940) were positive that the neonate's nystagmus to both rotational and caloric stimuli is of the same type as that of the adult. Other investigations reviewed by Peiper (1928) present similar contradictory findings. The presence of caloric nystagmus is likewise uncertain.

Summary. Static-kinesthetic sensitivity is demonstrated in the neonate by a variety of responses elicited by movement of the body as a whole, or in part. Beginnings of responses which will lead to upright postures and to walking are discernible.

Reactions to Internal (Organic) Stimuli

Sensitivity. The nature of internal stimuli and the sites of their operation are not well defined or known. But the general motility of the infant, when other stimuli are brought under control or reduced, is accepted by many as evidence that such sensitivity is present in the newborn infant. Indeed, the researches of Pratt, Nelson, and Sun (1930), Pratt (1934*b*), and especially of Irwin (1930), interpreted from this point of view, indicate that internal stimuli are responsible for most of its activity. As stated elsewhere in this chapter, external stimuli of short duration, although releasing responses which have present or future significance in the life of the child, add little to its total motility. External stimuli of longer duration inhibit activity which otherwise would be aroused by internal stimuli.

The functioning of respiratory and circulatory organs and of other parts of the viscera doubtless do contribute internal stimuli, but the preponderant number are apparently associated with the activities of the alimentary canal and of the excretory systems.

Conditions within or associated with the activities of the digestive tract are known to determine whether contact stimulation will arouse mouth orientation and sucking movements.

Nursing may be followed by *regurgitation,* and this, in turn, by *hiccuping.* Pendleton (1927), studying 40 newborn infants, found that hiccuping started about 10 minutes after regurgitation, lasted 5 to 15 minutes, and had a rate of about 18 per minute. Treatment by rapid administration of fluids soon stopped hiccuping in 72.5 per cent of the cases, immediately in 57.5 per cent of them. This suggests that gastric contents carried into the esophagus by re-

gurgitation provide the stimuli for hiccuping.

Wagner (1938*b*) has affirmed that

> the hiccough, generally attributed to pressure of a full stomach upon the diaphragm, has frequently been observed in the infant shortly after birth. However, no attempt has been made to proceed further and study the hiccough as an isolated behavior item.

From pneumographic records of 17 neonates she found a duration ranging from 35 seconds to 18 minutes and 20 seconds (mean = 6 minutes, 34 seconds). The mean interval between hiccups ranged from 2.6 seconds to 7.9 seconds (mean of all = 4.5 seconds). This would be at the rate of little more than 13 hiccups per minute as contrasted with Pendleton's (1927) rate of 18. Wagner also found that the number of hiccups per minute tended to decrease throughout the period.

Norman (1942) has reported fetal "hiccups" as early as 125 days before birth, the durations of hiccuping ranging from 1 to 29 minutes (mean duration = 8 minutes) and the frequencies ranging from 10 to 45 per minute. The hiccups apparently occur during periods of heightened activity of the fetus and are accompanied by cardiac acceleration of as much as 30 beats per minute—a phenomenon unobserved in the hiccuping of newborn infants. Anoxemia is suggested as a possible cause of this hiccuping.

The relations of general motility to content and pressure stimuli as well as to the muscular activity of the stomach have received careful study by Carlson and Ginsburg (1915), Taylor (1917), Irwin (1930, 1932*f*), and Richards (1936*a*, 1936*b*, 1936*c*). It is probable that a great deal of the child's total motility is in some way dependent upon alimentary processes, but whether it is directly related to activity of the stomach or more indirectly produced by some nutritional state is not known (the researches bearing upon these problems are given detailed consideration in the section on physiology).

In the final sequences of alimentation and assimilation, excretion and egestion occur. The excretory aspects of perspiration have no visible connection with general motility. Micturition may, as Pratt (1933) has elsewhere suggested, be preceded by slight activity with quiescence after the act. More activity precedes egestion or defecation. According to Dennis (1932*a*), the latter presents the following pattern response:

> With each . . . abdominal contraction the legs and toes are extended and raised and the forearms are held to the upper chest. At the same time the infant may grunt and his face often reddens.

Summary. Internal stimuli on the whole are of fairly long duration, and the responses, excepting those involving sphincter muscles, are of rhythmical or periodic incidence. The transition from fetal to postnatal life probably involves an even greater stepping-up of internal than of external stimuli. It is the internal stimuli which account for most of the motility of the infant. The rôle of external stimuli according to type, intensity, or duration is to add variable but negligible amounts to the total activity, or actually to reduce the total which would occur were they not present.

Responses

The Feeding Responses. The responses which orient the newborn mammal to the nipple of the mother's breast and effect an ingestion of milk are among the most fundamental in the young mammal's repertory.

First in the series of these responses are the ***head-mouth orientation*** movements.

The prerequisite condition for their arousal by contact stimulation is that the infant be approaching a nursing period rather than having just nursed. Pepys (1667) was one of the first to observe that if an infant's cheek is touched the head turns and the mouth opens to grasp the finger. This *"search reflex"* was described very carefully by Kussmaul (1859) and mentioned by Preyer (1882). According to Popper (1921), stroking contact of the cheek may evoke head turning, mouth opening, and snapping movements. Gentry and Aldrich (1948) have applied the term *rooting reflex* to the head-turning and mouth-opening responses. The reflexogenous zone of the *oral* responses has been shown by Minkowski (1928) to be quite extensive early in the fetal period, and Pratt, Nelson, and Sun (1930) have confirmed its extensiveness in the neonatal period. In terms of sucking or mouth responses to contact stimulation they found sensitivity ranging in decreasing order in the following areas: lips, above lips, below lips, cheek. Sensitivity was greater in the waking state and appeared to decrease with age in the cheek areas. Jensen (1932) found the head movements to increase with age upon stimulation of this area.

The nature and the extent of the response depend upon the area which is stimulated. When the cheek is touched the head turns toward the side stimulated and the mouth opens. If the area above the lips is stimulated the head is thrown back and the mouth opens to its widest extent. If contact is maintained, the head may shake vigorously from side to side. Similarly, if the area below the lips is touched the chin drops, the mouth flies open, and the head may bend forward.

These responses have been confirmed by Baliassnikowa and Model (1931–1932) and by Stirnimann (1937*a*). According to Stirnimann the child must be awake for any except simple reflexes to appear. Halverson (1938) interprets the significance of the response as follows:

> At birth the mouth is superior to the hand in what might be called directed activity and definiteness of function. Upon proper stimulation the mouth can both open and close and with the aid of head and neck movements institute a strenuous search for the stimulating object.

Certainly such coordinations are among the most effective made by the neonate, although in human beings the head and neck or "searching" movements must be regarded as atavistic survivals.

Lip reflexes are coordinated with head-mouth orientation and are more specific to the act of coupling and sucking. This limitation of response progresses as one moves from stimulation of the periphery of the reflexogenous zone toward the lip areas. Head movement decreases or changes character according to the locus of excitation.

Thompson's (1903) lip reflex, consisting of pursing or pouting, is released by tapping the surface of the upper lip. Its relation to the contact-aroused erection of the mother's nipple has been noted. This reflex has been confirmed by Lambanzi and Pianetta (1906), Blanton (1917), Popper (1921), Baliassnikowa and Model (1931–1932), and Stirnimann (1937*a*), who has found it elicited most frequently by stimulation of the corners of the mouth. Stirnimann (1936*a*) has also observed a tumescence of the inner surface of the lips.

Sucking and *swallowing* constitute the crucial elements of the feeding responses. Although present at birth, the sucking response increases in vigor during the neonatal period. The response has a long history of objective instrumentalized study from the early researches of Basch (1893), Lifschitz as reported by Bechterew (1908),

Pfaundler (1909), and Barth (1914), in which the infant sucked upon a bottle or the mother's breast through special types of nipple shield, or in which a pneumatic system recorded movements of the chin, to apparatus which measured the changes in pressure set up by the infant's sucking in a closed system such as Kashara's (1916), or manometric set-ups such as those devised by Jensen (1932) and Halverson (1938). The Roentgen kymograph studies of sucking, swallowing, and breathing made by Peiper (1931, 1935*b*) are likewise a contribution in methodology.

Peiper (1939*b*) demonstrated that the rhythm of the swallowing center is imposed upon that of the sucking center and this in turn upon that of the respiratory center. Halverson (1944) discovered that the character of breathing alters in the direction of costal movements during efficient sucking, and that good coordination may be present even in the premature infant (1946).

New aspects of the sucking response have been revealed by Balint (1948*a*, 1948*b*). The highly sensitive registration of the sucking responses of newborn infants obtainable by the Jacquet polygraph demonstrates the presence of a rhythmical clonus ("quivering") of the tongue. Its frequencies are 6–10 per second. In opposition to other observers he reported little change in the basic sucking rhythm throughout the nursing period. In fact, he was impressed by the stability of each infant's sucking rhythm. Some infants continued at their basic and lowest frequency; others, after a pause in the sucking, resumed at a higher rate, which then gradually subsided to the basic rhythm. In "normal" infants the sucking had greater regularity and the frequencies were lower than in those patterns found in infants suffering from "respiratory" or "intestinal" disorders.

Ribble, according to Norval (1946), asserted that 40 per cent of newborn infants had such feeble sucking movements that they were unable to obtain their nourishment without prompting or assistance. Norval, on the other hand, found only about 4 per cent to have inadequate sucking responses, although the newborn infant's approach is one of "dallying and repetitious trials" rather than of "greediness."

When sucking starts, general activity, according to Jensen (1932), begins to disappear. Salt solutions cause the response to deteriorate or cease, as do certain critical temperatures of milk. Wolowik (1927) has shown that when the 2-month-old child is nursing it requires electrical stimulation over three times as intense to cause crying as at other times. When the infant has stopped sucking, but while contact is yet maintained, other stimuli such as visual stimuli or those afforded by pulling the hair or pinching the big toe will, according to Jensen (1932), again initiate sucking. Under these conditions the organism is, he states, "set" to respond only in this way. Peiper (1938) terms this the dominance of the sucking center and holds (1937*a*) that this center shows two levels of excitation, one giving periodic sucking and the other regular and rhythmic sucking. The analogy to breathing as well as a developmental relationship are suggested (1939*a*). The sustained character of the orientation in sucking is striking.

Halverson (1938) considers sucking as arising from pronounced muscle tension. Simultaneous records of sucking pressure, gripping pressure of the hand, and observation of general activity show their maxima at the beginning of sucking, and they decrease together during the course of the feeding period. When the nursing process is hampered there is incidence of penial tumescence which is ascribed to marked abdominal pressure. Peiper (1931, 1935*b*)

and Hofmann and Peiper (1937) found that in the hungry suckling there were between 60 and 80 sucking movements, or 1 or 2 for every inspiration. Neither sucking nor breathing is interrupted by swallowing. Swallowing occurs during the phases between inspiration-expiration or expiration-inspiration.

Some have held that swallowing, as Baliassnikowa and Model (1931–1932) express it, is part of a chain reflex appearing when sucking fills the mouth. Jensen (1932) has observed that sucking, as upon air, may occur without swallowing. And sucking of some substances may be followed by rejection rather than continued swallowing.

Finger sucking is a common response in the neonate, appearing shortly after birth, according to Blanton (1917), Stirnimann (1933), and Kunst (1948). Dennis (1932*a*) has described the nursing posture of the child.

Peiper's review (1936*b*) is probably the most comprehensive treatment of the feeding responses which has appeared.

Defense or Protective Reflexes. This classification, although in common usage, is not entirely satisfactory. The terms are usually ill defined and bear the connotation of either conscious intent or unconscious purpose, whereas further study of the responses may disclose that the organism's response is determined by its structure rather than by the precise end which is to be accomplished. Here, as elsewhere, the need is for accurate and comprehensive description of behavior and of the conditions under which it appears and is modified.

There have been attempts to classify responses in terms of movement away from or movement toward the stimulus. Carmichael (1933) has reported the observations of various writers to the effect that the intensity of the stimulus determines the direction of movement. In terms of the life economy of the infant, however, movement of the part of the organism toward the stimulus or site of stimulation may lead, as in mouth orientation, to continued contact with the stimulus, or it may result in active pushing-away or rejection of the stimulus. Thus it is possible, without any implication of conscious purpose on the part of the infant, to term those responses "protective" which remove it or any part of the infant from stimuli, or those in which some part moves toward and pushes away a stimulus object applied to some part of the body. These latter responses are particularly significant because they demonstrate a certain amount of ability to orient in the environment and to localize the sources of excitation.

With this broad definition, the classification of responses such as the palpebral, pupillary, and mouth rejection as "protective" seems justifiable. The claim that other responses such as the Moro and the grasping reflex are defensive, in terms of the arboreal past of man, should be received with considerable skepticism. Similarly, Babinski's (1922) attempt to classify both extensor and flexor plantar responses as defense movements, the first by virtue of withdrawal of the toes and the latter in terms of "attack," has contributed little toward the understanding of the plantar responses. The purposive interpretation of these movements becomes somewhat difficult in the light of Pratt's (1934*d*, 1936*a*) demonstration that stimulation of the upper surface of the foot produces the *same types of movements* of the foot and toes as stimulation of the plantar surface, so that whether it is defense by withdrawal or defense by attack depends upon the location of the stimulus. Considerations such as these should lead to caution in interpreting the purpose of a response.

Among the withdrawal responses not cited elsewhere in this chapter are the spinal and abdominal reflexes described by Galant (1917). In all essentials these consist in a concave bowing or bending-away of the side of the body from stroking contact stimulation. Others, including Peiper, have differentiated between Galant's "spinal reflex" and the abdominal reflexes, but Galant (1930) is of the opinion that they are not different responses but rather the same response released from an extensive reflexogenous zone.

Of even more significance for future development of the infant are those responses in which continuous contact stimulation of some part of the body surface is followed by movement of hand, arm, or leg toward the locus of stimulation. When the infant's nose was held by the experimenter's fingers, Watson (1919) reported defense arm movements. Pratt, Nelson, and Sun (1930), Taylor (1934), and Daniels and Maudry (1935) were unable to confirm this.

The Shermans (1925) and the Shermans and Flory (1936) have reported similar defense movements, improving rapidly during the first few days after birth, to pressure exerted upon the infant's chin. Although Daniels and Maudry (1935) and others have not confirmed the Shermans' findings, the experimental controls of the latter in their later research seem to indicate that some coordinations of this type are present. Indeed such coordinations may mark the early beginning of the hand-mouth movements which play such an important rôle in the subsequent development of the child.

On the other hand, Hartmann-Karplus (1931) found no localizing movements when itch powder was applied to other parts of the body surface.

Crudden (1937) reported a localizing scratch reflex of the contralateral leg to the capsule in his investigations of thermal sensitivity. Peiper (1936*a*) also, applying curtain clamps to various parts of the body, found, at first, local reactions, followed frequently by movements of hand or foot to the part stimulated. When the infant's hands are each encased in cloths tied at the wrists they move against each other or against the sheet until, according to Stirnimann (1937*b*), the hands frequently become disengaged. He considers this impulsion toward freedom to be second only to that toward nourishment.

No adaptive movements (hand of the infant striking that of the experimenter) to head restraint were observed by Stoffels (1940–1941) unless the child was on its side, and then only in 5 per cent of the trials.

Stirnimann (1944*b*) discovered a defense response elicitable by application of the stethoscope over the heart but not over other chest areas. The infant's hand approached and pushed against the stethoscope. The response was not symmetrical like the Moro. It was aroused in 50 per cent of infants on the first day after birth but in only about 15 per cent by the age of 10–14 days.

The Oculo-Cephalo-Gyric Response. The visual pursuit movements described in the section on reactions to visual stimuli constitute further evidence that the newborn infant possesses responses which enable it to orient to some aspects of its environment. These orientations, unlike mouth orientation, have increasing importance among the activities of the organism. Indeed here is an early manifestation of what has been termed attention.

Palmar Response and Arm Movements. The response of the fingers in the palmar response is homologous to that of the toes in the plantar response, save for the variability between extension and flexion of the latter. From the first descriptions given, writers have differentiated between

the early neonatal and the later grasping by terming the grasping of the newborn infant involuntary while the adult form is voluntary, except in pathological cases. The voluntary type is said to appear when the involuntary type wanes. Halverson (1937) questions this and argues that there is chronological overlapping of the two. The earlier writers state that involuntary grasping disappears between 4 and 6 months, and Wagoner (1924) considers its persistence a sign of retardation.

Robinson (1891), Buchman (1895, 1900), and Mumford (1897) believed that neonatal grasping proved that, in the past, man or his ancestors lived in trees.

Givler (1921) was one of the first to suggest that the response might be perfected by exercise during the prenatal life and not result entirely from maturation.

The response was described as simian in nature—that is, palm and finger flexion without thumb opposition—by Buchman (1895, 1900). McGraw (1935, 1940*a*) likewise emphasizes its digital character when the child is partially or completely suspended. Halverson (1937), who has given this response most careful study, reports that the neonatal grasping reflex has two phases: first, closure to light pressure upon the palm; second, gripping or clinging as a proprioceptive response to pull upon the finger tendons. Closure disappears in 16 to 24 weeks, whereas the proprioceptive gripping or clinging disappears after 24 weeks. Closure is a specific or limited response; gripping has associated with it many other movements. McGraw (1940*a*), following Halverson, also distinguishes between the grasping of a contacted object and that produced by a pull upon the finger tendons, which she characterizes as suspension-grasp behavior.

The strength of the infant's grasp has been expressed most frequently in terms of the time the infant can sustain its own weight with one or both hands. The pioneers, Robinson (1891) and Buchman (1895, 1900), reported times as long as 2½ minutes using both hands, and a few seconds using one hand. Blanton (1917) found the child could support its weight for only a few seconds employing both hands. Richter (1934) suspended infants by both hands from parallel rods and obtained in different infants average suspension times ranging up to 60 seconds, with 128 seconds the longest time obtained. Valentine and Wagner (1934) employed the handle of a dynamometer as a lifting device, and, neglecting the fact that pulling to suspension is not the same situation as suspension of the infant, drew the following conclusion:

> It has been generally accepted as a fact that newborn infants are capable of supporting their own weight when grasping with one hand a rod of about the diameter of a lead pencil. The use of the dynamometer in this experiment, where the dynamometer was lifted vertically until the infant released the handle, emphatically disproved such an assumption, for the maximum grasping strength of the strongest subject was 2200 grams, less than the weight of the smallest subject.

The Shermans and Flory (1936) measured the strength of the grasp by the Chatillon Balance and found it to average 1732 grams in the right and 1765 grams in the left hand. A little over 10 per cent of the infants could lift themselves with one hand. Halverson (1937) found the clinging strength of the left hand to be slightly superior to that of the right. At birth the mean strength of the right hand is 1952 grams. Halverson found that infants support more than 70 per cent of their weight with both hands when pulled toward suspension. Of 97 infants less than 24 weeks old, 27, under these circumstances, sup-

ported their own weights with both hands, and one at 4 weeks did it with the right hand alone. Halverson states that "it was evident that some of them could have supported considerably more weight than their own mass." The relative strength of the different fingers was also determined by this investigator. Richter (1934) and Halverson (1937) both indicate that the response, measured in terms of suspension time and by the dynamometer, is not so great during the early part of the neonatal period.

The Shermans and Flory (1936) noted, as had earlier investigators, that the grasping reflex is weakest when the infant is asleep, and strongest when the infant is crying. Halverson (1937), testing the gripping pressure upon a small sensitive rubber capsule, found that the strength of the grasp was greatest at the beginning of nursing, decreasing as the infant approached satiety. Thus the grasping response reflects the degree of muscle tension.

The study of handedness in newborn infants has been approached, as we have seen, by measuring the relative strength of the grasping reflex in the right and left hands. The left hand appears at this stage to be stronger. Watson (1919) attempted to determine whether there was preferential motility in arm movements but could discover none. Stubbs and Irwin (1933) reported a significant difference, and Valentine and Wagner (1934) found greater motility in the right arm. This did not appear to be correlated with the later preferential reaching of some of the same subjects.

Reaching toward stimuli acting upon the visual sense organs does not occur during the neonatal period, but, as described in defense movements, there are rather direct movements toward the site of contact stimulation of some areas of the body. Allied to these is the searching-grasp response to stimulation of the dorsal surfaces of the fingers. Stirnimann (1941) states that he obtained it in almost all newborn infants, although Halverson had not observed the phenomenon before the sixteenth week. According to Stirnimann, this is a voluntary rather than a reflex response because it is seldom evoked by anything other than the experimenter's finger or a reasonable facsimile. He interprets this discrimination as an expression of a social impulse or drive.

Postural Responses. The researches upon these responses of the neonate have demonstrated their rôle in the development of the erect position, locomotion, and the complex activity of visual fixation.

Shirley (1933*a*) in her behavioral silhouettes of the developmental sequence showed that the just-born infant makes contact with the face when placed in the prone position but that by the terminus of the neonatal period the head is lifted so that the chin is raised. Gesell and Ames (1940) held that these postural adjustments of the head and the associated movements of the arms and legs are a segment of the developmental events which will culminate in an upright posture. McGraw (1941*e*) regarded a righting or rolling response of the infant in the supine position as one of the precursors of the upright posture. No such response was found in the neonate, although the body might be turned from back to side as part of general total movements or in consequence of the Moro response.

During the first three postnatal months the basic postural response, according to Gesell and Halverson (1942), is the tonic-neck reflex. Ling (1942) has stated that it is the characteristic *waking* posture. In this response the head is turned to one side with homolateral arm and leg extension. The contralateral leg and arm are flexed, the arm at the shoulder. The eyes stare upon or in the direction of the extended arm. The relation of flexion of the fingers and toes to the tonic-neck reflex was explored by Pacella and Barrera (1940).

Ames (1942) found that the prevailing leg postures involved either bilateral flexion or extension, with one leg tending to be more active in flexing and extending while the other leg remained flexed.

Locomotor Movements. The newborn infant possesses no effective means of movement from place to place. From its normal supine, prone, or lateral postures it may shift its position by various responses, but this involves little translation of the body in the horizontal plane.

Bauer (1926) obtained a "creeping phenomenon" when the neonate was placed on its abdomen and contact or resistance offered the soles of the feet. Under these circumstances the infant responds by thrusts of one or both feet, followed by alternate arm movements which tend to raise the body from the supporting surface. At the same time the body bends from side to side. These creeping responses are elicitable during the first 4 months and, according to Bauer, are second only to sucking in their complexity.

Peiper (1928) and Stirnimann (1938) have confirmed Bauer's observations, and Stirnimann, finding it present in an anencephalic subject, decided that it was a subcortical reflex. The creeping phenomenon of the neonate bears some relation to its stepping movements but neither, according to this writer, has any relation to later creeping or walking. McGraw (1941*c*) has reported greater activity in the lower than in the upper extremities when the infant is placed in the prone position.

Peiper (1929) discovered that, when the newborn infant is supported in an erect posture with the soles of the feet resting upon a table top, the legs extend upon contact and make alternate stepping movements, the length of the double step being about 20 cm. Frequently the leg, on being set forward, crosses in front of the other, preventing further progression. These stepping movements differ from later walking in that the activity in the neonate is confined to the lower extremities. The stepping movements are highly variable and uncertain of appearance. In a few months they disappear, and under the same conditions the suckling withdraws its feet. Peiper photographed the stepping movements and obtained footprints by having the infant step upon soot-blackened glazed paper. The discovery of stepping movements of the newborn infant was reported by McGraw (1932). She held that genuine "upright ambulation" is impossible at this period because of an undeveloped equilibratory apparatus. In a later analysis of the problem McGraw (1940*c*) confirmed some of Peiper's observations. She called attention to the narrow base of the steps. This, of course, contrasts with the wide base of the child that has arrived at the stage of walking without support. Stepping movements have greater incidence from 9 to 14 days than during the first 24 hours, according to Stirnimann (1938). The response disappears in 4 to 5 months.

The Plantar Responses. The literature upon these responses is probably more extensive than upon all other aspects of neonate behavior combined. This is, of course, no indication of a correspondingly important rôle in the life economy of the child, nor are these studies as significant for child psychology as for neurology. Indeed apt is the statement by Richards and Irwin (1934*c*) that "the popularity which this problem has been accorded may possibly be due to a seeming necessity for the student of infant reactions at some time in his career to do an experiment on infantile plantar phenomena."

In this section no attempt will be made to review the literature in detail. Those who wish to study the problems presented by the plantar responses should consult the following researches and reviews: Bersot

(1920, 1921), Minkowski (1926, 1928), Pratt, Nelson, and Sun (1930), Fulton and Keller (1932), Pratt (1934*d*), and especially the review by Richards and Irwin (1934*c*).

Historically, major interest and attention to these responses date from Babinski's (1896, 1898) correlation of extension of the big toe, and sometimes extension and fanning of the toes (1903), with pyramidal tract disturbances in adults and the prediction that such responses would be physiological in infants. Although Leri (1903–1904), Engstler (1905), and many others have reported the Babinski complex to prevail during the neonatal period, others, such as Feldman (1921) and the Shermans (1925), have found a higher percentage of flexion of the toes during this period. Burr (1921) and Wolff (1930) have reported variability so great as to make it seem inadvisable to speak of a "plantar reflex."

In the narrowest sense the term "Babinski" has applied to the limited extension of the big toe alone, but, as already stated, Babinski himself recognized that frequently the other toes were involved in the *signe d'éventail*, and that there was triple retraction of foot, leg, and thigh. Bersot (1920, 1921) and Minkowski (1932–1933) have recognized the necessity of reporting all the behavior segments which are activated by plantar stimulation, and also the necessity for exploring the extent of the reflexogenous zone from which the responses may be evoked.

The work of Richards and Irwin (1934*c*) indicates that toe extensions occur more frequently than flexions during the neonatal period. This research has additional importance because it demonstrates that one may not place too great reliance in the reliability of the clinical method. Indeed, the lack of agreement in many studies is probably the result as much of errors of observation as of differences in methods or of variability in stimulation. These same considerations have led Pratt (1934*d*, 1934*e*), in his studies of the reflexogenous zone and of the patterning of responses, to the belief that no further contributions can be made to the knowledge of plantar responses until frame analysis of motion-picture records is made.

Exploration of the reflexogenous zone tentatively indicates that plantar areas of the leg have greatest sensitivity and that their stimulation results in the greatest generalization of response, whereas stimulation of the hallux results in the most specific response. Leg and thigh segments are more likely and toe and foot segments less likely to be involved when the mesial surface of the leg is stimulated. When toe segments are viewed as one, they are about equally involved in responses, but leg and thigh are less frequently represented. About two-thirds of the toe movements are movements of extension and one-third of flexion. The foot, leg, and thigh manifest mostly flexor movements. Analysis of the responses observed revealed less than 200 different patterns, of which 4, or 2 per cent, accounted for 29 per cent of the observed responses, 6 per cent of the patterns accounted for 50 per cent of the responses, and 15 per cent of the patterns for 75 per cent of the responses. From this it is concluded that no one response pattern may be termed the plantar response. The five most frequent patterns are: foot flexion; extension of toes and foot flexion; extension of the hallux; toes extended, fanning, and foot flexion; hallux extension and foot flexion.

Ontogenetically, the work of Minkowski (1922) and others shows that during the latter part of the fetal period the prevailing response of the toes is flexion. Engstler (1905) and Bersot (1920, 1921) report that this is likewise true in prematures. Babinski (1922) and his associates

and Lantuejoul and Hartmann (1923) find flexion the rule during the first few hours after birth.

According to the Shermans (1925), the nature of the response depends upon the previous posture of the toes; repetition of the stimulus will change toe extension to flexion. This dependence upon the posture at the time of stimulation is also affirmed by Richards and Irwin (1934*b*, 1934*c*).

In sleep, according to Richards and Irwin's (1934*c*) research, and as reported by them in other studies, extension of the toe is not so great as when the infant is judged to be awake.

The movements of the segments of the leg in the plantar responses have been viewed by Babinski (1915, 1922) as defense movements. Their alteration with age has usually been correlated with myelinization of the pyramidal tracts.

The Foot-Grasping Response. The Stirnimanns (1940) have reviewed previous reports of a foot-grasping reflex in the newborn infant to light pressure upon the plantar surface near the toes. They report the presence of this tonic reflex in 98 per cent of 800 neonates which they investigated with a special esthesiometer. The toes flex and grasp at a minimal pressure between 40 and 70 grams. Galant (1931) has interpreted plantar flexion of the toes as a rudimentary foot-grasping reflex.

The Moro and "Startle" Responses. The relation or the differentiation of these responses, as noted in the section on reactions to auditory stimuli, is difficult. Moro (1918) himself was aware that stimuli other than jarring would release the response which he described, and that it was suggestive of fear. This identification of responses or at least common elements has come down through Peiper (1925*a*), Irwin (1932*g*), Pratt (1934*b*), Dennis (1934), and others. Strauss (1929), however, followed by Hunt, Clarke, and Hunt (1936), Hunt and Landis (1938), and Landis and Hunt (1939), differentiated a startle response from the Moro, even though both may be released by the same stimulus or the same types of stimuli.

After testing the Moro response in 250 newborn infants Stirnimann (1943) concluded that, although it resembled the fear reaction, no unpleasantness was involved because no infants cried upon being jarred or shaken. In his opinion the response is not an actual clasping or embrace since the extended arms will not clasp or hold to the experimenter's arm. Hence it should be called the reaction to shaking (Erschütterungsreaktion).

According to Moro (1918), the clasping response to jarring consists of an extension of the arms followed by their bowing and return toward the body. The response is symmetrical and the legs undergo much the same kind of movement. Freudenberg (1921) states that the arms extend, spread, and are adducted to the middle line of the body with the fingers spread and half flexed. The legs are extended, the toes spread and bent. Schaltenbrand (1925, 1928) has furnished essentially the same description with the further notation that it may be elicited not only by jarring but also by sudden noises, rotating the head on the body, or tapping the abdomen. According to Gordon (1929), the Moro simulates the fear response. He observed tremor of the hands in the clasping movement and less participation of the lower extremities. The response is symmetrical except in case of birth injuries. It disappears by the fourth month. Sanford (1931) confined his attention only to arm movements and found that fracture of the child's clavicle resulted in an asymmetrical response. Dupérié and Bargues (1932) have pointed out that the leg responses are highly variable. They were unable to evoke the response by auditory stimuli. McGraw

(1937) has described the movement of the trunk as follows:

> Simultaneously there is an extension of the spine, often involving a retraction of the head toward the interscapular part of the spine and a rolling of the body slightly to one side.

Whether the movement of the legs is flexor or extensor depends upon their position at the time of stimulation. She also claims that the response is usually followed by crying. Against this must be set Irwin's (1932*h*) studies on the effect of vertical elevation of the infant—this did not result in crying. Finally, Richards (1936*a*) has observed these responses to occur without the application of any experimental stimuli. Dennis (1935) doubts that the response actually disappears at 4 months.

Landis and Hunt (1939) have shown that Peiper's earlier observation of the more rapid fear response preceding the Moro is descriptive of the startle. The primary difference in the two patterns is:

> The startle pattern is primarily a flexion response, while the Moro reflex is primarily an extension response. In the latter the arms are extended straight out at the sides at right angles to the trunk, fingers extended, the trunk is arched backward, and the head is extended. Following the primary extension in the Moro reflex there is a secondary flexion response which has been described as a "clasping" response, but it is doubtful whether this is a true clasping response or merely a slow return to normal posture. The primary extension movement seems to be the genuinely significant portion of the response. Despite this gross difference in the two reactions, both Moro reflex and startle pattern may be called forth by many situations involving sudden unexpected stimulation.

Clarke's (1939) genetic studies of the response to auditory stimuli show that first they are typically Moro, then some elements of the response disappear and the character of movements changes from extension to flexion, giving the "startle."

Vocalization. The birth cry represents the first vocally produced sounds from the newborn infant, but it seems best to regard this as a respiratory response and not a true precursor of speech. Subsequent crying either in response to external or internal stimuli is, according to Schachter (1932*a*), a part of the generalized behavior which is characteristic of the neonate. It is also closely related to breathing and partakes of its rhythm in continuous crying. As we have seen, activity of this type ceases when auditory stimuli are presented, when the child is swung or rocked, and of course is terminated by sucking.

Although Sherman (1927*b*) has demonstrated that emotional patterns are not differentiated by differences in crying, it is nonetheless true that this type of activity is the infant's most powerful tool in acting upon its social environment and in thereby obtaining attention and care.

The durations, times, and probable causes of the crying of newborn infants have been tabulated by Aldrich, Sung, and Knop (1945*a*, 1945*b*, 1945*c*). The data were obtained by an observer stationed in the hospital nursery (average number of infants under observation = 20 at one time) and from reports by the individual mothers after they had returned home with their babies. Five probable causes of crying were assigned: hunger, vomiting, soiled diapers, wet diapers, and unknown. Crying ascribed to "hunger" was of longer duration than that resulting from unknown factors. Next in stimulating value came wet, and then soiled, diapers.

Two peaks in crying were noted: one at about 6 P.M. and the other about midnight. The authors consider the first to be produced by an interval between nursings of 5–6 hours. Crying is held to be a mani-

festation of individual need and not aroused by interstimulation within the nursery community. They believe that a child should not have to cry more than 3 minutes before having its needs satisfied.

The amount of crying increases up to the fourth day, levels off to the sixth, and thereafter declines. During the first 8 days the average total of crying was 117 minutes per day, with a range from 48.2 to 243 minutes. The hourly variation was from 1.3 to 11.2 minutes.

Fairbanks (1942) recorded the cries of an infant when the 2 o'clock feeding was withheld. The mean of the cry was 556 cycles per second, or 1 octave above an adult female and 2 octaves above an adult male speaking voice. The range was 5 octaves, or from 63 cycles to 2631 cycles per second. During the first 6 postnatal months the development was toward higher pitches.

Reviews of the researches upon the vocalization of neonates have been made by Irwin (1941*c*, 1946), Irwin and Curry (1941), and Irwin and Chen (1943). The most exhaustive studies of the development of vocalization during the early postnatal months have been made by Irwin and his students. Irwin and Curry (1941) ascertained that a behavior unit sample of the sound elements produced during 25 respirations was a more reliable sampling than that obtainable in a time sample. Recording the sounds in the International Phonetic Alphabet, they discovered that during the first 10 days front vowels predominate, with scarcely any middle, and no back, vowels. The crying included the following vowels: æ, ʌ, ɛ, ɪ, *u*. Consonant sounds were infrequent, the most common being an *h* with occasionally a *w* or a *k*. Chen and Irwin (1946*a*) found the mean number of vowels to be 4.5, and the mean number of consonants 2.7, during the first 2 postnatal months. Irwin and Chen (1946*b*) reported that at 1 month the infant produces 7.5 sounds as compared with the 35 sound elements used in adult English speech. In point of frequency vowel sounds occur about five times as often as consonant sounds, according to Irwin and Chen (1946*a*). Irwin's (1947*b*) analysis of consonant sounds according to place of articulation discloses that about 98 per cent are velars and glottals, the most frequently used consonants being: *k*, *g*, *h*, and ?. The sounds themselves he found (1947*c*) were plosives and fricatives.

The problems of the graphic representation of speech sounds have been explored by Irwin (1941*b*), and the various indices employed in the analysis of infant speech sounds have been evaluated by Chen and Irwin (1946*b*, 1946*c*) and by Irwin (1947*a*). The reliabilities of the data for frequency of speech elements and their patterning have been determined by Irwin and Chen (1941) and by Irwin (1945).

Even during the first 2 months there are, according to Brodbeck and Irwin (1946), statistically reliable differences between the vocalizations of orphanage and nonorphanage children.

Irwin's experimental findings of the course of vowel and consonant development in infants have been interpreted by McCarthy (1949) as illustrations of the "law of developmental direction." Thus she holds that the sequence from the front to back vowels exemplifies the anterior-posterior gradient. The trend of consonantal development from the sounds produced in the back of the oral cavity to those made with lips, tongue-tip, etc., is an instance of proximodistal development.

Lynip (1951) has pioneered in the use of the magnetic recorder and the Sound Spectrograph to pursue the development of vocalization in the child. By these means

the subjective appraisal of sounds which is involved in phonetic recording by observers is avoided. The new techniques make possible accurate, quantitative samplings of the vocalization of the child within the home environment.

Facial Responses. "Mimetic" responses of the musculature of the face and head play an important rôle in the anthropomorphism of neonate behavior and in this way serve to control or elicit differential responses from adults. The basis for conditioning of facial expressions is thereby provided.

Peiper (1935*a*), who has made the most detailed study of the origin, types, and significance of facial expressions in early infancy, has divided the responses into those which facilitate further stimulation of the sense organs and those which close or withdraw them from stimulation. Many of the responses are intimately associated with breathing movements.

Spitz and Wolf (1946) have confirmed reports, by Blanton (1917) and others, of the presence of smiling in the response repertory of the neonate. But they emphasize that it is not elicited by any specific external situations and that it does not represent a social response at this stage of development.

Miscellaneous. There are many reflexes of interest to the neurologist which have not been reviewed in this chapter. Among them are the tendon reflexes and the cremasteric reflex. The galvanic skin reflex, reported present during the first year by Jones (1930) and denied by Peiper (1924*a*), has not seemed to offer sufficient data for a detailed inclusion. Veĭnger (1950) has reported upon the postnatal ontogenesis of skin galvanic reflexes to visual and auditory stimuli. For a listing of some of the more obscure responses the reader should consult Dennis (1934).

Emotions

Many have inferred, on the basis of "expressive" movements or "mimetic" responses to auditory, olfactory, gustatory, tactual, and other stimuli, that the newborn infant experiences emotions or other affective psychic states.

The gross muscular responses evoked by intense auditory stimuli have been called *fear* from the time of Sachs (1893) on, but it remained for Watson (1919) to elevate the observed pattern into a primary emotion. Other stimuli releasing these responses are those provided by removal of support and by shaking or jarring. Moro (1918) had shown that the latter arouses a characteristic clasping response, and later writers, such as Peiper (1925*a*), Irwin (1932*g*), and Pratt (1933, 1934*b*), came to the conclusion that the Moro response is elicitable by a variety of stimuli, including the auditory. Whether the fear response and the Moro, despite variations, are one and the same response occurring to any sudden stimulus, or whether some of the early responses of the neonate form another pattern, the *startle*, which is an element in adult fears, is not as yet definitely established.

Furthermore, the quick reflexive nature of the responses to auditory stimuli followed by immediate return to quiescence, demonstrated in the researches of Peiper (1924*c*) and Pratt (1934*b*), does not conform to the temporal durations implied in the prevailing definitions of emotional responses. Also, movement in the vertical plane, dropping, or quick elevation did not produce crying or long-continued activity in the infants studied by Irwin (1932*h*).

In Watson's (1919) words, the emotion of fear consists of "a sudden catching of the breath, clutching randomly with the hands (the grasping reflex invariably appearing when the child is dropped), sudden

closing of the eyelids, puckering of the lips, then crying." (This should be compared with the descriptions of the Moro and the startle responses.)

Rage is another of the emotions termed primary by Watson (1919). The pattern comprises crying, screaming, stiffening the body, slashing or striking movements of hands and arms, and holding the breath so that the infant's face becomes flushed. These responses are said to come in consequence of hampering or restricting the infant's movements. Pratt, Nelson, and Sun (1930) repeated the experiment of restraining or holding the child's arms—claimed by Watson to be a potent stimulus for rage. Not only did such a pattern of responses fail to appear, but also in most instances no effects followed, or else restraint actually served to quiet the infant. Taylor (1934), who made the most careful attempt to reproduce Watson's experiments, was unable to obtain the patterns described by Watson. Dennis (1940), however, holds that these experimenters failed to elicit rage because they did not employ as intense and prolonged stimulation as Watson. Stoffels (1940–1941) applied restraint to infants in the form of the immobilization of the head or arms but discovered no evidence of a general stiffening of the body or of the adaptive defense movements claimed by some investigators. The responses actually observed started in the immobilized parts of the body and then became generalized. There was no essential pattern which would differentiate "rage" from those responses aroused by other stimulating conditions such as "cold" or "hunger."

Greenacre (1944) believes that the term *restraint*, as applied to infant reactions, should never be left undefined. Thus restraint may involve binding or swaddling to restrict movement; it may differ in intensity; it may vary in the speed or evenness with which it is exerted; or it may differ in regard to the portions of the body which are affected.

The third primary emotion postulated by Watson (1919) is *love*. This consists of a "cessation of crying, smiling, attempts at gurgling and cooing released by stimulation of some erogenous zone, tickling, shaking, gentle rocking, patting and turning upon the stomach across the attendant's knee."

According to Watson, all other emotions appear in consequence of the conditioning of the original innate patterns to other stimuli. This theory had great vogue because of its simplicity but overlooked, as Valentine (1930) was quick to point out, the possibility that some emotional reactions might not be elicitable at birth and yet appear later on as a result of maturation rather than as a product of conditioning.

The validity of the theory suffered most from Sherman's (1927*a*) demonstration that observers, presumably acquainted with infant behavior, were unable to agree in naming emotional patterns of behavior as observed in motion pictures unless the stimuli were likewise shown.

These researches have resulted in the abandonment of the theory of differentiated emotional patterns in the neonate. Indeed they have led Irwin (1932*h*), Pratt (1933), Dennis (1934), and Taylor (1934) to abandon the term "emotion" as applying to infant behavior. In its place they advocate a purely descriptive account of the extent of organismic involvement in a response under definite conditions of stimulation, age of the organism, and so on.

Bridges (1932, 1935, 1936), as a result of observational studies, has likewise concluded that the newborn infant does not have differentiated emotional responses but instead an agitation or general excitement from which, partly through maturation and

partly through experience, different emotions become differentiated.

Stirnimann (1943, 1944*a*) and Spitz and Wolf (1946) are inclined, in terms of "expressive movements," to endow infants with emotions in the sense of psychic states. Hence crying and screaming are regarded as indicative of feelings of unpleasantness or of negative emotions. Stirnimann postulates considerable differentiation and specificity of psychic states, whereas Spitz and Wolf hold to two primal emotional attitudes: one of accepting, and the other of rejecting, a stimulus.

Marquis (1943) criticized the Watsonian statement of the exciting conditions for emotions as not descriptive of the usual environment of the newborn infant. Instead she sees frustration of goal responses as the normal cause of emotional behavior. And in our culture this comes about repeatedly as a consequence of the spaced nursing periods arbitrarily imposed upon the infant. There are, however, points which need clarification before we can accept "frustration" as the source of emotional behavior in the neonate. First there should be a clear-cut and limiting definition of emotion in terms of the actual behavior of the infant rather than in terms of stimulus situations. Thus, are crying and generalized activity to be termed emotional behavior? And, if so, do they occur only in situations involving the frustration of goal responses? For example, what goal response is frustrated in the wet-diaper situation? In terms of Irwin's (1932*f*) correlation of activity with lapse of time from a nursing period it is also pertinent to inquire at what point in the cycle the "frustration" begins. What amount of general activity or what specific pattern of responses must emerge before the infant may be said to have an emotion or to manifest emotional behavior?

In general, students of early infantile behavior are inclined to the view that emotional behavior is represented by generalized rather than specific responses and that upon the acquisition of the specific responses depends the adequacy of the adjustment to the stimulating situation. This is in marked contrast with the position of certain educators who hold that one of the objectives of education is to develop the emotions.

Sleep

Criteria of Sleep and Depth of Sleep. The criteria of sleep in newborn infants are neither well defined nor universally accepted. The oldest and most widely employed, though perhaps naïve, is closure of the eyes. Supporting it is the criterion of decreased irritability and activity. Study of both adults and infants shows that neither is lacking during sleep.

The term *sleep* is usually defined by psychologists in terms of continuous gradations of irritability or of motility rather than in terms of the *either-or* of the two categories, *asleep* and *awake*.

Using this scientific criterion of sleep, Czerny (1892) differentiated gradations of sleep in terms of the strength of electrical stimuli necessary to awaken the infant. Depth of sleep, so expressed, is variable from infant to infant according to the antecedent condition or activities of the child.

Richter (1930) reported that palmar skin resistance increases with the depth of sleep in the neonate. Wenger and Irwin (1935, 1936) suggest that such resistance is basically correlated with muscular relaxation.

The most elaborate attempt to redefine sleep in terms of the degree of motility and of irritability of the newborn infant has been made by Wagner (1937). For her, sleep is a relative term, not antagonistic to the waking state but applying to different

degrees of reactivity which express degrees or depths of sleep. Thus:

> Now if an infant merely flexes its toes in response to one stimulus and moves its entire body in response to another, should we say it is equally asleep to both stimuli? It seems logical to consider it less deeply asleep to the stimulus to which it makes the greatest response. Taking an infant in any condition whatsoever, then, we can apply various stimuli and observe the responses made, judging the infant as being less deeply asleep to those stimuli to which it responds more.

Relating degree of reactivity (as expressed by extent and duration of responses to pain, tactual, olfactory, and auditory stimuli) to motility patterns, Wagner has set up seven stages of sleep ranging from the most profound, in which the infant is generally quiet, breathing is regular, and there are no eyelid or mouth movements to the shallowest, in which the infant is generally active, with eyes open and with mouth movement. According to her report the extent and duration of responses to the experimental stimuli increase as sleep becomes shallower.

Irwin's (1932*f*) measurement of motility from one nursing period to another shows, however, that Wagner's motility pattern of least depth of sleep actually is found in the period of least motility, but increased motility is demonstrated in periods manifesting some of Wagner's motility pattern of deeper sleep.

Temporal Incidence of Sleep and Location of Greatest Depth. Canestrini (1913), employing the technique developed by Czerny, placed the greatest depth of sleep at 45 to 60 minutes after falling asleep. In infants 2 months or older Marquis (1933) reported greatest depth (in terms of least temporal periods of activity) of sleep during the first half hour in daytime naps, and during the second hour in nighttime naps. Irwin's (1930, 1932*f*) studies show that activity is least after nursing, increasing as the next nursing period approaches. Greatest incidence of sleep (eyes closed) occurs about midway between the nursing periods.

The limited time samplings (90 minutes on the average) of Wagner (1937, 1939) and of Reynard and Dockeray (1939) provide an insufficient basis for determining the time of incidence of greatest depth of sleep in either diurnal periods or from one nursing period to another. Irwin (1930) in his 24-hour studies of activity has found greatest motility from 5 to 6 A.M. and least about noon. Similarly, in the measurement of motility between nursing periods least motility is shown immediately after nursing, with increasing activity up to the next nursing period, but Wagner's (1937) seven motility patterns do not agree with the observations made by Irwin. If the fundamental physiological state is most accurately described by actual measurement of general motility, then the duration and disposition of control periods in the researches of Pratt, Nelson, and Sun (1930) and of Pratt (1934*b*, 1934*c*) have greater validity than the alleged motility patterns which do not appear to be very well correlated with motility.

Amount of Sleep and Its Periodicity. Among the earlier writers, according to Peiper (1928), it was estimated that the neonate sleeps 20 hours of a day, but that the duration of each period of sleep is no more than 3 hours and is usually less. Pratt, Nelson, and Sun's (1930) records of control periods confirm these earlier estimates.

Wagner (1939) studied the sleep of newborn infants between 2 and 3:30 P.M., and in terms of her own criteria of sleep affirmed that infants are awake 40.3 per cent and sound asleep 12.7 per cent of the time. On the basis of 90 minutes of continuous observation in each 24 hours and with no

time samplings at any other part of the day, the author concludes that "Such findings contradict the layman's casual assumption that the newborn infant spends most of its time sleeping."

Age and Sleep. Czerny (1892) found that at later age periods, as contrasted with the neonatal, weaker electrical stimulation awakened the child. According to some writers, as the child grows older the total hours of sleep decrease but the length of sleep periods increases.

Reactivity during Sleep. It is generally believed that during sleep irritability is decreased, reaction times are lengthened, certain responses may not be evoked, and others may be altered. According to Wagner (1937), responses decrease in extent and duration as the depth of sleep increases. Despite the lessened irritability just mentioned, it should be noted that most investigations have taken place under the condition of sleep as expressed by the simplest criterion. In other words, quiescent infants have been selected so that the effects of experimental stimuli would not be masked by activity aroused by internal stimuli.

The postural responses during sleep have evoked considerable interest. Peiper (1928) found a rather well-defined sleep or resting posture in the arms, hands, and legs of the suckling. The legs were flexed upon the body, the fists clenched, and the arms extended so that in the most extreme form the upper arms were at right angles to the body and the forearms parallel to the head. Marquis (1933) reported that during the first year the dorsal posture of the body with the head turned to the right was most frequent among body and head postures. There was likewise bilateral, symmetrical flexion at the elbows. Irwin (1930) also gave a description of postures in the neonate which resemble those found at slightly older age periods. This picture, in all major essentials, was confirmed by Wagner (1938*c*). She emphasized that there were many variations of the pattern and that other postures are to be observed.

Canestrini (1913) found it difficult to distinguish waking from sleeping states in terms of curves of respiration and circulation. In his opinion respiratory intervals are longer in sleep and the brain pulsations are decreased.

The effect of sleep on specific responses are discussed in sections dealing with such responses and in those relating sensitivity to different stimulus modes.

Summary. The criteria of sleep, stated in terms of motility, postural or other response patterns, are unsatisfactory so far as the accurate and consistent expression of the physiological state of the organism is concerned. This state is best revealed by the minimal intensity of a given stimulus, typically electrical, necessary to elicit a particular response, and by the amount of measurable motility. The degree of reactivity and the level of motility will define the state of the infant but will not, of course, describe the effects of particular postures or of immediately preceding stimulation upon the responses to experimental stimuli.

In general, reactivity is less during sleep. Some responses are diminished or may not be evoked; others are viewed most easily against a background of lowered general motility. The newborn infant spends the greater part of the day in sleep, in the commonly accepted sense of the term. The child is not, however, immobile most of the time.

Learning

General observations of the neonate in the feeding situation disclose changes in behavior suggestive of learning during the course of the first month. Illustrative of these are the adjustments cited by Feld-

man (1920), whereby the infant, after a night feeding has been eliminated from his routine, begins to sleep during most of the night. Denisova and Figurin (1929), Ripin and Hetzer (1930), and Marquis (1941) have all reported evidence of early learning in relation to the feeding situation.

The first investigations of the Russian school of physiologists seemed to indicate that conditioned reflexes could not be established before the fifth month. The later research by Denisova and Figurin (1929) revealed that natural CR's of food-seeking movements to originally inadequate stimuli appeared in 23 to 27 days. Experimental CR's, however, were not established until the second month. Then auditory CR's began to appear, but visual CR's followed later in the second month.

Marquis (1931) reported the establishment of conditioned sucking and other responses to auditory stimuli by the fourth to fifth day. The auditory stimuli were produced by a buzzer and had a duration of 5 seconds before insertion of the nipple of the nursing bottle in the infant's mouth and the same duration after the insertion. The infant's responses were recorded by an observer, and the chin movements were registered upon the polygraph tape by means of a pneumatic system under the infant's chin. Conditioning to auditory stimuli in 7 out of 8 of the experimental group was said to be demonstrated by increase in mouth opening and by a decrease in general activity and crying, as contrasted with the nonappearance of such responses in a control group of 4 infants regularly stimulated by the buzzer at feeding times but not with access to the bottle immediately afterward. Near the end of the period of investigation the experimental group was subjected to auditory stimuli produced by a fall hammer striking a tin can, but general activity was not decreased nor was mouth opening elicited. Pratt (1933) has pointed out that this procedure is invalid because, without any conditioning at all, the neonate responds in a different fashion to stimuli of very short duration from those of longer duration—the latter acting to cause decreased activity. This criticism is reinforced by the results of researches reported by Weiss (1934) and Stubbs (1934).

Marinesco and Kreindler (1933), employing electric shock as the unconditioned stimulus and visual and auditory as the conditioning stimuli, did not establish any CR's during the neonatal period.

Kasatkin (1935) and Kasatkin and Levikova (1935*a*, 1935*b*) did not succeed in conditioning sucking or feeding responses to auditory or to visual stimuli in newborn infants. When CR's did appear at a later time the auditory preceded the visual.

Probably, in point of techniques and scope, Wenger's (1936) study of conditioning in the first half of the neonatal period is the most important investigation so far attempted. In some of the experiments, however, the number of infants was very small. Stimuli in the various experiments were well controlled, and responses were recorded by observers and registered by photography or by the polygraph. In one of the experiments eyelid closure conditioned to tactual vibratory stimuli applied to the plantar surface of the foot appeared on the fifth postnatal day, on 3 of which experimentation involving 124 paired stimulations was carried on. In another set of experiments the unconditioned stimuli were electric shocks, applied through an electrode at the plantar surface of the left big toe. This type of stimulus evoked a withdrawal movement described as a flexor twitch of the toes accompanied sometimes by other responses. When tactual vibratory stimuli were used, there was no unequivocal evidence of conditioning in the infant studied. Three out of 5 infants gave clear indication of the conditioning of the

flexor twitch and respiratory gasp in response to a pure tone stimulus. Withdrawal responses conditioned to visual stimuli appeared on the sixth postnatal day after 120 paired stimulations had been given. In a third type of experiment regularly intermittent auditory stimulation (buzzer) during feeding gave no evidence of conditioning during 8 weeks of stimulation. Wenger (1936) concluded that conditioning of certain types is possible in some newborn infants but that it is highly unstable.

The Wickenses (1940) applied an electric shock to the sole of the foot as the unconditioned stimulus releasing withdrawal movements, and a buzzer as the conditioning stimulus. Their experimental group of 12 infants received 12 paired stimulations a day for 3 consecutive days, and a control group of 12 infants received 12 shocks alone per day for 3 consecutive days. Both groups manifested the usual evidence of conditioning, but a second control group tested on the first day by the buzzer and again on the third day showed no response.

Kasatkin (1948) is reported to have undertaken conditioned-reflex experiments throughout the following developmental range: fetus, baby, and young child.

From this review of the experimental literature it would appear that the conditioning of newborn infants is difficult and, in fact, that it is not possible to establish such responses in all newborn infants. Spelt (1948), however, has reported that CR's are easily set up in the fetus *in utero* during the last 2 months of prenatal life. Employing a vibrotactile conditioned stimulus and a loud noise as the unconditioned stimulus, CR's appeared after 15–20 paired stimulations. In Wenger's (1936) investigation of neonates, 120 or more paired stimulations were required for the establishment of a conditioned response. There exists, therefore, an unresolved discrepancy between the findings of researches upon the conditioning of newborn infants and those upon the fetus before birth.

Summary. There is some evidence that certain responses may be conditioned to experimental stimuli during the neonatal period. The responses are difficult to establish, highly unstable, and cannot be set up in all infants.

Intelligence

Whether or not one may speak of the intelligence of the neonate depends upon the definition which is adopted. If intelligence is simply the capacity to learn it should be apparent from the researches reviewed in the preceding section on learning that some newborn infants possess this ability. Their learning, however, is confined to simple conditioned responses and is highly temporary. It is possible, as Ray (1932) and Spelt (1938, 1948) claim, that this capacity may be present before birth. Research upon the ability of the viable premature infant to acquire conditioned responses would throw light upon the amount of maturation of its nervous system as compared with that of the full-term infant.

Thurstone (1928), in terms of the mental-growth curves of older children, has calculated that the zero point of intelligence is at birth, or possibly in the fetal period.

If intelligence, however, is to be thought of as a general factor running through all the infant's activities, or as requiring symbolic processes, it is clear that the neonate is devoid of any such manifestations. Thus the correlational procedures of Furfey, Bonham, and Sargent (1930) offer no evidence of a *g* factor in newborn infants.

The usual approach to the problem of intelligence in young infants is to attempt to predict future "mental" growth in terms

of norms of motor development. It is assumed that early retardation of motor responses will be followed later by retardation in test performance, and that precocious motor development will be followed by precocious performance on tests. For the period of the neonate Shotwell and Gilliland (1943) have set up a scale of 15 items which are supposed to typify the average child of 4 weeks. Examination of the items of the scale in relation to the data presented in this chapter demonstrates that most of the responses are actually elicitable during the first 10 days after birth and some, such as the palpebral reflexes, are already present in the younger premature infants. Nevertheless, Drummond and Gilliland (1946) claim that in terms of the scale infants show progress from week to week, and that the scale performances of feeble-minded children resemble those of infants from 4 to 12 weeks old.

Gilliland (1948) maintains that the final revision of the Northwestern Infant Intelligence Test employs items which measure an adaptation to the specific environmental situations rather than simple physical development or maturation. IQ's are obtained by assigning 3 points of credit for each point of deviation from the norm for any given age, the norm being evaluated as 100 IQ. The reliabilities furnished are derived from correlation of odd and even item performances. Too few cases have been tested subsequently with the Stanford-Binet to furnish other evidence of reliability. Brunet's (1948) developmental scale of baby tests, drawn from the studies of Bühler and of Gesell, contains some items placed at 1 month which, in actuality, are present, in varying degrees, from birth on.

Irwin (1942) has proposed four criteria or conditions which must be met if an organism is to have intelligent behavior: (1) a functional cerebral cortex; (2) functional distance receptors; (3) an upright posture; and (4) the achievement of substitutive or symbolical behavior. Irwin concluded that the neonate does not meet these conditions. It simply possesses a repertory of motor responses, whereas intelligent behavior must await further maturation.

Even though intelligent behavior is absent in the neonate, it should be possible to determine whether precociousness or retardation of motor responses at this stage is correlated with precociousness or retardation at later stages, either in motor responses or in terms of the scores of intelligence tests. Measurements of physical traits may even be predictive of later motor responses. Thus Norval (1947) has shown that for two newborn babies of the same weight a difference of 1 inch in length means that on the average the longer child will walk 22 days earlier than the shorter child.

Individual, Sex, and Race Differences

The studies of newborn infants which have been productive of quantitative data have for the most part been concerned with the characteristics and the comparisons of *groups*. The aim has been to seek expressions of central tendency and of variability rather than to explore the patterns of *individual* attainments in terms of the measurements secured.

Campbell and Weech (1941), in investigations of those responses of the neonate which were thought to be the forerunners of erect locomotion and of creeping, did not discover any marked differentiation of individuals within the group. The researches of Balint (1948*a*, 1948*b*) upon the sucking response were clearly oriented with respect to the disclosure of individual differences in newborn infants. Instead of collecting mass data, wherein the identity

of the individual would be lost, he took pains to measure each individual repeatedly throughout the nursing period in order to compare its performance at one time with its performance at another time. In this way he learned that there is considerable consistency or constancy in the rhythm of sucking of a given infant but that the rhythm varies with different infants. The sucking behavior of neonates therefore manifests individual differences. These may be classified or grouped, however, into what is considered "normal" or into what is typical of infants having various disorders. Those suffering from respiratory or intestinal disturbances have higher-frequency rhythms and greater irregularity of sucking than "normal" infants.

Sex. In the "genital crisis," and under other physiological conditions of the newborn infant, reactions characteristic of each sex are observed, although differentiation of these phenomena is not complete because both sexes exhibit mammary secretion. Aside from the studies relating to the genital organs there are few dealing with sex differences in the behavior of neonates.

In terms of bodily and segmental movements reported in observational protocols, Gatewood and Weiss (1930) found that males were less active and had less vocalization than females. Pratt's (1932) comparisons of the activity of these same subjects in terms of percentage of time active, according to the stabilimeter-polygraph records, revealed that males were unreliably less active than females. Halverson (1941) states that "in *Profound Sleep* the boys had a significantly lower pulse rate and a correspondingly lower breathing rate than had girls."

Smith (1936), on the other hand, has found more activity and crying in males. She holds that the brightness values of hues, as determined by their effect upon activity, for males are similar to those of color-blind adults, whereas for females they are similar to those of partially color-blind adults. The sex differences with respect to auditory stimulation discovered by Stubbs (1934) were statistically unreliable.

Feldman (1921) and Richards and Irwin (1934*c*) have reported conflicting results regarding sex differences in the incidence and nature of toe movements in the plantar response. The differences found are apparently not statistically significant.

Race. Gatewood and Weiss (1930), in their tabulation of observed responses, came to the conclusion that Negro infants are less active than white infants. In terms of percentage of time the infants were active, Pratt (1932) found no significant race differences among these subjects. Bryan (1930) asserted that the Babinski is delayed longer in making its appearance in Negro than in white infants. Beasley (1933*a*) found a higher percentage of superior visual pursuit movements in Negroes on the first day and reported that these movements improved more rapidly than in the whites.

In summary, there is little unequivocal evidence of sex and race differences in newborn infants.

The Nature of the Neonate Organism

The Neonate as a Man in Miniature. The layman and the literary writer alike regard the newborn infant as a kind of man in miniature or a tabloid version of the adult. It is conceded that the infant is rather helpless, that it cannot talk, get about, or appreciably manipulate its surroundings. Its behavior, however, is anthropomorphized to the emotional, perceptional, and ideational levels of the adult.

The literary man is prone to fix upon quite common items of neonate behavior as symbolically betokening distinguishing

idiosyncrasies in later life. Or, waxing poetic in a pessimistic way, the birth cry becomes a wail of anguish at being expelled from the paradise of prenatal life into the terrors of postnatal existence. And, if the poetic philosopher be both disillusioned and sentimental, he may describe all goodness, virtue, and insight as indwelling in the innocence of the babe.

The literary man and the layman err in anthropomorphisms which recognize only a difference in size between the newborn infant and the adult. Their conception of the nature of the neonate is only a popular counterpart of the discarded speculations concerning the homunculus.

The psychoanalytic interpretation of the child is essentially an elaboration of the ideas that have just been described. The typical psychoanalyst evokes the associations of the psychoneurotic patient and attempts, through these, to locate the origin and nature of the traumatic experience. Usually the pursuit carries the practitioner back into the childhood of his patient and leads, almost inevitably, to an evaluation of infancy as mirrored in the psychoneurotic's accounts of his dreams and other experiences. This approach to the nature of the child through study of the adult bears a marked resemblance to G. Stanley Hall's questionnaires upon the earliest memories of adults.

Originally this quest into the ontogenetic past had its terminus in the preschool period (at the age of 2–3 years). When this did not suffice to resolve the difficulties of certain patients the psychoanalytic procedures were continued until the conclusion was reached that the truly original traumatic experience was birth itself. This conception has been imputed to Freud by Rank (1929) and many other psychoanalysts, even though there is evidence that Freud regarded it with considerable skepticism.

For Rank (1929), however, this hypothesis is the key to an understanding of the behavior of both the child and the adult. Before birth the child manifests a "mother libido." Hence birth, which separates the child from the libido object, generates a psychic trauma—the primal or original anxiety state. From this shock ensue these consequences: The childhood of individuals is their *normal* neurosis, which becomes *abnormal* if it continues into adult life; claustrophobia and the fear of the child at being left alone in the dark are produced because the individual is reminded of its separation from the womb of the mother; the fear of large animals arises because the child remembers the state of pregnancy; and fear of beasts of prey comes because of the child's desire to be eaten and hence symbolically return to the mother's womb. In short, infantile anxities or fears are simply a product of the original birth anxiety.

From all of this it follows, for Rank, that "every pleasure has as its final aim the re-establishment of the intrauterine primal pleasure." Thus the finger sucking of the neonate, for example, represents a substitute for the mother.

The ultimate goal of the psychoanalytic search, according to Rank (1929), is not even the catastrophic event of birth but rather some point in the uterine stage of development. This, in fact, is the position taken by Sadger (1941). According to this psychoanalyst the embryo experiences pleasure *and* pain. These are demonstrated by its "impulsive" movements and by sucking responses before birth. That is, such responses are expressive of "sexual sensations of pleasure" and hence of "mental states" in the embryo. He concedes that the higher psychic functions of "thinking" and "willing" may be absent or present only to a limited extent, but he is positive that "feeling" is hypertrophic. In the con-

tinuing life of the individual these mental states are "remembered" as unconscious memories.

During the course of his analyses Sadger (1941) discovered that the source of some psychoneuroses could not be located in the embryonic period. Some of his patients traced their memories to their origins as spermatozoa and ova or even beyond to the preconceptual attitudes of their parents—naturally as sensed by the original germ cells while still within the environment of the parental organism! To Sadger the verbal outpourings of his patients were proof that the germ cells, themselves, are endowed with psychic life and possess the capacity to learn and to remember. As previously noted in the section on birth trauma this is strikingly similar to the fanciful picture drawn by Sterne of the homunculus which was fated to be Tristram Shandy.

According to standard psychoanalytic doctrine the neonate is in an oral-erotic phase of development. Anal and sex-organ eroticism emerge later.

In summary, then, the psychoanalyst considers the young infant to have some of the psychic characteristics of adults. For him childhood and adult life constitute one long series of attempts to resolve the trauma of birth or the shocks or uncertainties of conception. Thus Sadger (1941) differentiates between the origins of guilt or of passive pleasure of the castration type in terms of the circumstances attendant upon the loss of the caudal filament of the spermatozoon when it penetrates the ovum.

The psychoanalytic thesis that nonnutritional sucking is evidence of an initial libidinal oral drive is challenged by the view that such sucking is secondary to, and derived from, the basic "hunger" drive. This is the position of Sears (1948), Davis *et al.* (1948), and Brodbeck (1950). Their investigations do not reveal nonnutritional sucking to be increased when infants are deprived of opportunities to nurse. Breast-fed and cup-fed babies manifest no difference in the amount of such sucking. In fact, when breast-fed infants are shifted to cup feeding there are significant decreases in nonnutritive sucking. Further, the strength or duration of sucking actually increases in infants that are breast fed.

Although their anthropomorphisms are less extreme, the members of the neoprimitivistic school of child care or development, such as Ribble (1944), Aldrich (1945), Trainham, Pilafian, and Kraft (1945), Frank, (1945), and Trainham and Montgomery (1946), are in agreement with the psychoanalysts that the young organism is very susceptible to emotional shock or trauma. Hence they hail the mother–newborn-infant relationship among so-called primitives as ideal because the child is nursed whenever it cries rather than at definite and fixed times. As neoprimitivists they hold that the mother should be able to differentiate the causes of crying and to nurse the infant when its cries indicate hunger. In the light of Sherman's (1927*b*) investigation of judgments upon the crying of newborn infants the validity of this hypothesis seems somewhat dubious.

Neoprimitivists subscribe to the doctrine of "felt needs" as the cues for care or training, and oppose any early attempts at cultural patterning with the slogan, "Baby knows best." Immediate and constant gratification of an infant's "needs," as interpreted from its cries, will not fixate crying as the pattern of the "spoiled baby" —the response will wither away of its own accord as the child matures. They relate that a child fed on the self-demand schedule eventually reduces its feedings to the number customarily found in the culture. They neglect to state how the age or time of weaning are to be determined by the "felt

needs" of the infant, and some do not adhere to their own expressed principles when they wake an infant in order to get it to feed!

Although the majority of pediatricians now appear, in theory, to adhere to the principle of self-demand feeding, it is, nevertheless, apparent that certain qualifications or reservations are being entertained. These are illustrated in the more temperate recommendations of Glaser (1948), Rowan-Legg (1949), and Weinfeld (1950). And beyond these there are portents of a reaction against the more doctrinaire aspects of the movement.

Orlansky's (1949) able evaluation of the neoprimitivists' theories of infant personality formation discloses their propensity to a maximum of speculation but a minimum of objectively verifiable data. It is indeed clear, as Vincent (1951) has observed, that trends in infant care ideas have a fadlike character and are not well grounded upon an impeccable body of empirical data. The views of the most publicized exponent of the doctrine of "mothering," Ribble, do not stand up factually when subjected to the critical analysis of Pinneau (1950), nor are they supported by Wolfle's (1949) observation that the young infant's means of *escape* from the caress are at first rather ineffectual.

Peiper (1941, 1942–1943, 1949) has judged as inadequate and mistaken those views which hold the infant to be a man in miniature. He has noted that in animal psychology we have learned not to ascribe human characteristics to animals but that in child psychology we are still interpreting infant behavior in terms of the experiences of adults. In the one we demand systematic, objective methods; in the other we are often content to accept the most uncritical anthropomorphisms or, as Spitz and Wolf (1946) phrase it, adultomorphisms.

Interpretations of the psychic life of the infant therefore run the gamut from the naïveté of the complete man in miniature to a more sophisticated appraisal based upon a knowledge of those sensory-motor systems which are functioning. Thus Minkowski (1947) ascribes a primitive psyche to the fetus. At first its responses are to humoral-visceral stimuli and imply a vegetative soul in the sense of Aristotle. Later it has elementary feelings of existence as conditioned by position and movement, and a dull memory of a life in water, warmth, and darkness.

The Neonate as a Recapitulation. The extension by G. Stanley Hall of the doctrine of biological recapitulation in the form of a cultural recapitulation, manifesting itself in childhood, is no longer acceptable to psychologists even though occasionally entertained by the layman.

As we have seen, Buchman (1895, 1900) and Mumford (1897) have cited the neonatal grasping reflex, and Moro (1918) the clasping or embrace reflex, as evidence that man's ancestors led an arboreal existence McGraw (1939) considers the behavior of the newborn infant to consist in part of atavistic reflexes.

Davidson (1914), in a critical review of the doctrine, has shown that the notion of a precise or complete biological recapitulation of the phylogenetic past is not supported by the data of embryology. This is in no sense a denial that vertebrate animals resemble each other more in early than in later developmental periods.

The Neonate as an Organism Developing Autonomy. From the time of implantation of the fertilized ovum in the uterus until birth the organism leads a parasitic type of existence. At birth the infant achieves autonomy of respiration, digestion, excretion, and the maintenance of body temperature. These are all vital activities

which the child must undertake if it is to live.

In the postnatal environment it has greater freedom of movement and the opportunity, by virtue of orienting responses, to react with some selectivity to aspects of a more complicated universe. It responds to some stimuli by movements which prolong stimulation, to others by withdrawal or rejection, and to some it at first responds and thereafter inhibits further motility.

The neonate cannot effectively manipulate its physical environment to provide food, care, and requisite protection. It is possessed of the ability to act upon its social environment by crying and by mimetic responses so that adults minister to its needs. In this manner the environment is effectively manipulated by proxy until the development of voluntary movements, particularly successful reaching to visually perceived objects and directed forms of locomotion, provides still further autonomy of action.

The Neonate as a System of Reflexes. Some neurologists have viewed the behavior of the newborn infant as that of a purely spinal being. Cruchet (1911, 1930), who represents this point of view, states that Virchow was the first to liken the reactions of the newborn infant to those of the decerebrate frog. De Crinis (1932), also, believes that the neonate is a reflex being of a lower type because the cerebral cortex is not functional. Peiper (1925*a*) holds that a part of the optic thalamus is functional at birth, and that athetoid movements are due to lack of inhibition from the corpus striatum. Langworthy (1933) maintains that "the behavior of the newborn is essentially that of a brain-stem preparation although medullation may extend as high as the upper end of the midbrain." Diffusiveness and lack of coordination of movements are interpreted as due to a lack of cerebral inhibition. Minkowski (1932–1933) views the newborn infant as a cortical and subcortical spinal being, with emphasis upon the subcortical spinal. Marquis (1931) advanced the idea that conditioning occurs at subcortical levels. The ability of the infant to inhibit responses to successive auditory stimuli is proof, according to Peiper (1930), that it is not a purely "spinal being." Kroh (1926) concurs in this judgment because of persistence of a set or disposition for the few hours elapsing from one feeding period to another.

According to the concensus of present-day theories the neural status of the neonate is essentially, if not entirely, that of a noncortical being. McGraw (1943) has related the observed behavior of the neonate to the data presented in Conel's (1939, 1941) histological studies and has concluded that no cortical influence is operating at this time. Following the neonatal period there is a transitional stage characterized by the onset of cortical function. Then comes the final stage of complete cortical dominance. McGraw (1941*b*) claims that the first evidence of cortical function is provided by the child's localization of a stimulated area; according to her this is not in the repertory of the newborn infant. Nevertheless, the researches of the Shermans (1925), the Shermans and Flory (1936), Peiper (1936*a*) and Crudden (1937) all seem to indicate the beginnings of cutaneous localization in the neonate. It is also demonstrated in the mouth-orientation response.

In an important paper on the neurological bases of mental development Peiper (1941) has characterized the newborn infant as a midbrain being because its behavior is essentially the same as that found in infants without cerebrums. It is not, however, the behavior of a purely reflex being. The attempts by extreme environ-

mentalists to account for neonate behavior in terms of prenatally established conditioned responses have been severely criticized by Dennis (1943). He has pointed out that acephalies have the same behavioral equipment as normal newborn infants but that even when they live for some time after birth they make no further progress.

The theory of simple, discrete reflexes as the primary origin of behavior, with the complex responses to be derived from environmental integration of separate, part activities to form coordinated wholes, was championed by Watson (1919). The only exceptions to this process were those patterns of responses termed "primary emotions." This conception of the nature of the neonate organism seems not to be supported by the studies of Bersot (1920, 1921), Minkowski (1928, 1932–1933), Pratt, Nelson, and Sun (1930), Coghill (1930*a*, 1930*b*, 1933), Irwin (1932*a*, 1932*b*, 1932*c*), Pratt (1934*a*), and Delman (1935).

Carmichael and his collaborators, Lehner (1937) and Smith (1939), have demonstrated that the generalization or specificity of a response depends in a given age period of the guinea pig upon the intensity of the stimuli. Coghill (1940), in a summary of basic studies upon the origin and nature of early movements in birds and mammals, states that Carmichael and Smith (1939) did not undertake their experiments during the period of earliest movements.

Without denying a relation between organismic involvement in a response and the intensity of the stimulus, it is still possible to affirm a genetic sequence from generalization to specificity, particularly in view of the fact that there is no good reason to believe that the various researches upon the developing child have been ranged in decreasing order of intensity of the stimuli.

The Neonate as a Developing Organism. In contrast with the view which regards the behavior of the newborn infant as completely describable in terms of simple, discrete reflexes, there is an organismic approach which attempts to describe and to pursue behavioral development ontogenetically. The neonate is considered to be a generalized organism because few of its responses are called forth by just one type of stimuli, few are limited to stimulation of just one sense organ or receptor area, and the responses are not sharply localized in a limited number of effector segments. In its most extreme form the organismic view would appear to neglect the observation of the varying participation of the parts of the neonate and to be content with affirmation that the organism was or was not responding.

From the stage of greatest generalization during the late fetal and the neonatal period, the infant for the most part develops in the direction of increasing specificity of response: stimuli, unless conditioning occurs to effect a generalization, become more "adequate"; the reflexogenous zones for a given response shrink; and there is progressively less involvement of the organism in the response.

Development or maturation does not take place at the same rate in all parts of an organism. Axial trends in the development of behavior are discernible.

Pratt (1937), in analyzing the behavior of the neonate from the stimulus-receptor angle, has shown that many responses such as the circulatory, respiratory, Moro, plantar, and palpebral are released by several types of stimuli acting upon different sense organs. Stimuli which are originally effective for some sense organ may become temporarily or more permanently ineffective; others, because of conditioning, become effective. Learning, as Pratt (1934*a*) has indicated, may produce a generalization

of responses to stimuli which were originally inadequate. Initial generalization of the conditioning stimulus before it becomes specifically restricted in releasing the response was demonstrated in Pavlov's (1928) classic experiments.

Bersot (1920, 1921) and Minkowski (1928) have noted the extremes in extent of reflexogenous zones of various responses during the fetal and neonatal stages of development, and have followed their subsequent restriction, especially in the case of the plantar response. Similarly, Galant (1930) has pointed out the extent of the reflexogenous zone of the spinal reflexes. Reduction of the reflexogenous zone of the sucking response during the first ten days was observed by Pratt, Nelson, and Sun (1930). Stirnimann (1937*a*) has determined differences in reactivity of the facial areas from which the mouth orientation response may be elicited. Pratt (1934*d*, 1934*e*, 1934*f*) has explored several areas within the reflexogenous zone of the plantar response to determine differences in sensitivity and specificity. Although certain of the reflexogenous zones appear to shrink as time goes on, they do not, according to Bersot (1920, 1921), completely disappear. If the intensity of the stimulus is increased, the responses may continue to be elicited from beyond the standard clinical areas.

The behavior of the newborn infant has frequently been described as random, uncoordinated, or diffuse. This impression has arisen because, even without external stimulation, not only is the infant active much of the time but that activity seems to involve most of the body. This general motility has been described and commented upon by Irwin (1930), Schachter (1932*b*), and many others. It is usually assumed that the basic cause of this play of activity is a lack of inhibition from the cerebrum. The principal exciting cause is probably organic and appears to be in some way related to events occurring in the alimentary tract. Gesell (1941) rejected the term "random" as applied to such movements. The infant reacts as it does because of its neuromotor apparatus. Seen in sequence its responses do have "form," possibly describable by the term "vermicular."

The earliest movements of neurogenic origin in the animals studied by Coghill (1929*a*, 1929*b*, 1930*b*) are not simple reflexes but rather movements which initially start with the head and trunk and which apparently involve the grosser musculature. This is followed by differentiation, so that movement of smaller segments, such as the extremities, occurs within the larger total pattern. When individuation is complete, specific responses may appear in relative localization when the total pattern is inhibited.

According to Minkowski's (1928, 1932–1933) analysis of fetal development, stimulation of a given area does not at first result in an active and extensive involvement of the organism. As maturation of the nervous system proceeds, crossed, long, and diagonal reflexes appear. Maximum generalization of response, in the sense of active participation of behavior segments, is then attained.

Irwin and Weiss (1930) set up the descriptive categories of "specific movements" and "mass activity" for neonate behavior. The former are those which are somewhat localized and which occur at a rate slow enough to be noted and recorded by an observer; the latter applies to activity which involves the whole organism at a rate too rapid for analysis. They state that either external or internal stimuli may release such mass activity and that the distinction between such activity and specific movements is quite arbitrary. Following this, Irwin (1932*c*) has considered "mass behavior" the matrix from which specific responses are later individuated.

Dennis (1932*b*) and Pratt (1934*a*) have held that "mass activity" is the result of stimuli operating upon an organism at a time when the development of the nervous system has brought about the functional connection of almost all receptors with almost all effectors, and that, antedating this phase, as indicated by the work of Bersot (1920, 1921) and Minkowski (1928), some of those responses exist in relative isolation and hence should not be considered as individuating from "mass behavior" as the matrix. Irwin (1933*a*), in reply to Dennis, advances the idea that there is a succession of "mass" patterns, with individuation proceeding from each one.

Carmichael (1934) and Coghill (1940) have also been critical of the concept of "mass behavior," Coghill holding that the term is inappropriate because of its implication of lack of differentiation and lack of organization, whereas organization is implied in the term "total pattern."

Bridgman and Carmichael (1935) and Carmichael and his collaborators, Lehner (1937) and Smith (1939), as a result of researches upon the fetal guinea pig, have come to the conclusion that some of the earliest neurogenic responses of the organism are reflex in nature. For this reason they are inclined to question both the concept of an initial total pattern from which reflexes become individuated and the view that the entire course of behavioral development may be summarized as from-generalization-to-specificity. Fitzgerald and Windle (1942) have objected that Coghill's thesis of development is not applicable to human fetal behavior. According to their researches the "mass reflexes" reported by Minkowski are the result of asphyxia. The earliest responses elicitable are individual or specific reflexes. During progressive anoxia these are the first to disappear; next the mass reflexes to intense stimulation are extinguished; and last of all the muscle excitability itself vanishes.

Michaels (1944) has contributed an interesting paper to the theory that pathological function in the adult represents a regression to early infantile behavior. He states that the functional symptoms of psychosomatic disorders have the form of responses which were the normal mode at earlier stages of development. Thus

> Just as the activities of the neonate are considered to be of a more generalized and less specific nature, so may the visceral somatic dysfunctions in the adult represent a recrudescence of visceral somatic functions in infancy.

The principal axial trends of development are the cephalocaudad and the proximodistal. The doctrine of development from fundamental to accessory movements, as expounded by Buck (1898), Moore (1901), and Shepardson (1907), is the forerunner of the idea that development proceeds proximodistally. More recently Irwin (1930), Shirley (1931*a*), and Marquis (1933) have all contributed evidence supporting this principle. Bersot (1920, 1921) has reported that some aspects of the plantar response run counter to this conception, and McGraw (1933) has asserted that, so far as the elements of the grasping reflex are concerned, it is the distal segments which show prior anatomical and functional differentiation. Irwin (1933*b*), in reviewing the literature, says:

> It would seem that the evidence in regard to the differentiation of vertebrate limbs including morphological structure as well as behavior is convincingly in favor of the proximodistal principle.

The work of the Shermans (1925) and the Shermans and Flory (1936) on pain sensitivity illustrates a cephalocaudad gradient in sensitivity and in rapidity of de-

velopment. The researches of Irwin (1930) and Shirley (1931*a*) also lend support to this principle of development in human infants.

The important need in the study of neonatal behavior and development is to obtain increasingly accurate and detailed descriptions of the infant's responses and the stimulating conditions under which they are obtained. This should include further exploration of the possibilities of learning, with particular reference to the comparison of premature and full-term infants. It should likewise make a comparison of the relative learning capacity of full-term infants and of prematures *after* they have attained the *actual* age of full-term infants. The generalizations regarding principles of organization and of development of behavior serve a legitimate end just as long as they do not impede further research or constrain the student to force all observations to fit these frames of reference.

Chapter 5

PHYSICAL GROWTH

Helen Thompson

There are important reasons why child psychology should be concerned with the course and characteristics of the child's physical growth. Anderson (1942) has said, "As soon as one works with children he becomes aware that behavior of the moment is an end product determined by many factors, some of which are clearly related to the physical make-up and physiological state of the child. . . . The child development worker . . . quickly becomes concerned with the problems of physical growth, body form, physiological adjustment, appetite, etc., all of which affect the adjustment of the child" (p. 129). Just as child behavior cannot be understood apart from the cultural forces impinging on it, so it cannot be understood apart from the internal stimuli in effect and the physical body through which it perceives, reacts, and functions, and to which others react. It is the child's physical maturity that governs, limits, and to a large extent determines his physical and social environment. A toddler whose eyes are at the level of an adult's knees sees a far different world from that envisioned by an adult; a child whose center of gravity is relatively low will have less difficulty in balance than one whose center of gravity is high. The mechanics of picking up an inch cube presents a different problem to the tiny hand of the 1-year-old from the one presented to the hand of the 5-year-old. Children may suffer emotionally from being a "Shrimp," "Tubby," "Redhead," or "Bucktooth." The taunt, "Brown eye turn around and tell a lie," can leave permanent personality scars. The adolescent who matures earlier or later than his friends has special social problems (Schonfield, 1950; Jones and Bayley, 1950) So, just as the physician must know how the child's personality and mind grow, the psychologist must know how the child grows physically.

In the conduct of experimental studies in child psychology the problem of equating groups for the purposes of control is a highly important part of the experiment. Should one use chronological age, or anatomical age, or physiological age, or some composite of these? How can such ages be measured? What is the relationship between them? Is it necessary to equate for physical fitness? How can it be judged? And what is the consensus as to body type? All these questions are pertinent in research studies of childhood.

The relationships between physical and mental growth are becoming more apparent as children are studied in greater awareness of the possibilities of interaction between mind and body. For instance, while science has not regressed to the notion of the fetus being marked by maternal impressions, it has progressed to an understanding of how maternal anxieties and fears may so affect fetal life and development as to leave a permanent imprint on the physiological and psychological functions of the child (Sontag, 1946). The effect of deprivation of personal attention and affection on phys-

ical development has long been recognized (Bakwin, 1942). Likewise, the undersized, undernourished child who whines and frets may set into action a chainlike series of social percussions and personality repercussions which may be of sufficient social handicap to destroy temporarily, if not permanently, the effectiveness or even the actual development of potential mentality. It may even be a fair prophecy that, in the investigations of individual physical and mental life histories, studies of social behavior and personality may find their fullest realization in the genetic analysis of physical individuality.

Furthermore, the student of mental growth may learn much from a study of physical growth with respect to methods and techniques of study. It is comforting as well as instructive to know that behavior changes from age to age complicate even such an objective determination as height or length. The 6-month-old infant cannot stand, whereas the 2-year-old child resists being placed supine and the 3-year-old assumes distorted and fairly rigid postures in his effort to cooperate. To the student of physical growth these behavior changes are as important to cope with as the changes in physical growth are important to the student of child psychology. Techniques in the one field are suggestive of possible techniques in the other field of study. To secure comparable measures of size, it is frequently necessary to take two measurements at critical ages using the two methods adapted to the younger and older child. Allowance for the change in method can then be made. A similar scheme may be employed to advantage in studies of behavior growth.

Growth is one of the most pervasive problems of child psychology. An understanding of psychological growth can be fostered by studying the laws of growth as revealed by physical growth. The law of cephalocaudal development, noted first in physical growth, was later studied and confirmed in relation to behavior development.

Surely, then, the child psychologist, as an intelligent scholar, teacher, researcher, or clinician, must know the outstanding facts of physical growth; otherwise his understanding, interpretations, conclusions, and treatment of the child may be delayed, incomplete, biased, or totally false.

Definition

There is considerable confusion about what is meant by the term physical growth. Some authors would use it to denote change in size; others, change in quantity; others, change in quality; and others, any combination of these characteristics. After a careful survey of the literature, Meredith (1945) concluded that the three terms growth, development, and maturation which are used in contradictory ways by different workers serve no "useful and significant distinction" as their proponents had claimed. He proposed using the terms interchangeably, giving preference to growth as being the shortest of the three terms. He defines physical growth as, "The entire series of anatomic and physiologic changes taking place between the beginning of prenatal life and the close of senility" (p. 445). In this chapter the discussion will be limited to anatomic changes and thus will deal with a delimited aspect of physical growth.

The Literature

The literature on the subject of physical growth is vast and widely scattered owing to a variety of scientific, professional, and business interests in the subject. Not only the anatomist, physical anthropologist, biometrist, and psychologist but also the obstetrician, pediatrist, dentist, educator, public-health doctor, actuarian, criminologist,

and eugenicist are led to research in this field. Fortunately, adequate summaries are available. For the period up to about 1925, the most useful and complete are those of Baldwin (1921), the Children's Bureau (1927), Scammon (1927*a*, 1927*b*), Martin (1928), and Meredith (1936*a*). Since 1926 the American literature on growth has been systematically reviewed by Brooks (1933), Dawson and Stoddard (1933), Jones (1933, 1936, 1939), Meredith and Stoddard (1936), Meredith (1939*a*, 1939*b*), Rothney (1941), Ames and Flory (1944), and Tuddenham and Snyder (1947). Krogman's extensive bibliography (1941*b*) includes foreign publications. *Child Development Abstracts*, begun in 1927, and *Biological Abstracts*, begun in 1926, cover the most important sources of publication.

In view of the scope of physical growth, a comprehensive summary of the literature cannot be given in the following pages. Instead, references will be selected on the basis of their importance to the child psychologist. No attempt at comprehensiveness will be made. The subject is too extensive.

Historical Summary

Although the first interest in mental development arose in relation to education, the first interest in bodily growth was the concern of the artist. The practical problem of realistically portraying the child led artists to study size and proportion in relation to age. In that early era, beauty values were considered in the absolute sense, and the artist searched for the perfect proportions of youth (Baldwin, 1921). Before 1799, measuring instruments in different centers of learning varied considerably in calibration, as a visit to any museum of physical science will demonstrate. The standard meter bar, constructed in 1799, gradually introduced uniformity. Its construction reflected a deep interest in measurement and served to stimulate further measurement. The human body was a natural subject. Quetelet (1871) was the first to systematize the study of physical growth. He is credited with originating the word *anthropometry*. His figures on body dimensions from birth to maturity are still quoted. Shortly before 1760 there were scientific studies of the weight and physical proportions of the newborn, but it was not until 1779 that the first seriatim study of physical growth was published (Buffon, 1837). This preceded Tiedemann's publication on mental development by only 8 years (Murchison and Langer, 1927).

It was practically 100 years later (Hall, 1896) that physical and mental growth were studied simultaneously, and even then the data were uncorrelated. In the last decade of the nineteenth century and the first decade of the twentieth century, however, there was general interest among psychologists in the relationship between mental and physical traits. Binet (1900, 1910) was concerned with head and face measurements. He attempted to find in them an index of mentality. His failure to establish a close relationship was followed by similar results from the laboratories in London. In this country Porter (1893), Gilbert (1895, 1897), and others were concerned with the relationship between mental and physical traits. Dull children tended to be smaller for their age; bright children tended to be larger. Crampton (1908), studying boys at adolescence, concluded that boys who matured early were better students. Goddard (1912), Binet and Simon (1914), and Doll (1916) were among those who studied the physical growth of the feeble-minded and found them physically inferior to the normal. Baldwin in 1921 stated:

> Another experimental study just completed shows that the mental age of the individual bears a direct relationship to the physiological age as indicated by height and weight. The results show that at each chronological age the physiologically accelerated boys and girls have a higher mental age than those of the average or below the average physiological age [pp. 196–197.]

His results were typical of others.

It was generally conceded that physical defects were likely to be associated with mental defects and physical acceleration and well-being associated with accelerated mental growth. Nevertheless, the correlation of mental and physical traits was found to be small, and general interest in the relationship waned. Clinical psychologists routinely noted height and weight but made little use of the data. Researchers in child psychology, to a large extent, lost interest in physical correlates. Two notable exceptions to this generalization are of course the Harvard Growth Study by Dearborn and the Iowa Child Welfare Research Station studies initiated by Baldwin.

Interest in physical development was revived in the middle 1920's with the advent of the various research centers for child development. The whole child, physical, mental, and emotional, as well as his environment and nutrition, became the subject for investigation (Krogman, 1940).

At the same time emphasis was put on longitudinal rather than cross-sectional studies, on individual growth rates and patterns of maturing rather than average growth trends. Again, relationship between the physical and mental was sought but this time in the individual life histories. Data thus accumulated have already yielded many studies, but it will probably be many years yet before the fruits of these researches are fully realized. Rothney (1941), in a summary of research findings, asserts that physical irregularities do not tend to create any particular types of personality or adjustment problems but that suitable or unsuitable educational procedures will probably determine the type of of response which will be made. This, however, may be a premature conclusion. Sontag (1946) concludes, "The unconscious cruelty of children toward anyone of them whose body does not conform to theirs in size, form, and function may be an important factor in the emotional adjustment of children lacking this conformity," and "A child's energy level or constitutional vitality may be very important in determining his response to what he interprets as a hostile environment." Bayley (1951) finds that somatic adrogyny is only one of a multiplicity of factors which influence a person's interest.

Techniques of Measurement

Physical anthropometry is the science particularly concerned with the techniques and instruments for the study of physical growth. Measuring, weighing, and comparing with standard scales might seem to be routine, mechanical procedures which anyone with general scientific training might easily perform. The problem is not so simple as that, however, if the collected data are to have value. For instance, Meredith and Goodman (1941) have shown that routine hospital records of length at birth are seriously unreliable when compared with records made by trained anthropometrists. Not only is the personal error of the novice great, but even among trained workers there is marked individual variation. Lincoln (1930) concludes: "It is apparent that when exact anthropometric measurements on individuals are desired, they must be obtained by methods which include the most careful checking."

The human body is surprisingly elastic and plastic. Boyd (1929) notes:

> In spite of common agreement in technique and practice, the human body cannot be measured with a high degree of precision; that height is more reliable than other dimensions; that the living is measured with less precision than the dead; that the degree of precision is different for different dimensions and for different measurements of the same dimension; and that daily physiological linear reduction affects both stature and body stem. . . . [She notes further that error results from] the inaccuracy of the examiner, his instruments and methods; the character of the endpoints of a given measurement; the amount of physiological linear reduction; and the degree to which the child's attitude affects the prescribed position [p. 396].

An appropriate selection of the following references should be consulted *before* initiating a study of physical growth.

Fetal period:
Schultz (1929); Scammon and Calkins (1929).

General techniques:
Baldwin (1921); Davenport (1927); Sullivan (1928); Martin (1928); Franzen (1929); McCloy (1936, 1938); Hrdlička (1939); Potter and Meredith (1948); Krogman (1948).

Infancy and early childhood:
Baldwin (1921); Thompson (1929); Bakwin and Bakwin (1931*a*); Davenport (1937, 1938); Gesell and Thompson (1938); Baum and Vickers (1941); Boyd (1945).

Skin and subcutaneous fat:
Franzen (1929); McCloy (1938); Reynolds (1950).

Bone, muscle, and overlying tissue by roentgenography:
Stuart, Hill, and Shaw (1940).

Radiographs to predict height:
Bayer and Bayley (1947).

Center of gravity:
Palmer (1944).

Somatotyping:
Sheldon, Stevens, and Tucker (1940); Dupertuis and Tanner (1951).

Whenever physical measurements are reported, it is important to specify clearly how the measures were taken and what precautions were observed to insure their validity and reliability.

Norms of Physical Growth

There is some confusion about the value and purpose of norms. Norms are not criteria for optimal growth. They are statistics for basic comparisons. They are mathematical devices to avoid the error of generalization from isolated cases. They are conclusions of scientific surveys, and as such they are indispensable scientific data which should be groundwork for the systematization and analysis of other data. Norms may be used as control-group data. By comparing experimental data, individual or group, with the norms, conclusions can be reached which will be valid to the extent that the norms and the experimental data have common attributes, except with respect to the variable in question.

Obviously, comparison with norms is valid only when similar techniques have been used in measurement. Theoretically this is so obvious that to mention it seems unnecessary. Practically, however, even psychologists trained in the importance of scientific control will use their own measurement techniques and then search through the literature for comparative norms, using the first figures they find which are measures of the dimension they have taken, forgetting entirely that techniques of measurement may make the comparisons completely invalid.

The more heterogeneous the composition of the group with respect to traits related to the normative trait, the greater will be the number of cases necessary to determine the norm, and the greater will be the variability of the trait as measured. The more highly selective the group on which norms

are based, the more precise will be their scientific usefulness. It is generally important to consider race, sex, and locale. Socio-economic status is important but not always easy to define. Individuals obviously atypical should be excluded. Factors which are operating at particular ages must be considered. The inclusion of premature children in a normative study of infancy will shift all values downward.

It was noted above that norms are not criteria for optimal growth. It should be noted also that what is normal for one individual is not normal for another. It is valid to compare an individual with the normal in order to analyze his particular growth pattern, but interpretation of any divergence must recognize individual growth differences. Appraisal of individual growth is most helpful in terms of past growth. A dwarf whose increment in stature is normal for a given period is growing relatively very rapidly considering his growth tempo in the past.

Norms of growth may be in terms of the central tendency and variability of groups, at regularly spaced chronological or other maturity age intervals, or in terms of the statistics of individual growth increments at these ages. Instead of using chronological age as a basis, Boas (1930) and Shuttleworth (1937, 1939) particularly give reasons for evaluating growth according to age at the time of maximum growth. Although this procedure may be highly desirable in the analysis of growth data, it cannot be applied practically at the time of measurement. The same comment applies to appraising growth in terms of size at maturity. It is possible to evaluate growth in terms of some maturity age measurable at the time, such as skeletal age or dental age, but the probable error in measuring these ages is large compared with the probable error of birth age, even considering the variability of conception age at birth. The use of norms, on any basis, must be tempered with the understanding and judgment required of all interpretive analysis.

It is not practical to give tables of growth norms in this handbook. A few selected norms would tend to emphasize their use when other growth data might be more pertinent. The following list of references will direct the researcher to the more outstanding source material.

Norms: Selected References

Body Growth

Fetal period:

Streeter (1920); Schultz (1926); Scammon and Calkins (1929).

Neonatal period:

Taylor (1919); Freeman and Platt (1932); Bakwin and Bakwin (1934*a*, 1934*b*); Hess, Mohr, and Bartelme (1934); Meredith and Brown (1939).

Infancy and early childhood:

Woodbury (1921); Freeman (1933); Bayley and Davis (1935); Bayley (1936); Bakwin and Bakwin (1936); Gesell and Thompson (1938); Pratman and Higgons (1938); Davenport (1938); Boyd (1941); Robinow (1942); Meredith (1943, 1946*a*).

Infancy and late childhood:

Freeman (1933); Simmons and Todd (1938); Vickers and Stuart (1943).

Infancy to maturity:

Bardeen (1920); Baldwin (1921); Baldwin, Wood, and Woodbury (1923); Englebach (1932); White House Conference (1933); Meredith (1935, 1943, 1947); Boynton (1936); McCloy (1938); Pryor (1941); Davenport (1944); Simmons (1944); Reynolds (1948).

Childhood:

Johnson (1925); Wilson, Sweeny, Stutsman, *et al.* (1930); Wallis (1931); Reynolds (1944).

School age to maturity:

Baldwin (1925); Franzen (1929); Gray and Ayres (1931); Palmer and Reed (1935);

Goldstein (1936); Palmer, Riiti, and Reed (1937); Dearborn, Rothney, and Shuttleworth (1938).

Adolescence:

Pryor (1936); Richey (1937); Shuttleworth (1937, 1938, 1939); Stone and Barker (1937); Greulich, Day, Lachman, *et al.* (1938); Greulich, Dorfman, Catchpole, *et al.* (1942); Shuttleworth (1949); Stolz and Stolz (1951).

Head and Face Growth

Wallis (1931); Bakwin and Bakwin (1931*a*, 1936); Fleming (1933); Bayley (1936); Boynton (1936); Goldstein (1936, 1939); Broadbent (1937); Klein, Palmer, and Kramer (1937); McCloy (1938); Davenport (1940); Boyd (1948).

Dentition

Boas (1927); Cattell (1928); Hellman (1933); Klein, Palmer, and Kramer (1937); Klein, Palmer, and Knutson (1938); Doering and Allen (1942); Robinow, Richards, and Anderson (1942); Hellman (1943); Sandler (1944); Meredith (1946*b*); Hurme (1948).

Skeletal Development

Graves (1921); Stevenson (1924); Pryor (1925); Baldwin, Busby, and Garside (1928); Sawtell (1929); Camp and Cilley (1931); Hodges (1933); Flory (1936); Kelly (1937); Todd (1937); Shuttleworth (1938); Francis and Werle (1939); Hill (1939); Sontag, Snell, and Anderson (1939); Christie *et al.* (1941); Maresh (1943); Noback (1943); Greulich and Thoms (1944); Reynolds (1945, 1947); Elgenmark (1946); Schmidt (1948); Christie (1949); House (1950).

Subcutaneous Fat

Reynolds (1950).

Head Hair

Trotter and Duggins (1948); Duggins and Trotter (1950); Trotter and Duggins (1950).

Miscellaneous

Surface area:

Boyd (1935); since measurement of surface area is so difficult, formulae have been developed for its estimation—Weinbach (1938).

Vital capacity:

Baldwin (1928); McCloy (1938).

Racial differences:

Weissenberg (1911); Shirokogoroff (1925); Appleton (1927); Godin (1935); Martin (1928); Wissler (1930); Fleming (1933); Steggerda and Densen (1936); Meredith (1939*a*); Krogman (1941*a*); Su and Liang (1940); Michelson (1943*a*, 1943*b*, 1943*c*); Goldstein (1947).

Weight (nutrition):

Baldwin, Wood, and Woodbury (1923); Pryor and Stolz (1933); Franzen and Palmer (1934); Royster (1936); Richey (1937); Daniels, Hutton, and Neil (1938); Dearborn and Rothney (1938); McCloy (1938); Peatman and Higgons (1938); Metheny (1939); Stuart, Hill, and Shaw (1940); Pryor (1941); Wetzel (1941); Stuart and Dwinell (1942); Massler (1945).

Center of gravity:

Palmer (1944).

Height predicted from skeletal age:

Bayley (1946).

Growth Trends

The physical growth of the child to be fully appreciated must be considered in relation to growth in general, but that subject would lead us too far astray. Robertson (1923), Davenport (1926*b*, 1934), Pearl (1928), Robbins, Brody, Hogan, *et al.* (1928), Huxley (1932), Courtis (1932, 1937), the Cold Spring Harbor *Symposium on Quantitative Biology* (1934, Vol. II), Hammett (1936), and Meredith (1945) are among the best sources treating the subject of growth comprehensively and from a theoretical point of view. The search for a theoretical curve of growth

generally applicable over any but a relatively short period has not been fruitful (Davenport, 1926*a*, 1926*b*, 1934, 1938; Davenport and Drager, 1936). There are certain mathematical equations which, for certain periods of growth or for general growth trends, are fair approximations, such as the autocatalytic curve suggested by Robertson (1923), the Gompertz curve

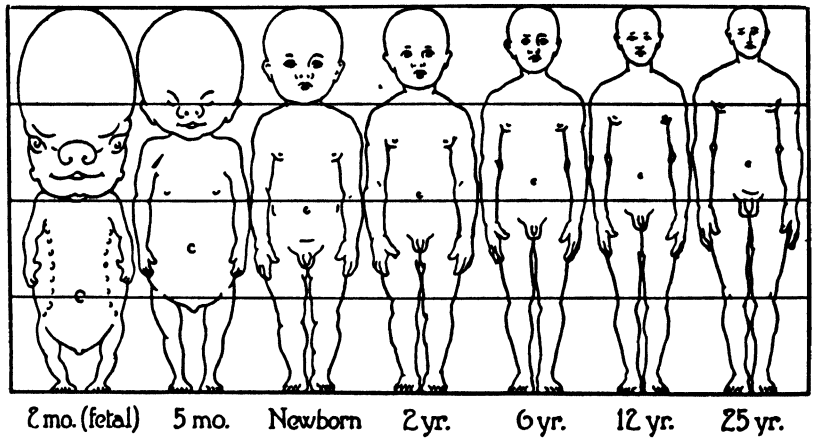

FIGURE 1. Changes in form and proportion of the human body during fetal and postnatal life. (From "Some Aspects of Form and Growth," by C. M. Jackson. In *Growth*, by W. J. Robbins, S. Brody, A. G. Hogan, C. M. Jackson, and C. W. Green. New Haven: Yale University Press, 1928, p. 118.)

recommended by Courtis (1932), the exponential curve of Huxley (1932), and the more complicated exponential curve of Jenss and Bayley (1937). Medawar (1944), however, has developed a mathematical method for representing the gross changes in the shape of man from the fifth fetal month to maturity. D'Arcy Thompson (1942) approaches the problem graphically in terms of differently timed growth rates of body parts.

The body does not grow as a whole and in all directions at once. Each part must be considered separately. In general, embryonic and fetal growth proceed cephalocaudally and proximodistally. That is, with few exceptions, head development precedes neck development, neck development precedes chest growth, chest growth precedes pelvic growth, and arm growth precedes leg growth; also upper-arm growth precedes lower-arm growth, which in turn precedes hand growth; and likewise for the lower extremities. Jackson (1914, 1928), who was the first to formulate this law with respect to human growth, concisely describes human morphogenesis from its initial differentiation to the adult body. The changes are pictured in Figure 1. Schultz (1926) and Scammon and Calkins (1929) have investigated the changes in body dimensions for the fetal period, that is, from about two months after conception to birth. Both authors note that during this period of growth the changes in bodily dimensions are proportional to the changes in total fetal length. In other words, although there is considerable change in body form during this period, the changes are those initiated in embryonic rather than in fetal life.

The complicated transformations occuring in prenatal life are simply and skill-

fully described by Gilbert (1938). She ends by describing the anomalies of development as misfortunes of growth at a critical stage. An analogy between physical and behavior growth processes suggests itself to the psychologist.

Racial characteristics appear even in fetal life. Schultz (1926) found distinct racial characteristics in the 5-month-old fetus when he compared the white and Negro specimens, but he noted no racial distinction in the fetus which was not present in adults of the same race; and, furthermore, the racial distinctions were found to increase rather than diminish with age.

Scammon (1930) has shown that in prenatal life the various parts of the body follow a similar growth trend, but after birth their course diverges (see Figure 2). He has grouped the various growth trends under four types: (1) the *lymphoid type,* which includes the thymus, lymph nodes, and intestinal lymphoid masses; (2) the *neural type,* that is, the brain and its parts, the dura, spinal cord, optic apparatus, and many head dimensions; (3) the *general type,* followed by the body as a whole, external dimensions excepting head and neck, respiratory and digestive organs, kidneys, aorta and pulmonary trunks, spleen, musculature as a whole, and skeleton as a whole; and (4) the *genital type,* characteristic of testes, ovaries, epididymis, uterine tubes, prostatic urethra, and seminal vesicles. Nature, however, is never as invariable as man-conceived laws, and Scammon notes divergences from the four types, such as neck circumference, which follows the neural growth curve through early childhood and then follows the curve for general body growth. The suprarenals are even more irregular and atypical. After birth they rapidly diminish in size and then grow slowly until prior to puberty, when they increase relatively rapidly. Other glands have their characteristic curves.

It is the consensus that postnatal growth changes are brought about by a multitude of determining factors, the understanding of which requires carefully controlled and analyzed studies.

The underlying principles of growth have been investigated by the technique of factor analysis. Carter and Krause (1936), analyzing the data of Bakwin and Bakwin (1934*a*) on newborns, find that, although all body measures show some correlation, "no two parts are highly intercorrelated" and "no single factor can account for a major part of the measured variance when widely different parts of human bodies are measured." They also find that "anthropometric data show greater complexity, lesser importance of each component, greater number of components, and greater specificity" than when mental test data are similarly analyzed. Since data from males and females separately yield these conclusions, the statistics do not result from unreliability of measurements.

Marshall (1936) has used factor analysis to study the growth factors of 18 measurements for the age period from birth to 6 years. He has found four group factors and a number of specific factors. One group factor is identified with subcutaneous fatty tissue, but the other three group factors are not identified in biological terms.

Mullen (1940), using Holzinger's method of factor analysis, which assumes a general factor plus group factors, studied data on girls between 7 and 17 years old. She identified a general size factor related to sexual maturation and two group factors. One factor was concerned with height, span, length of forearm, and lower-leg length. The other factor related to weight, bi-iliac and bitrochanteric diameters, chest girth, width, and depth. These two factors were considered significant with respect to body type.

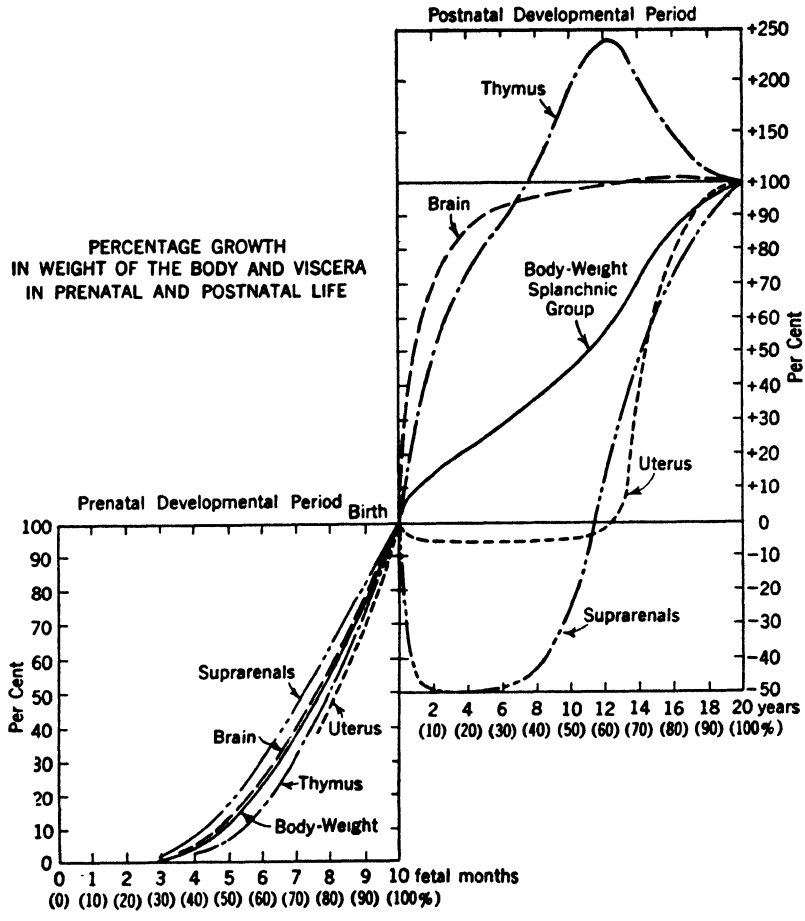

FIGURE 2. Graph showing relative (percentage) growth in weight of the human body and viscera during fetal and postnatal life. (From "Some Aspects of Form and Growth," by C. M. Jackson. In *Growth*, by W. J. Robbins, S. Brody, A. G. Hogan, C. M. Jackson, and C. W. Green. New Haven: Yale University Press, 1928, p. 132.) The horizontal base line (abscissa) indicates age; vertical distance (ordinate) indicates the percentage of the weight at the end of the period, prenatal or postnatal, which has been reached at the corresponding age. (Graph by R. E. Scammon.)

McCloy (1940), using Thurstone's method of factor analysis, and analyzing data on both sexes from birth to maturity, found four subdivisions of Scammon's general body growth: (1) fat growth which may be superimposed on any type of build; (2) general growth seen in the tall, long-limbed, excessively slender; (3) cross-section type seen in short, very stocky, broad-headed, short-limbed, lateral, or pyknic build; and (4) "Type IV," not definitely identified but most prominent in chest measurement and shoulder width. He concludes: "This would seem to leave us with at least seven types of growth instead of four" (as shown by Scammon).

TABLE 1 *

SIZE OF FETUS OR NEWBORN IN TERMS OF PREGNANCY DURATION

Number of Cases	Pregnancy Duration (Weeks)	Body Weight (Grams)		Total Length (Centimeters)		Head Girth (Centimeters)	
		Males	Females	Males	Females	Males	Females
4	28–29	1255.00	2020.00	38.50	43.25	27.00	31.25
5	30–31	1690.00	1630.00	42.17	40.50	30.00	29.25
11	32–33	2178.63	1906.67	44.88	42.00	31.79	30.00
23	34–35	2477.80	2308.46	46.35	45.96	32.89	31.96
22	36	2837.69	2778.89	48.42	47.28	34.29	33.38
28	37	3146.47	3097.27	49.44	48.41	34.41	34.00
77	38	3201.66	3064.44	49.82	49.21	34.86	34.53
124	39	3445.54	3191.19	50.79	49.38	35.44	34.57
180	40	3477.13	3413.95	50.84	50.40	35.63	35.13
	Full term (days)						
239	284–299	3601.25	3482.81	52.45	50.89	35.82	35.42
52	over 300	3927.86	3513.60	52.84	50.90	36.65	35.47

* Adapted from Kjölseth (1913).

Thurstone (1947) himself identifies seven factors for different growth areas of the body. Burt (1944), on the basis of his technique, distinguishes three: (1) a general factor; (2) a long bone factor; and (3) a breadth, thickness, girth factor.

It is apparent that factor analysis is one approach to the study of body types discussed on page 310.

The Newborn

Usually birth occurs between 270 and 290 days after the beginning of the last menstrual period before conception. If birth takes place earlier, the child is considered prematurely born; if later, postmaturely born. When, as frequently happens, the menstrual history indicates irregularity, or when birth weight is less than 5 pounds, an estimation of the length of term is based on clinical evaluation. Measurements of the body help in this determination; total length gives an approximation. Cates and Goodwin (1936) note that total length is a better criterion of maturity than chronological age even in full-term infants. Table 1, adapted from Kjölseth (1913), gives the average body weight, length, and head circumference according to pregnancy duration. Scammon (1922) finds that the "growth tendency of prematures is in general that of fetuses of the same size and age rather than of full-term children." This finding emphasizes ontogenetic age. Bakwin and Bakwin (1934*b*) find that newborns from a poverty-stricken environment are smaller in all dimensions measured than newborns from a more favorable environment, but that the infants from different environments are similarly proportioned.

Poor maternal diets are found in conjunction with still births, congenital defects, and functional immaturity as well as small weight and size (Stuart, 1947). Furthermore, these infants, though lighter and smaller, are more likely to be difficult to deliver.

It is a well-established fact that the full-term male infant is larger in all body measurements and weighs more than the full-term female infant. The closest approximation of the sexes is in pelvic width. Cates and Goodwin (1936) report that the weight of the male exceeds the weight of the female by 4 per cent and that the height of the male exceeds the height of the female by 2 per cent. The sex difference finding is consistent with the conclusions of both Schultz (1926) and Scammon and Calkins (1929), who report no sex differences when fetuses are compared in relation to total length rather than age.

Although there are racial differences in birth weight, seasonal variation in temperature has not been found to influence it (Brenton, 1922). Meredith and Brown (1939) have reviewed the literature on the effect of various factors on birth weight and weight gain during the first ten days of postnatal life and present further data from Iowa. They conclude that throughout the period "mean weight is least for first borns, intermediate for infants of second to fourth birth order, and greatest for infants of fifth and higher birth order." They, like Brenton, report no seasonal differences.

Although first borns, at birth, are smaller not only in weight but also in stature and head circumference, they are taller though not necessarily heavier between 1 and 14 years, according to Meredith (1950), who has studied available data. By adulthood, however, Howells (1948) finds no relationship between birth order and body form.

Postnatal Growth

The three composite measures of body growth commonly studied are weight, a three-dimensional measure; surface area, a two-dimensional measure; and height, a linear measure. Scammon (1930) notes that these three functions have the same growth trend except that the curve for surface area has less accentuated inflection points than the curve for weight, and more accentuated inflection points than the curve for length (see Figure 3). The general growth trend of the body as pictured by these curves is characterized by rapid increase in infancy, a slowing-down followed by steady increase in childhood, an increased growth rate beginning between 8 and 10 years and continuing to adolescence, followed by a fairly abrupt tapering-off of growth to maturity.

There is a characteristic sex difference in attaining maturity. Girls are generally more mature than boys of the same age. In early childhood, although girls are more mature, they are smaller. The preadolescent spurt starts earlier in girls than in boys, and, owing to this earlier spurt in growth, the girls temporarily surpass the boys in total size. But the girls' growth spurt is less intense and lasts for a shorter period than the boys' adolescent spurt. Finally, at maturity there is a greater discrepancy in measurements than existed earlier. The characteristic difference is exemplified by the height and weight curves pictured in Figure 4.

The changes in body proportions from birth to maturity are summarized in Section I of the White House Conference publication (1932). It is noted there that, although growth in the first half year after birth is rapid, changes in body proportion are relatively slight. From then to puberty head growth is slow, limb growth rapid,

and trunk growth intermediate. In males, from puberty to maturity, growth of the trunk and limbs is at first equal, then there follows a relatively rapid growth of the trunk. Growth in trunk girth continues to the over-all structure of the pelvis while girls tend to be either absolutely or relatively larger in measurements relating to the inner structure of the pelvis including inlet (Reynolds, 1945, 1947).

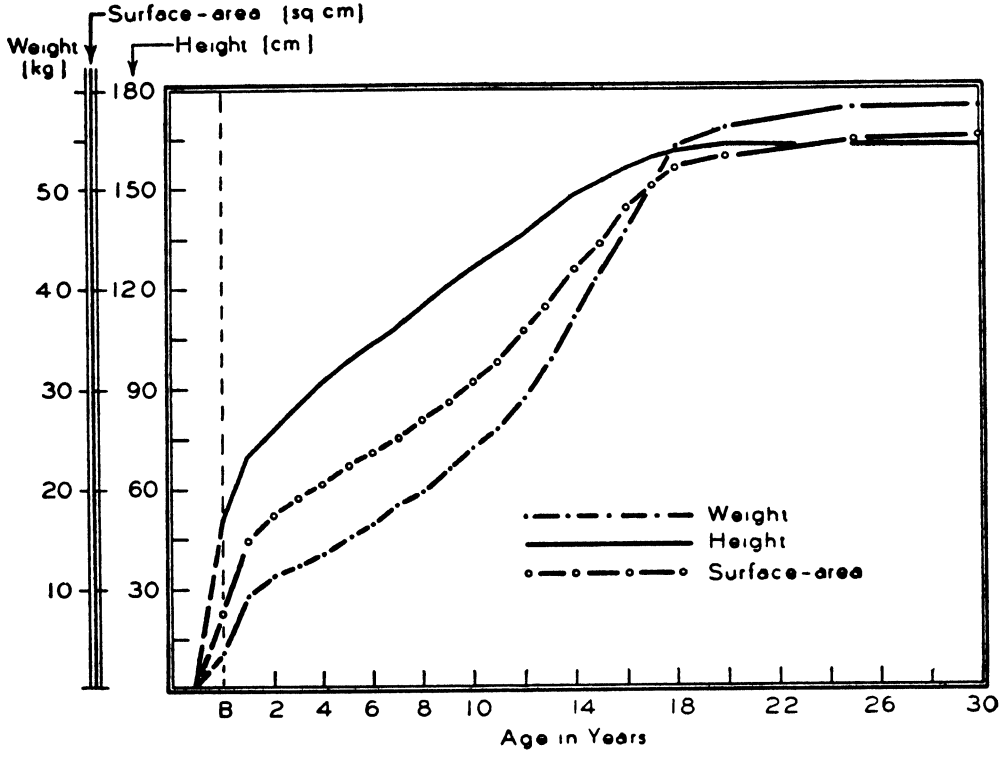

FIGURE 3. Growth curves for height, surface area, and weight drawn according to Quetelet's figures. (Given by E. Boyd in "Growth of the Surface Area of the Human Body," *Institute of Child Welfare Monographs.* Minneapolis: University of Minnesota Press, 1935, No. 10, p. 114.)

longer than growth in length. In females, from puberty to maturity, the trunk elongates in the lumbar region and the pelvis enlarges, while the lower extremities cease to grow in proportion to the trunk. As noted previously, growth in stature ceases earlier in girls, and their increase in trunk width, except in the pelvic region, is less marked during the later part of adolescence.

In infancy and prepuberal childhood, boys are larger in measurements relating

Other sex differences have been noted: Boynton (1936), comparing her study on girls with that of Meredith's on boys (1935), finds that boys are larger than girls in thoracic circumference and girth of forearm throughout the growth years; that girls have a larger thigh than boys from 3 to 18 years; that subcutaneous tissue measurements show a similar pattern for the sexes below 6 years, but from 13 to 18 years girls show a steady increase in this

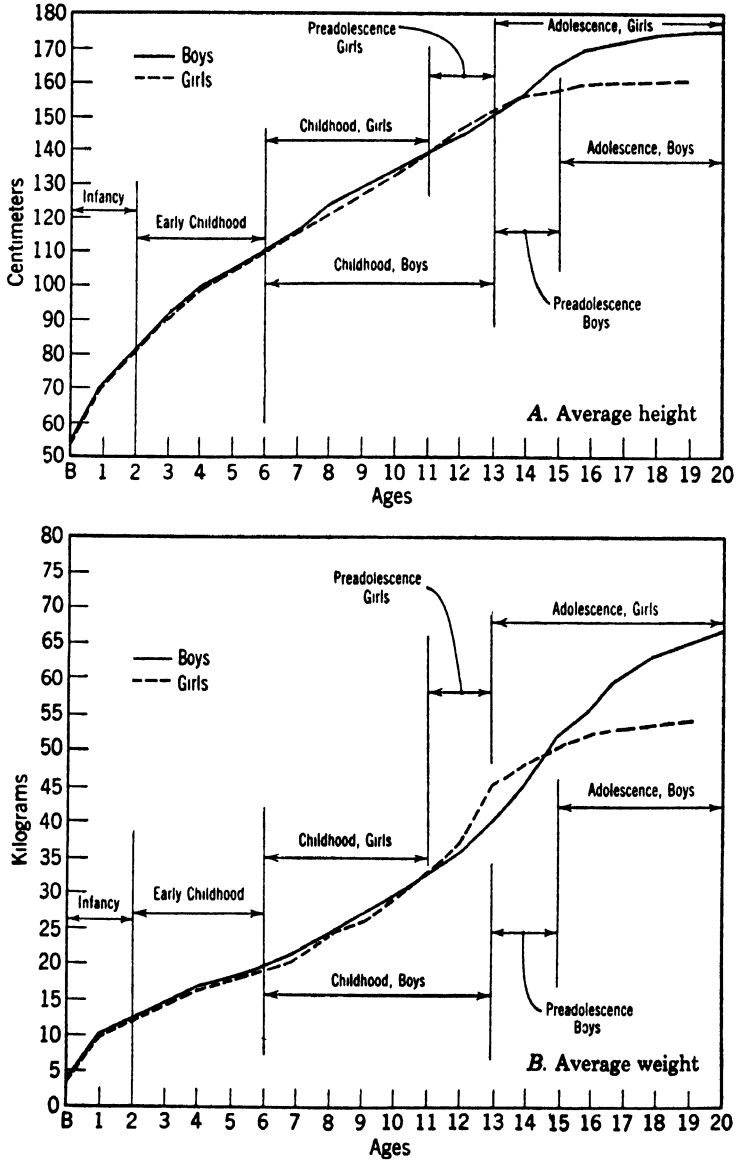

FIGURE 4. Growth of boys and girls from birth to maturity. (From Cole, *The Psychology of Adolescence*. New York: Rinehart and Co., 1948, pp. 18–19.) From age 6 to age 19 these results are based upon F. K. Shuttleworth, "Physical and Mental Growth of Boys and Girls Ages Six through Nineteen in Relation to Age and Maximum Growth," *Monographs of the Society for Research in Child Development, 4*, No. 3, 1939, 248, 249. Below age 6, the curves are averages of several studies, most of which are not longitudinal.

measurement, whereas this same measurement for boys decreases; that, relative to stature, boys exceed girls in girth of forearm and bicondylar diameter of left humerus from 11 to 18 years, whereas at this time girls surpass boys in growth of thigh; and that the bicondylar diameter of the left femur is larger in boys from 11 to 15 years, and larger in girls from 16 to 18 years. Girls have relatively longer legs throughout childhood (Davenport, 1944).

The relatively longer leg length of the females may be ascribed to their greater maturity. Wallis (1931) also finds more mature proportions of the female between 2 and 8 years with respect to hand-radius, trunk-arm, and arm-leg indices.

The male child not only is less mature and grows more rapidly than the female child of the same age, but also his chances for survival are less. In fetal life the ratio of male to female abortions in the third to the fifth month is from 1.07 to 1.22. According to Schultz (1921), Greulich (1931), and Holmes and Mentzer (1931), the ratio starts at a fairly high point, declines to between the sixth and seventh month of pregnancy, and then rises to the period of birth. Bakwin (1929) gives the mortality ratio at birth as between 1.30 and 1.40. On the third day after birth the ratio reaches its peak, between 1.45 and 1.50, and then declines sharply to a low point of 1.20 to 1.30 between 2 and 3 weeks; it rises again between 1 and 2 months, and then gradually decreases with age until the fourth year, when it is near unity. A slight rise occurs in the fifth year. After this the ratio may fall below unity in the teens and in the most active childbearing period.

The findings of Schultz (1921), who concludes that 1.08 to 1.09 males are conceived for every female, would not account for the greater disparity in mortality. Bakwin (1929) points out that there are seasonal and regional differences in the mortality sex ratio which suggest that the ratio depends on the amount of sunlight reaching the infant and that the male has greater need for this sunlight since he is growing faster and his calcium-regulatory mechanism is highly taxed.

These sex differences in growth are particularly important for the child psychologist. Since the differences in physical growth are pervasive, any well-controlled study must recognize and appraise a possible sex factor.

No seasonal influence has been found on growth in height, but the majority of investigators have found seasonal changes in postnatal body weight growth (Marshall, 1937). Summer and autumn are most conducive to weight gain for the preschool child; school children, likewise, have been shown to gain weight most rapidly in the fall, less rapidly in the summer, and least rapidly in the winter and spring months. The seasonal changes in weight growth have not been found to be related to food, colds, or minor illnesses. Since seasonal growth changes are confined to body weight, perhaps they reflect merely a seasonal difference in the water content of the body rather than a true growth trend.

Infancy

The rapidity of growth in infancy makes that period a particularly significant and important one. Bakwin and Bakwin (1931*b*) reported a general tendency for dimensional growth in the first postnatal year to progress in proportion to total length, as in prenatal life. Nevertheless, when infant growth is studied in detail, modifications in relative growth rate are apparent. Davenport (1938) finds the curve for neck and thigh growth to be highly aberrant and the shoulder and thoracic index changes to indicate special growth adaptations in infancy. Thompson

(1938) reports that between 8 and 56 weeks of age the head and thorax circumferences show a gradually decreasing relative growth rate and lower limb length shows a definitely increasing relative growth rate.

Between birth and 3 years, Bayley and Davis (1935) note, the growth rate in all dimensions decreases, more rapidly at first and then more slowly. They also report that, during the first year, growth ratios show a proportionately increasing width. Thompson (1938) notes that the solespubes length relative to total length reaches a critical minimum sometime after birth but before 8 weeks, and thereafter increases rapidly. This finding is in accord with that of Meredith and Knott (1938) with respect to the skelic index, or the ratio of lower limb to stem length. The ratio between lower limb length and total length is an important one because it differentiates the sexes. The females, relatively more mature than the males, have relatively longer lower limbs even as early as 8 weeks.

Cephalic and facial changes in infancy are discussed in the section devoted to face and head growth.

Ponderal growth in infancy follows the general course of growth. Pediatricians rely heavily and probably too exclusively on weight gain as evidence of adequate nutrition. Weight, however, is a sensitive indication of nutrition. Bakwin and Bakwin (1931*b*) report that infants from poor homes weigh less and are shorter in stature than infants from good homes and that the retardation in bodily dimensions accompanying retardation in weight is greater for the transverse than for the vertical dimensions. They also report (1936) that supervision of a group of infants from poor homes in a pediatric clinic raised the height and weight of these infants to that of the normal group and likewise changed the relative proportions from relative "linearity" to the normal of the control group.

Although male infants are larger than female infants of the same age (Bakwin and Bakwin, 1931*b;* Bayley and Davis, 1935; Thompson, 1938; Peatman and Higgons, 1938; and others) and although the growth increment tends to be larger for the male infant, the percentage rate of growth does not in general differ significantly in the two sexes (Thompson, 1938). Dunham, Jenss, and Christie (1939) emphasize the importance of considering both sex and race in studying the growth of infants. Colored infants have long been said to be smaller and to weigh less than white infants (Children's Bureau, 1927; Michelson, 1943*a*, 1943*b*, and 1943*c*; and others). However, Bakwin and Patrick (1944), as well as Scott, Cardozo, Smith, and DeLilly (1950), find no difference between white and Negro infants seen in private practice. They conclude that the slower growth previously reported was due to difference in economic status.

Childhood

During childhood, height and weight progress at a fairly uniform rate (Wallis, 1931). Rate of weight gain is nearly twice the rate of height gain. The lower limbs grow rapidly in proportion to the stem length (Meredith and Knott, 1938). Neither shoulder breadth nor pelvic breadth increases as rapidly as trunk length, but the pelvis broadens more rapidly than the shoulders. The total configurational change is a longer-legged, longer-bodied, and more rectilinear and flatter-bodied child.

Sex difference with respect to skelic index, that is, the ratio between lower extremities and stem lengths, disappears between 5 and 6 years and reappears at 7 years. Females then have the relatively longer legs, despite the fact that they are shorter. This difference continues through

the ninth year (Meredith and Knott), 1938).

Other sex differences during childhood have been noted on previous pages.

Adolescence

Adolescence, the second period of rapid postnatal growth, has received special attention. Greulich, Day, Lachman, *et al.* (1938) have made a well-rounded survey of the methods for studying physical, mental, and social adolescent growth. Shuttleworth (1937, 1939), Greulich, Dorfman, Catchpole, *et al.* (1942), Bayley (1943*a*, 1943*b*), Simmons and Greulich (1943), Greulich and Thoms (1944), and Stuart (1947) have made special studies of the body and skeletal changes occurring at this period. The period is a truly metamorphic one, as shown by the actual growth curve (Davenport, 1926*b*) and by the marked body changes which complete the differentiation of the sexes.

Girls enter the period of acceleration in height growth, on the average, at about 9 years of age, about 2 years earlier than boys (Boynton, 1936). Girls reach the maximum phase of growth at an average age of about 12.5 years, boys at about 14.8 years (Shuttleworth, 1939). Puberty is demarcated in girls by the menarche and in boys by active spermatozoa which may be found in the morning urine. Puberty is closely related to the age of maximum growth (Shuttleworth, 1939; Simmons and Greulich, 1943). The maximum increase in standing height never occurs after the menarche, and the intervals between the time of maximum growth increment and the menarche is greater in late-maturing girls than in those who mature early (Simmons and Greulich, 1943). Girls of early, average, or late menarche can be differentiated by assessment of their skeletal maturity in advance of their acceleration in height and weight (Simmons and Greulich, 1943).

The menarche normally occurs between 12 and 14 years of age and is preceded by a series of bodily changes. First the breasts enlarge, then pubic hair appears, and a little later axillary hair.

In boys, puberty is preceded by increased growth of the testes and penis, and perhaps a slight swelling of the breasts, then the appearance of pubic hair, followed by the appearance of axillary and facial hair. Voice change usually occurs after the appearance of pubic hair but before its lateral spread. Since the determination of spermatozoa in the urine requires laboratory analysis, the appearance of axillary hair has been used by some as an indication of puberty (Richey, 1937). Greulich, Dorfman, Catchpole, *et al.* (1942) have defined five stages of somatic sex characteristics in puberal and adolescent boys, giving actual photographs of breasts and genitals, as well as full-length pictures by which individual maturity may be appraised.

Boas and Wissler (1906) noted that the average growth curve minimizes the decline in growth rate in childhood and the increase at adolescence owing to the individual variation in age of growth rate change. Boas (1930, 1932) found that in some individuals physiological development, so far as it is expressed by stature, is rapid, energetic, and short, whereas in others it is sluggish and occupies a much longer period. His statistics for boys show that the earlier the maximum growth, the greater the maximum growth rate; and the taller the initial stature, the earlier the maximum growth rate.

With respect to the individual growth of girls at adolescence, Boas (1932) found that the interval between the moment of maximum rate of growth and the first menses is greater the earlier the maximum rate of growth; and that the earlier the

maximum rate of growth, the shorter the total period of growth. He also found that the type of growth curve characteristic of an individual is more closely related to the age of maximum growth than to the date of the first menses; and that individuals who have the same stature at an early age are, as adults, shorter the earlier the age of maximum growth rate.

Richey (1937), investigating growth rates before and after puberty in both sexes, found growth in height and weight slightly accelerated before puberty but more markedly decelerated after puberty. Although the prepubertal spurt in growth increases the disparity in size for children of early, average, and late puberty, the disparity is still more influenced by differences in growth rate after puberty.

The findings of Boas (1932), as well as Shuttleworth's own investigations, led Shuttleworth (1939) to make an extensive study of adolescence in terms of growth increments, relating them to the period of maximum growth. Comparing the growth curves of boys and girls with the same maximum growth age, he finds no crossing of the growth curves but, instead, he finds that at every age the boys are taller than the girls. Also, the growth increments of the boys are greater at every age than those of the girls, but the difference is particularly marked at the age of maximum growth. Analyzing the actual stature difference in terms of accelerating phase, initial decelerating phase, and final decelerating phase, Shuttleworth (1939) finds they contribute 3.67 cm., 5.88 cm., and 3.28 cm., respectively, making a total difference at maturity of 12.85 cm. When he compares children of the same sex but with different ages of maximum growth, he finds that those with later maximum growth ages are only slightly taller at maturity since they have a smaller initial decelerating increment and a smaller final decelerating increment, although their initial deceleration is of longer duration though of less intensity. In other words, the effect of the longer period of growth is canceled by generally less intense growth.

Because of the variability in growth rates associated with the time of maximum growth rate, stature can be predicted more accurately from stature at 6 to 10 years than it can at the following years. In general, Shuttleworth (1939, p. 61) concludes that girls who are tall at any age tend to be tall at maturity; but girls who are tall at 6 to 9 years are more likely to be taller at maturity (correlation .73 to .83) than girls who are tall at ages 11 and 12 years (correlation .64 to .71). Similarly, correlation in height of boys 6 to 10 years with their adult stature is .72 to .80, whereas the correlation in height of boys 13 to 14 years old with their mature stature is .56 to .61.

Age at puberty appears to be related to body build. Pryor (1936) finds that girls of broad body build menstruate earlier than girls of slender body build, and Bayley's data (1943*b*) show that early-maturing boys and girls tend to have broad hips and narrow shoulders. She also finds that early-maturing boys have a growth spurt resembling that of girls, and late-maturing girls have a spurt resembling that of boys. Tanner (1947) points out that this, as well as other evidence, supports the notion that the reaction of a tissue to hormonal stimulation depends on its age. Bayer (1940*b*) finds that disturbances in weight and menstruation are associated with deviations from normal build. Bruch (1941*b*), however, in a study of more than 200 children, finds that mere obesity is not related to delayed puberty in either boys or girls. Godin (1935) concludes that puberty is a germinal affair, and the maturity of the germ itself is an affair of nutrition. Pryor (1936) suggests that possibly the glandular balance of

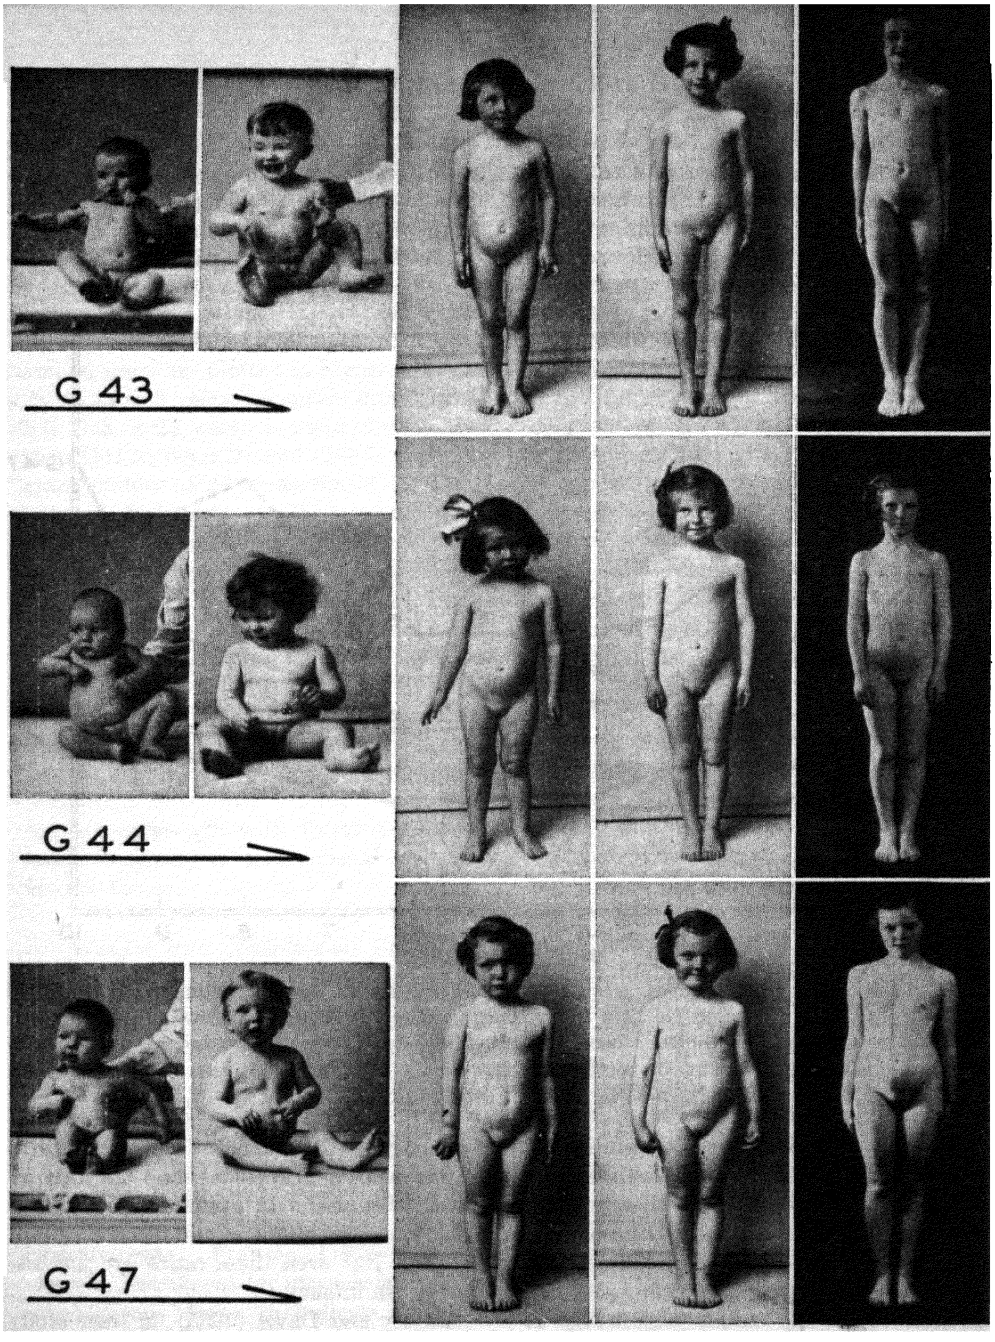

FIGURE 5. Changing body proportions of three girls all taller than average but of different body "types." (Thompson, The Clinic of Child Development, Yale University.)

body; gynandromorphy, or degree of bisexuality; texture, or the fineness or coarseness of structure; and hirsutism, or amount of body hair. All the above traits are rated on a seven-point scale by anthropometric and anthroposcopic methods. Hunt (1949) such as the stem length:recumbent length ratio (Hejinian and Hatt, 1929), have proved valid for certain periods of growth but lose their significance at other ages.

McCloy (1936), investigating the whole period of physical growth from birth to

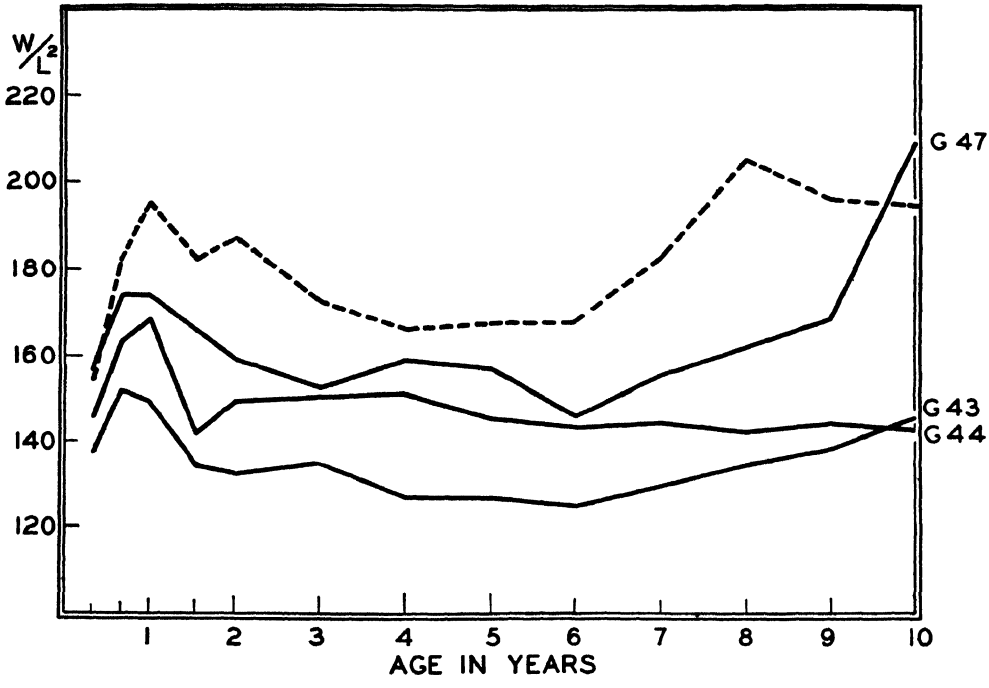

FIGURE 6. Individual changes in weight:length² index with age. (Thompson, unpublished data.) Girls G43, G44, and G47 are taller than average but of different body build. G43 is underweight for age and height; legs proportionately long. G44 approximates normal proportions. G47 is overweight for height; pelvis wide for body length. (See Figure 5, p. 311.) Dotted line represents index changes for short stocky girl.

emphasizes the complex relationship of the three embryonic layers and their interaction which complicates the theory underlying somatotyping. This may account for the change in body type with age.

Many complicated formulae have been devised to classify adults objectively according to type. When the problem of types is extended to childhood, it is further complicated by the changing proportions associated with growth. Certain indices, maturity by Thurstone's (1935)method of factor analysis, concludes that the two indices most useful in appraising body type are weight$^{1/3}$:height; and chest girth: height. But even these ratios are unsatisfactory in infancy.

Bayley and Davis (1935), in their study of the first 3 years of life, find weight: length^2 the most valid measure of relative chubbiness, or lateral-linear tendencies in build. But they are unable to predict from

indices at an early age what an individual's body build will be later. The pictures in Figure 5 show clearly the vagaries of growth. Three girls, all taller than average but of distinct body types, are pictured at various stages of growth.

The ratios weight:length^2 for these three children between the ages of 16 weeks and 10 years are plotted in Figure 6. From 28 weeks to 9 years the curves do not cross, but G43 at 28 weeks is more chubby then than G44 at 5 years; and G44 is decidedly more chubby at 28 weeks than G47 is at 5 years. Chubbiness, as Bayley and Davis (1935) find, reaches a peak between 9 and 12 months of age.

Tanner (1947) has shown that Burt's constants, since they provide a continuum rather than a discrete series, are of great value in studying type and the physiological nature of growth. Since individual variations are great, and it is actually a question of degree of type, Tanner's approach, combining as it does D'Arcy Thompson's concept of growth with Burt's concept of factor analysis, is a promising approach for the future.

Weight and Nutritional Status

Weight increase is a correlate of growth, but weight increase is not necessarily indicative of growth. Weight changes may be merely the result of changes in fatty deposits or in water content, both of which may be transitory modifications (Hammett, 1937; Simmons and Todd, 1938). Weight is more variable and more indicative of nutritional status than other physical measurements. Franzen (1929) has devised an instrument for measuring skin and subcutaneous tissue to indicate quantitatively the fatty deposits affecting weight. He and McCloy (1938) have established age and sex norms for this measure on various parts of the body. The norms are useful for transmuting body dimensions to skeletal dimensions and for thus determining body build more explicitly. Stuart, Hill, and Shaw (1940) have developed a technique for measuring the muscle and overlying tissues of the leg area by roentgenography. Norms for children from birth through 10 years are available (Stuart, Hill, and Shaw, 1940; Stuart and Dwinell, 1942).

Although weight is an acknowledged indication of nutritional status, optimum weight is an individual requirement, since it depends on age, stature, and body build as well as on nutrition. Age norms for weight, which even today are sometimes used, fail to consider that tall children of a given age should generally weigh more than short children of that age. Height-weight norms, which are widely used, account for differences in height but not in body build. Thus height-weight tables have received much criticism from Pryor and Stolz (1933), Royster (1936), Dearborn and Rothney (1938), Simmons and Todd (1938), and others.

Constructive suggestions for more valid nutritional appraisal methods are many. Pryor and Stolz (1933) express the index of nutrition in terms of the percentage deviation of the obtained weight from the weight norm for age, sex, height, and bi-iliac width to this weight norm. They furnish standard tables for ages 6 to 16 years. Franzen and Palmer's (1934) index of nutritional status for children between 7 and 12 years old employs the sum of arm girth with arm flexed, plus arm girth with arm extended, plus chest depth on inspiration, plus chest depth on expiration in terms of age, and bitrochanteric width. Individuals below a certain value are considered undernourished. Royster (1936) has established weight norms for Negro children between 5 and 15 years of age based on age, stature, and bi-iliac diameter. He emphasizes that the Negro child

is of a more slender build than the white child and should therefore be appraised only in terms of his own race. McCloy (1938) finds that normal weight is best predicted by four measurements: height, chest circumference corrected for fat, hip width corrected for fat, and knee width. From thirty regression equations, one for each sex and year for ages 4 through 18 years, he has computed tables from which normal weight may be derived. Clayton (1942) finds that McCloy's formula is reasonably accurate except for markedly overfat or emaciated children. Dearborn and Rothney (1938) have derived a formula for normal weight which is a simple function of chest width, chest depth, standing height, and bi-iliac width. It is useful for both sexes between 14 and 18 years of age. Wetzel (1941, 1943) has devised a grid by which a child's position may be determined in terms of his height, weight, and age. This grid carries seven channels. A child's growth curve normally progresses in a particular channel; deviation from this channel is indicative of change in health status. On a supplementary chart are five representative growth curves which include 76 per cent of those of each standard. A child's growth course may be evaluated, thus, in terms of his own standard. It should be noted, however, that this evaluation, no matter how individual, is based only on height, weight, and age. Only to that extent, therefore, can it assess an individual child.

Pyle and others (1948) have offered a method of indicating the variability of an individual's skeletal bone ages, known as the red graph method. It is based on Todd's inspectional method of appraisal. Its use, in combination with the Wetzel grid, is advocated to reveal a more complete appraisal of both skeletal and soft tissue growth (Mann and others, 1948).

Another channel diagram which utilizes calf girth and height in relation to age as an indication of ideal weight is advocated by Massler and Suher (1951). This differs from the Wetzel grid, which they claim merely indicates growth status and trend rather than the ideal.

Daniels, Hutton, and Neil (1938) advocate the use of the creatinine-height index for nutritional appraisal. The determined ratio is the urinary creatinine in milligrams in proportion to height cubed. They claim that this index accounts for poor skeletal development which other indices of nutrition do not measure.

The question of appropriate weight for any child of adolescent age is particularly difficult because of the great variability associated with accelerated, normal, and retarded puberty. At this age, Richey (1937) points out, no statement of overweight or underweight should be made without a consideration of maturity factors.

The underweight and overweight children present special problems for investigation by the child psychologist (McHale, 1926). Bruch (1939, 1940, 1941*b*) has made highly significant studies showing that obesity, even in severe cases, is commonly a dietary rather than an endocrine problem; that obesity is related to parental overprotection and overfeeding, and to deprivation of satisfying outlets and contacts so that, for the child, food intake assumes inordinate importance. Similarly, Bronstein, Wexler, Brown, and Halpern (1942) conclude that for 35 children whom they studied no endocrine reason could be found for their obesity. Instead, it appeared to be related to sedentary habits, abnormal appetites, parental attitudes, and other environmental factors.

There is the further question of the degree of deviation which a child may show from a method of assessment without being considered under- or overweight

Metheny (1939) concludes that any child found to be 3 per cent underweight or 10 per cent overweight, in terms of the normal weight predicted by McCloy's formula, should be examined fully. It is the consensus that, in addition to any standard of underweight or overweight, clinical judgment also should be used in appraising any individual child. Krogman (1951) points out the inadequacy of evaluations which do not take into consideration normal and abnormal variation.

Head and Face Growth

Head and face growth has had and will probably continue to have particular interest for the psychologist. It is therefore treated here more extensively than would otherwise be the case.

A comprehensive study of head and face growth has been made by Davenport (1940), who gives longitudinal data on the growth trends and analyzes causes for the irregularities which he finds. He lists an extensive bibliography on the subject and discusses the findings of others in relation to his study. He concludes that a multitude of factors operate to modify the growth trend and that any simple expression of the growth of these parts is inadequate. Some of the factors which influence the external cranial and facial dimensions are uterine pressure in fetal life, gravity at the age of sitting and walking, growth of sinuses and tooth alveoli, possibly masticatory pull, sex, race, and other inherited traits, nutrition, and glandular activities.

The growth centers of the head and face, like those of the rest of the body, have different periods of maximum activity. Todd (1935) comments that:

> Brain-case growth is characteristic of infancy and early childhood and with it go the antero-posterior and transverse dimensions of the face, including the zygamota or malar arches. Vertical or respiratory growth of the face attains maximum velocity in later childhood. Vertical growth of the jaws between floor of the nose and chin reaches its most vigorous phase at and after puberty [p. 262].

He comments further that, since the head and face are sensitive to any factors which affect growth at these ages, defective cranial size must date from infancy, deficient upper facial growth from childhood, and inadequate jaw growth from adolescence. In any individual instance, however, it is difficult to separate growth disturbances from inherited growth tendencies.

The head

The five most commonly studied head dimensions are length, anteroposterior diameter; breadth, maximum transverse diameter; frontal diameter from temporal bridge to temporal bridge; height, the projected vertical distance from ear to the vertex; and circumference. Landmarks to define these and other dimensions of the head and face are detailed by Sullivan (1928) Hrdlička (1939) and by other authors who discuss method. The cephalic index, the ratio of head breadth to head length, is used to distinguish long from round heads. The tabulated conventional terms are given by Hrdlička (1939) for making the distinctions. He points out that these are arbitrary rather than determined by nature.

Term	*Cephalic Index*
Hyperdolichocephaly	Below 70
Dolichocephaly	70–74.9
Mesocephaly	75–79.9
Brachycephaly	80–84.9
Hyperbrachycephaly	85 and above

The head and face differentiate early in prenatal life. Even in fetal life they grow more slowly than the body as a whole. Scammon and Calkins (1929) report that at 3 fetal months the total head and face

height is nearly one-third of the total fetal length; at 6 fetal months, about one-fourth; and at birth a little less than one-fourth. Absolutely, however, the cranial dimensions all increase rapidly in intrauterine life. Postnatally the head length and breadth continue to increase rapidly for 2 years and then slow down quickly, with a slight spurt at adolescence. Head circumference likewise follows this trend. Meredith (1935) points out that this type of growth characterizes neural growth as described by Scammon (1930). Although head growth has the same growth trend as the brain, it does not follow that cranial measurements are correlated with brain function.

Davenport (1940) expresses the rapid early head growth in terms of percentage of adult head length (190 mm.) at various ages: birth, 63 per cent; end of 6 months, 76 per cent; 1 year, 82 per cent; 2 years, 87 per cent; 3 years, 89 per cent; 5 years, 91 per cent; 10 years, 95 per cent; and 15 years, 98 per cent.

Bayley (1936) reports that head width increases more rapidly in the first 7 months, whereas head length increases more rapidly after 8 months. She found infants relatively dolichocephalic at birth. From birth to 7 months they rapidly become brachycephalic, and after 10 months they again become dolichocephalic. According to Davenport (1940), the head has practically finished its width growth at 3 years, whereas the head continues to grow in length but at a greatly reduced rate. Goldstein (1939), reporting on head growth of the same individuals between 2 and 16 years, finds for length a relatively high annual increment between 2 and 5 years, a sharp drop in the increment until 7 years, followed by pulsations of growth until adolescence. For width, he finds a comparatively high annual increase between 2 and 4 years, with a gradual decline, less steep than for length. Goldstein also finds the most common individual change in cephalic index to be a drop. Some individuals, however, showed no change and some even increased. Davenport (1940), reporting similarly on individual growth trends, finds that after the first year growth in length was much greater than in width in dolichocephalics, though the reverse was true for brachycephalics.

Absolute cephalic and facial measurements are less in the female than in the male (Davenport, 1940). Bayley (1936) states that the breadth difference tends to increase with age. The cephalic index of the sexes, according to Bayley, does not differentiate them until 11 months of age. Then the mean of the boys is higher than the mean of the girls. Between 5 and 6 years of age, this difference, according to Wallis (1931), diminishes until from 6 to 9 years of age the sexes are equal. Between 9 and 12 years the girls again have longer heads, but at 16 years boys equal and then surpass girls in cephalic index. Bayley (1936) concludes that the cephalic index is unrelated to body build as measured by weight/length^2 or stem length/total length, but that cephalic indices of the same children at different ages are fairly consistent.

Head height, particularly after 2 years of age, has a slower growth tempo than head length or breadth. Davenport (1940) reports that its growth is irregular and that decrease in head height is accompanied by increase in head width. Goldstein (1936) notes that head height is definitely greater in man than in the anthropoids.

The frontal breadth of the head grows irregularly. Davenport (1940) reports that it is near its final size at the age of 1 year. He also concludes that "Up to 4 years, as the breadth is increasing, the transverse frontal index decreases; but after that, as the forehead widens, the index increases."

The relative forehead width[1] tends to increase with age in all individuals studied.

Head circumference increases more regularly than other head dimensions. It is not a very reliable measure, however, since it is affected by different degrees of hair growth.

Intelligence and Cranial Dimensions. Psychologists have long sought a relationship between head measurements and intelligence. Hamilton (1936), in a review of the literature, finds a fairly consistently reported correlation of intelligence and cranial measurements of +.05 to +.10. He concludes that a true correlation would not exceed +.15.

Fernald and Southard (1918, 1921), in their macroscopic and microscopic study of the brains of feeble-minded, found a direct relationship with intelligence in only the extreme cases. It is not to be expected then that the external dimensions of the skull would be indicative of intellect. Ashby and Stewart (1933) did report a falling-off in size of the head measurements of the mentally deficient. The smaller measurements were most marked in the idiot region and affected equally head length, breadth, height, and ear-to-ear measurements, but they also found a more marked relationship between body size and IQ than between head size and IQ. Head growth, occurring genetically earlier than body growth, suffered less. This finding, Ashby and Stewart point out, tends to reinforce the notion that feeble-mindedness is an arrest or retardation in intelligence.

At the other extreme, the large head of a hydrocephalic may be associated with feeble-mindedness or normal intelligence.

Head Size and Race. Head length, particularly, varies with race. At 14 years of age the average head length of Negroes is 18.0 mm.; United States Nordics, 180.5 mm.; Jews, 177 mm.; and Italians, 175.0 mm. Although Negroes have the longest heads, the Nordics have the largest postauricular head segment, the largest ratio of height/length, and the relatively widest foreheads (Davenport, 1940).

[1] Head width/total length.

The face

Psychologists have not been as interested in face growth as they have been in cranial growth, but, with the present shift in emphasis from intelligence to personality and social behavior, greater interest in facial growth may develop, particularly as far as child psychology is concerned. Study of the face should be encouraged as a potentially profitable field of investigation in relation to behavior-growth studies. The face is easily measured and photographed, and its measurement does not involve disrobing as does measurement of the body.

Dimensions of the face are taken either by direct measurement or from roentgenological records. Some of the commonly studied dimensions are *total height:* the vertical distance from the nasion, which is a point near the depression at the upper part of the nose, to the menton, or anterior lower margin of the chin; *nasal height:* from the nasion to the point where the nasal septum joins the upper lip; *bizygomatic breadth:* the distance between the most lateral aspects of the upper jawbone; *bigonial breadth:* the distance between the lower points at the posterior angle of the lower jawbone; *upper face length:* from the auditory meatus to the nasion; and *lower face length:* from the auditory meatus to the menton. Other landmarks and diameters are used according to the interest of the investigator.

Krogman (1939) points out that normal growth of the face is continuous but not uniform; that different parts alternate in their velocity and intensity of growth. He reports that between birth and 6 years

growth is vigorous in all directions, as shown by the figures in Table 2.

TABLE 2

PERCENTAGE OF GROWTH AT VARIOUS AGES

	Age		
Dimension	*Birth*	*2 Years*	*5 Years*
Height	40	70	80
Breadth	60	80	85
Length	70	75	85

Davenport (1940) shows that, in relation to total face height, height of the nose increases most rapidly after birth, and height of the chin next. After 8 or 9 months postpartum he finds that the lower jaw builds up more rapidly than the upper until 2 or 3 years of age. Between 5 and 8 years growth is greater in the lower than in the upper facial measurements (Allen, 1948). From 6 to 12 years of age, according to Krogman (1939), growth occurs principally in height, least in length; from 12 to 20 years the increase is principally in length, and growth in breadth exceeds growth in height. Krogman states further that, in general, length and breadth growth precedes dentition and growth in height, and follows tooth eruption. Hellman (1933) notes that width is the largest dimension, height next, and length or depth least, and that between 5 and 22 years of age the largest dimension increases least and the smallest increases most. Hellman uses the gonion-menton diameter to measure length. He also comments that growth in height and length alternate and that increase in facial depth and width is more in the mandibular than in the zygomatic region and that increase in height is greatest in the ramus or posterior aspect of the lower jaw. Quoting Hellman (1933): "As children grow up . . . there is considerable loss of subcutaneous tissue and an increase in bony increment beneath it. In females the bony increment seems insufficient to make up for attenuation of the skin" (p. 1123). As a result girls beyond 16 or 17 years show no increase or an actual decrease in facial dimension. In boys the bony growth is greater and the growth trend is progressive.

Davenport (1940) finds that the interpupillary distance increases absolutely as the head enlarges but decreases relatively to bizygomatic width. He also notes that chin height increases differently in different individuals, probably under the influence of special glandular activities, and that the other elements of facial height also vary with individual differences in tooth and sinus development. Todd (1935) notes that generally growth of the female practically ceases at puberty but the male continues to grow for several years following puberty and that hence the majority of women have relatively smaller jaw growth. Although, absolutely, female facial dimensions are all smaller than those of the male, Hellman (1933) reports that the female face is relatively longer and that the male face is relatively deeper.

Many studies have noted the sensitivity of the transverse diameters of the face to disturbances of growth in early childhood. Boas (1911) finds a change in bizygomatic width of children transferred from Europe to the Lower East Side in New York. Bakwin and Bakwin (1931*c*) find that, relative to body length, infants with such diseases as eczema, tetany, and acute intestinal intoxication are smaller in bimolar and bigonial face widths than healthy infants from the same social environment. Broadbent (1937) also finds face growth affected by nutritional disturbances in childhood. In any individual instance, however, disturbances of growth are not easy to identify except by repeated measurements. The disturbances are imposed on inherited

growth tendencies, and to distinguish one from the other is not simple. It is not justifiable to conclude, for instance, that just because a child has a relatively narrow face he is suffering from malnutrition. With repeated measurements, abnormal growth trends can be recognized and, if it seems wise, remedial measures may be employed.

The relationship between facial growth and dentition is discussed under the section on dentition.

Skeletal Growth

Measurements of the external dimensions of the body, using skeletal landmarks, are gross measures of skeletal growth as far as size is concerned. Bone size and maturity, however, are not perfectly correlated. A child may be relatively small yet relatively mature; another child may be relatively large yet relatively immature. It is the differentiation and integration of the bony tissues which reveal the maturity aspect of growth. To understand the distinction it is necessary to review briefly the facts of bone growth.

Bony structure is originated by osteoblasts in either connective tissue or cartilage. The membrane bones of the face and cranium develop directly within the connective tissue, whereas the skeletal bones generally develop in the cartilage. Most bones, especially those formed in cartilage, have more than one center of ossification. In the human body there are over 800 centers of ossification, but half of them do not appear until after birth and centers continue to appear throughout the teens. Fusion begins as early as the eighth lunar month of fetal life and continues to middle age. At birth the infant has about 270 bones. The number increases to about 350 at puberty. This number increases, sometimes beyond the twenties, yet because of the fusion the final mature skeleton has only 206 bones (Arey, 1934). Certain long bones increase in size in the following manner: The cartilage increases in length, while progress in ossification takes place from the center, forming the diaphysis. Secondary ossification centers at the ends of the bone activate to form the epiphyses. When adult length is attained, cartilage proliferation ceases, but ossification continues, epiphyses and diaphysis unite and merge. Maturity is then reached (Arey, 1934, p. 339).

In 1896 the discovery of X-rays and their properties by Roentgen offered a means of studying the growth of the bony structure of the body in the living. Since then great advance has been made in standardization of the techniques of roentgenology and in the appraisal of bone growth. Hodges (1933) has published a most graphic and concise chart depicting the development of the human skeleton in general.

Psychologists have been most concerned with the hand-and-wrist ossification as an index of anatomical maturity. In normal development growth of the bones of the wrist and hand closely parallels general skeletal growth.. Pryor (1925) and others find sufficient lateral symmetry so that in general one hand only need be examined.

The literature up to 1935 is well reviewed by Flory (1936). The first methods of appraisal were naturally inspectional. Then, in an attempt at greater precision, measurement was resorted to. Baldwin, Busby, and Garside (1928) and others published figures for changes in area of the wrist bones from birth to 16 years and also computed anatomical indices which discounted for differences in wrist size. Flory (1936) and Todd (1937) each published an atlas of the osseous development of the hand with age standards. Wallis (1931) measured the width of the diaphysis and epiphysis of ulna and radius and used the

ratio of the two measures as an index of anatomical maturity. Both the above-cited publications noted great variability differences in time of first ossification of the carpal bones and warned against using this manifestation as an index of maturity. It is the consensus that matching with a standard series is the most reliable and predictive method of assessing maturity of ossification. According to Todd (1937),

> Maturity determinations in the skeleton are successional changes in outline of shaft ends and in contour of epiphysial ossification centers which mark the progress in skeletal maturation to its final adult form. Dates of appearance of ossification centers, whether in epiphyses or in short bones of wrist and ankle, are not maturity determinators. Like the features of the growing ends they are related to vitamin D activity [p. 40].

It is the different vulnerability of the different centers which causes different patterns of development. More specifically, Todd states:

> The principle of assessment is therefore the utilization of the most advanced centers, not the average of all, as a guide to actual bodily maturity. . . . In the hand it results in reservations on carpal bones and epiphysis of radius, eliminates epiphysis of ulna, and places greatest reliance upon metacarpal and phalangeal epiphyses [p. 15].

Flory (1936) gives very convincing figures to show that a skeletal age rating based on "bone appearance and development, epiphyseal appearance and development, and general developmental characteristics" in terms of a standard age scale is decidedly superior to evaluation in terms of total carpal area or in terms of ossification ratio (p. 105). If the age at which ossification in the hand is complete is used as a criterion of skeletal maturity, correlations with the criteria and carpal area are approximately .42 at 9 years, .48 at 11 years, .23 at 13 years, and .04 at 15 years, with PE's ranging between .06 and .08; correlations of ossification ratio (the area ossified in relation to a defined area of the wrist) with the criterion are approximately .52 at 9 years, .62 at 11 years, .40 at 13 years, and .33 at 15 years, with PE's between .04 and .08; correlations of skeletal months rating with the criterion are approximately .68 at 9 years, .75 at 11 years, .84 at 13 years, and .86 at 15 years, with a PE between .02 and .06. The greatest advantage of the skeletal age rating is at puberty. Skeletal age is comparable in many respects to mental age, and as such it is of value both in research and practice.

Todd (1937) gives 40 male standards and 35 female standards, spaced at not less than 6-month intervals, from birth up to 19 years. Flory's standards are 20 for each sex at yearly intervals from birth through 19 years. Both Flory and Todd accompany each standard with notes concerning the significance of its various characteristics.

Todd (1930) was enthusiastic in his evaluation of skeletal appraisal. He said:

> Wisely used record of differential maturity, combined with that of differential growth, throws light on vagaries of emotion, on problems of social adjustment, on failure in promotion and a host of problems that beset the teacher of the preadolescent grades 4–6.
>
> . . . Determinations of progress in physical maturation qualifying those of growth in stature and weight differentiate the outsized child, the subnormal child, the superior child of advanced physical development, the physical impress of malnutrition, of respiratory disorders such as hay fever and asthma, of the disharmonically progressing child who is a problem to himself

as well as to those responsible for his guidance and health.

Pyle and Menino (1939) have compared the Todd and Flory standards. They find a correlation of +.87 ±.03 between ratings based on the two standards for 50 unselected 3-year-old children. Skeletal age ratings according to Todd's atlas are more delayed in bone growth than according to Flory's atlas. The more frequent standard intervals of Todd's atlas are considered by Pyle and Menino "clearly advantageous for skeletal age assessments at all age levels below six years of age" (p. 34).

Pyle and others (1948) advocate indicating the degree of variability of skeletal ages of an individual rather than just a composite age. House (1950) found a normal variation of a year below and above the average value for 6-year-old children.

Although the appearance of ossification centers cannot be relied upon to judge maturity, they are sensitive indicators of nutrition. As such they must not be discarded in enthusiasm for the more stable growth phenomena. It is highly important from a psychological point of view to know of environmental disturbances. There is the possibility that they are related to fluctuations in behavior. Variability and probable age of appearance of the carpal bone and the radial and ulnar epiphyses as given by Flory (1936, p. 35) are reproduced in Table 3. The location of these bones in the wrist is shown graphically in Figure 7.

In spite of the general correlation between hand growth and body growth, Sontag, Snell, and Anderson (1939) claim that appraisal of the wrist and hand alone is not sufficient. Using roentgenograms of the left shoulder, elbow, wrist, hand, hip, knee, ankle, and foot, Sontag and his associates have established norms for thirteen ages from 1 month to 5 years. Their method reduces technical and subjective errors to a minimum. Elgenmark (1946) also finds that one cannot draw definite conclusions regarding ossification generally on the basis of a few isolated areas.

Francis and Werle (1939) charted the appearance of ossification centers for the skeleton in general from birth to 5 years. They give percentages of incidences of ossification separately for the sexes at birth, at 3, 6, 9, and 12 months of age, and at 6-month intervals thereafter. Age standards based on the 80 percentile are given for each ossification center. They conclude that

> The reason for variation in date of commencement of ossification and in its progressive development is not some obscure cause inherent in the germ plasm but the result of metabolic disturbance. . . . The centers of ossification appear in sheaves of miscellaneous composition but primary centers are more apt to be delayed in commencement of ossification than are centers appearing in epiphyses [p. 298].

Hill (1939) points out that

> In fetal life the record of maturity must depend largely on the appearance of centers since subepiphyseal surfaces are not yet defined and therefore cannot assist identification. . . . [But he also notes that] Because of the protection against nutritional maladies afforded by prenatal existence it may be expected that variability in date of appearance will not be as marked as in infancy [p. 251].

Using crown-rump length as a basis for classification and the 50 percentile as standard, Hill has charted the ossification of bone in fetal life, giving percentages of incidences of ossification for the ten lunar month ages. He also gives a list of stand-

TABLE 3 *

PERCENTAGE OF CHILDREN AT VARIOUS AGES WHOSE CARPAL BONES AND RADIAL AND ULNAR EPIPHYSES HAVE APPEARED

(Based on more than 6500 records)

* From Flory (1936, p. 35).

† The radial and ulnar epiphyses have been included here because Carter used both in determining the ossification ratio.

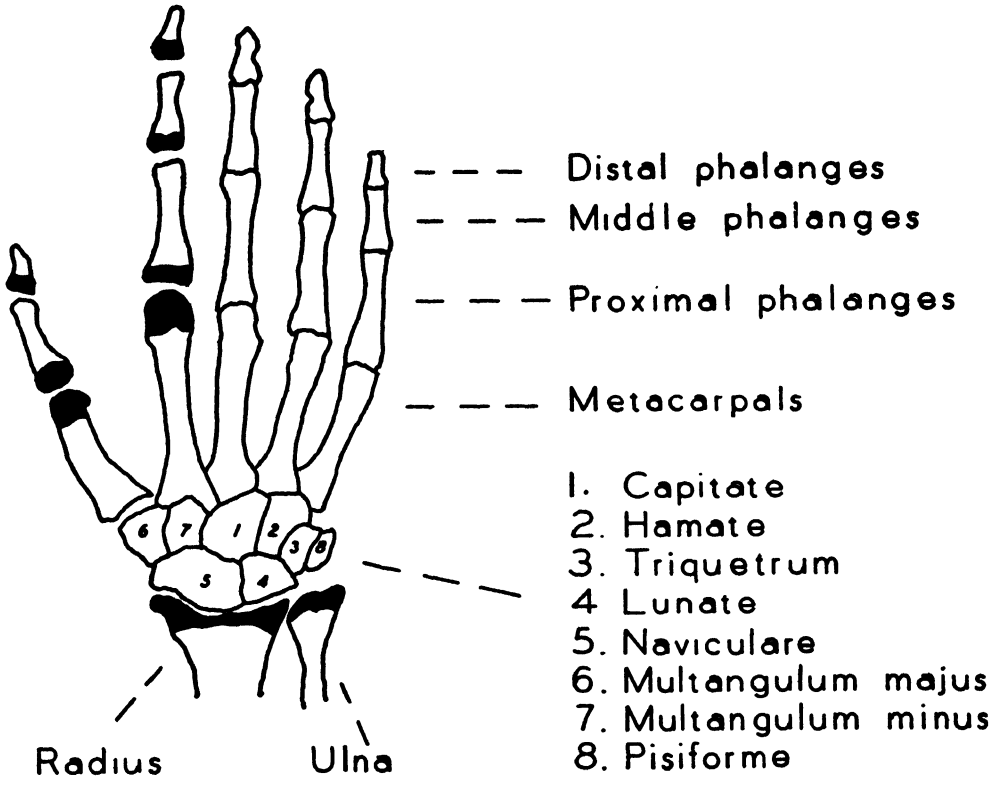

FIGURE 7. Diagrammatic drawing of the bones of the hand; epiphyses indicated by dark areas. (Adapted from H. Gray, in *Anatomy of the Human Body*. 21st ed., revised by W. H. Lewis. Philadelphia: Lea and Febiger, 1924, p. 230.)

ard degrees of ossification for these ages, basing his standard on the 50 percentile.

Sex Differences in Skeletal Growth

There is a well-defined sex difference in skeletal maturity which according to Flory's data gradually increases with age. There is a readily perceptible difference at birth, practically a year's difference at beginning elementary school age, and approximately a 2-year difference at high school entrance. This is consistent with sex differences in other aspects of physical growth. Female children, although smaller than male children of the same chronological age, are more mature and reach puberty earlier.

Hereditary factors may play a certain part in determining ossification rate. The correlation between deviations from the norm in ossification ratios are for brothers .62, for sisters .27, and for brothers and sisters .39 (Flory, 1936). Minor fluctuations in ossification rate tend to correct themselves in a year or two and should not be regarded too seriously. Variability in ossification maturity of children in general increases up to late adolescence, after which it decreases to the adult variability. Todd (1937) states that children from privileged homes are approximately 12 months ad-

vanced in ossification maturity and children from underprivileged homes are often 12 months retarded (p. 22). He also expresses the opinion that:

> A child retarded in maturity rating 12 months or more on our standards below his chronological age has experienced a setback in constitution from which he has not yet recovered even though he shows no signs of ill-health and neither parents nor physician can recall anything in the past history which would lead one to suspect constitutional disturbances [p. 15].

Child psychologists might profitably compare methods of bone maturity appraisal with methods of mental maturity appraisal. Can it be that a matching method such as the Gesell technique for appraising the preschool child is really a more reliable and valid technique in terms of prediction than a more exact and rigid measuremental method? Is the fact that Gesell has found a higher correlation between infant tests and mental development at later ages perhaps due to the superiority of his apparently less objective scale? Certainly the findings in the realm of skeletal growth should give child psychologists cause to reconsider more carefully the problem of behavior-maturity appraisal.

Dentition

The skeleton differentiates from the mesoderm, whereas the teeth develop from both mesoderm and ectoderm: enamel from the ectoderm and dentin; and dentine, pulp, and cement from the mesoderm. Teeth, hair, and nails are similar in that they all develop from skin tissue. Deciduous teeth are formed early in fetal life. The twenty enamel organs and their associated dental papilla of the deciduous teeth are present in the 10-week fetus; those for permanent molars are present at birth; those for the second molars at 6 months; those for the wisdom teeth or third molars are not found until the fifth year.

Eruption of deciduous teeth begins at about the age of 6 months; of the permanent teeth, at about 6 years. There is great variability in the time of eruption of deciduous teeth. Infants have been born with a tooth erupted, whereas children of 1 year of age may not yet have even a single tooth. Massler and Savara (1950) report that natal teeth occur once in 2,000 births; usually it is the lower central incisor, much more rarely the upper incisor. However, Meredith (1946*b*) estimates that only 1 per cent of white infants erupt their first tooth before 4 months of age and about the same percentage not until after 1 year of age; at 6 months one infant in three has at least one tooth erupted, and at 9 months the average infant has three teeth. Because of the great variability authors do not agree very precisely on the normal age of eruption. The ages given in Table 4 are approximations.

TABLE 4

DECIDUOUS TEETH: AGE OF ERUPTING AND SHEDDING *

Tooth	*Age of Erupting (Months)*	*Age of Shedding (Years)*
Median incisor	6–8	7
Lateral incisor	7–10	8
Canine	17–20	12
First molar	12–16	10
Second molar	18–24	11–12

* Modified from Arey (1934).

Teeth in the lower jaw usually erupt before the corresponding teeth in the upper jaw (Doering and Allen, 1942). There are very few data in the literature regarding sex differences in eruption ages for deciduous teeth. Study of the available data (Meredith, 1946) suggests that there is no

appreciable difference in the time of eruption of the first tooth but that, between 9 months and 2 years of age, males are more advanced than females.

Girls, however, are more precocious in shedding their deciduous teeth than boys, perhaps because the permanent dentition of females is more advanced at each age than the permanent dentition of males. Klein, Palmer, and Kramer (1937) give figures based on 4416 boys and girls at Hagerstown, Maryland, which are reproduced in Table 5.

TABLE 5

SHEDDING OF TEETH: NUMBER OF DECIDUOUS TEETH PRESENT

Age in years	6½	8½	10½	12½
Boys: Average number	16.9	11.4	6.0	1.3
Girls: Average number	16.0	10.6	4.3	0.8

Psychologists have been particularly concerned with the effect of thumb sucking on the primary teeth and the dental arch. Lewis (1937), from a study of models made yearly, finds that the type of thumb sucking most damaging to the shape of the arch is that in which the child holds the volar surface toward the palate. A child who persisted in thumb sucking until 3 years old, with resulting deformity, experienced a full correction of the deformity a year and a half after the habit was broken. Another child who broke the habit of sucking the right thumb at 9½ years showed subsequent improvement of the displacement and open bite. Cases where the habit was continued showed no self-correction. There were instances of thumb sucking with no resulting deformity; all such cases broke the habit between the first and second year.

Not only thumb sucking but also tongue pressures are considered important in the development of occlusion (Swinehart, 1950).

The eruption of permanent teeth begins with the eruption of the 6-year molar. The figures given by Klein, Palmer, and Kramer (1937) (Table 6) are derived from the percentage of children at successive ages who have the designated teeth erupted at the time of examination.

TABLE 6

AVERAGE ERUPTION AGE FOR THE PERMANENT TEETH *

Tooth	Upper Jaw (Years)		Lower Jaw (Years)	
	Boys	Girls	Boys	Girls
Central incisor	7.49	7.20	6.50	6.19
Lateral incisor	8.62	8.15	7.64	7.31
Canine	11.80	11.05	10.70	9.85
First premolar	10.42	10.00	10.75	10.20
Second premolar	11.18	10.82	11.45	11.00
First molar	6.64	6.54	6.44	6.12
Second molar	12.70	12.40	12.20	11.90

* Standard deviations range between 0.70 and 1.77.

With the exception of the first and second premolars, the teeth of the lower jaw erupt before the corresponding teeth of the upper jaw.

Hellman (1943) points out that there are two active periods of dentition with respect to the permanent teeth, separated by an interval of rest. The period of rest is from about 7 years 9 months to 10 years in females, and from about 8 years 4 months to 11 years in males.

The White House Conference data (1932, 1933) complete the story by giving the average age at which the third molars are beginning to erupt as follows: for boys, 18.59 years; for girls, 20.10 years.

Thus, with respect to permanent teeth, females are more precocious at least up to the teen ages, but by the end of the teens males are again more precocious.

The use of dental age has been suggested as an indication of anatomical maturity (Bean, 1914; Cattell, 1928). The wide variability in time of eruption of the teeth makes an assessment on that basis undesirable. Clinically, however, it is most important to include such an assessment as part of the total examination. As Krogman (1950) points out, problems in dental growth are evidence of more general organic problems.

There are certain ages when the teeth are particularly susceptible to metabolic and cellular disturbances, namely, the neonatal period, about 10 months of age, about 2½ years, and about 5 years of age (Massler, Schour, and Ponchar, 1941).

Naturally there is an intimate relationship between the growth of the face and dentition. The White House Conference (1932, 1933) summarizes three corresponding periods of development as follows:

> The first five years of life, during which the deciduous dentition is completed, and the most intensive antero-posterior growth of the face is taking place. The 10 years following, from 5 to 15, during which the deciduous dentition is shed, all but the third molars are erupted, and the most intensive lateral and vertical growth of the face is taking place. The 5 years following, from 15 to 20, during which the third molars erupt and residual vertical growth is still taking place in females and more intensive growth in males [Part 2, p. 143].

With the eruption and shedding of the first 20 teeth and the eruption of the 32 permanent teeth, together with the accompanying growth of the jaw, there are bound to be associated changes in occlusion. Hellman (1932, 1933) notes that the percentage of normal occlusion in a group of children drops from 70 per cent at 4 years to 22 per cent at 9 years and then gradually increases with age. However, some types of malocclusion are not self-corrective and need orthodontic care.

Normal growth changes in dentition bring many psychological problems. A few examples may be cited. If an infant is being nursed at the age when his first tooth erupts, he may hurt his mother's breast. Her reaction and his are important in establishing their relationship. Similar problems are encountered in the bottle-fed infant. In the older child, teeth used to bite others can become effective though undesirable weapons. If an infant is temporarily indisposed by the eruption of teeth and loses his appetite, this may cause maternal concern because he does not eat. Insistence on his eating may start feeding problems.

When teeth are lost, particularly front teeth, speech becomes difficult; children may be taunted. "All I want for Christmas is my two front teeth" may not be amusing to the 7-year-old! Malocclusion, likewise, is a source of psychological problems due either to unesthetic and malfunctioning teeth or to the uncomfortable and disfiguring corrective braces.

Although these problems are extrinsic to dental growth, they can be avoided or corrected only when normal dental growth changes are understood and considered. The psychological significance of the mouth as a medium of satisfying inner drives and of the teeth as a medium of expressing tension and aggression is surely of sufficient importance to warrant close study of their physical growth by the psychologist.

Conclusion

The physical growth changes discussed in this chapter relate principally to morphological changes which are the outward manifestations of more fundamental growth phenomena. This is a reflection of research interests, knowledge, available techniques

for measurement, and sources for research. There is a growing interest in the more physiological, the biochemical, and the electropotential changes with age (Jones, 1947; Sontag, 1947; Clark, 1948). These aspects of growth are more intimately related to functional changes and thence to behavior phenomena. Studied in this way, physical characteristics become as integral a part of an individual's personality as behavior traits. Then the problem of mental and physical relationships changes from an interest in a one-to-one relationship to an interest in a more analytic growth association.

CHAPTER 6

THE ONTOGENESIS OF INFANT BEHAVIOR

ARNOLD GESELL

Introduction

Ontogeny is the life history or development of an individual organism. This chapter will concern itself mainly with the first 2 postnatal years of the human life cycle and with that outward aspect of life which goes by the familiar name of *behavior*. Behavior is in a sense more than an aspect; it is the very essence and a culminating manifestation of the life processes of the individual, including the all-pervading process of growth. Biologically —or shall we say semantically—the infant is a growing action system. He comes by his "mind" in the same way that he comes by his body, namely, through the mechanisms of development. Our task is to formulate some of the general principles which underlie the developmental patterning of his total action system.

Comparative Considerations

The individual is a member of a species. His most fundamental behavior characteristics are those which are common to the species as a whole. Less fundamental are those which are peculiar to a breed or stock, differentiated within the species. Some patterns of behavior are so primitive that they are common to a wide range of species. The startle reflex, universal among infants and children, is also found in primates and among lower mammals in types as widely separated as bear and badger. The tonic neck reflex, which plays such a prominent rôle in the early ontogenesis of infant behavior, has been investigated in the rabbit as well as in man (Magnus, 1924). The lowly *Amblystoma* embodies generic patterns of terrestrial locomotion. This primitive vertebrate in the hands of Coghill (1929) has become a touchstone for elucidating problems of human behavior.

Infancy is the period in which the individual realizes his racial inheritance. This inheritance is the end product of evolutionary processes which trace back to an extremely remote antiquity. But infancy itself is a product of evolution. It was evolved not only to perpetuate a groundwork of racial inheritance, but also to add thereto a contingent margin of specific modifiability. In the more complex orders of life, such as fish, amphibian, reptile, bird, and mammal, the postnatal period of immaturity has become a recognizable part of the individual life cycle and plays an important part in the economy of that cycle. Infancy was evolved to subserve the needs of individual growth. It lengthens as the organism becomes more complex. It varies significantly among different species.

The study of infancy in its broadest sense must therefore be a comparative science. The most general laws of development will prove to be applicable to all vertebrates, not excluding either fish or man. In spite of the bewildering diversity of the behavior characteristics of widely varying species,

certain developmental sequences must be common to large groups and orders. Differences in gestation, longevity, size, and growth cycle yield to quantitative comparative study of correlated behavior characteristics. The findings of chemical embryology and of electro-chemistry suggest that there is a general physiology of development. There are far-reaching implications in the fact that the thyroid substance of ox or sheep will profoundly influence the ontogenesis of the behavior of a cretinous infant (Gesell, Amatruda, and Culotta, 1936).

It would take a lengthy syllabus to list and classify resemblances in the behavior of human and infrahuman species. Lashley and Watson (1913) made a valuable pioneering study on the development of a young monkey, reporting the age of appearance in a macaque of such behavior items as creeping, winking, eye following, walking, running, thumb opposition, and grasping. Boutan in 1914 compared adaptation in problem-solving situations of a gibbon and young child; and Yerkes in 1916 contrasted the behavior of a 4-year-old orangutan and a 3-year-old child in a problem-solving situation.

Jacobsen, Jacobsen, and Yoshioka (1932) and Kellogg and Kellogg (1933) each reported on the behaviorial development of a young chimpanzee and compared responses to infant tests in the four fields of behavior—motor, adaptive, language, and personal-social—with those of normal infants at the same ages. Experimental studies of form discrimination (Gellermann, 1933) and responses to problem-solving situations (Brainard, 1930) make direct comparisons between chimpanzees and pre-school children. A. W. Yerkes (1935) has explored the possibility of investigating problems of behavior in chimpanzee infancy.

Riesen and Kinder (1952) report a detailed study on the postural development of infant chimpanzees.

Madam Kohts (1935) compared the behavior of a male chimpanzee during the age period of ½ to 4 years with that of her son from birth to 4 years of age. She sums up her observations as follows:

> (1) In the functional biological field: the chimpanzee totally ignores the possibility of walking erect and of freeing his hands for carrying weights. (2) In the sphere of imitation: the chimpanzee is devoid of imitation in so far as human sounds are concerned and generally fails to extend or improve his imitatory behavior. (3) In respect of emotional, altruistic and social behavior: the chimpanzee fails to understand the advantages of friendly sympathetic intercourse with creatures standing on a lower biological level than himself. (4) With regard to habit-forming: the chimpanzee does not improve in the motor habits connected with the use of tools and household implements. (5) In the sphere of playful behavior: he does not indulge in creative constructional play.

On the basis of the foregoing evidence, Madam Kohts concludes: "It is impossible to say that he [the chimpanzee] is 'almost human'; we must go even further and state quite definitely that he is 'by no means human.'"

The comparative study of interspecies resemblances must be approached with critical caution, because many of the similarities are offset by important contextual differences. Similarities often are apparent when differences are hidden and profound. On evolutionary grounds one may expect the highest degree of resemblance in the ontogenesis of anthropoid and of human species. At no phase of the entire life cycle, however, are *Homo* and *Anthropos* the same. Human characteristics are not superadded as a late installment upon a lower primitive stage. They inhere in the very beginnings of fetal and postnatal behavior.

The pre-eminence of human infancy lies in the scope, the depth, and the duration of plasticity. There is a maturation of basic motor patterns as in subhuman species; but this proceeds less rigidly and the total behavior complex is suspended in a state of greater formativeness. This increased modifiability is extremely sensitive to social milieu. In the impersonal aspects of adaptive behavior of the nonlanguage type (practical intelligence) there is a high degree of early correspondence between man and other primates. Some of this correspondence is so consistent as to justify a phyletic and even recapitulatory explanation. Transcending and pervading the interspecies similarities, however, is a generalized conditionability or responsiveness to other personalities which is distinctively human.

Principles of Developmental Morphology

In the comparative study of behavior one cannot escape problems of pattern and form. When Goethe coined the word *Morphologie,* he was interested in the forms of flowers and skulls. To this day the term carries physical connotations. But the concepts of morphology can be extended to the phenomena of behavior. Morphology is the science of form. The dictionary reminds us that form is the shape of anything as distinguished from the substance of that thing. Behavior has shape.

The shapes which behaviors assume can be investigated in their own scientific right. A morphological approach leads to the description and measurement of specific forms, the systematic study of topographic relations and correlations of such forms, their ontogenetic progression and involution, their comparative features among individuals and among species.

"Structure is only the intimate expression of function" was a leading maxim of John Hunter. In a monistic (but not mystic) sense, "the mind" may be regarded as a living, growing "structure" even though it lacks corporeal tangibility. It is a complex, organized, and organizing action system which manifests itself in characteristic forms of behavior—in patterns of posture, locomotion, prehension, manipulation, of perception, communication, and social response. The action systems of embryo, fetus, infant, and child undergo pattern changes which are so sequential and orderly that we may be certain that the patterning process is governed by mechanisms of form regulation—the same mechanisms which are being established by the science of embryology.

Experimental embryology is now one of the most active and flourishing of all the life sciences. It has undertaken the analysis of development, particularly as it affects the anatomy of the organism. Investigators, however, are using functional and behavior criteria increasingly to define the somatic anatomy. This is natural, for, by the principle of hierarchical continuity, there is but one physiology of development. The growth of tissues, of organs, and of behavior is obedient to identical laws of developmental morphology.

It cannot, therefore, be doubted that the general physiology of mental development will find its deeper roots in the same scientific soil which is now intesively cultivated in laboratories of experimental embryology. Already many of the current morphogenetic concepts have more than value analogy to psychical processes: embryonic field, gradient theory, regional determination, autonomous induction, complementary induction, potency, polarity, symmetry, time correlation, etc. Associationism as a psychological tradition has come down from Aristotle and still has con-

siderable vitality, as shown by a prodigious preoccupation with problems of learning and the conditioned reflex. The laws of association deal with the factors of contiguity, assimilation, frequency, primacy, intensity, duration, context, acquaintance, maturity. Needless to say, these laws will some day be reformulated in terms of the biology and physiology of development. The full coordination of animal and child psychology will depend upon such reformulations.

Psychological growth, like somatic growth, is a morphogenetic process. It produces a progressive organization of behavior forms. Our scientific knowledge of this process is still very meager. We lack the grammar and the lexicon for defining form characteristics. We need morphographic as well as mathematical methods which will simplify and generalize form phenomena.

It is possible, however, to define several principles of development which have psychomorphological implications. These principles concern the shaping of the action system and its trends in oriented space and oriented time. The principle of *developmental direction*, for example, recognizes that the action system of the infant does not increase symmetrically like an expanding balloon but is subject to the far-reaching consequences of the biological factor of anteroposterior differentiation.

The very architectonics of the neuromuscular system determines not only a cephalocaudal course but also the relationships between paired and opposed motor organs. We shall propose a principle of *reciprocal interweaving* to characterize this aspect of behavior organization.

Laterality is distinctly a morphological phenomenon, in that it represents a form of dynamic asymmetry. It represents a significant principle of *functional asymmetry*.

During ontogenesis the total action system undergoes specific differentiation in restricted spheres. This orderly specification is governed by a principle of *individuating maturation*.

The growing organism is of necessity in a state of unstable and shifting equilibrium. Also, of necessity, it must restrict the modes and degrees of instability. The oscillations of the organism are self-limited by a principle of *regulatory fluctuation*.

A brief discussion of these five principles may serve to delineate some of the general features of the ontogeny of infant behavior. The several principles are not entirely absolute, and they certainly do not operate independently or in isolation. They overlap and modify each other in interesting and significant ways.

General Sequences of Early Behavior Growth

As a background for the discussion of the several principles of development it will be profitable to take a panoramic glance at the whole domain of behavior development in the first 5 years of life. This domain can be envisaged as four major fields of functional organization: (1) motor behavior, (2) adaptive behavior, (3) language behavior, (4) personal-social behavior.

1. Motor characteristics include postural reactions, prehension, locomotion, general bodily coordination, and specific motor skills.

2. Adaptive behavior is a convenient category for those varied adjustments—perceptual, orientational, manual, and verbal—which reflect the child's capacity to initiate new experience and to profit by past experience. This adaptivity includes alertness, intelligence, and various forms of constructiveness and exploitation.

3. Language embraces all behavior which has to do with soliloquy, dramatic

expression, communication, and comprehension.

4. Personal-social behavior embraces the child's personal reactions to other persons and to the impacts of culture; his adjustments to domestic life, to property, to social groups, and to community conventions.

These four major fields of behavior comprise most of the visible patterns of child behavior. They do not, of course, fall neatly into separate compartments. The child always reacts as an integer.

Elsewhere the writer and his collaborators have summarized the ontogenetic trends of development in the four behavior fields at ten age levels from 4 weeks to 5 years (Gesell, Halverson, Thompson, *et al.*, 1940, Chapters III, IV).

Figure 1 depicts the trends and sequences of early behavior growth. The chart includes the fetal period to indicate the continuity of the growth cycle. The ontogenetic organization of behavior begins long before birth. The general direction of this organization is from head to foot, from proximal to distal segments, and from fundamental to accessory control. Lips and tongue lead, eye muscles follow, then neck, shoulder, arms, hands, fingers, trunk, legs, feet. The chart reflects this law of developmental direction; it also suggests that the four distinguishable fields of behavior develop conjointly in close coordination. The motor field of development presents the most evident and extrinsic continuity between the prenatal and postnatal periods (Gesell and Amatruda, 1941).

In terse terms the trends of behavior development are:

In the *first quarter* (4–16 weeks) of the first year the infant gains control of his twelve oculomotor muscles.

In the *second quarter* (16–28 weeks) he comes into command of the muscles which support his head and move his arms. He reaches out for things.

In the *third quarter* (28–40 weeks) he gains command of his trunk and hands. He sits. He grasps, transfers, and manipulates objects.

In the *fourth quarter* (40–52 weeks) he extends command to his legs and feet; to his forefinger and thumb. He pokes and plucks. He stands upright.

In the *second year* he walks and runs; articulates words and phrases; acquires bowel and bladder control; attains a rudimentary sense of personal identity and of personal possession.

In the *third year* he speaks in sentences, using words as tools of thought. He shows a positive propensity to understand his environment and to comply with cultural demands. He is no longer a "mere" infant.

In the *fourth year* he asks innumerable questions, perceives analogies, displays an active tendency to conceptualize and generalize. He is nearly self-dependent in routines of home life.

At *five* he is well matured in motor control. He hops and skips. He talks without infantile articulation. He can narrate a long tale. He prefers associative play; he feels socialized pride in clothes and accomplishment. He is a self-assured, conforming citizen in his small world.

The Principle of Developmental Direction

The principle of developmental direction is reflected in the foregoing summary of developmental trends. The phenomena of polarity and of gradients (electrochemical and otherwise) underlie this principle. The direction of early embryonic growth is determined by the longitudinal gradient of the mesoderm. This gradient governs alike the course of somatic organization and that of behaviorial organization. In the growth of the fetus there is an unmistakable precocity in the development of the anterior end of the organism. At the close of the second fetal month the height of the head rivals the length of the trunk, and the

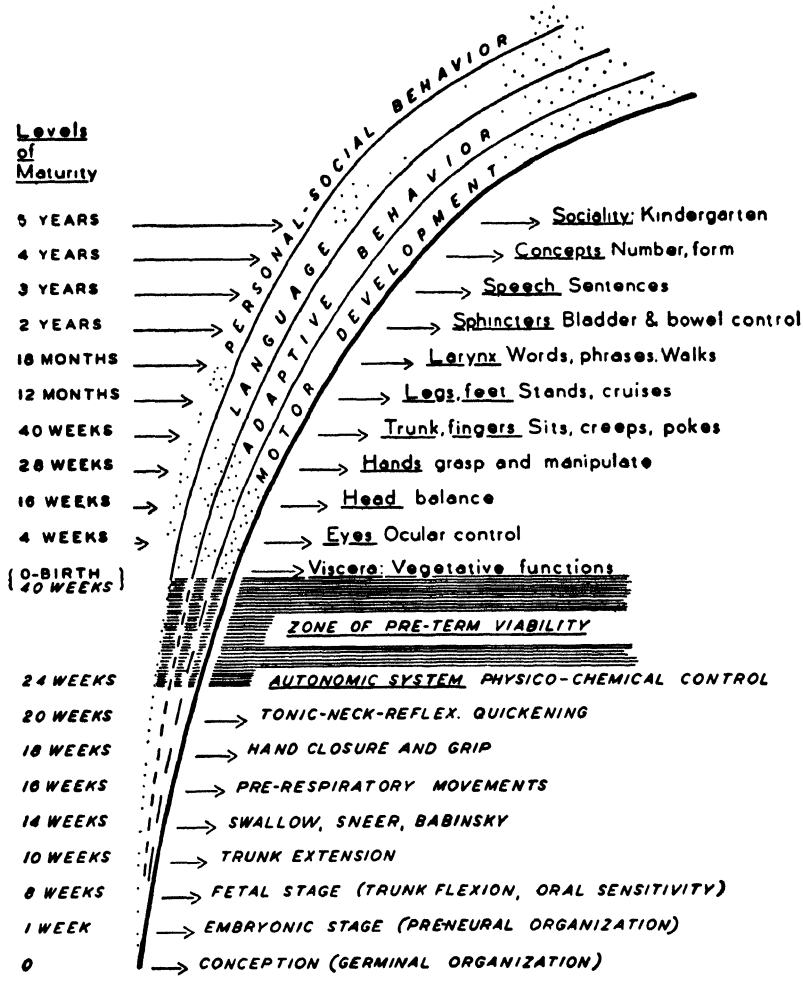

FIGURE 1. Ontogenetic trends and sequences of behavior growth. (From *Developmental Diagnosis: Normal and Abnormal Child Development,* by A. Gesell and C. S. Amatruda. New York: Paul B. Hoeber, 1947, p. 9.)

umbilicus is at the level of the cervical vertebrae. The posteriorward migration of the umbilicus is a reflection of the cephalocaudad trend. This trend, however, must not be taken too literally, for the caudad appendage of the embryo, which was prominent in the middle of the second month, is already beginning to regress at the end of that month.

There are many apparent exceptions to the directional rule which do not, however, impair the validity of the general principle. Some of the exceptions arise out of the fact that there are successive head-to-foot

sweeps of development so that the trend repeats itself at certain periods appropriate to the ascending levels of organization. We thus expect to find cyclical evidence of the trend in the preneural as well as in the neural stage and in late as well as early stages of infancy.

The principle is well illustrated in the behavior characteristics of the 20-week-old infant. His trunk is still so flaccid that he must be propped or strapped in a chair to maintain a sitting posture. When he is so secured, however, his eyes, head, and shoulders exhibit heightened activity and intensified tonus. The pelvic zone and the lower extremities at 20 weeks are, in comparison, very immature.

Evidence of the cephalocaudad trend will be seen in a later summary of the ontogenetic sequences of prone behavior patterns. The very fact that this sequence converges toward and culminates in the assumption of the erect posture suggests the presence of a unidirectional principle. The principle does not operate with complete simplicity, however, because the mastery of the erect posture depends in turn upon the development of the functions of equilibrium which have a cephalic as well as a caudad status.

Just as neuromotor organization proceeds from head to foot in the direction of the longitudinal axis, so it tends to proceed from the central to peripheral segments. The fundamental axial muscles are among the first to react in a coordinated manner, as shown by the primitive body flexion of the fetus. There is a progressive advance of motor control from the larger, fundamental muscles to the smaller muscles which execute the more refined movements. This trend from fundamental or proximal to accessory and distal control is illustrated in the ontogenesis of postural attitudes, of prehensory approach, manipulation, and prone locomotion.

During the earlier periods of development the arms and also the legs tend to react as wholes, the impulses arising mainly from the shoulder and the pelvic girdles. With advancing maturity, mobility asserts itself at the elbow and wrist joints and at the knee and ankle joints. Forearm, foreleg, hand, and foot show specific segmental activity. The cephalocaudad and the proximal-distal trends overlap and correlate. For this reason, independent activity of the distal segments becomes apparent in the upper extremities before the lower extremities. In the field of prehension, as Halverson (1933) has pointed out, from 16 weeks on, the elbow and digits participate in reaching movements with increasing effectiveness, until at 40 weeks they closely approximate the shoulder in efficiency, whereas trunk and wrist remain functionally retarded.

In the ontogenesis of prehension there is not only a proximal-distal trend but also an ulnar-radial shift. This shift is closely bound up with the growth of thumb opposition. At 20 weeks a crude palmar grasp, often favoring the ulnar aspect of the palm, is evident; but after 28 weeks there is an obvious preference for radial as opposed to ulnar grasp and manipulation. The developmental shift from ulnar to radial grasp is so strong that the infant actually displays a well-defined intolerance as well as motor rejection when an object is pressed against the ulnar aspect of the palm. At 40 weeks he extends his index finger and makes oblique radial approach upon objects which require precise prehension. He brings the volar pad of the thumb against the volar pad of the index (Gesell and Halverson, 1936).

The operation of the cephalocaudad principle in relation to other developmental principles is further illustrated in the sum-

mary of the ontogenetic sequence of the prone behavior of the human infant, summarized in Table 1.

The Principle of Reciprocal Interweaving

It is natural that the metaphor of the loom should constantly reappear in the description and interpretation of the developmental process. The products of growth are envisaged as a fabric in which threads and designs are visible. Even at the molecular level the analogy of warp and woof becomes helpful. Wrinch conceives the chromosome as a structure constituted of two elements: long filaments of identical protein molecules in parallel, and a set of ringlike nucleic acid molecules surrounding these filaments and holding them together in a wooflike manner. From such an arrangement and the asymmetric constitution of biomolecules, fabric issues.

The bilateral nature of the anatomy of the human physique and of its musculature suggests that the balance and opposition of its paired organs need to be interrelated in an orderly manner during the long period of ontogenesis. Even single members are bilateral or bivalent in the sense that they have both flexor and extensor activators. Accordingly, in the four-limbed infant there are many double aspect structures (and functions) to be coordinately interwoven: anterior bilateral, posterior bilateral, ipsilateral, crossed lateral, flexor, and extensor.

Flexion and extension are the most fundamental components of muscular movement. Sherrington (1906) has formulated a law of "reciprocal innervation" which shows the functional relationhips of these components in the counteraction of antagonistic muscles. The inhibition of one set of muscles while the opposing muscles are in excitation is a condition for effective movement. Reciprocal innervation is a mode of coordination, a physiological mechanism.

In the ontogenesis of the neuromotor system a complicated integration must likewise be achieved between antagonistic muscles. Appropriate structures for subserving inhibition must be progressively provided. There is a mode of growth which asserts itself in a developmental fluctuation of dominance in flexors versus extensors and also in unilateral and crossed lateral versus bilateral muscle groups. Inasmuch as behavior patterning and structural growth are intimately correlated, we shall describe this developmental principle or mechanism as a reciprocal interweaving process.

Neurologically, this process implies an intricate cross-stitching or involuted interlacing which organizes opposing muscle systems into reciprocal and increasingly mature relationships. Functionally, such a process results in a progressive spiral kind of reincorporation of sequential forms of behavior.

These phenomena of fluctuating dominance and of progressive reintegration can be advantageously studied in the development of prone behavior in the human infant, because the prolongation of human infancy widens the scope and lengthens the cycle of observable motor development. It takes the average infant a full year to acquire the upright posture. We have distinguished at least twenty-three stages in the patterning of the prone behavior which evenuates in standing and walking (Gesell and Ames, 1940). From the standpoint of ontogenesis these stages may be envisaged as a series of postural transformations whereby the infant by slow but sure sequence finally achieves the upright posture. None of the stages or patterns can be dismissed as being merely recapitulatory or vestigial. Each stage, however transient,

TABLE 1

Developmental Stages of Prone Behavior in the Human Infant

(The age at which a given action pattern typically makes its appearance is indicated in parentheses.)

Flexor Dominance	Extensor Dominance
1. *Passive kneel* (1 week) Both arms and both legs are *symmetrically* and sharply *flexed*. Cheek contacts platform, or head may be everted.	
	2*A*. *Passive leg extension* (4 weeks) The legs passively assume a *symmetric extended* posture. Arms still *flex*, fists at shoulders. Head lifts slightly less than 45°.
2*B*. *Active kneel* (about 4 weeks) Infant spontaneously draws up one knee at a time by (*unilateral*) *flexion*.	
	3*A*. *Active leg extension* (8 weeks) Legs actively assume a *symmetric extended* posture. Arms *flex* slightly forward.
3*B*. *One-knee thrust* (about 8 weeks) Infant draws up one knee by *flexion* with an abducted thrust (*unilateral*). Head lifts from 45 to 90°.	
	4*A*. *Alternate extensor kick* (12 weeks) Infant lies with legs well *extended* and kicks in *alternation*. Fists at temples. Head lifts slightly.
4*B*. *Abducted one-knee thrust* (about 12 weeks) Infant draws up one knee by *flexion* with increased abduction (*unilateral*). Head lifts 45 to 90°.	
	5. *Swimming* (16 weeks) Back arches so that infant's weight rests only on abdomen and lower chest. Arms lift, *flexed symmetrically*. Legs lift, in *symmetric extension*. Head lifts 90°.
6. *Simultaneous low creep* (20 weeks) Both arms and both legs are *flexed symmetrically*. Face and chest contact the supporting surface but abdomen is lifted.	
	7. *Frogging* (24 weeks) Arms are *flexed or extended symmetrically*. Legs are *extended symmetrically* in abduction, feet everted. Head lifts 90°.

TABLE 1 (*Continued*)

Flexor Dominance	Extensor Dominance
8. *Advanced unilateral knee thrust*	
9. *Same with foot eversion* (28 weeks) Both arms *extend symmetrically*, or one *extends* and one *flexes*. Infant draws up one knee by *flexion* with an abducted thrust. (9) Same except that foot is everted. Head lifts 90° or more.	
	10. *Pivoting* (29 weeks) Arms alternately *flex and extend*, one after the other, causing trunk to pivot on abdomen. *Symmetrical* leg extension is followed by forward *flexion* of one knee, in abduction. Head lifts 90° or more.
11*A*. *Inferior low creep* (30 weeks) Arms *flex symmetrically*. One knee flexes forward in adduction. Other knee then *flexes* forward after heel has rotated outward. Weight rests on side of body. Head everted, cheek on platform.	
	11*B*. *Backward crawl* (31 weeks) Legs *extend symmetrically* and passively and abdomen rests on the supporting surface. Infant pushes body backward from *symmetrically flexed* arms which come to extension as body pushes away from them. Head lifts less than 90°.
12. *Low creep* (32 weeks) Both arms are *flexed symmetrically*. Legs *flex* forward in adduction, *one at a time*. Face and chest contact supporting surface but abdomen is lifted.	
	13*A*. *Crawling* (34 weeks) Legs *extend symmetrically* and are dragged forward passively. Infant pulls trunk forward by *extending*, then *simultaneously flexing* both forearms. Head lifts 90° or more. 13*B*. Later (34½ weeks) pulls weight forward by *extending* and then *flexing* forearms *one at a time*.
14. *High creep* (35 weeks) Both arms are *extended* and both legs are *flexed symmetrically*. Knees are forward under trunk in adduction, lifting abdomen and chest from supporting surface. Head is well up from floor and eyes look ahead.	
	15. *Backward creep* (36 weeks) Infant is in the high creep position. *Extends* first one leg then the other, lowering abdomen and falling backward. Arms are *flexed symmetrically*.

TABLE 1 (*Continued*)

Flexor Dominance	Extensor Dominance
16. *Rocking* (about 36 weeks) Arms *extend symmetrically* and both legs are *flexed symmetrically*. Knees are forward under trunk, lifting abdomen and chest from supporting surface. Infant rocks back and forth, remaining in one location.	
	17. *Creep-crawl* (37 weeks) In high creep position, both arms *extended* and both legs *flexed*. Falls forward, both legs coming to *extension*. Arms *extend* forward and infant attains high creep position again. Progresses in this fashion.
18. *Creeps* (40 weeks)	
19. *Creeps, near step one foot* (42 weeks) Both arms extend downward from shoulder, then *extend* forward, *alternately*. Legs *flex* forward, *alternately*. Arm and leg on opposite sides of body move simultaneously.	
	20. *Creeps, step with one foot* (45 weeks) Arms *extend* forward *alternately*. Legs move forward *alternately, one flexed, one extended.*
	21*A*. *Plantigrade position* (49 weeks) Arms and legs both *extend* downward.
	21*B*. *Plantigrade progression* (49½ weeks) Arms and legs *extend* forward, *alternately;* left hand and right foot moving at same time.
	22. *Standing* (56 weeks) Trunk upright. Arms and legs *extend bilaterally.*
	23. *Walking* (60 weeks) Arms and legs both *extended*, move *alternately.*

appears to be a necessary feature of developmental mechanics, because of the numerous motor relationships which must be coordinated, that is, reciprocally interwoven. The upright posture ultimately involves a permanent preponderance of the extensor systems, but it is attained only after a long series of preparatory coordinations.

Table 1 [1] summarizes the distinguishing features of twenty-three developmental stages, with special reference to abduction, adduction, bilaterality, unilaterality, ipsilaterality, and crossed laterality. The left-hand column lists the stages in which flexor characteristics predominate; the right-hand column lists "extensor" stages. The dis-

[1] This tabulation outlines what may be regarded as an ideal sequence of stages. Every one of the stages has been observed in a number of children but not all the stages have been observed in all the children. For example, in 20 cases under observation from 6 months to 1 year, 93.5 per cent of all possible stages were observed, that is, 262 stages out of a possible 280 (Ames, 1937). A few of the stages listed in the table are almost evanescent, but they cannot be excluded from a complete outline of the ontogenetic sequence.

tinctions are based on a careful cinemanalysis of research records. The entire gamut of stages is depicted in a silent film entitled *Prone Progression in the Human Infant* (Gesell, 1938a).

The Total Developmental Sweep. Inasmuch as the patterning of prone behavior affords us a slowed-motion glimpse into the very ordering of development, it is profitable to take a panoramic view of the entire pageant of stages. The nature of this developmental flow can be best appreciated when contemplated in its totality. The infant has four extremities. Viewed in ample perspective, the action patterns of these extremities do not assume a straight-line seriation. The course of development turns on itself in a manner to suggest a spiral kind of neuromotor organization characteristic of reciprocal interweaving. When the movements of arms and legs are charted on a maturity grid, the significance of this "spiral" recurrence becomes apparent (Figure 2).

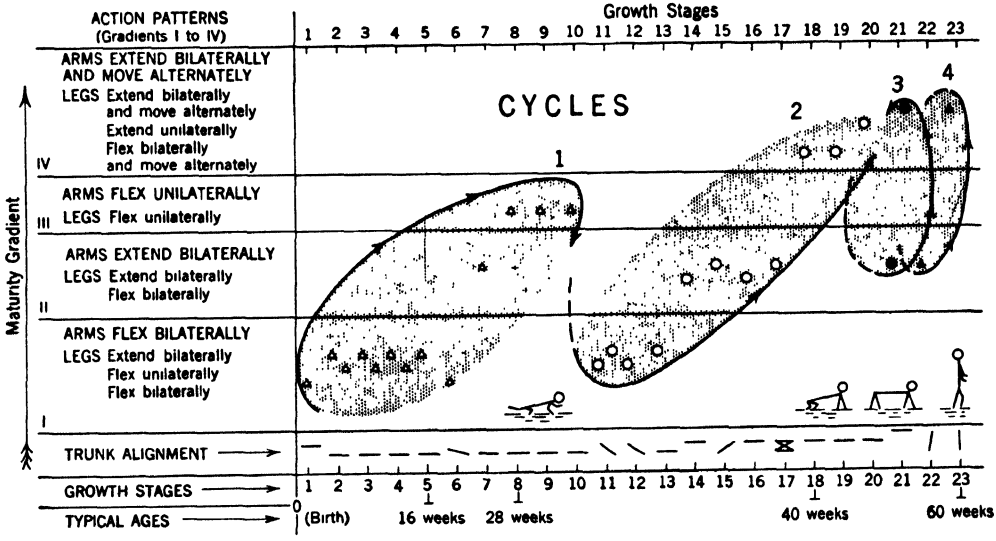

FIGURE 2. Growth cycles in the patterning of prone behavior.

The infant's prone behavior progresses from an immature to a more mature state, but three or four times it partially reverts to a less mature state. In the first ten stages the infant advances from a primitive bilateral flexion of arms and legs to unilateral flexion of arms and legs, unilaterality signifying greater maturity. The trunk remains throughout in primordial contact with the ground surface. But in the last of these ten stages (pivoting), the infant is able to use his upper extremities for circular locomotion and extrication. This terminates the first of four developmental cycles.

The second cycle entails the elevation of the trunk above its prostrate position. In accomplishing this new adjustment, the arms revert temporarily to their primitive posture of bilateral flexion, but the developmental patterning proceeds unabated even though in the crawling stage (stage 13) the trunk relapses to a groveling level. At stage 18, arms are extended forward

bilaterally, legs are flexed bilaterally, and each pair of limbs moves alternately. This is classic creeping which all but terminates the ontogenetic sequence. Stages 19 and 20 are transitional to upright posture.

To achieve the exalted status of bipedal locomotion the developmental spiral takes two more short turns at ascending levels, constituting the third and fourth cycles. In both these short cycles there is a partial reversion to immobile bilateral extension, namely, in the plantigrade stance and in standing. Each cycle, however, culminates in locomotion; the third cycle, in plantigrade progression; the fourth, in walking. It takes the average human infant about 60 weeks to attain independent walking. For a half year he is virtually immobile in the prone position. Before he acquires the upright posture he exhibits a number of primitive and abortive modes of locomotion: rolling, pivoting, forward crawl, backward crawl, regression, rocking, creep-crawling, creeping, and cruising. The very diversity of these activities testifies to the complexity of the process of developmental patterning. Some of the patterns have a recapitulatory suggestion, but they may be mainly regarded as functional expressions of transient but necessary stages in the organization of the neuromotor system.

The general direction of this ontogenetic organization is unmistakably cephalocaudal. The infant can lift his head in the first week of life; not until the end of the first year does he stand on his feet. The expansion of his neuromotor coordination also proceeds in general from proximal to distal segments. Upper arm and upper leg come into postural integration before forearm, foreleg, hands, and feet. The foot is both a caudal and distal terminus, the final fulcrum for locomotion. These directional trends are simple when compared with the intricate interweaving which is essential for functional organization.

Development of Handedness. Detailed long-range studies of the development of handedness in individual infants and children make it evident that the principle of reciprocal interweaving is well exemplified in this field of ontogenesis. Two pairs of opposing trends appear to be in mutual rivalry: bilaterality vs. unilaterality, and right vs. left. This gives rise to many inflections and combinations. These trends are probably not in actual conflict or in true competition but in developmental flux.

In brief, the course of behavior in a right-handed subject in the seated position is typically somewhat as follows (Gesell and Ames, 1947): contact of object unilateral and with the left hand, 16–20 weeks; bilateral contact at 24 weeks; unilateral, usually right hand at 28 weeks; bilateral at 32; unilateral through the rest of the first year with now right, now left, predominating; right-hand dominance 52–56 weeks; marked interchangeability with considerable use of both hands or of left hand at 80 weeks; right hand at 2 years; considerable bilaterality from 2½ to 4 years; right-handedness in general predominating from then on through 10 years.

Directionality of Drawing. Studies of the drawing behavior of preschool children as they copy simple forms indicate that the child's drawing products as well as his actual movements frequently illustrate the developmental mechanism of reciprocal interweaving (Gesell and Ames, 1946). Opposed trends in the child's drawing of a circle are: (*a*) drawing clockwise and drawing counterclockwise, (*b*) starting at the top and starting at the bottom. At 30–36 months of age, the child characteristically draws a circle counterclockwise, starting at the top. At 42 months, clockwise starting at the bottom. At 48 months, counterclockwise, starting at the top. A 60 months, clockwise starting at top or bottom. At

72 months and following, counterclockwise starting at the top as does the average adult.)

Visual Behavior. The principle of reciprocal interweaving has proved to be of special significance in the ontogenesis of visual behavior. Human vision is an extremely complex function and does not by any means develop in a uniform, straight-line manner. This development involves complicated interwoven relationships which bring into reciprocal balance the numerous opposed functions of the total visual act. The patterning of vision is thus greatly influenced by the current maturity status of the organism. Developmental optics may be defined as the study of the organization of the visual functions in their dynamic relation to the ontogenesis of the action system.

The eyes take the lead in the conquest and manipulation of space. The baby takes hold of the physical world ocularly long before he grasps it manually. He can pick up a pellet (7 mm. in diameter) with his eyes full 20 weeks before he picks it up with his fingers.

Although an infant stares vaguely into faraway space, his structured visual world begins in the near vicinity of his eyes. For him the space-world is not a fixed, static absolute. It is a plastic domain which he manipulates in terms of the nascent powers of his growing action system. The supine infant, the runabout infant, the sedentary school child, each has his own space-world with a distinctive set of planes of regard. Biological space is a function of the organism. The space-world of the myope differs from that of the hyperope. Every child organizes his space-world in obedience to laws of development, general for the species and unique for himself.

This organizational process operates in three basic functional fields: skeletal, visceral, and cortical. These fields are correlated with the three primary embryological divisions and with the conventional fixation-focus-fusion triad. The *skeletal* component of this functional complex seeks and holds a visual image (optical stimulus); the *visceral* component discriminates and defines the image; the *cortical* unifies and interprets it.

The three functional fields develop conjointly but by no means uniformly. The ratio between skeletal, visceral, and cortical manifestations varies with advancing stages of maturity. In the course of individual development, gradients of performance are built up concurrently but unevenly in the three basic functional fields. Four factors enter into these gradients: (1) *coordination,* which refers to the teaming of the eyes and right-vs.-left dominances; (2) *reach,* which refers to the distance and precedence of the planes of regard; (3) *scope,* which concerns the important relationships between central and peripheral vision; (4) *drift,* which denotes the growth trends signified by the break and recovery span of ocular ductions, the preferred zones of regard, and accommodation and dominant directionalities.

All these variables and gradients are subject to the organizing processes of growth. Accordingly, each age of infancy and childhood affords a distinctive constellation of visual behavior patterns. With so many components and variants entering into the functional complex of the visual system, it is natural that no two children should see exactly alike. The possible constellations of visual components, normal, atypical, and abnormal, are beyond enumeration. The individual variations, however, are governed by a general ground plan of ontogenetic development (Gesell, Ilg, and Bullis, 1949).

Ontogenesis involves many counterpoised functions which must be brought into reciprocal control: peripheral vs. central vision; near vs. far fixation; skeletal vs. visceral adjustments, etc. The developmental resolution of such opposites is accomplished through a reciprocal type of organization.

This ontogenetic principle is so far-reaching that it may be stated in the form of a law as follows:

The organization of reciprocal relationships between two counteracting functions or neuromotor systems is ontogenetically manifested by somewhat periodic shifting of ascendancy of the component functions or systems, with progressive modulation and integration of the resultant behavior patterns.

The Principle of Functional Asymmetry

The principle of functional asymmetry is a special inflection of the principle of reciprocal interweaving and is inseparable therefrom. Bilateral and ipsilateral members must be brought into parallel and diagonal coordination. This takes an enormous amount of dovetailing, which is accounted for by the principle and process of neuromotor interweaving.

But man, in spite of his bilateral, construction, does not face the world on a frontal plane of symmetry. He confronts it at an angle, and he makes his escapes, also, obliquely. He develops monolateral aptitudes and preferences in handedness, eyedness, footedness, and other forms of unidexterity. Perfect ambidexterity, if it exists, would seem to be almost an abnormality, because effective attentional adjustments require an asymmetric focalization of motor set. The behavioral center of gravity always tends to shift to an eccentric position. Unidexterity of hand, foot, or eye does not so much represent an absolute difference in skill as a predilection for stabilized psychomotor orientations.

These orientations are fundamentally postural sets; and they are asymmetric. Ideally reciprocal interweaving operates to preserve harmony and balance; but in actuality there is a superadded ontogenetic deflection to insure the greater efficiency of functional asymmetry.

The tonic neck reflex (t.n.r.) is an asymmetric pattern of behavior, common to man and beast. Magnus, in his classic work, *Körperstellung*, reported an analysis of the postural reaction of decerebrate quadrupeds when their heads were experimentally turned to an extreme right or left position. He found a characteristic response: (1) extension of the forelimb on the side toward which the head was turned; (2) flexion of the opposite forelimb. The reflex occurred in pure form when the labyrinths were extirpated, and it was ascribed to proprioceptive impulses arising in the neck from torsion.

Magnus (1924, 1925) demonstrated the existence of the tonic neck reflex in idiots and patients suffering from extrapyramidal tract lesions; he was unable to induce the reflex in 26 normal infants a few hours to 16 weeks of age. He came to the conclusion that in man the tonic neck reflex is a pathologic phenomenon.

This conclusion is somewhat amazing because we have found the tonic neck response a ubiquitous, indeed a dominating, characteristic of normal infancy in the first 3 months of life. In a clinical sense the response should be regarded as abnormal only when it occurs in children of more advanced age who are suffering from arrest or damage of the central nervous system. In our normative survey of the ontogenetic

sequences of behavior pattern, 26 to 49 infants were examined at lunar-month intervals up to the age of 56 weeks (Gesell and Thompson, 1934, 1938). It is a remarkable fact that 100 per cent of the infants at 4 weeks of age, when observed in a free supine posture, spontaneously maintained the cephalic symmetry displaces tonic neck asymmetry. The ontogenetic trends which underlie these transformations of postural pattern are plotted in Figure 3.

The accompanying illustrations show that this attitudinal pattern is clearly evident in the spontaneous waking postures of the

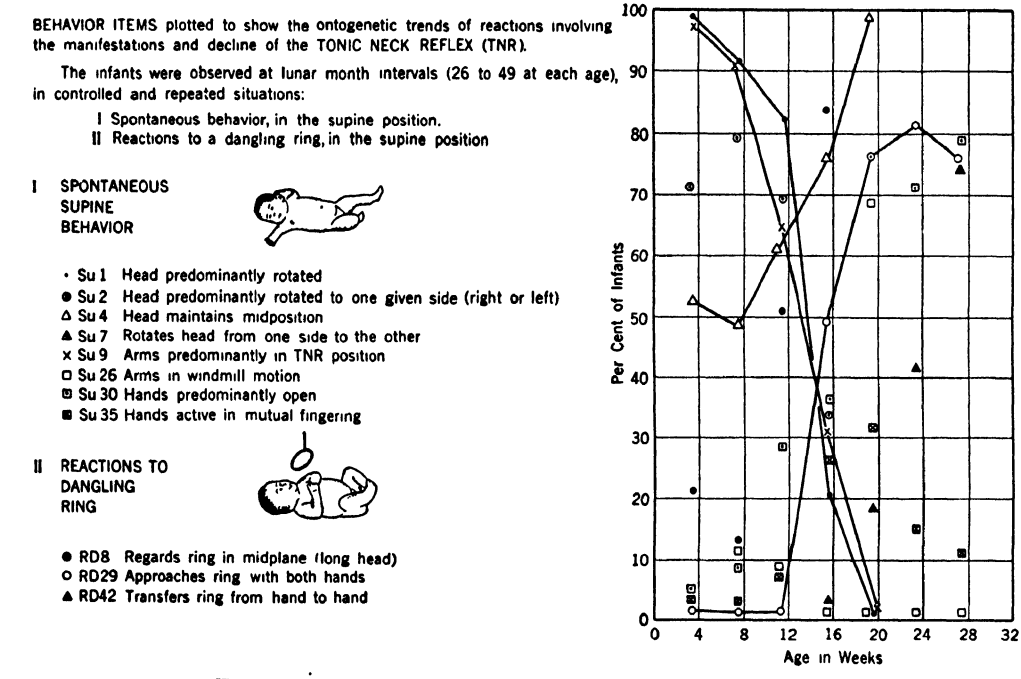

FIGURE 3. Ontogenetic trends underlying tonic neck reflex.

head predominantly rotated to one side; 100 per cent likewise held their arms in characteristic t.n.r. attitudes. We conclude that the t.n.r is a normal and virtually universal feature of neonatal infancy. Indeed, for 8 weeks the t.n.r. holds strong sway; at 12 weeks it is less conspicuous; at 16 weeks it is in transition; at 20 weeks in eclipse, for at 20 weeks 100 per cent of our normative infants maintained the head in midposition. And when the head is predominantly held in midposition, at least one-half of each t.n.r. subsides, and tonic normal infant, whether he lies quiescent or active. Figure 4 illustrates t.n.r. in a rabbit and in a normal infant. The rabbit is adapted from Magnus; the infant is a healthy 8-week-old subject basking in the soft light of the photographic dome. Both are in the right t.n.r. Figure 5 pictures two normal infants, both 6 weeks of age. One is in right t.n.r. and the other in left t.n.r. In each instance the face-arm and face-legs are in extension, the contralateral extremities in flexion. Note the striking semblance to a fencing stance. Figure 6

shows a normal infant who at 1, 6, 8, and 12 weeks of age spontaneously and consistently exhibited a right t.n.r.

Figure 7 pictures the same infant at 24 weeks of age. The spontaneous asymmetry of the earlier ages has been superseded by a symmetric attitude in which both arms flex and the hands engage above the chest

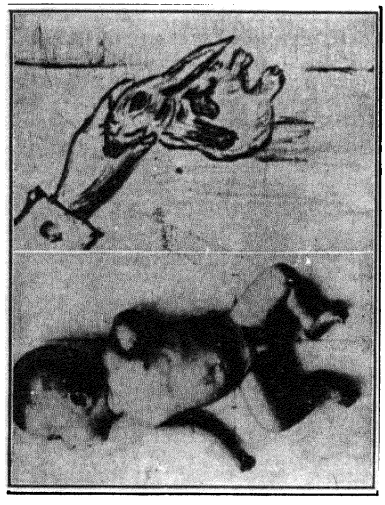

FIGURE 4. Right tonic neck reflex in rabbit and child.

in the midline. This is a lawful developmental sequence. The t.n.r. mechanisms are not extinguished at 24 weeks; they are simply submerged by symmetric bilateral patterns. In another month the bilateral in turn will give way to new unilateral patterns: one-hand reaching, one-handed manipulation, and hand-to-hand transfer, and ultimately to well-defined dextrality or sinistrality. Throughout early human development there is an almost periodic interweaving maturation, now of symmetric and then of asymmetric behavior forms, with corresponding shifts in postural manifestations.

When a large number of normal infants are examined at intervals during the first 3 months, we find that at least one-third consistently assume a right t.n.r.; possibly a third, the left t.n.r.; and the remainder adopt either right or left in a somewhat ambivalent manner. These figures are crude (the problem needs refined study), but they suggest important trends and individual differences in the genesis of laterality. Handedness is a partial and sometimes a misleading index of physiologic unilaterality. It is probable, however, that emphatic, constitutional left-handedness is correlated with a strong infantile left t.n.r.

Morphogenetically, the human t.n.r. should not be envisaged as a stereotyped reflex but as a growing pattern, changing with the maturity and the economy of the

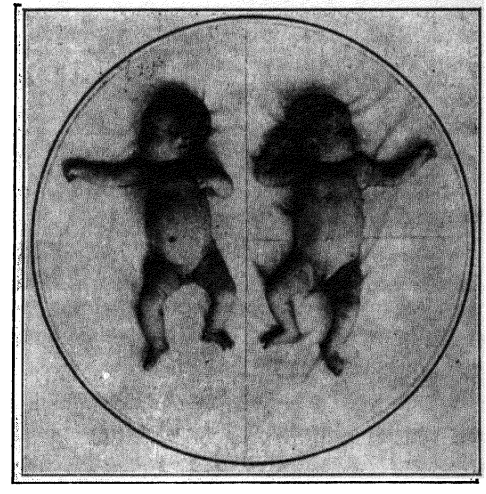

FIGURE 5. Right and left tonic neck reflex in 6-week-old infants.

organism. Torsion of the head to one side in a living fetus 20 weeks old arouses a movement of the arm on that side. This is a rudimentary t.n.r. which becomes better defined and elaborated in the latter half of the prenatal period. Fifteen minutes after the birth of a normal infant, I have detected a greater tonicity in the right as

opposed to the left arm (the legs were in equal relaxation). This discrepancy was predictive of a left t.n.r., in which the right or occiput arm tends to show the greater tonus. The infant was kept under continuous observation for 14 days and nights, and, although he was placed in varying postures, he consistently displayed

The submergence of the naïve t.n.r. of early infancy is the result of the ascendancy of cortical controls, probably in the motor and premotor regions, if Bieber and Fulton's (1938) data, regarding ablation, for monkeys and baboons apply to man. This probability is strengthened by our findings in a case of cerebral palsy, in which nec-

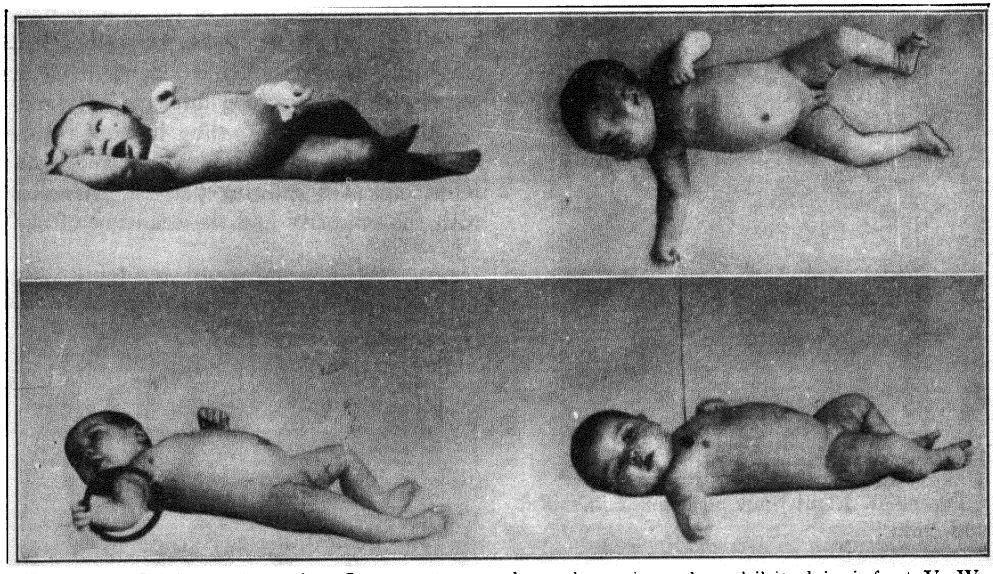

FIGURE 6. Right tonic neck reflex spontaneously and consistently exhibited in infant V. W. at 1, 6, 8, and 12 weeks of age.

a waxing left t.n.r. Another infant, belonging to the right wing, was photographed daily in a standard supine position, from the fifteenth day throughout most of the first year of life. This infant spent approximately one-half of the 834 seconds of cinematically recorded behavior up to the eighty-second day in t.n.r. Sixty-five separate t.n.r.'s were observed; only one of these was leftward.

Figure 8 graphs the incidence of these t.n.r.'s, which fell to zero on the ninetieth day, when the head preferred a midposition and the arms assumed more symmetric and versatile attitudes.

ropsy (at the age of 14 years) revealed a severe but uncomplicated birth lesion of the basal ganglia (status marmoratus). The boy in question, A.C., was afflicted with extreme double athetosis and, although intelligent, could not sit, walk, talk, grasp, or even hold up his head sustainedly. Cinema records of his spontaneous behavior in the supine position were made at the age of 7 years. Subjected to frame-by-frame analysis, these records revealed temporal and spatial patterns remarkably similar to those of the activated t.n.r. of normal infancy. Figure 9 portrays eleven comparable phases in the arm and head

movements of the palsied boy, aged 7 years, and of a normal infant, 4 weeks old.

These phases may be envisaged as a slashing windmill reaction emerging out of and returning to a basic t.n.r. attitude. The presence of the t.n.r. was obscured

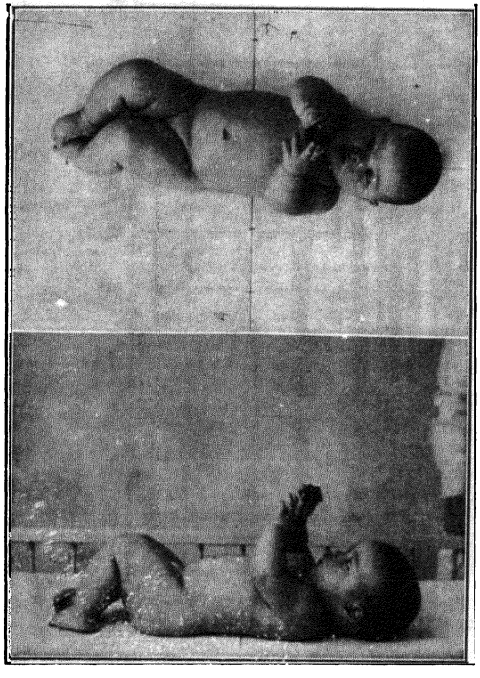

FIGURE 7. Symmetric prehensory and postural patterns at 24 weeks. Simultaneous photographs taken with one camera at zenith and the other at the horizon of the photographic dome.

by lively athetotic movements, but, when the cinema films were quantitatively studied, it was found that this boy was in a t.n.r. posture 41 to 56 per cent of the recorded time at 7, 10, and 13 years of age. The head generally took the lead in initiating the t.n.r. attitude. In no instance was a reversed t.n.r. attitude (head averted to one side with the arm of that side flexed) assumed even momentarily. All this suggests that the proprioceptive stimulus in the neck was operating to bring about the natural reflex.

The process of transformation from t.n.r. to symmetric postures is extremely complex. It is not a process of simple substitution but one of progressive interlocking so that neither symmetry nor asymmetry gains permanent or complete ascendancy. The addiction of the young infant to t.n.r. postures is both a symptom and a condition of his behavior growth. The infantile t.n.r. represents a morphogenetic stage in which fundamental neurological coordinations are laid down to form the framework for later postural, manual, locomotor, and psychomotor reactions. Indeed, the t.n.r. is part of the ground plan of the organism pervasively identified with its unitary, total action system.

The t.n.r. accordingly has an ecology. More or less directly it subserves adaptations to the environment, prior to birth as well as later. The t.n.r. helps the fetus to accommodate to the conformation of the uterine cavity, and it may even facilitate the longitudinal presentation and orientation of the fetus at the entrance of the birth canal. The t.n.r. of the neonatal infant is well suited to postural attitudes which the child needs to assume when suckled at the breast. The activated windmill t.n.r. of the early weeks with its intensification of grasp responses suggests vestiges of arboreal groping and gripping. The future and formative references of the t.n.r., however, are more significant. The t.n.r. attitude promotes and channelizes visual fixation by the infant on his extended hand; it leads to hand inspection, to eye-hand coordinations, to prehensory approach, and eventually to unidextrality. It contributes to the organization of the diagonal reflexes of prone locomotion. It reduces the hazard of suffocation to the infant and is well adapted to acts of rejec-

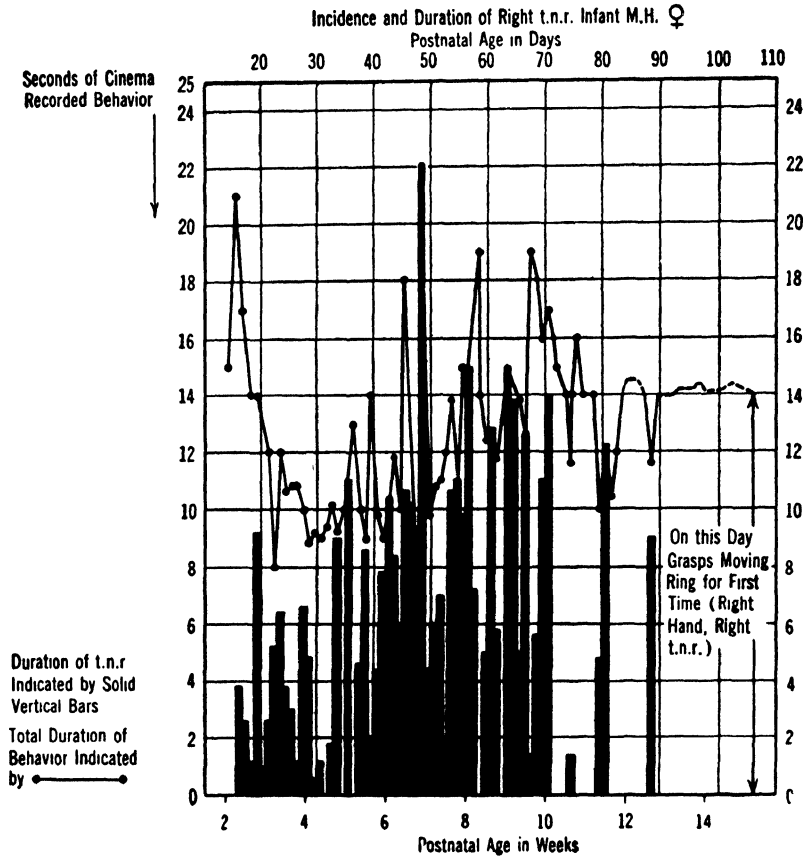

FIGURE 8. Duration and incidence by ages of the right tonic neck reflex in infant M. H. between 2 and 16 weeks of age.

tion, extrication, and withdrawal. Elaborated and inflected, it finally figures in innumerable adult acts of skill, aggression, and extrication. Attitudinal asymmetry always remains in reflex reserve, as well as subject to voluntary mobilization.

The Principle of Individuating Maturation

This principle may help us to recognize the mechanism by means of which the behavioral organism achieves its species characteristicness and yet at the same time makes specific adaptations within its environmental field. From the moment of fertilization, intrinsic and extrinsic factors cooperate in a unitary manner; but the original impulse of growth and the matrix of morphogenesis are endogeneous rather than exogenous. The so-called environment, whether internal or external, does not generate the progressions of development. Environmental factors support, inflect, and specify; but they do not engender the basic forms and sequences of ontogenesis.

Even before the human embryo has a nervous system it is a perfectly integrated

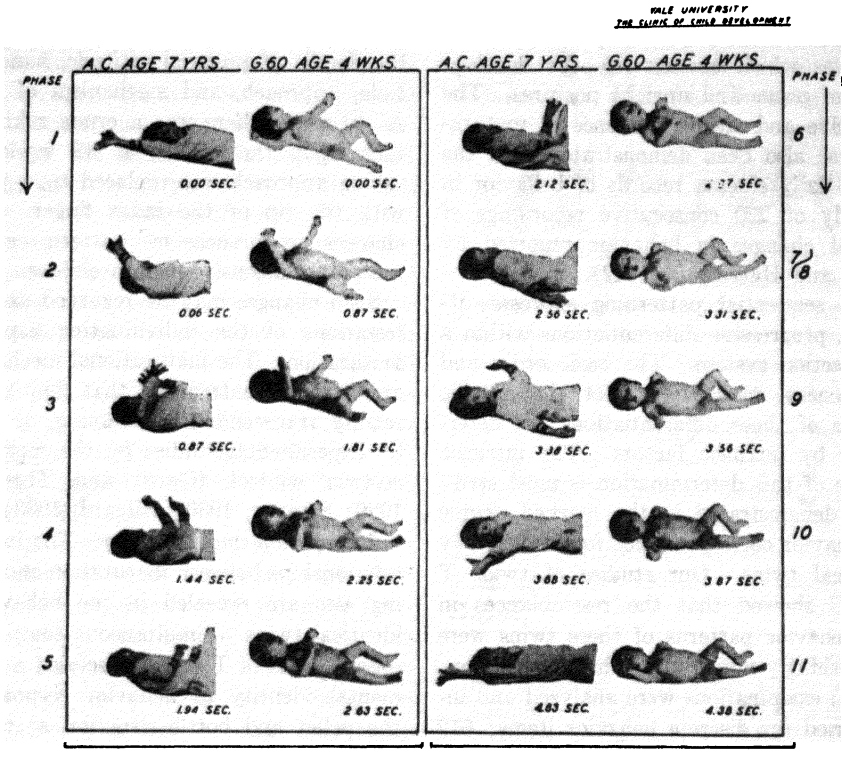

FIGURE 9. Comparable consecutive phases of the athetotic action pattern of A. C., aged 7 years, and of the spontaneous supine action pattern of a normal infant, G60, aged 4 weeks. (From "Correlations of Behavior and Neuro-pathology in a Case of Cerebral Palsy from Birth Injury," by A. Gesell and H. M. Zimmerman. *American Journal of Psychiatry*, 1937, *94*, Plate 3.) Eleven phases, with the elapsed time indicated in seconds, are shown side by side in vertical columns. These phases may be envisaged as a slashing windmill reaction emerging out of and returning to a basic tonic neck reflex attitude.

organism. It changes in shape and dimensions with each passing hour. It grows. This process of growth which derives its fundamental impulsions and directions from the zygote produces continuous reconfiguration. It configures the embryonic vesicle, the blastodermic layers, the skeleton, the skull, the profile of fetal, infantile, and adult nose, and the primary organization of the neuromotor system.

The function of the nervous system is to maintain the integrity of the organism and to anticipate the specific demands of the environment with provisional and preparatory arrangements. These forereference arrangements are not determined by stimulation from the outside world. Experience does not create them. Coghill (1929) has shown that the primary neural mechanism of walking (in *Amblystoma*) is laid down before the animal can respond at all to its environment. The primary attitude of the organism and the initiative of attitude are thus intrinsically determined. We apply the term "maturation" to this intrinsic and prospective aspect of onto-

genetic patterning. It has been abundantly illustrated in the sequential series of motor attitudes which characterize the development of prone and upright postures. The pervasive and steady influence of maturation has also been demonstrated with the aid of daily cinema records of behavior in a study of 220 consecutive recordings of diurnal changes in behavior reported by Gesell and Halverson (1942).

The sequential patterning expresses itself in progressive differentiations within a total action system. The basic order and the general modality if not the specific outline of these differentiations are determined by intrinsic factors. The intrinsic nature of this determination is most strikingly demonstrated in the marked degree of behavior correspondence found in highly identical twins. Our studies of twins T and C showed that the resemblances in the behavior patterns of these twins were astonishingly numerous. Thirteen developmental examinations were analyzed and inventoried for discrete behavior items; 612 separate comparative ratings of such items were made. There were 99 items of minor disparity and 513 items of identical or virtually identical correspondence.

In the field of pellet prehension, this parity was very neatly disclosed. A small pellet, 8 mm. in diameter, was placed on a tabletop before each child, within easy reach. At 28 weeks both the twins, being somewhat retarded in their development, were visually unheedful of the pellet, though they definitely regarded a cube. At 38 weeks they addressed themselves in an identical manner to the pellet. The hands were placed in full pronation, the fingers were fully extended and spread apart in a fanlike manner. The thumb was extended almost at right angles. The photographic record of their attack upon the pellet in the motion pictures shows an almost uncanny degree of identity in the details of postural attitude, hand attitude, approach, and mechanism of grasp. At 40 weeks there was a crude raking attack upon the pellet; at 42 weeks this raking approach was replaced by a poking with the tip of the index finger. These changes in prehensory pattern occurred contemporaneously in both children.

Such changes may be regarded as manifestations of the individuating aspect of maturation. The maturational mechanisms are so firmly entrenched that they are not readily transcended by training, as shown by experimental studies by the method of co-twin control (Gesell and Thompson, 1929; Strayer, 1930; Hilgard, 1933).

Maturation and Learning. The intimate relationships between maturation and learning also are revealed in the behavior of identical twins. Simultaneous comparative observations of T and C disclosed a fundamental identity of behavior responses in the pellet and bottle situation at the age of 48 weeks. The twins were in the same crib, seated back to back, and each confronting her own examining table. Two examiners simultaneously held a small 4-ounce glass bottle in view and dropped an 8-mm. pellet into the bottle. Three trials were made with each child. The examiner, having dropped the pellet into the bottle, gave the bottle to the child.

Both children watched this dropping of the pellet with the same transfixed attention. Both children on the first trial, and again on the second trial, seized the bottle, apparently heedless of the contained pellet; but both children on the third trial (without, of course, any influence of imitation) pursued the pellet by poking at it against the glass—identical capacity to profit by experience.

In this instance we find that the correspondence of behavior patternings extends into the minute fields of specific adaptation or of learning. It may be readily granted that maturational factors primarily account for the similarity in capacity and general maturity displayed by these twins. Perhaps these same maturational factors also account for the more detailed correspondences, such as the mode of visual attention, the primary preoccupation with the bottle, and the secondary interest in the pellet. Within a brief span of time we see the spontaneous behavior patterns undergo a specific adaptation and call this adaptation learning. The distinctive criteria of maturation and learning, however, are not easily applied.

Let us assume that on the morrow, in the pellet-and-bottle situation, both children poke immediately with extended forefinger against the side of the bottle. Is this fixation of behavior due to the experience of the previous day? Shall the assimilative processes of the intervening night be regarded as maturation because the modification did not occur in immediate response to the situation; or shall it be called learning because it is virtually a specific adaptation to stimuli recently in the external environment? The fixation of the poking pattern, however, proves to be temporary, because in another lunar month, without specific experience, these same twins adaptively tilt both bottle and hand, and thrust the extended index finger into the open mouth of the bottle in pursuit of the pellet. Is this incremental differentiation of behavior pattern to be attributed to maturation or to learning?

The concept of maturation emphasizes the unity of the organism and the priority of the total pattern of response. The unity of the organism is not to be regarded as a mystical abstraction, but as a reality, namely, the functional unity of the total reaction system. Herrick (1929) identifies it particularly with the diffuse nervous network of

> . . . neuropil which pervades the brain substance and binds it all together as a functional unit. Into this neuropil there is a continuous discharge from every sensory surface of the body, fluctuating from moment to moment but always acting. Here growth is going on as long as learning is possible, here the total pattern expands, and here partial patterns are individuated.

Here also is the anatomic basis for conditioning of the Pavlovian type.

The basic ontogenetic forms of individuation are the result of maturation Conditioning is superimposed, as it were, upon a maturational substrate. As conceived by Coghill,

> Conditioning of reaction is accompanied by restriction (narrowing) of the zone of adequate stimulation and concomitant restriction in the field of action. The primacy of structural basis for this is in the mechanism of the total pattern.

Which pattern, be it remembered, "is a growing thing."

For this reason all learning involves growth. According to Herrick (1929):

> It involves a change, more or less stable in the anatomical structure of the body, and the neuropil as the most labile part of the nervous system plays the most significant part in this reorganization of the mechanisms of behavior.

Maturation and Acculturation. The individual comes into his racial (and ancestral) inheritance through the processes of *maturation.* He comes into his social inheritance through processes of *acculturation.* These two processes operate and in-

teract in close conjunction. Only through systematic studies of child development, naturalistic, biometric, and experimental, can we gain an insight into the relationship of maturation and acculturation. Here indeed is one of the most comprehensive and crucial problems of the life sciences. In this problem genetic psychology and cultural anthropology have a common stake.

The distinction between maturation and acculturation must not be drawn too sharply, but it must be made. Malinowski (1937) has characterized culture as "a large-scale molding matrix." His meaning is, of course, clear and up to a certain point incontrovertible; but in the interpretation of child development I should prefer to reserve the term "matrix" for the maturational mechanisms which literally establish the basic patterns of behavior and of growth career. A matrix is that which gives form and foundation to something which is incorporated, in this instance, through growth. By growth we do not mean a mystical essence, but a physiological process of organization which is registered in the structural and functional unity of the individual. In this sense the maturational matrix is the primary determinant of child behavior.

Growth is a unifying concept which resolves the dualism of heredity and environment. Environmental factors support, inflect, and modify; but they do not generate the progressions of development. Growth is an impulsion and as a cycle of morphogenetic events is uniquely a character of the living organism. Neither physical nor cultural environment contains any architectonic arrangements like the mechanisms of growth. Culture accumulates; it does not grow. The glove goes on the hand; the hand determines the glove. And the hand, by the way, is a primitive survival, shockingly similar to the hand of the ancient tortoise who swam the seas and walked the earth millions of years before the advent of man.

The Principle of Self-Regulatory Fluctuation

Every living organism is a storer and distributor of energy. The human infant is no exception. His daily cycle of activity and rest reflects the way in which he husbands and expends his energies; it also reflects a method of growth. "Aging and death may be considered to result from the gradual degradation of the original energy which caused the formation of an organism in the environmental field" (Eulenberg-Wiener, 1938).

The living system during the period of active growth is in a state of formative instability combined with a progressive movement toward stability. The so-called growth gains represent consolidations of stability. This opposition between two apparently opposing tendencies results in see-saw fluctuations. The maturing organism does not advance in a straight line but oscillates along a "spiral" course between two self-limited poles.

A spiral kind of organization was also suggested in the phenomenon of reciprocal interweaving. The concept of spirality is not mystical if, in spite of its vagueness, we simply let it denote metaphorically the devious but progressive involutions by which structure and function are jointly matured. The organism at times seems to retreat from a locus of maturity which it had already attained. Temporarily such a retreat may look like an abandonment. It would be abandonment if it continued on one tangent. The course of development, however, being spiral, turns back toward the point of departure; and it does not return precisely to this point. It returns to the same region but at a higher level. The neurological result is an inter-

woven texture which expresses itself in progressive patterns of behavior. The unity of the ground plan of the organism is preserved. It is a process of reincorporation and consolidation, rather than one of hierarchical stratification.

Many of the ephemeral variabilities of human functioning may be due to fluctuations or inconstancies of internal milieu. On the other hand, advanced forms of adaptive variability may be dependent upon a highly stable milieu and a consolidated developmental organization. Productive modifiability implies stability as well as a certain degree of instability. Stability and variability coexist not as contradictory opposites, but as mutual complements. The relationships are extremely complicated and specific. They may be studied in a dynamic aspect in narrow fields restricted to small periods of duration. They may be studied in a developmental aspect against the broader time frame of the ontogenetic cycle.

Fluctuation is therefore a normal expression of the self-regulatory mechanisms of development. Elsewhere we have presented objective data illustrating the operation of this principle in the development of feeding behavior (Gesell and Ilg, 1937). Detailed observations were made on the spontaneous self-demand schedule of a healthy infant throughout the first year of life. This infant, child J, was fed on the basis of her own carefully observed demands, and with minor exceptions her sleep was not disturbed. Accurate records of times of feeding, food intake, naps, and sleeping were made daily by a physician and a full-time nurse. This undertaking proved to be a long-range experiment which revealed the capacities of self-regulation in an infant who was literally allowed to shape her own behavior day.

Each behavior day was recorded and charted. The entire chart for the period of a year spreads, on ordinary plotting paper, to the formidable length of 7 feet. In the accompanying graphs we reproduce sections of this chart. Figure 10 covers 49 successive days for the age period of 3 to 10 weeks. Figure 11 condenses the total record by plotting 60 successive Thursdays from 3 to 63 weeks. The charts may be read both horizontally and vertically. The shaded areas, read across, show the sleeping periods for a 24-hour cycle. The open circles indicate bottle feedings; a figure in the circle designates ounces of intake.

Lines drawn vertically or obliquely connect these circles and show shifts in the times of feeding. Ages in weeks are ranged in the vertical column at the left. When the chart is examined as a whole, and is scanned from top to bottom, it reveals the process of adjustment by which an infant accomplishes revisions in a schedule of feedings and sleepings.

This process of adjustment is marked by fluctuations, particularly in the first quarter of the year. Compare on the chart the schedules at 3 weeks and at 8 weeks. (The shaded areas represent stretches of sleep; the open spaces, stretches of waking activity, including feeding.) At 3 weeks there are 7 feedings; at 8 weeks there are 5 feedings. This reduction was brought about by following the cues furnished by the infant herself. As early as the age of 4 weeks the chart gives evidence of a readjustment; this infant sleeps for a longer continuous period prior to the early morning and early afternoon bottles; she also sleeps longer in the early night; in so doing she skips her 7 P.M. bottle but demands her 11 P.M. bottle at 10 P.M. The result of this innovation is a 6-bottle day on Thursday of the fourth week. On Friday and Saturday she swings back, with deflections from her usual routine, to a 7-bottle day. On Sunday she advances her adjustment and has only 6 feedings. During the

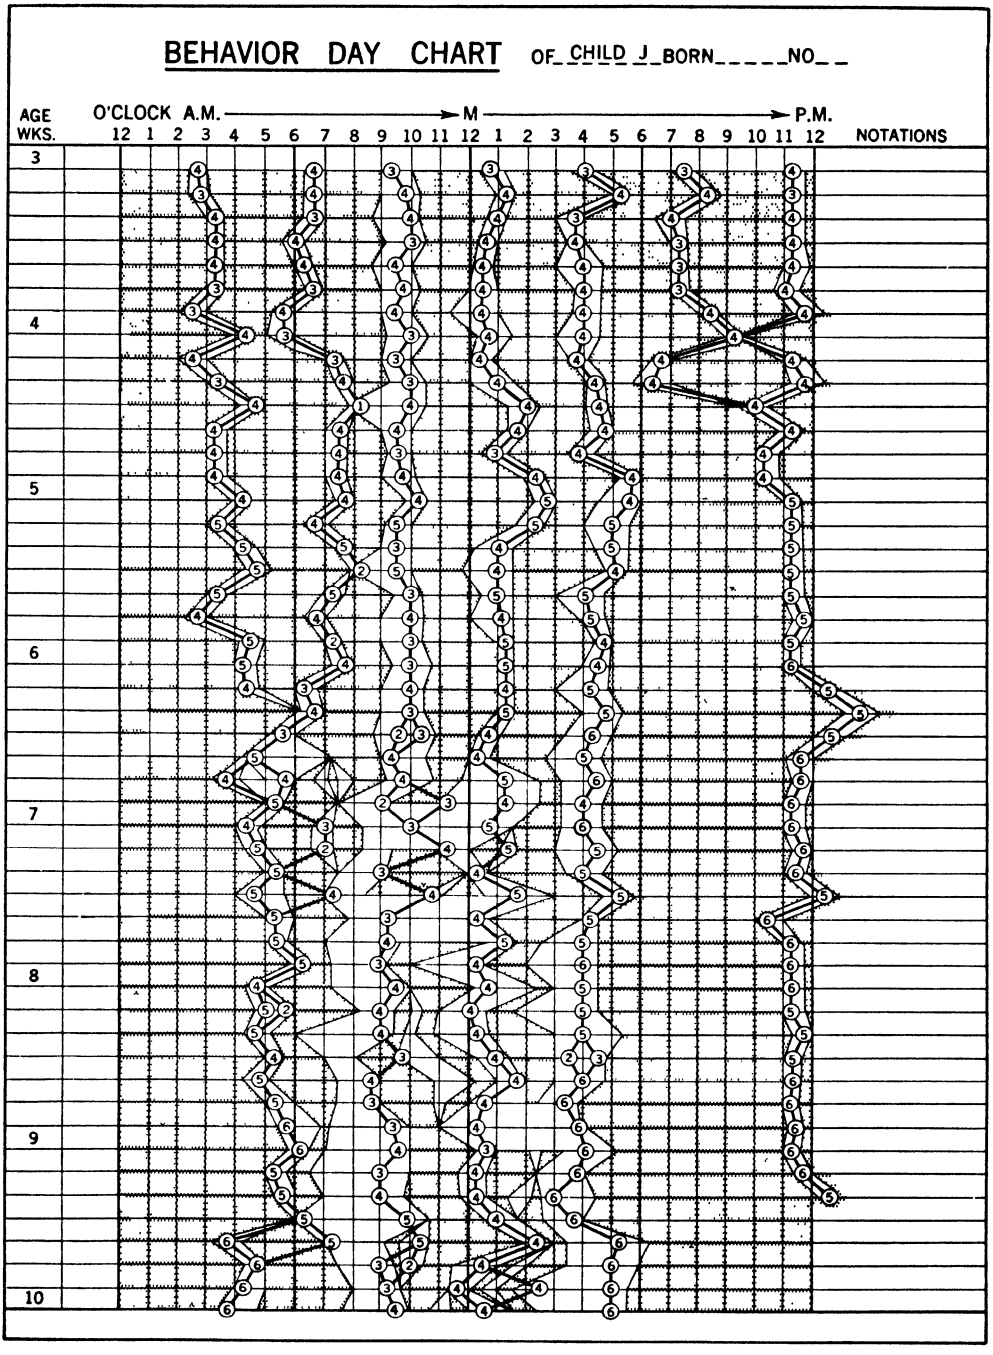

FIGURE 10. Child J. Feeding schedule from 3 to 10 weeks. (From *The Feeding Behavior of Infants: A Pediatric Approach to the Mental Hygiene of Early Life*, by A. Gesell and F. L. Ilg. Philadelphia: J. B. Lippincott Co., 1937, p. 95.)

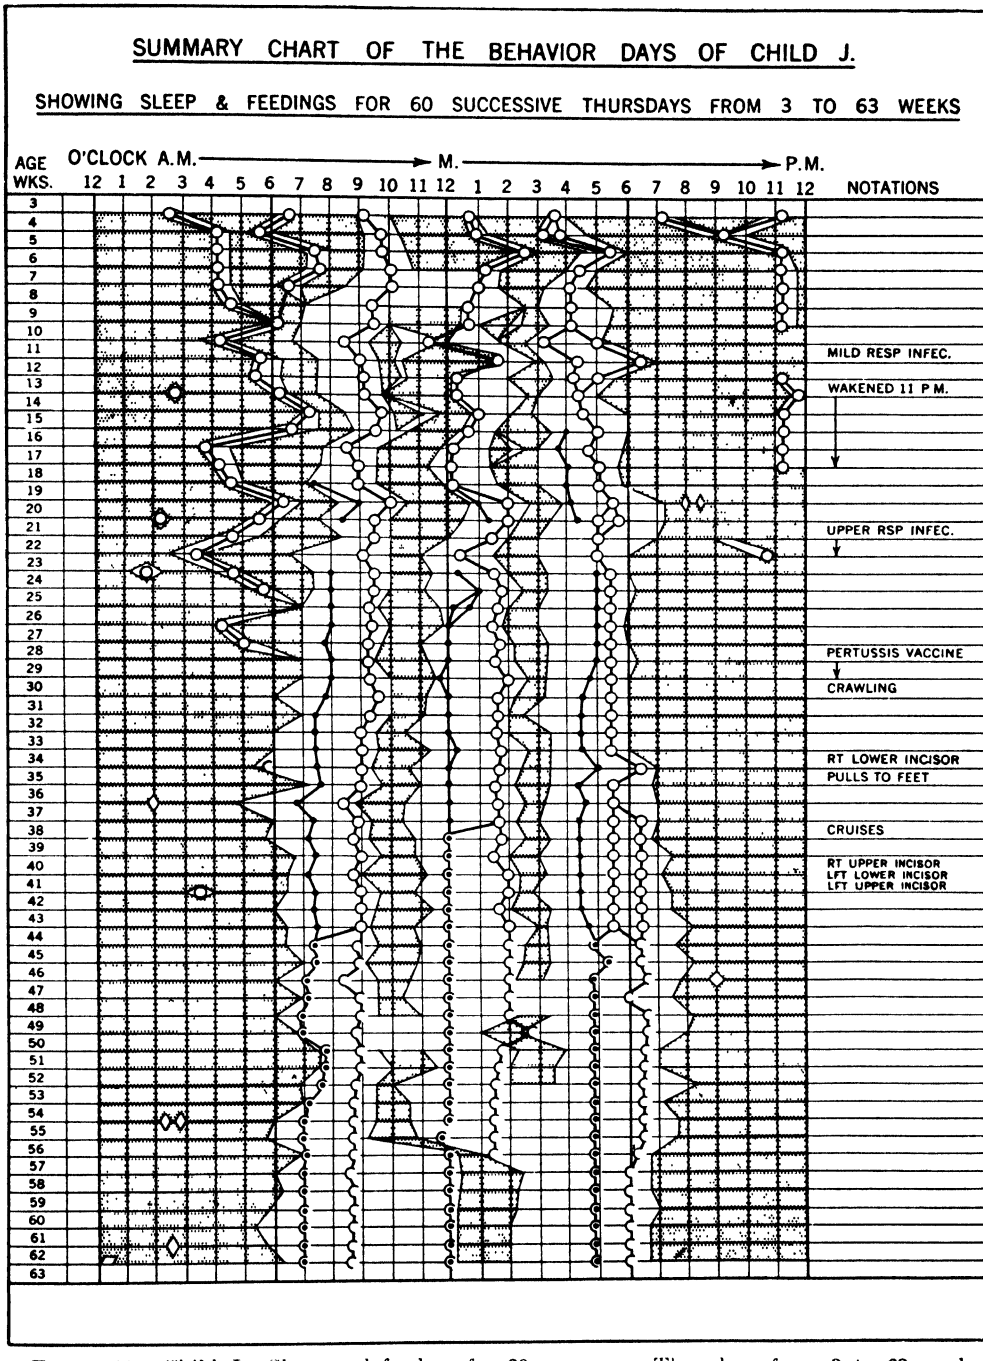

FIGURE 11. Child J. Sleep and feeding for 60 successive Thursdays from 3 to 63 weeks. (From *The Feeding Behavior of Infants: A Pediatric Approach to the Mental Hygiene of Early Life*, by A. Gesell and F. L. Ilg. Philadelphia: J. B. Lippincott Co., 1937, p. 97.)

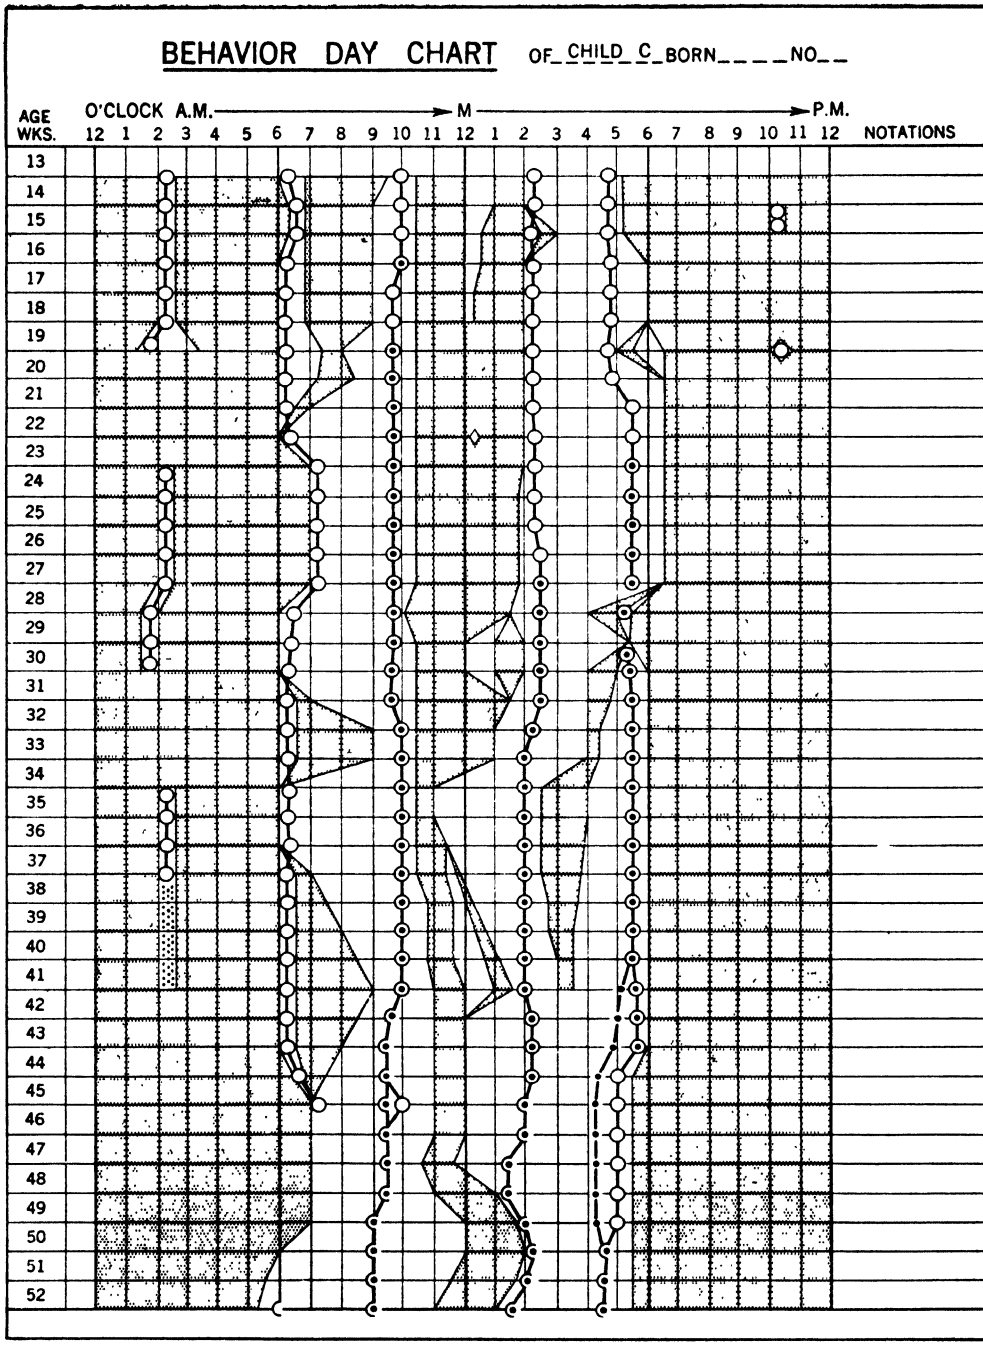

FIGURE 12. Child C. Sleep and feeding from 13 to 25 weeks. (From *The Feeding Behavior of Infants: A Pediatric Approach to the Mental Hygiene of Early Life,* by A. Gesell and F. L. Ilg. Philadelphia: J. B. Lippincott Co., 1937, p. 101.)

next 2 weeks she "settles down" to a relatively steady schedule of 6 feedings. But her morning and afternoon periods of daytime wakefulness are gradually widening, as shown by almost diurnal fluctuations in her schedule.

Superficially, these charted fluctuations seem to be irregular and whimsical. Looked at in perspective, however, they prove to be expressions of a basic mechanism of adjustment. The fluctuations are tentative approaches and approximations to a future schedule. When a future schedule is attained it, too, undergoes fluctuations directed toward a yet more future schedule. This is a growth process; or, if one prefers another concept, this is how the organism "learns."

The range of fluctuation in feeding schedules varies with different infants. In some the coefficient of fluctuation is high; in others, it is low. The latter accommodate themselves most readily to imposed schedules. In this category falls child C, whose feeding schedules are charted in Figure 12. The chart is plotted in terms of weeks rather than days. Although the diurnal variability is somewhat obscured by this condensation, the chart reveals the type of infant who shows a high degree of punctuality in his self-demands.

The almost periodic fluctuation displayed in the acquisition of sleep rhythms is shown in Figure 13. The neonate sleeps most of the 24 hours of day and night. His brief waking periods are largely spent in feeding, but even in these periods he may be in a somnolent stage, suggestive of fetal "hibernation." Sleep is not a reflexive type of reaction which comes to immediate completion with birth. Even in the uterus the infant is "learning" to awake and to sleep. A developmental process of differentiation is already taking place which will sharpen postnatally into rhythmic distinctions between sleep and activity. As early as 6 weeks the infant may become fussy at evening because he desires sociability or perceptual experience in preference to sleep. Often he quiets if he is allowed to remain in a room where he may watch persons move about or may regard the lights. Physiologically, we may think of this as a method of acquiring the ability to postpone

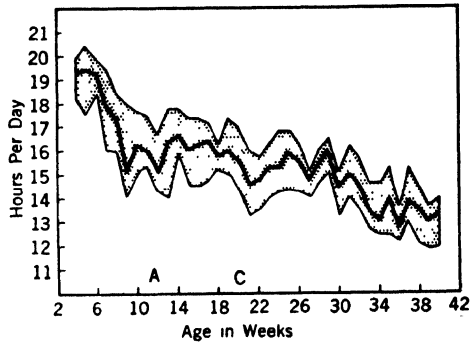

FIGURE 13 Child J. Sleep chart from 4 to 40 weeks. (From *The Feeding Behavior of Infants: A Pediatric Approach to the Mental Hygiene of Early Life*, by A Gesell and F. L. Ilg. Philadelphia: J. B. Lippincott Co., 1937, p 99.)

and to channelize sleep, which formerly engrossed almost the entire cycle of the day.

As the infant matures, the total duration of sleep per day constantly fluctuates but steadily diminishes. This is indicated in the accompanying graph (Figure 13), which plots the average hours of sleep per week, and the extremes of variation within each week, for child J from 4 to 40 weeks. It will be noted that the ups and downs show a rhythmic character. But the downs in the end exceed the ups, so that the average amount of diurnal sleep falls from 19 hours in the fourth week to 13 hours in the fortieth week. The number of naps likewise may rise and fall repeatedly but with a trend toward reduction. Usually the early morning and evening naps are the first to shorten and to disappear by

merging with the night sleep. The later morning and the afternoon naps persist ordinarily throughout the first year. There is a kind of competition between these two naps. Sometimes as early as 28 weeks the afternoon nap shortens and soon gives way to the morning nap. Typically, however, there is a longer period of fluctuation and readjustment, and the afternoon nap wins out and gains ascendancy in the daily schedule by the beginning of the second year.

Such progressive fluctuations, culminating in a more stable response, are characteristic of all behavior development, including feeding behavior. The fluctuations, instead of being regarded as undesirable or as fortuitous irregularities, should be interpreted as effortful attempts on the part of the organism to accomplish increasingly mature adjustments. From this point of view, fluctuations have a positive function in the economy of growth and learning.

The Individuality of Growth Careers

By virtue of the foregoing principles the human infant shows a strong tendency to develop along well-defined morphogenetic lines characteristic of the species. Inherited engrams, or comparable regulators, not only determine behavior forms common to the race, but they also determine behavior modes and idiosyncrasies peculiar to the individual. The growth career of each individual infant assumes a distinctive pattern.

The range of individual differentiation is wide and diverse. Only in extremely similar monozygotic twins do we find a high degree of developmental correspondence between two individuals. In such twinship the resemblance may extend even to the timing and the minute details of physical and behavioral patterning. A study of twins A and B (Gesell and Blake, 1936) may be cited here to indicate the precision with which the ontogenetic mechanisms operate.

These twin girls at the age of 12 years presented a duplication of bilateral coloboma involving each of their four eyes. These colobomas were amazingly alike in size, shape, position, and pigmentation. Genetically each coloboma traced back to a defective closure of the fetal ocular cleft. If a single "environmental" adversity caused the notching of the optic cup (in an embryo approximately 7 mm. long) it must have operated coincidentally within an extremely brief and critical interval on four rapidly organizing structures which simultaneously reached identical levels of maturity. This is an excessively remote possibility. It is still more unlikely that four defects of as many choroids, so similar in size, outline, position, and pigmentation, could have occurred at different times in consequence of four separate moments of infection, of irritation, or of damage neatly directed at each of the four eyes. It is, however, conceivable that the original single zygote or the constitutive factors in the twin embryos, which already held the hereditary determiners of all four eyes, held also the specific factors (or mutations) which delimited the development of the choroid. Similar specific factors would likewise account for the persisting remnant of the left hyaloid artery and for the correspondences of the shape and refraction of the four eyes. These eyes were derived from a single cell with one genetic constitution. Similar specific factors must also account for the striking resemblance in the emotional, intellectual, and motor make-up of these twins, including even their handwriting and the spellings and comparable misspellings of simple dictated words, such as *day, eat, sit, let, box, belong, door, yes, low, soft.*

Numerous studies of twins are now available for further analysis of the influence of genetic and epigenetic factors in the production of individuality (Carter, 1940). The medical literature on the pathological correspondences in twins is particularly suggestive with respect to the intrinsic developmental factors involved.

We have studied one highly identical pair of twins at the Yale Clinic of Child Development over a period of 20 years. By repeated physical and mental measurements, by systematic motion-picture records of behavior and experimental observations using the method of co-twin control, we have followed the life careers of these twin girls from infancy to adolescence (Gesell and Thompson, 1941). In the co-twin control studies, we trained one twin (T) and reserved the other twin (C) as a comparative control, to determine the effects of intensive training in such sample functions as stair-climbing, block-building, vocabulary, and manual coordination. These effects proved to be relatively impermanent: the untrained twin attained the equivalent skill as soon as she reached the requisite maturity. Numerous tests at advancing ages revealed an amazing parallelism in their physical and mental growth.

On close analysis, however, even this remarkably similar pair of twins presented consistent individual differences, many of which could be traced back to infancy. The differences are slight but they are durable. Here are some of them. T is quicker, more direct, more decisive; C is more deliberate, more inclusive, more relaxed. T is a bit brighter; but C is more sociable, more communicative. T shows a predilection for straight and angular lines in her drawings of a house, of smoke, of curtains, and of balloon strings. C favors curves. Her curtains are flounced, her smoke curls. In attentional characteristics, T's pick-up is more prompt, she focalizes more sharply, is more alert for details. C's attention is more generally alert, more imaginative, more roving. These differences are slight in degree; but they are permanent in the perspective of 14 years. They are permanent because they are constitutional.

The remarkable correspondences in many instances of twinship serve to emphasize the frequency and diversity of developmental variability among ordinary siblings. Some of the variations can be interpreted in terms of the ontogenetic principles which have just been outlined. Motor ineptitudes, for example, may arise out of exaggerations or defects in the process of reciprocal interweaving; many so-called regressions, likewise. The different modes by which children learn to walk and to run are impressive for variety of style. And often a style of acquiring motor control pervades other fields of behavioral adaptation. It is increasingly clear that many behavior difficulties with accompanying personality manifestations are based upon confused laterality or faulty functional asymmetry. Many forms of abnormality in mental life can be construed, following Coghill's suggestion, as due to excessive individuation. We have already called attention to the wide range of individual differences with respect to the amplitude of self-regulatory fluctuations. A thoroughly healthy individual is not likely to display any extreme deviations or deficiencies in the physiology of development represented by the five ontogenetic principles which have been described.

Nature is infinite in variety and variability Even identical twins are not perfectly identical. The popular impression that all babies are much alike, especially young babies, cannot be confirmed. This impression has received some scientific support from psychologists who hold that the behavior of infants is chiefly patterned

through conditioning processes and through specific learning.

On the basis of the conditioning theory of development, individual differences at birth are slight and increase with age. The investigations at Yale, including the detailed biogenetic studies of twins T and C, of the normative infants and selected subjects of the naturalistic survey all point in a different direction. One study (Gesell, assisted by Ames, 1937) was based upon an analysis of the cinema records of five different infants. The children were photographed under homelike conditions at lunar-month intervals throughout the first year of life. These extensive cinema records embraced the major events of the infant's day—sleeping, waking, bath, dressing and undressing, feeding, play, and social behavior at advancing age levels. Additional cinema records and psychological observations of the same children were made at the age of 5.

A trained and unbiased observer (L.B.A.), *who had never seen the infants*, made a detailed analysis of the cinema records covering the first year of life. On the basis of the objective evidence of the films alone, an estimate of fifteen behavior traits was made and the children were arranged in rank order for each trait. The same children were again studied at the age of 5 and were again rated with respect to the fifteen behavior traits which they had displayed in infancy. The two appraisals were made independently.

Is the strength of a behavior trait in the first year of life predictive of a similar strength in the fifth year? The fifteen traits of behavior individuality which were considered were: (1) energy output, (2) motor demeanor, (3) self-dependence, (4) social responsiveness, (5) family attachment, (6) communicativeness, (7) adaptivity, (8) exploitation of environment, (9) "humor" sense, (10) emotional maladjustment, (11) emotional expressiveness, (12) reaction to success, (13) reaction to restriction, (14) readiness of smiling, (15) readiness of crying.

For each child and for each trait at 1 year and again at 5 years a comparative judgment was made. Out of the 75 comparative judgments, 48 coincided; 21 showed a displacement of 1 rank order only; 5, a displacement of 2; and 1, a displacement of 3 (Figure 14).

Every infant seems to have what may be called a motor habitude or characteristicness which expresses itself in postural demeanor and modes of movement. This characteristicness is difficult of description because it is the compound result of numerous factors, including skeletal frame, disposition of musculature, speed, synergy, smoothness and precision of action.

Some of these factors, however, yield to quantitative study. One of the most accessible of these is laterality. A consistent laterality in both handedness and footedness showed itself in all the children.

In general bodily control and also in manual dexterity, the four children for whom quantitative data were secured readily fell into the following rank order: 1, boy D; 2, boy A; 3, girl B; and 4, boy B.

Several hundred feet of cinema records were available for measuring the prehension time of these children in controlled normative situations. The interval consumed between the zero moment of reaching to the moment of grasp of the test object was computed by counting cinema frames. Each frame has a time value of 0.05 second. The prehension time (that is, the reach-grasp time) increased with the rank order as follows: boy D (rank order 1), 40 seconds; boy A (rank order 2), 47 seconds; girl B (rank order 3), 50 seconds; and boy B (rank order 4), 60 seconds.

In these time values we apparently have a rather basic trait of motor individuality,

for this rank order held up with consistency when the patterns of prone progression were measured in detail. For these measurements over 1000 feet of film depicting creeping behavior were available. a single forward placement of each of the four members. The total time required for one creep advance was determined for each of the subjects in turn. The time values ranged from 0.7 to 1.6 seconds for such a

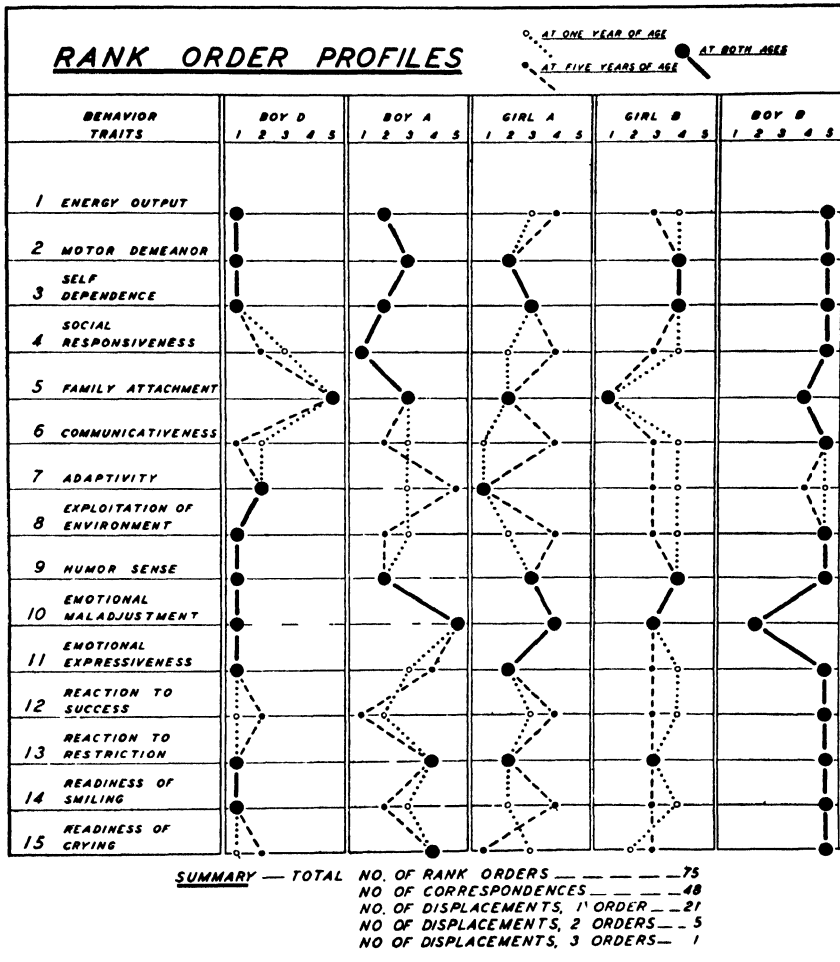

FIGURE 14. Rank order profiles for individuality traits in infancy and at 5 years.

Creeping speed, like prehension time, was measured by counting frames, in this instance the number of frames which recorded a forward movement of a hand or of a leg. A *creep advance* represents a single cycle of progression accomplished by single creep advance. Once more the resulting rank order was identical with that just given in the preceding paragraph.

In other stages of prone behavior—namely, the *near-step advance* and the *one-step advance*—as well as in simple hands-

and-knees creeping, the time values for the four children retained their characteristic motor rank order.

Another individual difference asserted itself with respect to the age at which the various stages of prone locomotion were attained. For example, the ages when the near-step stage was attained were: boy D, 36 weeks; boy A, 40 weeks; girl B, 48 weeks; boy B, 48 weeks. When the nascent ages for the entire sequence of 23 stages in the ontogenesis of progression are expressed in terms of summated rank for each of the four children, we get a significant series of values: boy D, 38; boy A, 43; girl B, 70; boy B, 78. Again the rank order remains true to the characteristic order established by the measurement of specific motor traits.

Another cinema study (Ames, 1940) on the constancy of individual differences analyzed the locomotor and manual behavior of eight infants over a 3-year period. When the eight subjects were arranged in rank order with regard to speed of combining pellet with bottle and cup with spoon, creeping speed, and time of attaining successive stages of prone behavior, six retained the same relative rank order for each type of behavior. Only two subjects varied in position. Such psychomotor constancy bespeaks a persisting factor in the make-up of individuality.

Developmental Studies by Projective Techniques

More recent investigations at the Gesell Institute of Child Development have demonstrated that projective techniques reveal developmental progressions as well as distinctive traits of individuality. These traits, themselves, evidently undergo maturity changes with growth. The several Rorschach variables (movement responses, color responses, shading responses, and the like) change in a characteristic manner from age to age. Even the general character of the total response at a given age is in some measure predictable. Ames and associates (1952) have shown the presence of maturational factors for each of thirteen age levels from 2 to 10 years. Similar mechanisms may well operate throughout the following decade.

The child's reactions to the Rorschach ink-blots do not become steadily better integrated as he grows older. Ages of relative equilibrium alternate to some extent with ages of lessened equilibrium. An age period which appears to be well organized may be followed by a period which suggests inner disturbance.

Such fluctuations must be interpreted with clinical caution. A total configuration of response, which in an adult might signify disturbance, may be benign or even typical in a young child. The same is true of so-called danger signals such as contamination and confabulation, use of oligophrenic detail, pure color response, and perseveration of a single response.

Developmental trends have also been identified in child responses to the projective technique of Hellersberg and the Kaleidoblock test of Lowenfeld (Ames and Hellersberg, 1949; Ames and Learned, 1952*a*). An additional volume by Hoeber on Rorschach responses in late life (ages 70–100) is in press.

The Stability of Mental Growth Careers

In illustrating the principles of development, we have most frequently referred to motor and psychomotor characteristics. This is natural because these so-called motor phenomena are the most objective and measurable. It must not be thought, however, that the ontogenetic principles operate only in the motor sphere. It will be

well to inquire whether they do not pervade the total domain of psychological growth, including language, adaptive, and personal-social behavior.

Growth is a morphogenetic process of progressive individuation and integration which leads to specific ends. To a considerable extent these ends are inherent in the organism. The organism also displays a prodigious capacity to adapt to circumstances, exigencies, and adversities. In this sense the growth of the individual is plastic and labile. But the individual retains durable characteristicness, and this is the stable aspect of growth.

The writer, in 1928, published the mental growth curves of thirty-three infants and young children whose behavior development had been repeatedly appraised by clinical examinations. We have followed the subsequent careers of thirty of these children, who are now in their teens or older. By comparing the early with the later findings, we can in retrospect determine the predictiveness of the first appraisals, many of which were made during the first year of life.

The group of thirty cases comprised a wide variety of developmental conditions: normal, retarded, mentally defective, superior, premature and postmature infants, a case of cerebral palsy with approximations to normal mentality, cases of cretinism, mongolism, hemihypertrophy, and *pubertas praecox*.

How consistent over a decade and more have been these mental growth careers? In no instance did the course of growth prove whimsical or erratic. In only one case within the period of 10 years was there a marked alteration of trend, namely, from a low average to a high average level (child B.D.). In a few defectives there was a progressive retardation without deterioration. For all others there was a maintenance of the general trend which was ascertained by the early examinations.

Graphs were plotted for DQ and IQ, but the detailed case records also incorporated after each examination our clinical appraisals, which were by no means always identical with the psychometric quotients. These interpretive clinical judgments, we believe, have more significance than the raw quotients in investigating the consistency and stability of mental growth careers.

Our clinical evidence based on normative determinations demonstrates a high degree of consistency in the trends of early and later growth. Take, for example, the six siblings reported elsewhere (Gesell, 1928) as children D.E., E.F., F.G., G.H., H.I., and I.J. Three of these children over a period of 10 years have clung unmistakably to a normal course of behavior development; the other three, as decisively, to a subnormal course. It took no diagnostic subtlety to distinguish between these two kinds of growth potentiality on the basis of one behavior examination in infancy. The point is that these infant behavior pictures were unambiguously prophetic of the later careers. The predictions, therefore, were accurate. They were safe, also, because nature is never so whimsical as to mix up sectors of the growth curves of two sets of individuals as differently endowed as D.E. and I.J. (Figure 15).

In a similar way the predictive estimates of three distinctively superior children in our group did not miss the mark. The estimates were made before the children could read or write, which means that there was a high degree of indicativeness in the early behavior symptoms.

In less well-defined behavior pictures, equally confident predictions are not forthcoming because we do not have the techniques or acumen to identify and assess the indicators; but a comparable latent

predictiveness resides in these pictures as well.

When there is a fairly even balance between the endogenous and the sustaining or exogenous factors, the trends of mental growth, whether subnormal, superior, or mediocre, are likely to be the most consistent. Developmental diagnosis and prognosis then come nearest to their mark. When, however, the organism is under stress of distortion because of unfavorable conditions, its ultimate adjustments as expressed in growth characteristics become least predictable. There are too many variables to appraise. External environment can be estimated with some shrewdness; but not so readily the internal developmental reserves.

These hidden reserves are the intrinsic insurance factors with which we have had to reckon repeatedly in cases of atypical and irregular behavior development. The concept of insurance factors is not mystical. It is derived from experimental embryology and from clinical observation. The surgical excisions, transplantations, and other interferences with the growing tissues of laboratory embryos have demonstrated that the organism is protected with a remarkable fund of reserve mechanisms which promptly or gradually move into every breach and fill it in some way, either through regeneration or compensatory and substitutive growth. If the lesion is too great, the organism dies. If the lesion is not too severe, and the organism not too old, growth may continue in a more or less normal manner.

In the development of the nervous system and in the ontogenesis of behavior, the

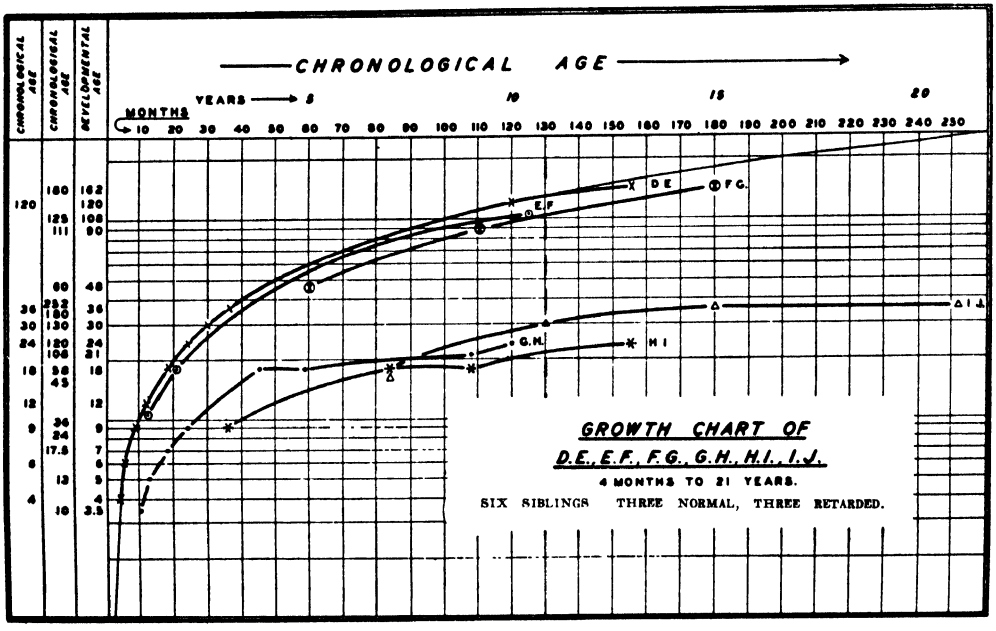

FIGURE 15. Growth graphs of D. E., E. F., F. G., G. H., H. I., I. J. (From *Biographies of Child Development: The Mental Growth Careers of Eighty-four Infants and Children,* by A. Gesell, B. M. Castner, H. Thompson, and C. S. Amatruda. New York: Paul B. Hoeber, 1939, p. 26.)

human organism displays comparable insurance mechanisms. Locked in inner recesses beyond diagnostic scrutiny are reserve factors which may come to the rescue when development is retarded or impaired. As a poison stimulates the formation of antibodies, so certain errors or depressions of development stimulate a regulatory self-correction. These reserve factors, however, are not a single generalized capacity. They are specific biochemical and somatic structures almost infinite in number and variety, and of many degrees of availability. They are present in defective as well as normal individuals. They are probably most abundant in the most vital and best endowed. Vitality is an index of the plenitude and vigor of these very insurance factors. In spheres of behavior they operate not only during the period of growth, but also in old age, at least in the most "vital" individuals.

If there is a principle of uncertainty in the physiology of development it is a biological principle which rests upon important individual differences with respect to these insurance factors. Since they vary in amount, it is difficult to ascertain their strength in those inscrutable infants who present an inadequate and yet not decisively defective behavior picture. Here diagnosis must be wary, sometimes for a whole year or more, because sometimes the insurance factors come tardily and slowly into full force. But if they are present, and if the attendant conditions permit, they will ultimately assert themselves. When there is no counteracting deteriorating process, the tendency of growth will be toward something better and toward an optimal organization of the available equipment.

General Conclusion

Behavior at all stages of development is patterned. Patterning is displayed in the phase of the moment, in the dynamic sequence of specific behavior events, and in the progressive differentiations of the ontogenetic cycle.

The forms of behavior are governed by laws of developmental morphology, and these forms can be analyzed in terms of time and space.

The basic configurations, correlations, and successions of behavior patterns are determined by a process of maturation. The tenacity of this process has been demonstrated by developmental studies of both premature and full-term infants and by experimental studies of monozygotic twins. The rôle of maturation is most conspicuous in the fetus and infant, but it persists throughout the life cycle until the growth potential completely subsides.

A psychic constitution is more than a general diathesis. It is a structured product of growth. It endures, but it also changes during the life cycle.

The psychic individual is a distinctive entity by virtue of a certain characteristicness in his manifold behavior tendencies and in his secular pattern of growth. Such characteristicness can be investigated from the standpoint of form and can be formulated by morphographic methods. A systematic study of the ontogenesis of behavior thus becomes a psychomorphological approach to the ancient problem of constitution and type.

CHAPTER 7

LEARNING IN CHILDREN

NORMAN L. MUNN

Introduction

Learning may be said to occur whenever behavior undergoes incremental modification of a more or less permanent nature as a result of activity, special training, or observation. To say that learning involves an *incremental* modification is to distinguish it from fatigue, which is also due to activity, but with which a performance decrement is associated. By indicating that the learning process involves a more or less *permanent* modification, we differentiate it from sensory adaptation, which disappears soon after removal of the stimulating circumstances. Finally, by including the statement that learning depends upon *activity, special training,* or *observation,* we point to the fact that it differs from modification which depends upon maturation *per se.*

In order to approximate complete coverage of experimental investigations on learning in children, one must take cognizance of conditioning, acquisition of motor skill, memorizing and related mnemonic functions, and problem solving.

Investigations of learning in children, rather than introducing new problems and essentially novel techniques, have followed the leads of animal and adult human psychology. The first investigation of conditioned responses in children (Krasnogorski, 1909) involved modification of the technique of Pavlov, who more than a decade earlier had begun his pioneer investigations on conditioned salivary response in dogs. Researches on learning of motor skills in children began to appear some time after the experiments of Thorndike (1898) and Small (1899) on animals and those of Bryan and Harter (1897), Swift (1903), and Book (1908) on learning of skills by human adults. The earliest published experiments on learning of motor skills which involved children as subjects are those of Judd (1908) on dart throwing and those of Hicks and Carr (1912) on maze learning. In researches carried out since 1912 the maze technique has figured prominently.

Investigations of mnemonic processes in children began shortly after Ebbinghaus's pioneer study on himself. Jacobs (1887) devised the memory-span test and used it with children. Binet and Henri (1894) worked with the memory span and included memory-span tests in their intelligence scales. Several of the early memorizing experiments (Steffens, 1900; Pentschew, 1903; Radossawljewitsch, 1907) involved children incidentally.

Problem solving, apart from that incidentally involved in the school subjects, has been extensively investigated only in comparatively recent years. Nevertheless, Lindley (1897) studied how children and adults solve various unicursal puzzles. He also, as we shall indicate more fully later, made some pertinent observations on differences in the way in which children and adults attack such problems. Widespread interest in the experimental investigation of

problem solving by children has, however, appeared only since publication of Köhler's (1925) researches on problem solving in apes. Investigations of the rôle of incentives and of various other factors relating to economical learning have also followed leads given by animal and adult human psychology.

In many investigations of learning, inclusion of children has been merely incidental. Early students of child development, although they investigated many other problems with children directly, tended, as far as learning was concerned, to accept and apply results obtained with animals and human adults. This accounts, in part at least, for a long delay in the appearance of researches aimed at determining how *children* learn.

The Conditioned Response

During his study of gastric secretion in dogs, Pavlov (1889–1890) observed that stimuli frequently associated with the presence of food become, in themselves, adequate to arouse secretory responses such as salivation. Salivation in response to hitherto neutral stimuli, such as sounds and skin irritation, was later referred to by Pavlov (1903) as a *psychic secretion.* Bekhterev, another Russian investigator, began in 1906 to develop what he termed *associative reflexes* in dogs. In response to shock on the foot or leg, withdrawal or *protective* reflexes were aroused. Bekhterev observed elicitation of similar reflexes by previously *neutral* stimuli after such had been presented in association with shock. Numerous researches based upon the above observations were soon carried out by Pavlov, Bekhterev, and their students.

That conditioned responses are relatively simple habits is doubted by no psychologist. Much of the controversy concerning them hinges upon the claim of Pavlov, Watson, and others that all learning, no matter how complex, results from conditioning. Habits are referred to by these investigators as chains of conditioned reflexes, or as compound conditioned responses. Our present discussion will avoid theoretical issues by describing the conditioned response in children merely as a type of habit formation. Whether or not all learning may adequately be envisaged in terms of conditioning will be determined only after more data are available. For an excellent discussion of the present status of this controversy the reader is referred to Hilgard and Marquis (1940) and Hilgard (1948).

Prenatal Conditioning. The possibility that certain "reflexes" of the newborn are responses conditioned prior to birth (Holt, 1931) has led several investigators to attempt conditioning of fetuses.[1] The two earliest attempts (Ray, 1932; Sontag and Wallace, 1934) were either unsuccessful or ambiguous in result. However, Spelt (1938, 1948) has reported success. Details of the experiment are reported in the latter publication. Responses of 16 fetuses between the ages of 7 and 9 months were studied through application of tambours to the mother's abdomen and also through maternal responses to felt movement. The recorded data are illustrated in Figure 1 and described in the legend.

A loud clapper elicited movement in all but the youngest fetuses. Before conditioning, there was never any response to vibrotactile stimulation of the maternal abdomen. In some cases, as few as 15 paired stimulations elicited movement to the tactile vibration alone. From 5 to 11 successive conditioned responses were obtained. One fetus which was studied extensively ex-

1 See Dennis (1943), who discusses this problem in detail and maintains that, despite the views of Holt and others, responses of the newborn are products of maturation rather than conditioning.

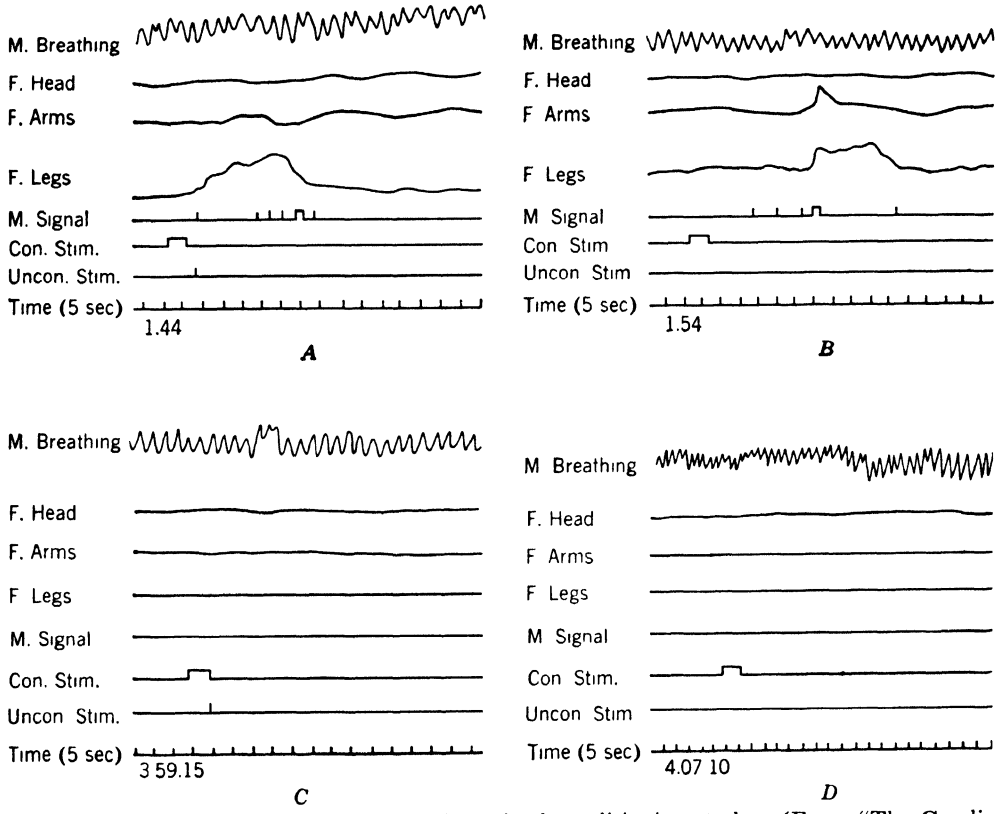

FIGURE 1. Sample kymograph records from fetal conditioning study. (From "The Conditioning of the Human Fetus *in Utero*," by D. K. Spelt. *Journal of Experimental Psychology*, 1948, *38*, 344. By permission of the publisher.) *A*, showing response to both stimuli, and *B*, showing response to *CS*, obtained from same *S*. *C* is a record from a non-pregnant control *S*. *D* shows result of applying *CS* alone in late pregnancy without previous conditioning trials.

hibited retention of conditioning over a period of 18 days. It also demonstrated experimental extinction and spontaneous recovery. Control experiments utilizing the vibrotactile stimulus alone demonstrated that movement to vibration does not develop as a function of age. The conditioned-response procedure applied to non-pregnant subjects produced nothing simulating the results obtained with pregnant subjects. These findings, and the fact that the mothers knew nothing of the nature of the experiment, or indeed that they were serving in an experiment, support the claim that the movements were fetal and not produced by maternal reactions. Although maternal movements, breathing, and sighing, distorted the records, the fetal movements were readily discerned.

Conditioning in Newborn Infants. Conditioning experiments on infants in the first week of life have been reported by Marquis (1931), Wenger (1936) and Wickens and Wickens (1940). In the investigation by Marquis, 10 infants between the ages of 2 and 9 days were stimulated with a buzzer for 5 seconds prior to each feeding period. Within 5 days of training, 8 of these in-

fants began to exhibit sucking and mouth-opening responses to the buzzer. Correlated diminution of crying and of general activity also appeared. Four control infants stimulated with the buzzer, but without associated food, failed to exhibit conditioned responses.

This experiment is criticized by Wenger (1936) on the basis that controls were inadequate and observation of responses too subjective. He failed to obtain conditioned feeding reactions in two newborn infants. That newborn infants may be conditioned, however, is shown by results obtained in his experiments involving eyelid, limb withdrawal, and respiratory responses. In conditioning of eyelid responses the unconditioned stimulus was a flash of light and the conditioned stimulus a tactile vibration of the foot. Tactile vibration preceded light by 3 seconds. During control tests, six 9-day-old infants exhibited lid responses to a tactile stimulation of the foot in 29 per cent of the presentations. The range was from 23 to 34 per cent. Infants with whom conditioning begin on the second day of life, however, reached percentages of 58 to 74 by the ninth day. Acquisition curves showed much daily fluctuation, and Wenger therefore concluded that, although conditioning is undoubtedly present, it is quite unstable.

Wenger also obtained conditioning when the unconditioned stimulus comprised an electric shock which elicited foot withdrawal and respiratory changes. Tactile vibration at the sternum served as the conditioned stimulus. One infant which exhibited no flexion responses to tactile stimulation 2 days after birth was, by the ninth day, making such responses to 50 per cent of the stimulations.

More acceptable evidence of conditioning than could be obtained with tactile vibration at the sternum was disclosed when a tone of 1084 cycles, and having a loudness of 50 decibels above the adult threshold, was substituted. Under these conditions, 3 infants exhibited conditioned flexion and respiratory responses. Two infants trained with a flash of light as the conditioned stimulus also exhibited conditioned withdrawal. They reached a mean percentage of 46 withdrawals. The percentage for controls of the same age was 13. In this, as in all the earlier experiments, conditioning was far from stable.

Wickens and Wickens (1940) criticize the results of the above studies on conditioning in neonates chiefly on the ground that controls were not adequate. Their own study, involving 36 infants younger than 10 days, utilized shock to the right foot as the unconditioned stimulus and the sound of a buzzer as the conditioned stimulus. An experimental group of 12 infants was given 36 paired stimulations of buzzer and shock, 12 each day for 3 days. One control group was tested at intervals with the shock alone. Another was tested with the buzzer alone. This was to check the possibility that maturation might make the infants responsive to the buzzer. In subsequent tests with the buzzer alone, the experimental and first-mentioned control groups gave similar results. This was true in terms of the number of responses to the point of extinction and for spontaneous recovery on the next day. Only 1 infant out of the 12 in the second control group gave any response to the buzzer, thus showing that maturation alone could not account for results with the other groups. A check demonstrated that the results could not be attributed to artifacts of the experimental situation. Two possible explanations of the failure to find a difference in the buzzer-shock and shock alone groups are mentioned. The most likely explanation is that both the shock and the buzzer constituted a *change* in the stimulus complex and that the infants were conditioned to such a change rather than

to the buzzer or shock as such. More specifically, it may be that the shock represents a change as well as a stimulus for reflex withdrawal. The sound of the buzzer, especially when presented in the same context as the shock, also represents a change in the same stimulus complex. It does not seem strange, therefore, that withdrawal should occur to the buzzer even though it has not been paired with shock. Such stimulus generalization is perhaps the basis for other examples of pseudo-conditioning (Grether, 1938).

Thus, although the findings are not as clear as one might wish, there seems good evidence for supposing that neonates as well as fetuses are susceptible to conditioning.

Marquis (1941) claims that, whether or not the above studies are accepted as evidence of neonatal conditioning, it is a well-known fact that newborn infants readily adapt to a feeding schedule. She recorded general bodily activity in, respectively, (1) a 4-hour schedule during the period of hospitalization, (2) a 3-hour schedule for 9 days and then a 4-hour schedule, and (3) a self-schedule, i.e., fed only when "hungry." There was clear evidence of adaptation. Adaptation was especially shown in the group shifted from a 3- to a 4-hour schedule. This shift produced a large and statistically significant increase in activity, particularly evident during the last hour before feeding. Marquis claims that this change in activity gives proof of a temporal form of conditioned response, set up according to the law of effect. She claims, moreover, that this sort of modification illustrates the earliest form of human acculturation.

Investigations of Conditioned Responses during Later Infancy. Conditioned feeding reactions in infants between the second and fourth months of life have been investigated by Denisova and Figurin (1929) [1] and Kantrow (1937). All but 1 of Denisova and Figurin's 11 infants were between the ages of 10 and 23 days at the beginning of the experiment. Natural conditioned responses, consisting of food-getting reactions to previously neutral stimuli, but occurring without experimental training, appeared between the ages of 21 and 27 days. For some of the infants, experimental training comprised presentation of a bell for 15 seconds before and 30 seconds after feeding began. In other cases, the conditioned stimulus was a bell or a bell and light. Feeding reactions to these stimuli appeared at ages ranging from 33 to 77 days, and after 132 to 350 trials.

A more comprehensive and carefully conducted investigation than the one just described is Kantrow's (1937). Sixteen infants aged 44 to 117 days at the beginning of the experiment rapidly developed conditioned feeding reactions to the sound of a buzzer. Sucking movements were recorded by placing over each infant's chin a harness attached to the pen of a polygraph. Other responses, such as crying and general activity, were noted. A control period of variable length (to avoid conditioning to a temporal sequence) preceded onset of the buzzer, which was sounded for 20 seconds. At the end of 5 seconds of stimulation with the buzzer, a bottle, which had been kept outside the visual field, was inserted in the infant's mouth. Stimulation with the buzzer continued for 15 seconds after feeding began. The stimulating sequence and the nature of responses at different stages of conditioning are indicated in Figure 2. Stable conditioned sucking responses appeared within 1 to 5 days, after 3 to 9 experimental feedings and 16 to 72 paired stimulations. An acquisition curve based upon the difference in the means for

[1] This research has been published only in Russian. The present summary is based upon Razran's (1933).

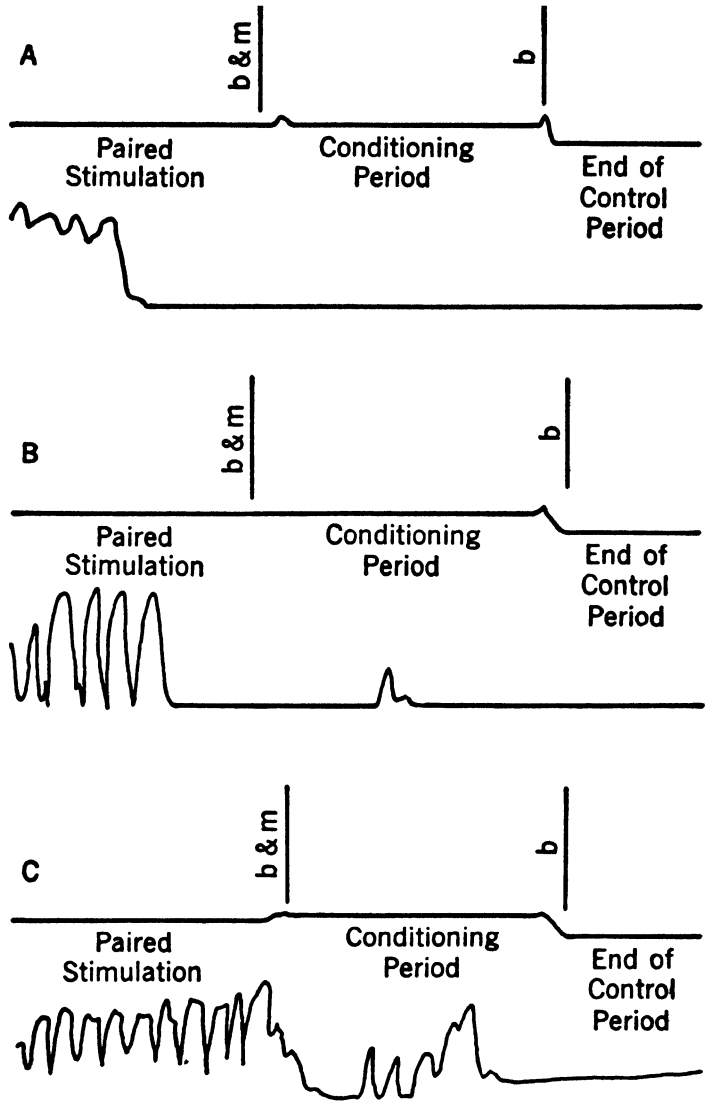

FIGURE 2. Sample sucking records of an infant before and after conditioning to the sound of a buzzer. (From "An Investigation of Conditioned Feeding Responses and Concomitant Adaptive Behavior in Young Infants," by R. W. Kantrow. *University of Iowa Studies in Child Welfare,* 1937, *13,* 11. By permission of the publisher.) Read from right to left. At the end of a control period of variable duration, a buzzer *b* was sounded for 5 seconds, the conditioning period. At the end of this period, the nipple was placed in the infant's mouth and the buzzer continued for another 15 seconds, *b & m*. The lower line in each part of the figure is a record of sucking activity. It was obtained by means of a chin harness attached to the pen of a polygraph. *A*. First experimental feeding, fifth paired stimulation. *B*. Fifth experimental feeding, thirty-second paired stimulation. Note anticipatory feeding reaction. *C*. Eighth experimental feeding, fifty-fourth paired stimulation. Note conditioned sucking activity.

sucking during successive groups of control and conditioning periods is shown in Figure 3. Continued presentation of paired stimulations beyond the ninth experimental session led to a plateau and, finally, to a drop in the acquisition curves. Crying and general activity at first showed a gradual decrease as a function of experimental pairing of the buzzer and feeding. They then increased at about the same time as appearance of the sucking decrement mentioned above. Analysis of the data in terms of degree of hunger at the time of the tests indicated that, unless the infant was hungry, little conditioning appeared. Curves based upon sucking activity during experimental extinction, produced by successive stimulations with the buzzer alone, represent what approximates a mirror image of the curve shown in Figure 3. An increase in general activity and in the amount of time spent in crying was also noted during extinction experiments.

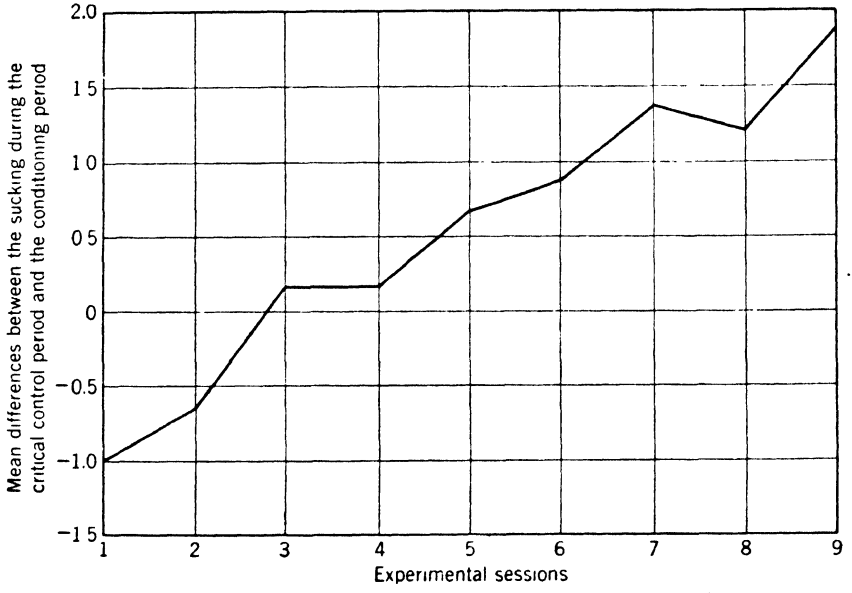

FIGURE 3. Acquisition curve of conditioned sucking in fifteen infants for nine consecutive experimental feedings. Conditioning of the blink to a puff of air was studied by Morgan and Morgan (1944) in 50 infants ranging in age from 5 to 75 days. The conditioned stimulus was movement of the hand that held the bulb. On each trial the bulb was brought before the infant's eyes, and, if he did not wink within 2 seconds, it was squeezed, producing the unconditioned stimulus. Evidence is presented which suggests that the conditioned wink under these conditions cannot be produced before an age of around 45 days.

Conditioned differential sucking activity to tones and to intensities of light has been developed by Kasatkin and Levikova (1935*a*, 1935*b*) in infants between 1 and 2 months of age.

Conditioning of emotional responses in infants has been studied by several investigators. Since emotional behavior is the subject of another chapter in this book, however, we shall not undertake a detailed discussion of these studies. It is sufficient to say, at this point, that Watson and Rayner (1920) and H. E. Jones (1930*a*, 1930*b*) have succeeded in conditioning fear reactions and galvanic skin responses, respectively, to previously neutral stimuli. Retention of the conditioned responses over periods ranging up to 7 months was noted by Jones. Moss (1924) conditioned two children, the younger of whom was 2 years old, to dislike the sound of a snapper which was associated with squirting of vinegar into the mouth. Bregman (1934) was unsuccessful in her attempt to condition emotional attitudes of 15 infants between the ages of 8 and 16 months. Sounds assumed to be disagreeable were associated with some objects while supposedly agreeable sounds were associated with others. Negative and positive reactions to these objects which might be expected from the nature of associated stimuli did not appear. Although there were no consistent changes in attitude as a result of the conditioning procedure, some infants at times evidenced negative reactions to stimuli associated with the noise. As Wenger (1936) has pointed out, there is no proof of the agreeableness and disagreeableness, for infants, of the sounds used in this investigation. Bregman's claim that conditioning *per se* cannot account for changes in the emotional attitudes of infants seems unwarranted in the light of her results.

Although the restricted data so far available do not justify any extensive generalizations, one may, in summary, say that investigations of conditioning in infants have shown that: (1) sucking, blinking, limb withdrawal, respiration, crying, general activity, galvanic skin responses, and fear reactions may be conditioned to tactual, visual, and auditory stimuli during infancy; (2) although newborn infants may be conditioned, the reactions are often lacking in stability; (3) older infants tend to evidence more stability of conditioned reactions than the newborn; (4) conditioning of the sucking reaction is dependent upon existence of hunger; (5) retention of conditioned responses developed in infancy has in some instances been observed over periods ranging up to 7 months; (6) spontaneous recovery following extinction training has been observed; (7) continued presentation of the paired stimuli may, after conditioning has developed, lead to a decrement in the frequency of conditioned reactions; and (8) the curve of extinction for conditioned feeding reactions approximates a mirror image of the curve of acquisition.

Conditioned-Response Studies with Older Children. Investigations of conditioned responses in children beyond the period of infancy have been numerous. Razran (1933) has summarized more than 30 researches from the Russian laboratories alone. In the following discussion we shall consider only a few studies which are more or less representative of those with children beyond infancy.

As indicated earlier, the pioneer research on conditioned responses in children was Krasnogorski's (1909). In Krasnogorski's initial experiment a child of 3½ years was conditioned so that salivation first elicited only by food occurred in response to a bell. The index of salivary response was swallowing. In later experiments with other children, Krasnogorski placed a tambour over the thyroid cartilage and recorded the swallowing reactions on a kymograph. He also used mouth opening as the response to be conditioned. Later still, saliva was collected by means of suction cups (saliometers) placed over the salivary glands. As Razran's review indicates, the

experiments from Krasnogorski's laboratory have, in general procedure, results, and interpretatoin, closely paralleled those of Pavlov on dogs. Krasnogorski (1925) has reviewed in English some of his investigations of conditioning in normal and neurotic children. Mateer (1918), whose research on 50 normal and 14 subnormal children will be mentioned again later, utilized Krasnogorski's general technique. The unconditioned stimulus, which elicited mouth opening and swallowing, was chocolate placed in the mouth. Pulling a bandage over the child's eyes just prior to presentation of the chocolate served as the conditioned stimulus.

Still another technique used to develop conditioned responses in children is that of Marinesco and Kreindler (1933). It involves a modification of Bekhterev's general procedure in that the reaction conditioned is withdrawal of a limb from weak electrical stimulation. An electrode is attached to the child's abdomen and another to the foot or hand. The arrangement is such that shock is felt in the limb. A thread attached to the limb and, through a pulley system, to the marker on a kymograph drum serves to record retraction of the arm or leg. The conditioned stimulus is the sounding of a metronome for 50 seconds before onset of the shock, which lasts for 20 seconds. A tracing from part of the record obtained in conditioning a child of 26 months is shown in Figure 4. One will note that there is, in this case, no evidence of conditioning at the tenth trial. At the eleventh trial, however, the foot is partially withdrawn in response to the metronome. A more marked withdrawal appears at the twelfth presentation of the metronome.

Use of this technique has enabled Marinesco and Kreindler to demonstrate clearly, in children between the ages of 15 and 30 months, many of the phenomena of conditioning disclosed in experiments with animals. The chief phenomena observed in this study were:

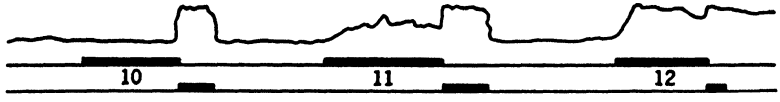

FIGURE 4. Conditioned withdrawal in a child of 26 months. (From "Des réflexes conditionnels: I. l'Organisation des réflexes conditionnels chez l'enfant," by G. Marinesco and A. Kreindler. *Journal de Psychologie*, 1933, *30*, 873.) *Bottom line:* duration of electric shock. *Second line from bottom:* duration of metronome. *Top line:* foot withdrawal.

1. *Conditioned differentiation of movements.* At first all limbs responded despite the fact that only one was stimulated. During the course of conditioning, however, retraction of limbs other than the one stimulated decreased in amplitude and finally ceased.
2. *External inhibition.* Presentation of a second stimulus, such as light, while the metronome was sounding reduced the amplitude of movements previously made to the metronome.
3. *Trace responses.* When stimulation with shock followed cessation of the metronome by several seconds, the conditioned retraction was delayed for a corresponding interval of time.
4. *Experimental extinction.* Continued presentation of the metronome, without following it with shock, led to diminished conditioned responses and, finally, to their disappearance.
5. *Spontaneous recovery.* After conditioned responses had disappeared as a result of extinction training, they reappeared without further training.

6. *Higher-order conditioning.* After the metronome aroused withdrawal responses it was, with occasional further reinforcement, used as the conditioning stimulus in training with other stimuli to be conditioned.

Changes in semantic conditioning as a function of age have been investigated by Riess (1946), using 68 children ranging in age from 7 to 15 years. After the electrodermal response of each child had been conditioned to certain words, using a buzzer for reinforcement, the magnitude of the EDR to homophones (won, one), antonyms (won, lost), and synonyms (won, beat) was measured. There was transfer from the originally conditioned words to the semantically related words, but the efficacy of the latter types varied with age. The lowest age group (average 7 years, 10 months) responded maximally to homophones, the intermediate group (10 years, 8 months) to antonyms, and the older age group to synonyms.

In a somewhat similar experiment except that purely verbal methods were used, Goodwin, Long, and Welch (1945) found that 8–10 year olds who memorized words at the species level showed a degree of generalization to the genus level. Most subjects vaguely grasped the species-genus relationship.

The studies so far considered in this chapter have dealt with what Hilgard and Marquis (1940) call "classical" as distinguished from "instrumental" conditioning. The latter receives this designation because, in it, the subject's response is instrumental in bringing a reward or escape from punishment. The two studies that we are about to consider fall within the "instrumental" classification because the child gets a reward (piece of candy) by making the response to be conditioned.

Ivanov-Smolensky (1927*a*, 1927*b*) was first to use an instrumental technique with children. His general experimental situation is illustrated in Figure 5. The child is seated before the apparatus with a rubber bulb in his hand. As the experimenter, who is in an adjoining room, presses his bulb, food is released and slides down a tube toward the child. Just before release of the food, a bell or other conditioned stimulus is activated. The child observes the food through a small window on the tube and, by pressing his bulb, is able to obtain it. Presentation of the conditioned and unconditioned stimuli and pressing of the child's bulb are recorded objectively by kymographic or other means. Children between the ages of 4 and 15 years have been conditioned in 2 to 88 trials to make stable grasping reactions upon presentation of such conditioned stimuli as the sound of a bell and the flash of a light. Investigations from Ivanov-Smolensky's laboratory are reviewed by Razran (1933). They demonstrate individual differences in susceptibility to conditioning, higher-order conditioning, statistically unreliable differences in the speed with which conditioned grasping and withdrawal responses are developed, and development of reflexes to chains of stimuli. There has also been an attempt to classify children into excitable, inhibitable, labile, and inert types upon the basis of their conditioning behavior. However, only 13 children were used in this study. Bayne, Winsor, and Winters (1929), using the Ivanov-Smolensky technique, found that conditioning to red light was obtained in 8 to 10 trials in two 6-year-old children. A 4-year-old child, however, required over 200 trials to develop grasping responses to the sound of a metronome.

The following study falls within the classification of instrumental responses that Skinner (1938) has designated "operant." This is because the child's response to the lever is "emitted" rather than being elicited by some external stimulus, like the falling

candy of Ivanov-Smolensky's study. Pressing the lever occurs as a result of internal processes, not as a response to a stimulus present at the moment of response, as the blink is produced by a puff of air or withdrawal by an electric shock. Skinner designates the latter as "respondent."

obtained with a child whose drive for candy was weak. In this case, periods of rapid response alternated with periods of no response. Curves 2 and 3 were made by children with an intermediate to strong drive for candy. The second curve will serve to illustrate the meaning of such conditioning

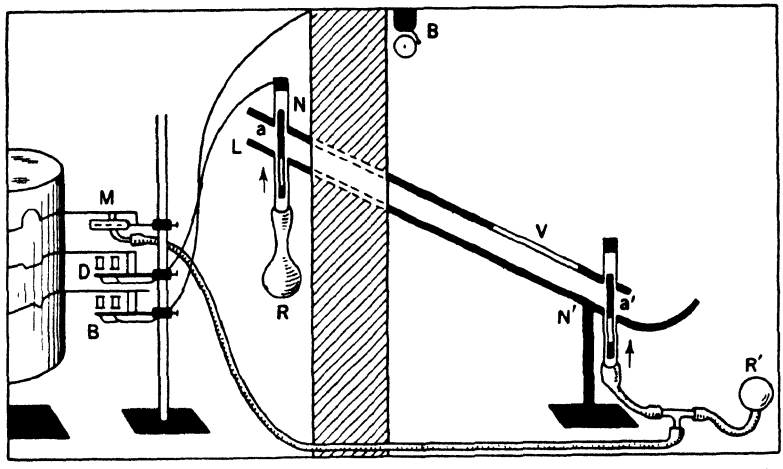

FIGURE 5. Ivanov-Smolensky's method of conditioning. (From "On the Methods of Examining the Conditioned Food Reflexes in Children and in Mental Disorders," by A. G. Ivanov-Smolensky. *Brain*, 1927, *50*, 139. By permission of the publisher.) The experimenter, seated in the room at the left, presses the bulb *R* and causes a piece of chocolate, *a*, on the shelf, *L*, to slide down the tube *N*-*N'*. As the chocolate passes the window, *V*, in the adjoining room it may be seen by the child, who sits with his hand over the bulb *R'*. By pressing this bulb and thus causing a photographic shutter to move upwards, the child releases the chocolate, which falls into the position *a'*. A Marey tambour, *M*, records the child's grasping response on a kymograph drum. The signal marker, *D*, likewise records release of the chocolate by the experimenter. In conditioning experiments a bell, *B*, or some other stimulus, is presented just before the release of the food and its presentation recorded by the signal marker, *B*. Conditioning is evidenced by grasping at the sound of the bell or prior to observation of food.

Warren and Brown's (1943) investigation is a repetition of the Skinner experiment, but with children rather than rats as subjects. The response of pressing a lever in the playroom was reinforced (rewarded) by the appearance of a pellet of candy in a food tray under the lever. Nine children between the ages of 2 and 5 years completed the experiment. Typical conditioning curves for individual children are shown in Figure 6. The irregular curve (1) was

curves. The child whose lever-pressing is here represented did not press the lever once in the first few minutes. By the eighth minute, however, responses were occurring at the rate of around 20 per minute. The rate of response gradually declined until the thirty-ninth minute. Then the rate increased and remained approximately constant at around 8.2 responses per minute. Each experimental period lasted 22 minutes, but the curves were plotted

without showing a break after every 22 minutes.

In addition to demonstrating the Skinner-type operant conditioning in children, this experiment also provides data on experimental extinction, spontaneous recovery, disinhibition, and periodic reconditioning. The experimenters conclude that, within certain limitations related to the use of children, their results are similar to those reported for operant conditioning in rats.

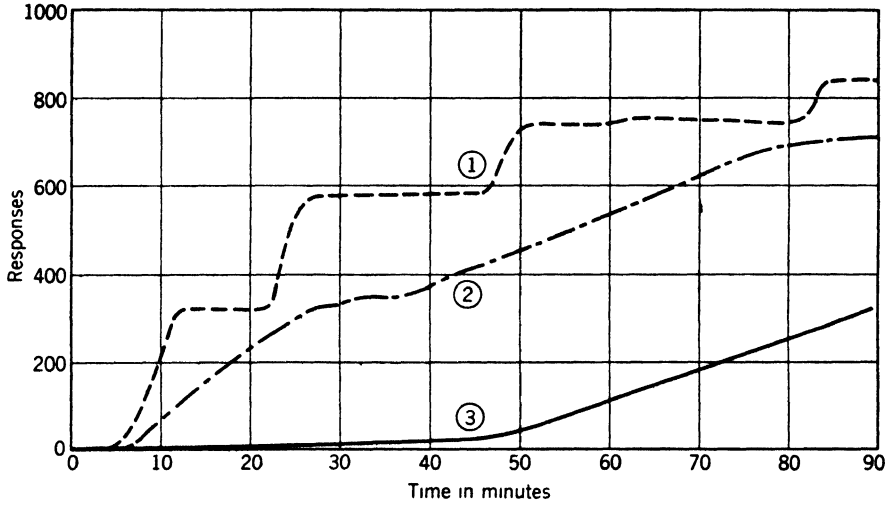

FIGURE 6. The total number of responses emitted is plotted as a function of the length of time elapsed during the initial conditioning periods in which every response was reinforced. The points represent data for single subjects, and the curves are drawn by inspection. (From "Conditioned Operant Response Phenomena in Children," by A. B. Warren and R. H. Brown. *Journal of General Psychology*, 1943, *28*, p. 188.)

Speed of Conditioning as a Function of Age and Intelligence. Mateer's (1918) investigation (see page 382) involved 50 normal and 14 subnormal children between the ages of 12 and 90 months. For normal children the correlation between CA and the number of trials required to produce two successive anticipatory responses was .571 ± .06. The approximate average number of trials required at successive yearly age levels, for the normal group aged 1 to 7 years, was 8, 7, 5, 4, 4, 5, and 4, respectively. These results suggest that, within the age range of 1 to 4 years, and for the type of response involved, susceptibility to conditioning increases with chronological age. The other extensive investigations, however, show results not in agreement with the above. Osipova (1926) conditioned withdrawal reactions in children between the ages of 7 and 19 years. He found that the average number of trials increased with age. The correlation between CA and speed of formation of the conditioned withdrawal response was −.358 ± .033. A biserial correlation based upon 144 cases between 14 and 19 years was −.716 ± .06. Osipova's findings are supported by those of Dernowa-Yarmolenko (1933), who conditioned 1000 subjects between the ages of 8 and 19 years. Each subject was told to raise his hand when the examiner did so. The examiner then tapped on the table with a pencil. Two seconds later he raised his left hand. Ten such paired presentations of

the tap and hand raising were presented. Anticipatory hand raising was noted, that is, raising the hand after a tap but before the examiner raised his hand. The percentage of subjects exhibiting anticipatory conditioned reactions within 10 trials was 90 at 8 years. In successive yearly age levels the percentage gradually decreased until, at the upper levels, very few were responding. With increasing age, furthermore, the number of associations of the two stimuli required to produce conditioned reactions increased and the number of conditioned reactions in 10 trials decreased.

In considering the results of Osipova and Mateer, Razran (1935) suggests that conditioning of the laboratory type may be rendered more difficult as an individual grows beyond the early years of childhood, not because of decreased susceptibility to conditioning *per se* but because "instrumental mastery of verbal and conscious processes," with an associated decrease in naïveté, makes him *less willing to submit to the procedure*. Researches by Razran (1936) on adults conditioned indirectly, while they were engaged in other activities, lend support to this view. Mitrano (1939) has attempted to overcome deleterious attitudinal factors by using feeble-minded children and adults as subjects.

Mateer found a correlation of .588 ± .06 between speed of conditioning and MA. Osipova (1926), on the other hand, obtained a biserial correlation of −.540 ± .08 between intelligence and speed of forming the conditioned withdrawal reaction. On the basis of the results so far available, therefore, it would be hazardous to make any generalizations about the relation between speed of conditioning and intelligence. If Razran's view is correct, one might expect a negative correlation between intelligence and the speed of laboratory conditioning.

Solution of Behavior Problems by Conditioned-Response Procedures. Krasnogorski (1925, 1933), Ivanov-Smolensky (1927*a*, 1927*b*), Seham (1932), and Gesell (1938) have reviewed applications of conditioned-response procedure to child psychiatry. From the standpoint of indicating actual accomplishment, however, these reviews are quite disappointing. They merely describe general techniques and what these *promise* for solution of behavior problems. Nevertheless, a few specific applications of conditioned-response principles have been made in this field.

Aldrich (1928) and Marinesco, Sager, and Kreindler (1931) have used conditioned-response procedures to determine the presence of hearing in, respectively, a 3-month-old infant thought to be deaf and a 9-year-old functionally mute child.

Jones's (1924*a*) elimination of a child's fear response by conditioning is well known.

Morgan (1938), Mowrer and Mowrer (1938), and Morgan and Witmer (1939) have been highly successful in eliminating enuresis by a conditioned-response procedure. The problem involved in enuresis is very well stated by Mowrer and Mowrer (1938):

> Learning to awaken to the relatively vague and not very intense pressure created by a filling bladder, while successfully ignoring many other potentially disturbing stimuli, must be for the young child something of a feat, especially in view of the pre-existence of a strictly reflex, subcortical neural mechanism for the autonomic relief of this need [p. 437].

Use of conditioned-reflex procedure here has as its aims, (1) causing the child to associate *getting up* with bladder tension and (2) making the child responsive to bladder tension in its earlier stages, that is, lowering his threshold for this stimulus.

All the above studies have involved essentially the same technique for producing these effects. The child was required to sleep on a mat which, when urination began, short-circuited and rang a bell. Each child was instructed to get up as soon as the bell rang, to open a switch disconnecting the bell, and then to go to the bathroom and finish urinating. All of Mowrer and Mowrer's 30 cases between the ages of 3 and 13 years were cured of enuresis within 4 to 8 weeks. They learned, in other words, to anticipate the ringing of the bell by arising before bladder tension became so great as to cause reflex urination. Morgan and Witmer report that 4 of their 5 subjects were cured of enuresis by this method in 4 to 14 nights. Morgan says that all children who cooperate are readily cured by application of this technique.

The technique just described has been used successfully by Deacon (1939) with feebleminded children at Vineland. Smith (1948) describes this and other conditioned-response methods used by him in the treatment of enuritics.

Learning of Sensorimotor Skills

Acquisition of sensorimotor skills is of singular importance during early childhood. The chief problems of adjustment which confront the infant concern acquisition of skills necessary for manipulation of and orientation with respect to its environment. Some of these skills, such as crawling, walking, and finger-thumb opposition, are probably functions more of maturation than of learning. Even when learning is shown to be involved in the acquisition of such skills, it is, as Dennis (1935) has so aptly pointed out, frequently autogenous. Such learning results from the child's own untutored activities rather than from specific training. On the other hand, there are many skills, such as talking, writing, and buttoning clothes, which fail to develop unless specific training or opportunities for imitation are provided. These skills and the various factors which influence their acquisition will be our prime concern in the following discussions.

The Relative Influence of Maturation and Learning. Acquisition of skill which results from learning is our chief concern, yet we cannot ignore the fact that learning and maturation are concomitant factors in child development. Although some skills develop primarily as a result of maturation and others primarily as a result of learning, the two processes are reciprocally related. This relationship is of especial importance during early childhood when the neuromuscular system is undergoing rapid growth and when, at the same time, there are numerous influences to encourage learning. With increasing age there is a relative decrease in the importance of new maturational factors.

These considerations indicate that investigation of the learning process *per se* in young children must take cognizance of maturation. Failure to control maturational influences has greatly lessened the value of many early, and even some recent, studies on learning in children. In some instances a loose use of the term *learning* has been involved. Thus Kirkpatrick (1899) describes how a child "learns" to walk. Ketterlinus (1931) presents a study which illustrates the ambiguity of interpretation which results when the possible improvement in skill resulting from maturation is ignored. The problem was to determine whether children between 2 and 5 years of age are able to adjust to mirror reversal. The experiment covered a period of 4 weeks, with two trials on a certain day each week. One problem was to pick up objects and put them in a cup. The objects and cup were seen only in a mirror. Age groups of 2, 3, and 4 years

were used. Each age group began the experiment with a lower time score than did the preceding one. This may be interpreted as due to the effect of maturation or perhaps to general training which preceded the experiment. Acquisition curves show a decrease in time during the course of the experiment. The *rate* at which a curve dropped, however, was greatest for the youngest group and least for the oldest. This is what one might expect were maturation an important factor. If learning were the chief factor, would one not expect the older, more mature group, to learn faster than the younger group? It might be claimed, on the other hand, that since the 4-year-old group began with the lowest time score it was closer to the physiological limit and thus could not be expected to improve as much as the younger groups.

Such ambiguity of interpretation could have been prevented by using a control group matched with the experimental group in terms of age, sex, intelligence, and initial ability on the tests in question. The same criticism applies to Beebe's (1933, 1934) investigations of *motor learning* in children. Since no control groups were used, the curves obtained cannot be interpreted with any degree of certainty.

Several investigations of learning at the early age levels have used the method of co-twin control or have utilized a trained and an untrained group matched in terms of age, sex, intelligence, and initial performance. The co-twin control investigations of Gesell and Thompson (1929) on climbing and cube manipulation, Strayer (1930) on speech, Hilgard (1933) on walking boards, cutting, and ring tossing, McGraw (1935) on a variety of motor activities, and Mirenva (1935) on jumping, throwing at a target, and rolling a ball toward a target all indicate the strong influence of maturation at early age levels.

Hilgard's (1932) investigation of climbing, cutting, and buttoning activities involved trained and untrained groups of approximately equivalent initial ability. The average time score for a group given 12 weeks of practice in climbing dropped from 18 to 8½ seconds, approximately. Tests at the end of the experimental periods indicated that the average time score of the untrained group had dropped to 13 seconds. Within 1 week of further training, however, the score for this group approximated that of the trained group. Both groups improved in cutting and buttoning, but the untrained group was not able to reach the level of the trained group within an additional week of practice.

Acquisition of skills more complex than the above is also markedly influenced by maturation and nonexperimental training. Hicks (1930*a*) found that 8 weeks of throwing at a moving target yielded no greater gains than were produced in the control group by "structural growth and general practice which had a direct bearing on the specific skill." The children had an age range of 2½ to 6½ years. In a further report concerning such skills as tracing between two lines and making perforations, Hicks (1930*b*) obtained similar results. Hicks and Ralph (1931) found that children ranging in age from 24 to 40 months thread the Porteus diamond maze as well without training as they do after 7 weeks of training. The trained and untrained groups began the experiment with a score of 23 points. Two trials per week for 7 weeks yielded the following successive average scores: 27.2, 24.4, 27.9, 26.2, 27.7, 29.7, 29.4. Tests at the eighth week yielded an average score of 31.8 for the trained group. The group which had received no training since the initial tests made an average score of 32.1 Hence the improvement of the trained group was matched by that of the untrained group.

Maturation, and perhaps to a certain degree nonexperimental training, produced as much improvement in skill as did specific training.

Mattson's (1933) investigation with a rolling-ball maze yielded results somewhat like the above when the maze pattern was simple. With more complicated patterns, however, the trained group gave a significantly better performance than the untrained, and the advantage possessed by the trained group increased as the complexity of the maze pattern increased. Since Mattson's is the most thorough investigation of the relative influence of maturation and specific practice in acquisition of a complex skill, we shall consider it in some detail.

The maze patterns used by Mattson are illustrated in Figure 7. Instruction in how to manipulate the maze—that is, press it down in various directions upon its supports so as to make the ball roll in different directions—was given each child at the beginning of the experiment. The goal was then shown and the experimenter said:

> *This is the house where the marble lives, and this is where we put it* [putting the ball at the starting point of the labyrinth]. *Do you think you can find the path right down to the little house? Press very hard every time so that the bell rings, and if the gate is shut, and the marble can't go any farther, try another way. Now begin.*

The subjects were 24 boys and 26 girls ranging in age from 58 to 72 months. Their average age was 64.7 months, and their average IQ, 103.4. Practice and control groups were matched for age, sex, IQ, and maze scores for the initial 4 days of training. Training was given on all three patterns each day. The order of presentation was such that, in 9 daily trials, each pattern came once as first, once as second, and once as third. Distribution of practice for the two groups is indicated in Table 1. The two groups, it will be observed from the table, differed only in that the practice

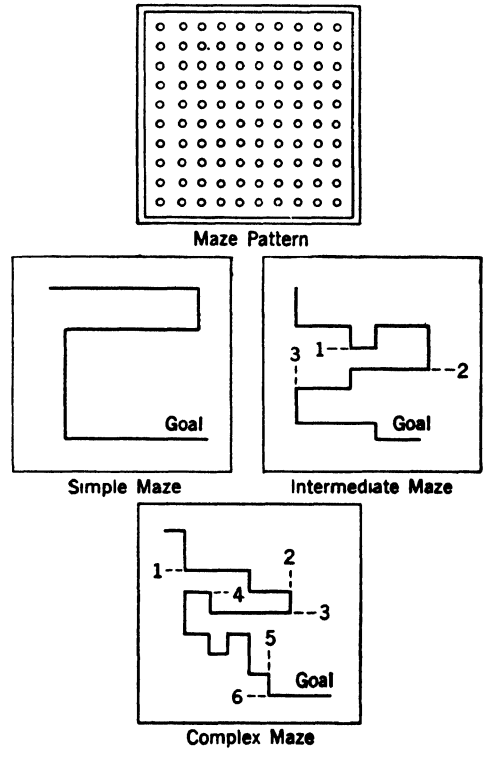

FIGURE 7. Three maze patterns used to investigate the influence of maturation and learning in acquisition of a complex skill. (From "The Relation between the Complexity of the Habit to Be Acquired and the Form of the Learning Curve in Young Children," by M. L. Mattson. *Genetic Psychology Monographs*, 1933, *13*, 332. By permission of The Journal Press, publisher.) The top view illustrates the rows of screws which made an invisible pathway, through which the ball rolled as the maze was tilted in different directions. Small gates placed at appropriate positions blocked further progress of the ball in certain directions. These gates were placed so that the ball could reach the exit only by rolling along the paths indicated in the remaining diagrams, which show the three degrees of complexity involved.

group had 26 more days of tests than the control group.

Progress was measured in time and errors. The means, differences, and reliability of the differences for the two groups on each of the mazes are given in Tables 2 and 3. From the data in these tables it is apparent that, although the practice and control groups began the experiment with approximately equal performances, the subjects who had 26 days of additional practice manifested superior performances on each of the three mazes. This was true in the test at the end of training and also in the retest given 60 days later. It held true for both time and error scores. All these differences except those for time scores on the simple maze in the test period and on the two simpler mazes in the retest were statistically reliable. It is also

clearly apparent from the data summarized in Tables 2 and 3 that the advantage of the trained group over the untrained was greater as the complexity of the task increased. A study of relative differences based upon ratios of gain and percentages of gain or loss supported the above conclusions.

This study suggests that earlier investigations in which there was as much gain from maturation and possibly general practice as from specific practice derived their result from the simplicity of the tasks involved. Comparison of learning curves from these studies with those of Mattson for the two complex mazes shows relatively little gain even in the practice groups. One might conclude that, when large gains are made by the practice group, the group left to depend upon maturation will be shown to suffer a disadvantage in later tests.

Learning of Sensorimotor Skills as a Function of Age. Investigations of the relative influence of maturation and learning in acquisition of motor skills have demonstrated that *at early age levels, and for skills that are simple or which show little short-time improvement from either maturation or practice,* the effect of increasing maturation is to make given amounts of practice increasingly effective.

When skills as complicated as manipulating Mattson's mazes II and III are concerned, little if any improvement occurs in the absence of practice. Would older children, however, learn such skills more readily than younger ones? One might expect an affirmative answer for two reasons. In the first place, it seems reasonable to suppose that the older child, having a sensory, neural, and muscular system of greater maturity, should profit more from given amounts of practice than a younger child. In the second place, the older child has a wider previous experience upon which to draw in acquiring new skills and this might be expected to give him an advantage over the younger child.

Since previous experience is a variable and an uncontrollable factor when human beings are concerned, students of the age effect in learning would do well to eliminate the differential effect of experience as much as possible. This was accomplished in Stone's (1929–1930) experiments by using rats which were reared in a relatively constant environment before the tests. If human subjects are used, experiential advantages of the older individual can be reduced to a minimum only by studying the acquisition of skills far removed from those of everyday life. Certain maze problems call for approximately such skills.

The most comprehensive and thorough investigation of the age function in maze learning by children is McGinnis's (1929). Young's (1922) slot maze was used. Each child was required to push a stylus in the form of a shoe along a grooved pathway until the figure of a boy was reached. The subject was instructed to "take the shoe to the boy" as quickly as possible. There were 20 children, 10 boys and 10 girls, in each of three age groups. The average ages were approximately 3, 4, and 5 years. Average IQ's were, respectively, 107.9, 117.5, and 103.8 Each child was given 5 trials daily 5 days per week until a total of 50 trials had been completed. Learning curves based upon median time and error scores are shown in Figure 8. It will be observed that the median time and error scores for the first 5 trials decreased with age. Final levels of performance, however, were similar. The average number of errors for successive age groups beginning with the youngest was: 153.7 ± 19.7, 108.9 ± 10.5, and 78.6 ± 16.4. The difference of 75.1 between average error scores of the 3- and 5-year groups alone approxi-

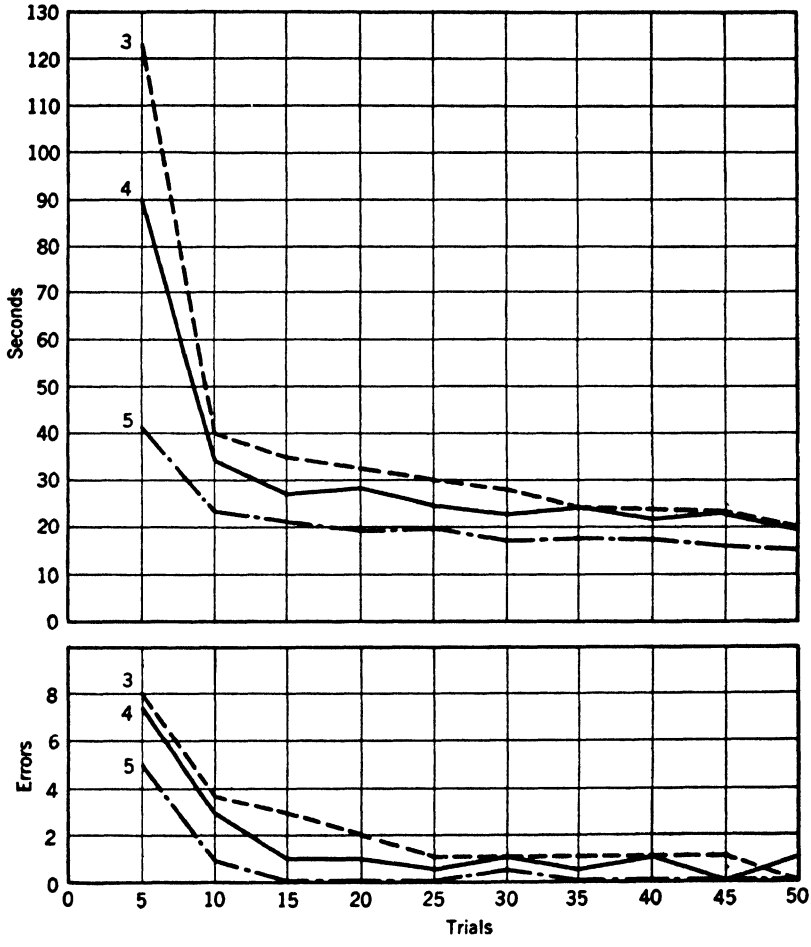

FIGURE 8. Learning curves for time and errors for three age groups. (From "The Acquisition and Interference of Motor-Habits in Young Children," by E. McGinnis. *Genetic Psychology Monographs*, 1929, *6*, 241, 244. By permission of the publisher.)

mated statistical reliability, its critical ratio being 2.9. The average time in seconds for successively older groups was: 2071.2 ± 68.7, 1954.3 ± 51.8, and 1211.4 ± 38.8. Differences between the time scores of the groups showed the older to be superior. However, only the differences between the 4- and 5-year and 3- and 5-year groups were statistically reliable.

Despite better maze performance of the successively older groups, *learning during the course of the experiment* was similar regardless of age. McGinnis (1929) calculated the differences in time between the initial and final trials for each of the groups. The percentage of gain was similar (91 to 93) for each age group. When averages for the first five trials were compared with those for the last five, the percentage gain was slightly greater for the 3- and 4-year groups (85) than for the 5-year group (75). Analysis of initial and

final error scores shows that the *younger* the group the greater the absolute gains.

The older groups, since they began the maze performance at a greater level of efficiency than the younger, were initially closer to their physiological limit in time and closer to perfection in terms of error scores. It is quite possible, therefore, that the actual degree of improvement is not shown by data indicating gain in final over initial scores.

Another approach to this problem is through analysis of changes in variability. Coefficients of variation were larger for the initial than for the last trial, suggesting that intragroup individual differences had been decreased by training. The decrease was greatest for the oldest and least for the youngest group. This suggests that practice reduced the variability of the oldest more than it reduced the variability of the youngest group. Apart from this suggestion there is no clear evidence of differential *learning ability* at the three age levels studied.

Other investigations of maze learning at different age levels have been performed by Hicks and Carr (1912), Gould and Perrin (1916), Wieg (1932), and Wenger (1933). Analysis of the results of these investigations fails to reveal any consistent evidence of age changes in maze-learning ability.

Studies of the effect of age on acquisition of skills other than maze performance also yield results which are either negative or equivocal. Clinton's (1930) study of mirror drawing at yearly age levels from 6 to 17 shows that the average number of lines drawn within a 5-minute learning period increases from 4.7 at 6 years to 30.8 at 17 years for boys and from 2.9 at 6 years to 38.6 at 17 years for girls. On the surface it would appear that there is greater adaptation to the mirror distortion, within the 5-minute learning period, at successively higher yearly age levels. Although the author mentions learning curves, he gives no information concerning the initial and final performance at each age level. Without such information one is unable to ascertain how much actual learning occurred within the 5-minute periods. It might be expected that successively higher age groups, as a result of increased experience with mirrors, would start the test with higher scores. This alone may account for the apparent age differences in learning

Investigations by Dunford (1930), Renshaw (1930), and Renshaw, Wherry, and Newlin (1930) fail to show any evidence that, in learning to localize a point on the skin by touching it with the eyes closed, the rate of learning differs for children and adults. There are age differences in the initial and final accuracies, to be sure, but improvement resulting from a given amount of practice is roughly the same for child and adult groups.

Hicks (1931) studied acquisition of skill in hitting a moving target. No age differences in learning ability appeared. The initial and final scores increased in successive yearly age levels from 3 to 6, but the gains were similar in each group. In this experiment, moreover, a control group to test the influence of maturation gained as much as the trained group

The only remaining experiments on the influence of age in learning of motor skills by children are those of Eigler (1932) and Langhorne (1933). Eigler studied the problem of learning to synchronize a finger reaction with a recurring flash of light. Twenty-two children between 2 and 6 years and 20 adults were subjects. Age differences in favor of the older groups are suggested. It is apparent, however, that there were differences in the motivation and in the fundamental coordinating ability of the groups. These, rather than differences in learning ability *per se*, could easily

account for the observed differences in adaptation. For example, younger children were more afraid of the shocks given for asynchronized responses than were the older children and adults. In Langhorne's experiment groups of children from 7 to 17 years of age were given training in operation of the Renshaw-Weiss pursuitmeter. The problem was to maintain contact between a stylus and a revolving lever arm. Seventy-eight subjects, 45 boys and 33 girls, whose data are treated separately, took part in the experiment. Langhorne does not say how many of each sex were in each group. From the fact, however, that there were groups at 10 different age levels in the boys and at 9 different age levels in the girls, it is apparent that the average size of the groups could not have been greater than 4. Langhorne concludes that there was greater learning ability at successively higher age levels. His results fail to show this. Although the initial and final scores tend to increase with age, the degree of improvement resulting from the amount of practice given is not related to this factor in any definite way. Analysis of the data for boys in terms of percentage of improvement indicates that the age groups from 14 to 17 have higher percentages of gain than the lower age groups. Below 14, however, there is no consistent variation with age. Even less evidence of improved learning ability with age was found in the female groups. In any event, such data are meaningless unless the size of the groups is such as to warrant comparisons.

One is forced to conclude that, if the learning of such motor skills as have so far been studied improves with age, the results fail to show clear evidence of it. Although children of increasing age usually evidence an increasingly high initial level of performance, which may be accounted for on the basis of greater maturity, greater experience, or both, the gross amount and percentage of improvement resulting from given amounts of practice do not appear to change in any consistent way as a function of age. It may be said, of course, that since the older children begin with a higher level of performance (closer to the upper limit) than younger ones, the actual relative accomplishment within the same range of practice is not measured by gross gains. McGinnis (1929) reported decreasing intragroup variability as a function of given amounts of practice at successively higher age levels. This may be an index of the relative gains from training if the groups are sufficiently large to warrant use of the statistical procedures involved. As will be recalled, however, the largest single age group comprised only 20 children.

Sex Differences in Learning of Sensorimotor Skills. Several problems discussed in the preceding section have been used to investigate the influence of sex on learning of sensorimotor skills. In reporting standardization data on his slot maze, Young (1922) mentioned that girls have greater difficulty than boys in completing two trials within the time limit of 5 minutes each. Easby-Grave (1924), using the same test with 6-year-old children, 256 boys and 244 girls, found that of those who failed to complete both tests, 75 per cent were girls. Since only two trials were given, these studies are measures more of initial ability than of learning. The previously mentioned investigation of McGinnis (1929), in which 30 boys and 30 girls were used, showed the same sort of initial advantage for boys as was found in the above studies with the Young slot maze. With continued training, however, this difference disappeared and the girls' final performance approximated that of the boys. In terms of gross improvement as a result of a given amount of training, the girls were thus ahead. We have already men-

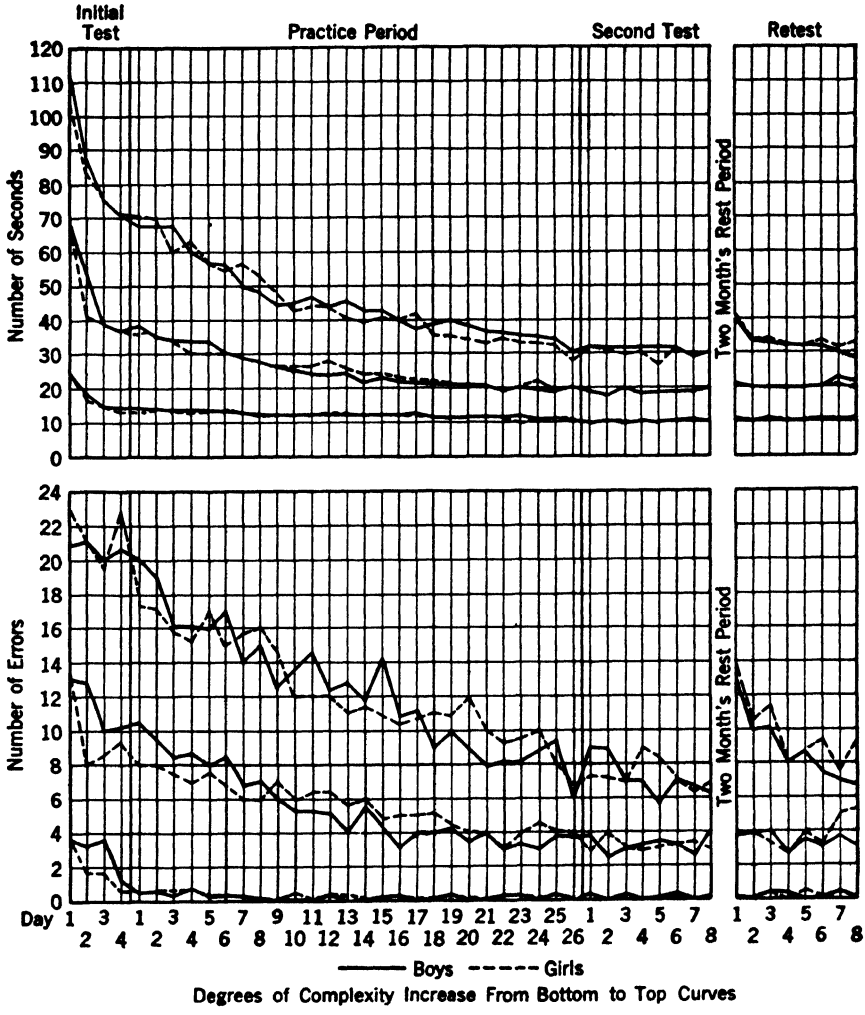

FIGURE 9. Learning curves for time and errors for boys and girls who learned rolling ball mazes of three degrees of complexity. (From "The Relation between the Complexity of the Habit to Be Acquired and the Form of the Learning Curve in Young Children," by M. L. Mattson. *Genetic Psychology Monographs,* 1933, *13,* 369. By permission of the publisher.) For a description of the problem, see page 389 of the present discussion.

tioned the dubious nature of such comparisons.

Wieg (1932) found no difference between the performances of boys and girls in learning her grooved finger and toe mazes. Using a maze through which the subjects walked, Batalla (1936) investigated the learning ability of 58 boys and 50 girls having an average age of approximately 12 years. Boys began the problem with better scores than the girls and their final performance was still superior, although the gross difference became increasingly smaller as a function of practice. Batalla

says that girls require more trials than boys to satisfy the criterion of learning, but he reports no figures to support this observation. The problem is said to be more interesting to boys than to girls, hence there existed a difference in motivation which may have influenced learning.

Mattson (1933), whose study has already received some consideration in this chapter, reports data concerning sex differences in maze performance. Sex comparisons are somewhat questionable owing to the fact that there were only 12 to 13 children of each sex on each of the three mazes. Mattson believes, however, that if sex differences in maze learning existed she should have found at least some suggestion of their presence. The learning curves for time and errors are shown in Figure 9. They are almost identical for the two sexes.

Investigations of other motor skills also reveal little or no evidence of a sex difference in learning *per se*. Hicks (1931) found that, in throwing balls at a moving target, the average initial score of 13 boys was 14, whereas that of 17 girls was 9.9. The average final scores for boys was 14.6, and that for girls, 12.9. On the basis of such data, one might conclude that girls had learned more than boys as a result of an equal amount of practice. Such a conclusion, however, can hardly be justified when it is recalled that so few subjects are involved, that little learning is evident in either group, and that an untrained control group to measure maturational effects improves as much as trained children.

Clinton's (1930) investigation of mirror drawing demonstrated that, although girls make poorer scores than boys at lower age levels, at higher age levels the girls surpass the boys. Learning curves are reported to be more regular for girls than for boys, but they or the data on which they are based do not appear in the article. In her motor-coordination study, Eigler (1932) found no evidence for a difference in favor of either sex. Langhorne (1933) found no consistent sex difference in his investigation with the Renshaw-Weiss polygraph. At the lower age levels the initial scores of the girls were poorer than those of the boys. At higher age levels, however, there was no difference. The validity of comparisons at any age level in this investigation is, as mentioned earlier, very doubtful because of the smallness of the groups.

Perl (1933) found no significant sex difference in the learning of a simple motor skill, which comprised making small gates (⋀⋀) as fast as possible. Good learning curves were obtained for 20 one-minute periods of practice. The learning curves for 46 fourth-grade boys and 53 fourth-grade girls of approximately the same IQ were similar in shape and, where they did not overlap, were quite close together. Both raw and T scores yielded similar curves. A slight apparent superiority of the boys was unreliable statistically.

On the basis of these investigations it must be concluded that a differential influence of sex in the learning of simple motor skills such as those investigated has not been disclosed. Although the initial scores of boys have in several studies been higher than for girls, perhaps as a result of previous differences in experience, the gross amount of progress resulting from given amounts of training has been similar for both sexes.

Learning of Sensorimotor Skills as a Function of Intelligence. Investigations of the relation between intelligence test performance and learning of sensorimotor skills in young children agree in forcing the conclusion that, at early ages at least, there is no significant correlation.[1] One study

1 Ruch (1925) presents data for card sorting which indicate a small correlation between intelligence and learning. The correlation decreased in successive practice periods. Correlations between time to sort 100

with adolescents has yielded results not in agreement with those at early and later age levels, hence we shall discuss this last.

McGinnis (1929), training children between 3 and 5 years of age on a stylus maze, found rank-order correlations ranging from $-.280 \pm .291$ to $.600 \pm .202$ between IQ and total time scores. Correlations between IQ and total errors ranged from $.100 \pm .221$ to $.660 \pm .178$. Owing to their large probable errors, few of the correlations for the different groups of subjects can be regarded as reliable. Initial scores and IQ also yielded insignificant correlations. McGinnis concluded that maze performance is not "related very highly to the function which is measured by scores on an intelligence test."

Performance on Mattson's (1933) rolling-ball mazes (see page 389) by children averaging 65 months was likewise unrelated to intelligence test performance. Mean time for 38 days of training yielded correlations with IQ of $-.66 \pm .28$ to $-.28 \pm .12$. Mean errors for the 38 days of training gave correlations with IQ of $-.04 \pm .09$ to $-.06 \pm .09$.

Learning by young children of sensorimotor skills other than maze performance also has little or no relation to intelligence test scores. Goodenough and Brian (1929) trained children in their fourth year to toss quoits over a ring. Rank-order correlation of the number of ringers with results on a battery of intelligence tests was $-.349$. The PE is not reported, but the authors say that this correlation is probably without significance. Hicks (1930*a*) found a correlation of only .05 between performance in throwing at a moving target and mental age, with CA held constant. The age of the subjects was between 2½ and 6½ years.

Another skill the learning of which has been studied in relation to intelligence is mirror drawing. Wilson (1928) gave 20 boys 20 trials each on a six-pointed star. The ages ran from 8½ to 12¾ years. IQ's ranged from 76 to 148. Separate learning curves were constructed for each boy. These curves indicate no differential influence of intelligence in the acquiring of this skill.

Against all these results suggesting no relation between learning of motor skills and intelligence test scores must be placed data obtained by Knotts and Miles (1929). Two mazes of the Warden multiple-U pattern, one stylus and one raised, were learned by groups of blind and seeing adolescents. For both groups and both mazes, time scores yielded small and unreliable correlations with MA. Insignificant correlations between trials and errors and MA were found on the stylus maze for *blind* and on the raised finger maze for seeing subjects. However, the correlations between MA and, respectively, trials and errors were $-.75 \pm .07$ and $-.75 \pm .07$ for *seeing* subjects on the stylus maze. Data for blind subjects learning the raised finger maze yielded correlations almost as large as these, the correlations being $-.61 \pm .09$ and $-.62 \pm .09$. All four correlations are statistically significant. They therefore suggest that the more intelligent the individual the fewer the trials and errors likely to be involved in mastery of the respective mazes.

The above-mentioned studies force upon us the conclusion that, as far as young children are concerned, learning to thread mazes, to hit a moving target, to throw quoits over a peg, and to overcome effects of mirror distortion in drawing star patterns is unrelated to scores on intelligence tests. The experiment with adolescents is out of line with these findings for younger

cards and MA (with CA partialed out) went from .329 ± .083 on the first trial to .107 ± .092 on the fifth. Fifty-two seventh- to ninth-grade children were subjects.

children and with findings obtained on similar problems with adults. The reason for this discrepancy is not apparent.

Incentives and the Learning of Sensorimotor Skills. Investigations of learning in animals and human adults have shown that the efficiency with which problems are mastered, and in some cases whether or not they are mastered at all, is a function of incentives. Similar investigations on learning in children have been few. Studies by Chapman and Feder (1917) on addition, cancellation, and substitution, Hurlock (1924) on intelligence test performance, Flügel (1928) on addition, Chase (1932) and Anderson and Smith (1933) on squeezing a dynamometer, and Mast (1937) on time required to open a box, although they deal with other factors than learning of motor skills *per se*, show that special incentives such as material rewards, praise, and reproof lead children to increase their effort in the performance of a task.[1]

Abel (1936) has reported a thoroughgoing investigation of the rôle of motivation in learning of a sensorimotor skill by children. She used a raised finger maze of the pattern shown in Figure 10. The subjects were 100 boys between the ages of 9 and 10 years. Their IQ's ranged from 100 to 129. Each child was shown how to proceed from the entrance to the exit of a simple maze by running his index finger along the raised pathway. The subjects were separated into five groups equivalent in CA and MA. They were given 30 trials at a single sitting. Group I received no reward other than that which might be inherent in the situation. The members of Group II received a material reward, a penny, at the end of each trial. A verbal reward, "Good," "Very good," and "Let me see if you can make even fewer mistakes this time," was given Group III. Group IV received no special reward for the first 15 trials. Beginning with the sixteenth trial, however, each child was given a penny per trial. Members of Group V received the above-mentioned verbal reward until the sixteenth trial, at which time the material reward was substituted. Abel's aim in adding and in changing incentives at the middle of the training period was to determine whether children, like the rats tested by Tolman (1932) and his students,

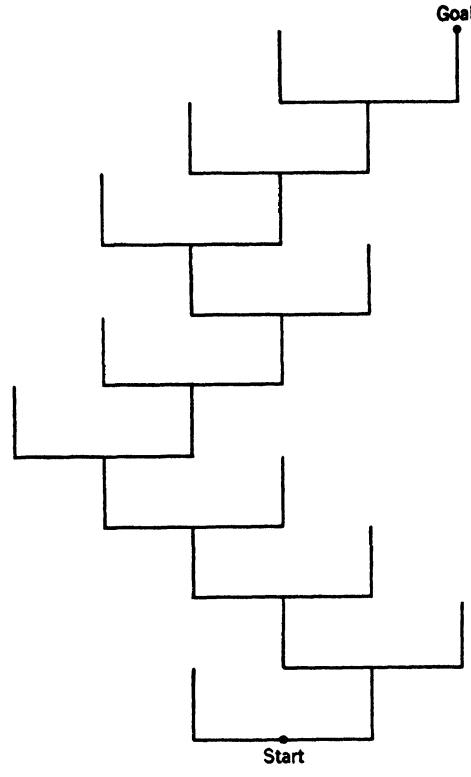

FIGURE 10. The Warden U maze which was used to investigate the influence of different incentives. (From "The Effects of Shift in Motivation upon the Learning of a Sensorimotor Task," by L. B. Abel. *Archives of Psychology*, 1936, *29*, 16. By permission of the publisher.)

1 For comprehensive reviews of the rôle of incentives in child behavior, see Hurlock (1931), Abel (1936), and Munn (1942).

would show a sharp change in performance following introduction of the different incentives.

As the error curves in Figure 11 indicate, Groups I to III improved. However, the group with no special reward showed least, and that with the material reward most, improvement. In Figure 12 are represented data for the two change-of-incentive groups (IV and V). One will observe that the introduction of a different incentive beginning with the sixteenth trial led to no obvious change in the rate of learning such as was found in experiments of a somewhat comparable nature with rats. Comparison of the mean number of errors in the first 15 as compared with the last 15 trials, however, suggests an increased rate of learning subsequent to the change. When equations for the curves before and after the change were determined and the slope lines compared, it was also apparent that the introduction of new incentives had effected a greater rate of learning.

In order to determine whether the change in mean errors and in slope was greater than could be expected in terms of sampling errors, Abel used a method suggested by Fisher (1930, pp. 75–139). She determined the $P/2$ of the differences in the respective means and slopes. Since 15 trials were involved, a $P/2$ of 0.05 or less would indicate a reliable difference. The $P/2$ of the difference between the means of the first and second halves of both the curves in Figure 12 was 0.00. Change from a verbal to a material reward yielded a $P/2$ of 0.00 for the difference between the respective slopes. However, the two slopes for, respectively, no reward and material reward had a $P/2$ for the difference in slope of 0.39, suggesting unreliability of this difference.

Another method of analyzing the data was to compare the final levels of performance in terms of the mean number of errors in the last 5 trials. The means were: *no reward–reward,* 1.675; *material reward,* 1.675; *verbal reward–material reward,* 1.875; *verbal reward,* 2.325; and *no reward,* 2.625. The differences between the first and third and second and third means are not statistically reliable. The difference between the *verbal and material reward* groups, however, has a critical ratio (D/σ_{diff}) of 3.110, indicating that there are approximately 100 chances in 100 of a difference greater than zero. The difference between the means for the *verbal reward* and *no reward–reward* groups is equally reliable. There are, however, only 99.7 chances out of 100 that the difference in the means of the *verbal reward* and *verbal reward–material reward* groups is also greater than zero. One must conclude, therefore, that *material reward, no reward–reward,* and *verbal reward–material reward* are of approximately equal value as incentives to learning the present maze and that their incentive value is greater than a *verbal reward* or *no special reward.* The latter condition, although it produced learning, was least effective.

Abel points out that it makes no significant difference whether a material reward is given throughout learning or whether it is given only in the last 15 trials. In other words, 15 pennies in the last half of training elicited as much in terms of final achievement as 30 pennies, 1 per trial throughout training. She also suggests that a verbal reward, while stimulating for the first 10 trials or so, gradually loses effectiveness.

In a second experiment with the same maze and following the same method of scoring and analysis, but involving children with lower than average IQ's, Abel determined the effect of giving rewards *only when a certain amount of progress had been achieved.* Whereas the children of the experiment described above received

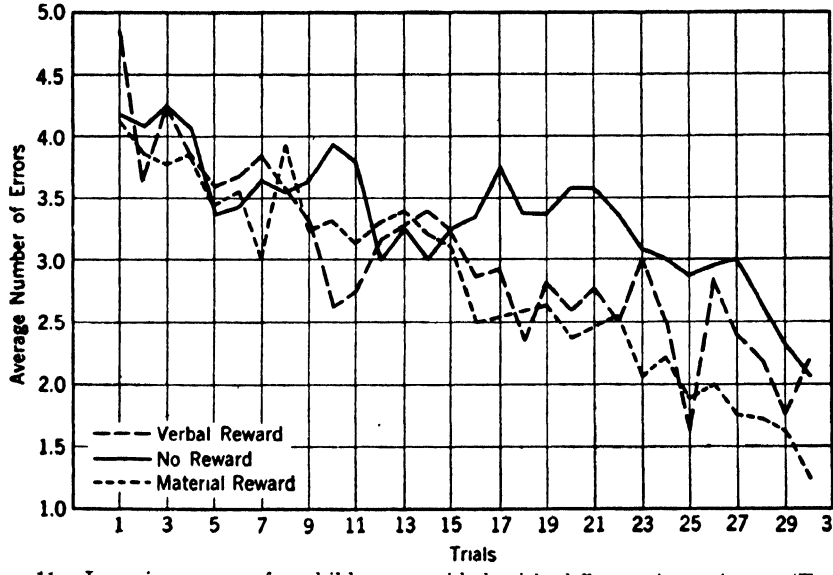

FIGURE 11. Learning curves for children provided with different incentives. (From "The Effects of Shift in Motivation upon the Learning of a Sensori-motor Task," by L. B. Abel. *Archives of Psychology*, 1936, *29*, 22, 23. By permission of the publisher.)

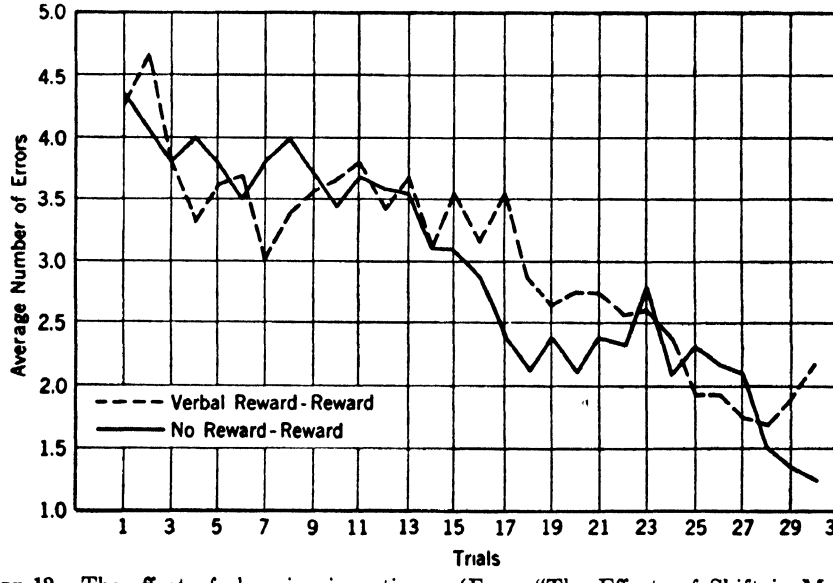

FIGURE 12. The effect of changing incentives. (From "The Effects of Shift in Motivation upon the Learning of a Sensori-motor Task," by L. B. Abel. *Archives of Psychology*, 1936, *29*, 23, 24. By permission of the publisher.)

a reward at the end of each trial, regardless of whether or not they had progressed, those of the present experiment were promised the rewards for improvement and were given them only when they improved. Five groups paralleled those of the experiment discussed above. There was, however, an additional group (maximum material reward), the members of which were promised a quarter for every trial without an error. Few of them received the reward; nevertheless, this group manifested more improvement than any other group in either experiment. The difference, however, is clearly apparent only in the last 5 trials, when the curve, which has continually crossed the others, shows a precipitous drop.

Despite the lower intelligence of the children and the changed nature of the incentives, the results for the other five groups of the second experiment did not differ greatly from those of the first experiment. The only statistically significant difference between the results of the two experiments was for the *material reward* group. The average number of errors in the last 5 trials for this group in the first experiment was 1.675; in the second experiment it was 2.260. The difference is 3.4 times its standard error. Abel concludes, therefore, that "The effect of reward dependent upon improvement with a group of average intelligence does not seem to be as great as that of reward, administered at every trial, with a group of superior intelligence" (p. 50).

An interesting outcome of the present experiments is Abel's failure to find clear evidence of the so-called *latent* learning disclosed in experiments with rats. The unrewarded rats, it will be recalled, failed to show consistent signs of learning before being given a special incentive, such as food or water. When the incentive was introduced there was an extremely rapid drop in the learning curves. This was interpreted as application of learning which had been taking place, but which had not been utilized before an incentive was introduced. As far as children are concerned, learning of the above sensorimotor skill despite the absence of special incentives may be attributed to inherent interest of the task, to desire to finish the experiment and get out to play, to desire to please the experimenter, or perhaps to competitive factors such as desire of the subject to better his own performance or to do as well as or better than others. The fact that children evidenced so much learning without the presence of material or verbal rewards perhaps also explains the absence of a precipitous drop in the learning curves after the introduction of these special incentives. In any event, the rats were hungry or thirsty, and such factors are undoubtedly of much greater motivating value than the relatively artificial incentives which can be offered children.

Jones (1945) has made a novel approach to the problem of incentives in sensorimotor learning, his subjects being 114 junior high school children. The children first rated, for preferential (affective) value, certain stimuli which were later used to signal correct responses in learning the punchboard maze. The stimuli were a light, a tone, a buzzer, and a vibrator. Jones's aim was to discover any possible relationship between the preferential value of these cues and the efficiency of learning a certain pattern on the punchboard, to which the child responded by sticking a stylus into the holes. Punching each correct hole elicited the particular signal. The experiment was designed so as to rule out the influence of every factor but the signaling cue. Jones found, however, that the degree to which the children liked or disliked the respective cues had no bearing upon time or error scores or upon the shape of the learning

curve. He says that one can expect no gain from "sugar-coating" a response by providing a "supplementary pleasant experience" to accompany it.

The relative efficacy of praise and reproof in substitution learning was studied by Schmidt (1941) but without results unqualifiedly in favor of either incentive. The person administering positive or negative reinforcement was the most significant variable. Grace (1948), using punchboard learning and different kinds of approval for correct performance, found that the personality of the child was a more significant variable than the kind of approval.

Holodnak's (1943) 6- to 10-year-olds learned a punchboard maze more efficiently when the correct responses were signaled than when the incorrect responses were similarly signaled. The results are interpreted as favoring positive over negative guidance in learning.

Learning of Sensorimotor Skills as a Function of the Training Procedure. Many skills which depend upon specific training for their acquisition will develop regardless of the precise method of training adopted. It is obvious, however, that some methods of training may be more effective than others. We have already indicated that training which involves certain incentives is more effective than that which involves others. In the present section we are interested in the relative efficacy of different training procedures used under constant conditions of motivation. For example, given a certain motivation, does more or less improvement result when the skill to be acquired is demonstrated frequently? What advantages, if any, will accrue if the child is given manual guidance in the task to be performed? Does faster learning or a higher level of achievement result when the correct procedure is enforced from the start, or is it better to allow the child, by random trial and error, to find the correct procedure for himself?

Gates and Taylor (1923) have made one approach to this problem. These investigators were interested in determining whether motor control in writing is facilitated by "putting the child through" the various movements to be made. One group, consisting of 21 kindergarten children, was given an opportunity to learn to write the letters *a b c d e* by tracing them through tissue paper.[1] A group of comparable age, motor ability, and intelligence, but consisting of only 14 children, *copied* the letters throughout the learning period. This group was thus free to make many mistakes which the tracing group would not be very likely to make. Five minutes of daily practice for 5 days were given the *tracing* group. In terms of the number of strokes required to write each letter, the mean scores on the 5 successive days were 11.4, 20.6, 20.8, 24.2, and 29.8. In a 5-minute *copying* test, given on the sixth day, the mean score for this group was 8.2. During the 5 days of training in *copying* the same letters freehand, the other group gained in their mean score as follows: 3.7, 7.2, 13.5, 17.6, and 19.5. On the sixth day their copying score was 21.1. In other words, the copying skill of this group, a skill which approximates that called for in everyday life, and which is the aim of training, was more than twice as good as that of the group which was, as it were, put through the appropriate movement with little chance of making errors.

In further training with the letters *e–g* and, later, with the letters *f–j*, both groups continued to improve. When called upon to *copy* letters that they had neither traced

1 This is comparable to the "putting-through" technique used by Carr and his students with white rats. The procedure was not effective as a training technique with rats. See Munn (1938, pp. 342–343) for a brief review of these studies.

nor copied before, both groups had low scores. The mean score of the *tracing* group, however, was only 0.77, as compared with 4.6 for the *copying* group. Thus the transfer value was also greater for the copying than for the tracing procedure.

Melcher's (1934) investigation of stylus maze learning in preschool children who were given visual, manual, and visual and manual guidance indicated that very little learning occurs with such guidance. The learning which did appear may be attributed to the test trials (2 out of every 6 guided trials), during which the children were free to learn by trial and error.

On the basis of the above investigations and those with rats and human adults, one must conclude that more rapid learning of such motor skills as writing and threading a stylus maze occurs when the individual is free to initiate his own movements and to make incorrect as well as correct responses than when he is manually guided in the correct performance.

Goodenough and Brian (1929) determined the relative efficacy of different kinds and amounts of *verbal guidance* upon the learning by 4-year-old children of a ring-toss skill. Although two of the three groups were very small and no statistical analysis of differences is therefore warranted, marked differences in the effectiveness of the methods are clearly suggested. All children, regardless of verbal guidance or its absence, were similarly motivated. They were given praise and encouragement for "ringers" and also received stickers, which changed in nature from day to day, to paste on the wall.

Group A, consisting of 4 boys and 6 girls, was given the following instructions:

> This is a game where we try to throw rings over a post. You stand here on this base—be sure both of your feet are in the base all the time—and I'll hand you the rings. Try to throw them on the post over there. Do you see what I mean? All right, go ahead.

No criticism or verbal guidance was given this group.

Group B, comprising 2 boys and 4 girls, was shown how to throw the ring and was given critical verbal guidance throughout the experiment. The initial instructions were like those for the above group except that the experimenter said, "I'll show you how it is done," and then demonstrated. Whenever the child failed to get a "ringer" the experimenter pointed out the source of error, saying, for example, "Not quite so far next time," "A little bit higher so it won't hit the post," etc. These children were also told to hold the ring at the point of juncture of the rope so as to insure better balance. Each chose his own general procedure, some throwing overhand and others underhand, some throwing the ring down onto the peg and some squatting and throwing it up. Within this group the method was changed by the child from time to time, often without adequate test of a given procedure.

Group C, consisting of 2 boys and 2 girls, was required to adhere to a constant method of holding and throwing the ring. Members of this group were instructed to grasp the ring at the point of juncture, to hold it horizontally before them, and, after swinging it a few times, to pitch it forward and upward toward the post. Furthermore, they were given verbal guidance which matched that of Group B.

Twenty trials per day for 50 days were given each child. Scoring was in terms of the number of "ringers" in each 20 tosses. Two children in Group A and 1 in Group B failed to gain. All other children manifested absolute gains ranging from 4 to 56 in Group A, 5 to 47 in Group B, and 21

to 70 in Group C. The corresponding percentage gains ranged from 5 to 287, 24 to 147, and 53 to 175. The median gains for Groups A to C, respectively, were 11.5, or 36 per cent; 17.5, or 66 per cent; and 42.5, or 92 per cent. Until the thirtieth day of the experiment, learning curves overlapped considerably. The highest curve was that of Group C, the next that of Group A, and the lowest that of Group B. If the groups were not so small, we should be justified in concluding that, for this game and for children of this age and intelligence, the best procedure is to enforce from the start a given effective method and to combine this with verbal guidance. In terms of the percentage of gain, if not on the basis of the latter part of the learning curves, we might also be justified in concluding that verbal guidance, even without a standardized throwing procedure, is more effective than leaving the child entirely to his own resources. As the situation stands, however, what might have been a very significant experimental test of the efficacy of verbal guidance is ruined by the fact that groups are too small to warrant any definite conclusions concerning this aspect of the investigation.

In good learners there was a marked tendency for successes to be grouped. This suggests that these children continued to use those responses which they observed to be associated with success. Poor learners showed little evidence of such observation and application. Errors immediately following success were usually due to throws beyond the post. Analysis of individual learning data indicated the following factors to be significant in determining success or failure: overconfidence and undue caution; setting-up of stereotyped undesirable reactions; false association of cause and effect; peculiar associations of meaning with verbal expressions, as when "trying hard" was assumed to be synonymous with "throwing with great violence"; incorrect focusing of attention, such as looking at arm instead of goal; and random changes in procedure.

Another approach to this problem is Cox's (1933). Thirty-eight boys from the two upper classes of an English elementary school practiced assembling, wiring, and stripping an electric-lamp holder. They were merely told to repeat the operations at top speed until each day's series had been completed. Time required to perform the operations was recorded. Under these conditions no significantly greater progress occurred than was exhibited by a control group of 32 boys given only initial and final tests. Similar results were obtained with adult subjects trained by this technique. In a further investigation with experimental and control groups of adults, initial tests on assembling and stripping were followed, in the experimental group, by 11 days of special instruction and performance of supervised exercises. Under these conditions the experimental group made gains significantly greater than did the control group. The author points out that much more rapid and efficient learning of such operations occurs when, rather than being left to their own resources, individuals are given special exercises and verbal guidance. Undoubtedly the effectiveness of such training would differ for different skills and for individuals of different levels of maturity.

Transfer of Motor Skill.[1] We have already mentioned the fact that Gates and

[1] Judd's (1908) study of transfer involved dart throwing, but transfer comprised application of principles to motor skill rather than transfer of skill *per se*. One group of fifth- and sixth-grade boys received instruction in principles of refraction while another, comparable, group received no such instruction. Both groups were then required to hit a target placed 12 inches under water. They were equally successful. Thus knowledge of principles failed to aid the instructed group. When the target was shifted to 4 inches of water, however, boys with a knowledge of

Taylor (1923) found greater transfer from copying the letters *a–e* to copying the letters *f–j* than when the letters *a–e* were merely traced. Since we do not know what success entirely untrained children would have in copying the letters *f–j* under identical conditions, it is impossible to determine the actual transfer in the two cases.

McGinnis (1929) investigated transfer in maze performance. The maze was of the stylus type (McGinnis, 1928), apparently with open alleys. Invisible stops placed at appropriate points limited the movements of the stylus. Four patterns, the paths of which covered the same distance but went in different directions, were used. Since the patterns were not of equal difficulty, scores were equated in terms of their relative difficulty. Four groups, each comprising six 4-year-old children equated in intelligence, received training on the maze patterns in the order AB, BA, ABCD, BADC, respectively. Scoring was in terms of time and errors for 40 trials, in the case of the first two groups, and 50 trials in the case of the others. Positive transfer occurred in every group regardless of the fact that some patterns, by changes in the direction of the goal, were calculated to produce negative transfer. The percentage saved in transferring from one maze pattern to the other ranged from 12.6 to 41.8 seconds and 9.4 to 35.8 errors.

Wieg (1932) investigated bilateral transfer, using a grooved multiple-T maze through which the index finger or big toe could be run. Her aim was to measure transfer from right hand to left hand, from left hand to right hand, from left hand to left foot, from right foot to left foot, from right foot to right hand, and from left foot to left hand. Twenty-four boys and 20 girls, ranging in age from 66 to 78 months, were grouped in sets of 4. These were equated in terms of IQ, CA, socioeconomic status, sex, and initial maze-learning ability. All subjects were first given 3 successive trials with each hand and each foot for 2 days. They were then divided into different groups and given 3 daily trials until they had reached a criterion of not more than 2 errors in 3 successive trials. Time and errors were the bases of comparison. There was, in most cases, a saving in speed and in errors during learning with the transfer limb. The number of cases was too small to allow determination of the reliability of transfer scores. There was, however, a suggestion of greater transfer effects going from a less efficient to a more efficient limb, as from foot to hand or from left to right hand. A greater transfer was apparent in going from the right foot to each of the other limbs than from any one of these limbs to another. A group of adults showed larger transfer scores than children. The reliability of this difference, like that between the various directions of transfer, cannot be determined; hence the results can be regarded merely as suggestive.

Significant transfer from one stylus maze pattern to another was obtained by Jones and Yoshioka (1938) in an investigation with 81 boys and 71 girls, each approximately 13½ years of age. The groups learned different patterns and used different procedures. When these differences were balanced, however, there were lower error scores for the learning of the second than for the learning of the first maze. In different groups the critical ratio ranged from 1.62 to 3.68.

The error curves are shown in Figure 13. One will note that there is an average advantage of 5½ errors in the initial trial

the principles of refraction made a much more rapid adjustment than did those without such knowledge. As the result of this and other researches, Judd came to the conclusion that "generalization" plays a large part in determining the magnitude and direction (positive or negative) of transfer when such occurs. For a further discussion of transfer, see pages 423–425.

with the second maze and that, although this advantage decreases considerably, the two curves remain separated until the fifteenth trial. In accounting for transfer, Jones and Yoshioka (1938) say:

> Factors in this transfer probably include an increase in effort to observe and remember the results of maze exploration, although it may be pointed out that the second order shows fewer errors even on the first trial. The subject is acquainted with both his time and error record on the first test, and commonly seeks to improve his record [pp. 471–472].

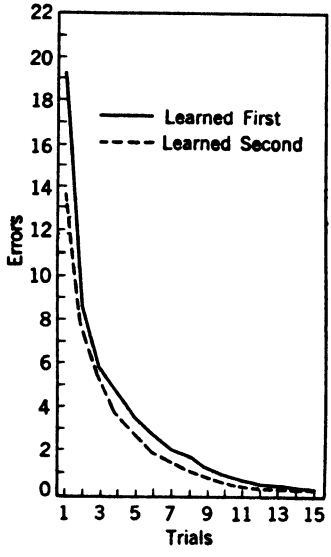

FIGURE 13. Transfer in learning of stylus mazes. (From "Differential Errors in Children's Learning on a Stylus Maze," by H. E. Jones and J. B. Yoshioka. *Journal of Comparative Psychology*, 1938, *25*, 470. By permission of the publisher, Williams and Wilkins Co.)

The existence of transfer in this experiment is made all the more interesting when it is pointed out that all the subjects had received previous training on stylus and body mazes from time to time. Without such previous training the present transfer would probably have been greater. The experimental results are further analyzed by Yoshioka and Jones (1945) in terms of learning at different stages of practice.

Using sixth- and seventh-grade pupils, Jones and Batalla (1944) found no evidence of transfer from a large alley maze to a stylus maze of the same pattern, or vice versa. They feel that failure to show transfer in this experiment indicates absence of configural and insightful learning. In another maze experiment, Batalla (1943) had previously found absence of insightful behavior.

In this connection one will recall Cox's experiment (1933) which was discussed earlier (page 405). Practice in assembling and stripping electric light holders did not enable a group of 38 boys to do any better in a final test than a control group given only the initial and final tests. The result was similar to that obtained with adults. Specific training, verbal instructions alone and combined with exercises designed to bring important aspects to the learner's attention, did have a transfer value for adults. No children were used under the latter conditions.[1]

Memory

Most experiments in memory deal with learning, recall, recognition, or relearning of symbolic materials such as numbers, words, nonsense syllables, poems, prose passages, and figures. The chief emphasis is upon retention of the effects of previous

1 Transfer in discrimination learning (the transposition problem) has been studied by Alberts and Ehrenfreund (1951), Hunter (1952), Jackson (1939), Jackson and others (1938, 1939, 1940, 1943), and Kuenne (1946, 1946*a*, 1948). These studies deal with conditions which contribute to the relational type of response. Alberts and Ehrenfreund found that transposition in older children differs from that in younger children, the difference being attributable to verbalization in the latter. Hunter's (1952) paper deals with theoretical aspects of transposition in children.

stimulation. Retention may be measured in terms of ability to make appropriate responses in the absence of stimuli which originally elicited them (delayed reaction and reproduction), in terms of ability to differentiate old and new stimuli (recognition), or in terms of ability to relearn previous material with a saving of time and effort.

The earliest measurable evidence of a child's ability to respond in terms of absent stimuli comes from tests of the delayed-reaction type. These yield a measure of retentivity prior to the time when conventionalized symbols such as are used in most memory tests have been acquired. Hence we shall begin our discussion of memory in children by considering delayed reaction. This discussion will be followed by a summary of other researches on memory.

Delayed Reaction. The principle underlying delayed-reaction tests is that of presenting stimuli toward which differential responses are required and then removing the stimuli prior to response. In the original Carr-Hunter (Hunter, 1913) method, for instance, the animal was confronted by three compartments, only one of which was lighted in a given trial. The lighted compartment, which offered the only means of escape, varied in position from trial to trial. At first the subject had to learn that escape was possible only through the lighted compartment. The delayed-reaction tests were those in which a differential response to the compartments was required *after the light had been turned off*. The interval between removal of the external differentiating stimulus and the time of response was gradually increased until the subject could no longer remember which door had been lighted.

Instead of escaping through the lighted or previously lighted door, Hunter's child subjects pressed a button corresponding to the position of the door. Since the animals and children in this experiment first had to *learn* that the lighted door was the correct one, this has been called the *indirect* method of testing delayed reaction. The *direct* method, also first used by Hunter (1917), does not require specific training by the experimenter before delay tests are instituted. Hunter and later investigators obtained the child's attention while hiding a toy or some other desirable object in or under one of two or more devices such as boxes, plates, or cups. After an interval, they determined whether the child could locate the hidden object.

In Hunter's investigation, for example, a girl of 13 months was confronted with three similar boxes having hinged covers. A toy with which she had been playing was placed in one of the boxes. When he ascertained that the infant had seen in which box the toy was placed, Hunter disoriented her and, after given intervals, offered an opportunity to find the toy. She located the toy with a high degree of accuracy after intervals between 8 and 12 seconds. At 16 months of age she responded with high accuracy after 24 seconds.

All investigations of delayed reaction in children, except Hunter's first one with animals and children, have involved modifications of the *direct* method just described. Some of these studies have been carried out as routine clinical tests; others have involved intensive experimental investigation.

The most extensive clinical tests of memory in infants are described by Bühler (1930). The earliest test is for infants of 3 months. In this test, the face of the tester appears and then disappears. If it looks for the face or seems disturbed by its absence, the infant is credited with memory. Bühler claims that the 3-month-old infant characteristically searches for, or is disturbed by disappearance of, the tester's

face.[1] In a test at the 5-month level, a toy is presented and then removed. The infant is credited with memory if it looks "searchingly" in the direction in which the toy has disappeared.

One of the best delayed-reaction tests of this general type is that devised by Bühler (1930) and Hetzer and Wislitzky (1930) for use with children ranging in age from 10 to 24 months. A ball containing a chicken which pops out is placed in the child's hand. The child plays with the ball, making the chicken appear and disappear. Then the ball is removed and other activity is encouraged. Some time later a ball which looks like the previous one, but does not contain a chicken, is presented. The child is credited with memory if, upon squeezing the new ball, it shows "astonishment," looks "questioningly" at the tester, or puts its finger in the hole when a chicken fails to appear. The maximum delay followed by evidence of memory is about 1 minute at 10 to 11 months, 8 minutes at 15 to 17 months, 15 minutes at 19 to 20 months, and 17 minutes at 21 to 24 months.

Allen (1931) has investigated delayed reaction in 50 boys and 50 girls approximately 1 year old. Each child sat on its mother's lap during the experiment. Three boxes which looked exactly alike were placed on a card table at equal distances from the subject, as shown in Figure 14. Various toys were used as lures. While the mother's eyes were closed (to prevent helpful attitudes), but while the infant was watching, a toy was tapped on a box three times and dropped in, where it was out of sight. The table was then pulled out of the infant's reach for periods ranging from 10 to 165 seconds. At the end of a delay period, the table was pushed toward the child, who was thus given an opportunity to respond. Three tests in rapid succession, with the toy in a different box each time, were given after 10-, 20-, and 30-second delay periods. For longer delays there were fewer tests, the exact number differing somewhat from one subject to another. Loss of interest during the longer delays was one reason for this variation.

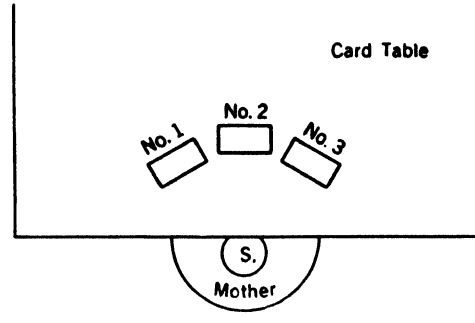

FIGURE 14. Arrangement for measuring delayed reaction in infants. (From "Individual Differences in Delayed Reaction of Infants," by C. N. Allen. *Archives of Psychology*, 1931, *19*, 14. By permission of the publisher.)

Since there were three possible locations for the toy, chance accuracy would approximate 33 per cent. Accuracy after a 10-second delay was 61 per cent for boys and 66 per cent for girls. After a 20-second delay, it was 65 per cent for boys and 57 per cent for girls. A 30-second delay was followed by accuracy, respectively, of 50 and 48 per cent. With a 45-second delay the percentages were 19 and 36, respectively. The number of cases at longer delays was too small to make the results worthy of consideration. Sex differences were insignificant.

The experiments of Hunter, Bühler, Hetzer and Wislitzky, and Allen all agree

1 Hurlock and Schwartz (1932) have summarized many biographical reports of this type of response in infants. Preyer mentions an infant of 3 months who cried and looked around the room when his nurse disappeared. Shinn reports such behavior in a child of 4 months. Fact and interpretation are so interwoven in such studies that one cannot be sure of their validity. A chance response, occurring once, may be taken as an indication of memory.

in demonstrating that memory of the delayed-reaction type (that is, recall memory) is present during the first year of life. These experiments differ, however, in their findings with respect to the maximum correct delays. The discrepancies with respect to this factor may be attributed to different test situations and to different criteria of successful delay. Bühler and her co-workers, it will be recalled, report maximum delays of *1 minute* as occurring in the first year. Hunter and Allen, however, report maximum delays no longer than *30 seconds*. The "naturalness" and interest value of Bühler's tests perhaps contribute to the longer delays in her studies. Another factor of possible importance, however, is the criterion of response. In Hunter and Allen's experiments, the child was required to make a clear-cut overt differential response, whereas in Bühler's tests facial expression and fingering of the ball were accepted as indicative of memory.

The most extensive investigation of delayed reaction in preschool children is Skalet's (1931). Sixty children between 2 and 5½ years were given tests similar in principle to those discussed above. In the first group of experiments, a child was confronted with three plates under one of which a cooky was placed. After seeing the cooky hidden under a given plate, the subject was taken out of the room. Upon his return to the original situation, the child was required to locate the hidden cooky. If it was located without error, he was allowed to eat it. In successive trials the cooky varied in position in a random manner. Average accuracy of response was 64.8 per cent after delays of 1 to 3 days. After delays of 21 to 29 days, accuracy dropped to 46.2 per cent. Longer delays were followed by merely chance accuracy. The correlation between age and maximum correct delay was .478 ± .077. Skalet points out that verbal symbols enabled the preschool children to make correct delays after long periods. The great difference in maximum correct delays between the ages of 1 and 2 years may be accounted for partly on the ground that the older child has acquired linguistic substitutes for absent stimuli.

The response required in Skalet's second group of experiments was to select from a random array of figures the one observed in isolation some time previously. She thus obtained a measure of delayed reaction in terms of recognition. In one set of tests, familiar animals were involved. In another, Skalet used geometrical figures of various kinds. Familiar animals gave the best results. For these tests the correlation between maximum correct delay and age was .669 ± .093. Tests with geometrical figures were too difficult for most children.

Two investigations of how certain stimulus factors influence correct delayed reactions in children have been reported. The first deals with the position of the subject, and the second with the position and color of the stimuli. In his original delayed-reaction experiment, Hunter (1913) found that some animals did not perform correctly unless allowed to maintain a fixed bodily orientation during delay. He supposed that a continuing kinesthetic cue was being used. Hunter's findings suggested to Emerson (1931) that the delayed reactions of children might be affected differentially by introducing variations in the degree of bodily orientation during delay Thirty-two children, ranging in age from 27 to 59 months, were each shown an easel which contained a board with 42 pegs arranged in 7 rows of 6 each. While a child was watching, the experimenter placed a ring over one peg. The child was then required to turn to a similar easel and place a ring over the corresponding peg. In each test the delay was approximately

5 seconds. Nine degrees of orientation were involved. They ranged from stepping to an easel at the side of the stimulus easel to going round to an easel facing in the opposite direction. Scores for correct placement were low throughout. With no disorientation, the average number of correct responses was 17.82. With the first degree of disorientation indicated above, the average score dropped to 6.45. When the positions of the stimulus and the response easels were back to back, the average score was only 1.81. There was an increase in scores with age. The average number of correct placements throughout the experiment correlated .77 ± .05 with CA and .758 ± .05 with MA.

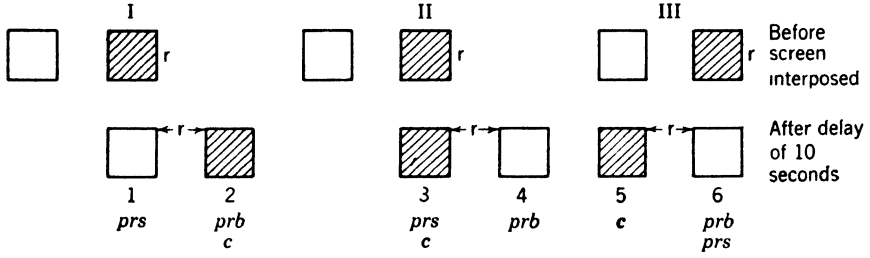

FIGURE 15. Critical tests of cues used in delayed reaction. (From "The Perception of Children: A Genetic Study Employing the Critical Choice Delayed Reaction," by N. E. Miller. *Journal of Genetic Psychology*, 1934, *44*, 327. By permission of the Journal Press, publisher.) The top line represents the original position of the boxes in each of the three tests. The lower line represents the critical choice positions. Each box is dsignated by a number for purposes of reference. *c*, choice on the basis of color; *prs*, response to position of box with respect to the child's own position; *prb*, response in terms of the position of one box in relation to the position of the other box. If the cue were color, boxes 2, 3, and 5 would be selected. Should the cue be position of the box with respect to himself, the subject would respond to boxes 1, 3, and 6. However, if the box presenting two cues were selected, the child would respond to 2, 3, and 6. There are four other theoretically possible cues.

Miller's (1934) investigation concerns the question of how certain exteroceptive stimulus relations affect accuracy of delayed response. His problem may be framed in the following question: When the child makes a delayed response, does the implicit symbol represent the *absolute* position, color, or other aspect of the box in which the lure has been hidden or does it represent some *relation* between this and other boxes? Miller refers to his test situations as involving "critical choice delayed reaction." A 10-second delay was used in each situation. Ninety-eight children between 11½ and 162 months of age served as subjects. The first experiment was conducted as follows: A child was seated opposite the experimenter and was asked, "Do you like to play games?" Two boxes of the same size, but one red and the other yellow, were placed in front of the child. The experimenter said: "See the boxes. Now I'm going to hide the dog under a box. Look!" The toy was hidden. A screen was then interposed between the boxes and the child for 10 seconds. At the end of this interval, the experimenter said, "See if you can find the dog." After each response he said, "Fine!," and again hid the toy. The child was then asked, "Can you find it this time?" Various lures besides the toy dog were used.

As soon as the child completed two successive correct responses, critical tests to

determine the cues utilized were introduced. The nature of these tests can best be grasped by referring to Figure 15. Three critical tests are represented. The idea was to see whether, in these tests, the child would select a box of the same color as that under which he had seen the lure placed, whether he would select the box having the same relation with respect to his own position, whether he would select the one having the same position relative to the other box, whether he would select on the basis of two of these cues combined, or whether he would select on the basis of some other possible combination of cues. In the critical tests each box contained the toy, although the subject had seen it placed in only one box.

The 11½- to 24-month-old children, of which there were 4, all responded in terms of *position relative to the other box.* In successive age groups, however, there was a gradual decrease in the frequency of this type of response. Response in terms of *color* began, with a frequency of 20 per cent, in the age group of 25 to 36 months. The group contained 11 subjects. Color was an increasingly frequent basis of response until the 5-year level, after which its frequency decreased. *Position relative to the subject* was not a very frequent cue at any age level. Response in terms of the *box with two cues in its favor* was also quite infrequent at all ages. *Unclassified* responses increased with age, reaching a frequency of about 30 per cent at the 120- to 162-month level.

When the distance between the two boxes was doubled, the youngest age group responded 66 per cent in terms of *position relative to the other box* and 33 per cent in terms of *position relative to the subject.* Under these conditions, however, color again became an increasingly important cue in successively older groups.

In a number of further experiments involving principles similar to those of the above tests, use of such cues as position relative to a group of other boxes, different color from a group of boxes alike in color, and combinations of color and position cues was tested. In general, the results of these experiments show that the child below 2 years of age has some representation of the *position of one box relative to another.* This symbol serves as the chief basis of response when he is required to remember under which box he has previously seen a toy placed. Older children, on the other hand, frequently retain a representation of *color,* which symbol enables them to remember the box containing a toy.

Retention after a Single Presentation. Retention of materials seen or heard a single time has been investigated extensively in children. The problem is usually stated more specifically as one of immediate memory or memory span. It was first investigated by Jacobs (1887).[1] Special

[1] Materials used to test the memory span of children have included *digits:* Jacobs (1887), Bolton (1892), Henri (1902), Smedley (1902), Humpstone (1917), Pintner and Paterson (1917), Ide (1920), Town (1921), Starr (1923), Easby-Grave (1924), Gesell (1925), Young (1928), Hallowell (1928), McCaulley (1928), Hurlock and Newmark (1931), Wilson and Fleming (1937), and Terman and Merrill (1937); *speech sounds:* Metraux (1944); *letters:* Jacobs (1887); *words:* Kirkpatrick (1894), Henri (1902), Burt (1909), Whipple (1915), Achilles (1920), Stutsman (1926), Hurlock and Newmark (1931), Lumley and Calhoun (1934), and Wilson and Fleming (1937); *objects:* Dewey, Child, and Ruml (1920), Bronner, Healy, Lowe, and Shimberg (1927), and McElwee (1933); *movements:* Baldwin and Stecher (1924), Hurlock and Newmark (1931), Mallay (1935), and Werner (1940); *figures:* Achilles (1920), Allport (1930), Komatsu (1931), Shimidu (1934), Hall (1936); *pictures:* Stern (1904), Squire (1912), Carpenter (1913), Myers (1913), Winch (1914), Town (1921), Baldwin and Stecher (1924), J. A. McGeoch (1925, 1928), Bayley (1926), Conrad and Jones (1929), and Holaday and Stoddard (1933); and *narratives:* Shaw (1896), Yoakum (1921), Bassett (1929), Dietze (1931, 1932), Hurlock and Newmark (1931), Dietze and Jones (1931), Northway (1936), Terman and Merrill (1937), Loder (1937), and Morris (1939).

studies have had as their aims (1) to ascertain how differences in age, intelligence, and sex affect the memory span; (2) to compare the memory span for different kinds of material; (3) to determine the relative efficacy of visual and auditory means of presentation; (4) to observe differences in results obtained when recall or recognition tests of retention are used; and (5), especially in the case of narratives, figures, and pictures, to determine the nature of differences between the original and "recalled" material.

That the memory span of children increases with age has been shown for all kinds of material investigated. The auditory-vocal memory span for digits, as indicated by Starr's (1923) investigation with 2000 children between the ages of 4 and 15 years, is 4 between the fourth and fifth years, 5 between the sixth and eighth years, 6 between the ninth and twelfth years, and 7 beyond the twelfth year. Other studies on auditory-vocal digit span summarized by Hurlock and Newmark (1931), as well as the Terman-Merrill (1937) norms, are in close agreement with these. Although the memory span for words, letters, objects, figures, and ideas in a narrative also increases with age, the particular span is dependent upon the meaning of the materials involved.

Most investigations have shown a positive, but medium, correlation between intelligence and memory span for various types of material. In Bayley's (1926) study, which involved 100 subjects between approximately 3 and 6 years old, correlations between MA and memory span for digits ranged from .40 at the third year to .67 at the sixth year. Correlations between memory span for objects and MA ranged from .44 to .58. Hurlock and Newmark (1931) report the following correlations between the IQ and memory spans of 20 preschool children: *digits*, .59 ± .11; *syllables*, .72 ± .08; *concrete words*, .52 ± .11; *abstract words*, .55 ± .11; *pictures*, .61 ± .09; *movements*, .59 ± .11; *ideas in a narrative*, .76 ± .07; and *commands*, .64 ± .09. Clark's (1924) investigation suggests that, although there is a positive correlation between intelligence and digit span at early age levels, the correlation is negligible at the high school level.

It is generally claimed that memory spans for boys and girls show a difference in favor of the latter. This view is based, primarily, upon the researches of Kirkpatrick (1894) and Pyle (1920), both of whom measured memory span for words. The developmental range in both studies combined was from about the third grade to the high school level. That a sex difference exists in the memory span for digits is doubtful. Several studies involving both sexes fail to mention a difference, and Pintner and Paterson (1917) and Bryan (1934) found none. Some investigations involving pictures (Shimidu, 1934) and narratives (Shaw, 1896; Bassett, 1929; Dietze, 1932) have disclosed slight superiority of boys. It is of course quite possible that, where meaningful materials of this nature are involved, a sex difference indicates differential acquaintance with the material rather than differences in retentivity.

As reported by Hurlock and Newmark (1931), the average memory span of preschool children for digits is 5 ± 1.00; for concrete words, 4.3 ± 0.65; for abstract words, 3.0 ± 0.30; for syllables in a sentence, 15.1 ± 1.20; for pictures, 1.2 ± 0.35; for movements, 4.3 ± 0.65; for ideas in a narrative, 4.3 ± 0.00; and for commands, 3.3 ± 0.50. Whipple (1915) reports that meaning greatly affects the size of the memory span for words.

Smedley's (1902) results show that the memory span for digits does not differ for auditory and visual methods of presenta-

tion until the age of approximately 9 years. After this age the visual span exceeds the auditory. Jones (1927) likewise finds no difference in the digit memory span for visual and auditory presentation. All his subjects were under 9 years of age.

Recognition is apparently easier than recall. Achilles (1920) found that children between 8½ and 11½ years of age recognized an average of 23.95 words and recalled an average of only 5.22 words. For forms, the recognition and recall scores were, respectively, 9.61 and 3.97. Syllables yielded scores of 9.41 and 1.86. An older group exhibited higher scores than these, but the relative difference in favor of recognition as compared with recall scores was similar. In Hurlock and Newmark's (1931) study the memory span for pictures was 1.2 by the recall and 6.1 by the recognition method. Shimidu (1934) reports similar results.

Recall of pictures observed a single time was first investigated extensively by Stern (1904), who framed the problem as one of *aussage* or testimony. He found that children not only fail to report items in the picture but they also add details of their own and, when questioned, respond to suggestions given. The test is thus not one of memory *per se*. Nevertheless, when items fall within the individual's range of experience and vocabulary and when fictitious details are ignored, the number of items reported is fundamentally a measure of recall memory. Winch (1914) tested 200 children, most of whom were between the ages of 3 and 8 years. Stern's picture was used. At successive age levels the average number of items reported was 8.3, 16.1, 26.5, 30.0, and 35.6. The items involved (boy, woman, bread, knife, etc.) were represented in the previous experience of even the youngest child. It is possible, however, that differences in ability to observe and differences in vocabulary, as well as in memory *per se*, contributed to the increments in score at successively higher age levels. Similar experiments have been reported by McGeoch (1925, 1928) with, respectively, normal versus subnormal children and normal children between the ages of 9 and 14 years. Beyond the level of intelligence requisite to observation, intelligence did not affect the number of items reported. Recall scores of normal children increased with age, but increments became small and statistically insignificant at the upper age levels. Conrad and Jones (1929), who tested recall of the contents of three entertaining motion pictures by means of completion and multiple-choice tests involving a simple vocabulary, found that scores increased rapidly between the ages of 10 and 20 years. These studies lead to the conclusion, therefore, that recall of pictures witnessed a single time improves as a function of age. How much of the improved recall is based upon increased adequacy of observation and how much upon increased retentivity *per se* is not apparent.

Allport (1930) and Hall (1936) have investigated changes in reproductions of pictures observed a single time. In Allport's study, 275 children between the ages of 10 and 13 years were shown a simple drawing and then required to reproduce it. Further reproductions were drawn after intervals of 2 weeks and 4 months. Few perfect reproductions appeared. The figures did not, however, lose their identifiability in reproduction. Alterations from the original were chiefly in size, symmetry, and simplicity. Allport suggests that dynamic brain processes "force memory traces into typical lines of change." Hall showed pictures and diagrams to over 200 children between the ages of 9 and 15 years. Each child was told that he would be required to reproduce the picture or diagram after seeing it for a short period (20 seconds). As shown in Figure 16, the general charac-

teristics of the pictures and diagrams were retained while details differed. Naming of the object was a factor in determining the nature of reproductions. A given picture, for example, was referred to by different subjects as "tents," "mountains," "pyramids," and "blades of grass." When called upon to reproduce what they had observed, the subjects were markedly influenced by such verbalizations. Familiar objects tended

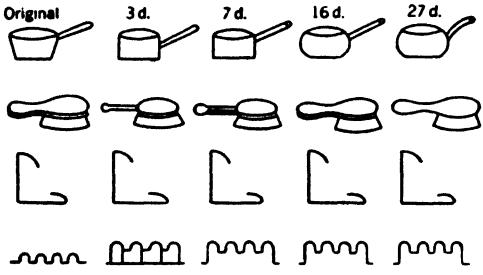

FIGURE 16. Examples of successive changes of diagrams and pictures. (From "The Effects of a Time Interval on Recall," by V. Hall. *British Journal of Psychology*, 1936, *27*, 44. By permission of the publisher.)

to change gradually and diagrams suddenly in repeated reproduction.

Studies somewhat comparable to the above, but utilizing narratives instead of visual materials, have been made by Northway (1936) and Wees and Line (1937). Northway's subjects, ranging in age from 10 to 15 years and coming from private and public schools, read a story once and, immediately after doing so, attempted a written reproduction. This reproduction was read by another child who, in turn, attempted to reproduce it. Some reproductions were made after a week's interval. Three stories, each having 250 words, were used. Older children tended to retain the story in its own form more accurately and for a longer time than younger ones. Changes, additions, and omissions were usually such as to recast the story in familiar phraseology and settings. The more unfamiliar the material the greater was the tendency to recast it. In some instances the story "reproduced" was almost entirely of the child's invention. As one might expect, however, the theme was usually retained with greater accuracy than the details. In Wees and Line's research sixth-grade children read a story and attempted to reproduce it. The same story was presented to different children in changed form. Wees and Line's chief finding is that the nature of the reproduction is determined by the form in which the story is presented.

Memorizing. When materials such as those discussed above are presented repeatedly and retention is measured after each repetition, we have a typical learning experiment. This type of experiment and those considered earlier in the present chapter differ chiefly in that the child is here required to learn symbols rather than movements as such.

The first reported experiment in memorizing in which children were subjects is Steffen's (1900). Children were used only incidentally.[1] In this, as in most of the early memorizing experiments with adults and children, nonsense syllables and poems were learned.

Foster (1928) investigated memorizing of narratives by nursery school children varying in CA from 2 years and 7 months

1 Other early studies with children are by Pentschew (1903), Radossawljewitsch (1907), Busemann (1911), and Meumann (1913). The number of children included in these investigations was too small to warrant comparison of their memorizing ability with that of the adults involved. In any event, comparison of child and adult learning of symbolic materials may be invalidated by the fact that the symbols have different degrees of meaning for children and adults. Motivation is another possible differentiating factor. Nevertheless, Meumann (1913) discusses alleged differences between the memorizing ability of children and adults. Studies in which memorizing by a single child has been intensively investigated are reported by Winch (1904), Guillet (1909), and Hildreth (1935).

to 4 years and 9 months and in MA from 3 years and 2 months to 5 years and 8 months. Fifteen boys and 16 girls were involved. Stories containing 388 to 472 words were each read to a child 10 times. After the first reading of a story, pauses were introduced at predetermined intervals and the subject was encouraged to continue the narrative as far as possible. His score per repetition was the number of words correctly recalled. Whenever a correct reproduction was made, the experimenter said, "Good." Incorrect reproductions were corrected. After 10 repetitions (9 recall tests) had been given a new story was begun. One repetition was given daily. Twenty-two of the children learned 8 stories in this manner while the rest learned 3 to 4.

A learning curve based upon the mean number of words per child per story for the 8 stories is presented in Figure 17. One notes that the curve is approximately linear, and that the limit of achievement was not reached during the 9 tests. Similarly plotted curves for subjects below a CA of 3 years and 4 months and an MA of 3 years and 10 months, however, show a decided flattening after the eighth repetition. Mean scores of the lowest CA group went from approximately 1 on the first repetition to 8 on the last, whereas the comparable scores of the five oldest children went from 9 to 73. Similarly, the scores of the lowest MA group went from 1 to 8, whereas those of the highest went from 5 to 64. The correlation between CA and total score for all stories was .74; that between MA and total score for all stories, .65. Although the number of subjects was small, the above data all agree in suggesting that the memorizing of narratives by young children increases with age and intelligence. Whether this increase is in mnemonic ability *per se* or in attitudes, previous experience, or the like, cannot be determined. Although girls were slightly higher than boys in MA, their average scores were lower than those of boys on 7 of the 9 stories. Since the groups were so small, this may not represent a true sex difference.

Several investigators of memorizing in children have used variations of the paired-associates method. The color-naming studies of Lund (1927) and Jersild (1932) are of this variety. Children were shown colors

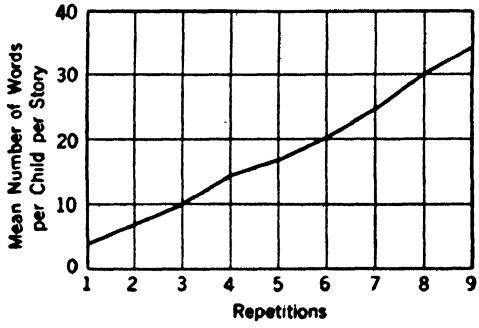

FIGURE 17. Curve for memorizing of stories. (From "Verbal Memory in the Pre-school Child," by J. C. Foster. *Journal of Genetic Psychology*, 1928, *35*, 31. By permission of the publisher.)

and required to recall the appropriate names as quickly as possible. Lund's 5-year-old child and Jersild's 7- to 8-year-old children exhibited an initial rapid increase in speed of naming. This was followed by slow improvement. Jersild used a control group which, despite the fact that it performed only an initial and a final test, also improved. The improvement of this group was less than one half that shown by the trained group. After an interval of 4 months without intervening experimental practice, however, the speed of naming in both groups was approximately equal. Only the control group showed improvement during the interval. It appears that the maturation and/or incidental learning of this group enabled it to approximate what the

other group had achieved by experimental practice.

Experiments by Meek (1925) and Kirkwood (1926) also involved paired associates. Meek required 68 children between the ages of 4 and 6 years to associate names of objects with the objects when confusing words (having the first, last, two middle letters, etc., of the key word) were presented simultaneously. Thus the word *ball* appeared on a box containing a ball but, associated with this box were other, empty boxes containing the words *burr, feel, sale, bake,* and *kill.* The other words to be learned in this way were *flag, doll, lion, duck,* and *rose.* Improvement was measured in terms of time, number of corrections, and number of false recognitions in each practice period. Six practice periods separated by intervals of 1 to 30 days were given. Each period was terminated after a specified number of correct recognitions, the number depending upon differences in the training procedure for different groups. Meek's results indicate no conclusive evidence of improvement in memorizing as a function of age. This is perhaps due to the fact that her procedure was not comparable at different age levels. The correlation between MA and time required to learn *ball* to the point of two recognitions ranged, for the age groups of 4 to 6 years, between .302 ± .101 and .456 ± .142. When corrections made in learning all words were correlated with MA the correlations ranged from −.011 ± .189 to .583 ± .128. Correlations increased at each successive age group. The last correlation, based upon data from only 14 children, however, is alone statistically significant. Most of the learning curves show a sharp improvement in the first few periods, followed by little or no improvement. One of the most interesting aspects of this investigation is the analysis of individual cases. This analysis shows that temporary excitement, boredom, worry over a scolding from the mother given prior to the experiment, daydreaming, etc., lead to marked variations in memorizing.

Kirkwood (1926) investigated association of pictures and blocks having a vague resemblance to each other. Her subjects were 180 preschool children. Twenty blocks and 20 pictures were used. At each practice period the experimenter picked up pictures in random order and asked the child to hand her "the block that goes with this picture." In some instances the block was handed to the child and he was required to select the correct picture. Learning curves based upon the number of correct associations exhibited a rapid rise and then flattened upon approaching the upper limit of 20.

The relation of age and intelligence to memorizing has been the subject of special investigations by Wilson (1931*a*, 1931*b*, 1931*c*) and Stroud and Maul (1933). Wilson found that dull children were, on the average, inferior to bright children in memorizing shorthand characters and descriptive selections. In some individual cases, however, bright children were surpassed by dull children. In Stroud and Maul's study, 172 subjects between the ages of 7 and 11 years, 26 subjects aged 14 years, and 28 subjects aged 18 years were given 10 minutes' practice with nonsense syllables and, on a different occasion, 15 minutes' practice with poems. The number of nonsense syllables and the number of lines of the poems recalled increased with age. Correlations between CA and recall scores, however, decreased from .61 for poems and .49 for nonsense syllables to approximately zero when MA was partialed out. The correlation between MA and recall scores was .67 ± .024 for poetry and .61 ± .028 for nonsense syllables. Stroud and Maul therefore conclude that memorizing ability is significantly related to in-

telligence, a conclusion supported, it will be recalled, by the data of Meek (1925) and Foster (1928).

The Relative Efficacy of Different Memorizing Procedures. If certain memorizing procedures result in faster learning and in better retention than others, it is important that these procedures be discovered and applied in classroom teaching. A few approaches to this problem have been made in the laboratory and the classroom and with both adults and children as subjects. Use of children in such research was at first incidental. There has been a tendency, however, to investigate the relative efficacy of different procedures with large groups of children as subjects and, at the same time, to approximate schoolroom conditions as closely as possible.

Several investigators have attempted to determine the relative merits of *whole versus part procedures.* Steffens (1900) was the first to investigate this problem. She found that her adult subjects and two children learned poems more rapidly when the poems were read from beginning to end than when verses were learned separately and later connected. Neumann (1907), who required 6 children between the ages of 9½ and 10½ years to associate German and foreign words by whole and part procedures, also found the whole procedure to be superior. He observed, however, that the effectiveness of this procedure increased with increasing intelligence.

Winch (1924) did not find the whole to be superior to the part procedure. He worked under classroom conditions with large groups of children. The children were paired on the basis of age and memory ability as determined by a preliminary test. One child of a pair learned poems by the whole method, whereas his partner learned the same poems by the pure part procedure. Three separate experiments were performed, involving groups of 26 to 38 children ranging in age from 11 years and 8 months to 13 years and 1 month. With the exception of the results for one poem at one age level all data were in favor of the part procedure. Pechstein (1926) found no reliable evidence in favor of either whole or part methods in his investigation with bright and dull children.

The equivocal nature of the above findings led McGeoch (1931) to carry out a further investigation, which appears to be the most thorough yet performed on this problem with children as subjects. Her subjects were 33 gifted and 35 normal children, all approximately 10 years old. The IQ of the gifted group averaged 151 and that of the normal group, 99. The groups were divided equally with respect to sex. Turkish-English vocabularies, nonsense syllable-English pairs, and poems were memorized by whole or part methods. In learning of the last two types of material a progressive part procedure, as well as whole and pure part procedures, was used. The same number of repetitions, in the case of paired associates, and the same time, in the case of poems, were given with each procedure. Scores for paired associates comprised the number of associates recalled upon presentation, singly and in changed order, of the initial members of the pairs. Memorizing of poems was scored in terms of the number of lines recalled.

Data obtained with the Turkish-English vocabulary yielded unequivocal evidence of the superiority of the whole procedure both for gifted and average children. Furthermore, the superiority of this procedure was greater for gifted than for average children. The means, SD's, differences, and standard errors of the differences are given in Table 4. One will observe that all differences between the whole and part procedures for both learning and retention are statistically significant. Nonsense syllable–English pairs

TABLE 4

COMPARISON OF METHODS

Group	No.	Whole		Part		Whole Minus Part		P/W
		Mean	SD	Mean	SD	Diff.	$SD_{diff.}$	
Learning								
Gifted	31	5.06	1.55	2.53	1.27	2.53	0.29	50%
Normal	32	2.42	1.32	1.48	.87	.94	.20	61%
Normal/Gifted		48%		58%				
Retention								
Gifted	31	4.12	1.49	2.17	1.36	1.95	0.26	52%
Normal	32	1.76	1.21	.78	.74	.98	.18	44%
Normal/Gifted		43%		36%				

yielded results in the same direction, but few of the differences were found to be statistically significant. The progressive part procedure gave ambiguous results, in some instances being more effective and in others less effective than the whole method. None of the differences was significant statistically. Poems were learned better by gifted than by average children. However, slight differences between the scores for whole, progressive part, and pure part methods were statistically insignificant. McGeoch concluded that the effectiveness of the whole and part methods depends upon the intelligence of the subjects and the type of material to be memorized.

In a study reported briefly by Northway (1937), poems of varying difficulty, as determined by their "thought content," were memorized by school children. There was no clear superiority of the whole or part procedure. The relative effectiveness of the two procedures differed from one poem to another, and there was no clear relation between the efficiency of the procedure and the difficulty of the poem. It is suggested, however, that poems of intermediate difficulty were learned best by the whole method, whereas those of lesser and greater difficulty were learned about as effectively by either method. Griffiths (1938), as the result of a study involving 14-year-old boys, claims that simple materials are learned with equal efficiency by either part or whole methods but that difficult material should be approached in

terms of the whole method at first and then in parts.[1]

The results of researches on whole versus part methods of learning in adults are also conflicting. On the basis of findings so far reported one must conclude that, even for memorizing of a given type of material—for example, poems—findings differ concerning the relative effectiveness of the whole and part procedures. One investigator finds the whole procedure most effective, another the part procedure, and still another finds no difference. Woodworth (1938), after critically evaluating all the literature on whole versus part learning, says that the net result is somewhat as follows:

> The parts are easier to learn than the whole and the learner is often happier and better adjusted to the problem when beginning with the parts. He carries over some of the skill and knowledge gained in learning the parts into the subsequent learning of the whole performance. But he finds that putting together the parts is a serious problem requiring much further work. In the end he may have saved time and energy by commencing with the parts —or he may not—much depending on the size and difficulty of the total task and the learner's poise and technique. If he can adjust himself to the whole method and handle it properly, he can learn quite complex performances effectively by the whole method. In a practical situation it is probably best to start with the whole method while feeling free to concentrate at any time on a part where something special is to be learned [p. 223].

The relative efficacy of *massed and distributed practice* has been investigated extensively with animals and adults. Such researches have shown some form of distribution to be more efficient than massing of practice periods. Similar experiments with children have been few and inadequate.

Munn (1909), in her study of the learning curve, found that short frequent practice periods led to faster learning of a substitution problem by both children and adults than long practice periods. With the exception of this study and a master's thesis, the results of which are summarized by Peterson (1933, pp. 428–430), all reported work with children on this problem has involved memorizing.[2]

Kirkwood (1926) required two matched groups of 11 children each to associate pictures and blocks which were vaguely similar (see page 417). Upon being presented with each of 20 blocks the child was required to select its associated picture. Each day's score was the number of correct associations. One group practiced every day; the other practiced on alternate days. The results are summarized in Table 5. One will observe that the group with a greater distribution of practice not only achieved the criterion of 3 successive correct trials 5 practice periods earlier than the other group, but also attained higher scores at every trial.

Foster (1928) found distributed practice to yield better results than massed practice in the learning of narratives by 29 nursery school children. After one story had been given a single repetition daily for 10 days, another story, assumed to be of approximately equal difficulty, was given 5 daily repetitions for 2 days. The average number of words recalled per repetition was consistently higher for distributed than for

1 Of some relevance in this connection is the study by Hildreth (1942) on solving of jigsaw puzzles by children. The most efficient results were obtained when the children first saw the whole picture.

2 This thesis, by Long, deals with distribution of practice in dart throwing. There were only 10 boys in each group, the initial ability of the two groups was markedly different, and only a minute statistical analysis, which seems unwarranted in the light of the small number of subjects, discloses any difference in the effectiveness of the two procedures.

TABLE 5

AVERAGE SCORES OBTAINED BY TWENTY-TWO PAIRED CHILDREN IN ASSOCIATING PICTURES WITH BLOCKS

Practice Periods													
1	2	3	4	5	6	7	8	9	10	11	12	13	14
Practice Once Daily													
10.2	14.9	16.5	18.8	19.1	19.0	19.8	19.6	19.3	20.0	19.7	20.0	20.0	20.0
Practice on Alternate Days													
11.3	15.2	18.9	19.6	20.0	19.8	20.0	20.0	20.0					

massed practice. A few individuals, however, had higher scores for massed than for distributed practice. Although the trend of Foster's results is in line with that of other researches on distribution of practice, her experiment lacks conclusiveness owing to the fact that a different poem was memorized under each of the conditions.

The advantage of rests between practice periods has been attributed to decreased fatigue, to preservation of neural traces following removal of the stimuli which aroused them, to opportunities for recitation or rehearsal, and to more rapid dropping-out of inhibitory than of facilitory associations during an interval. Any or all of these factors may operate in a given instance. The phenomenon under discussion is also possibly related to better retention of incomplete than of completed tasks (Zeigarnik, 1927) and reminiscence (Hovland, 1938*a*). For a discussion of this, see pages 425–430.

Another problem concerns the relative efficacy of *recitation and passive reading* of materials to be recalled. It has long been known that retention is poor unless the individual intends to memorize.[1] Myers (1913), for example, found that children and adults fail to remember many items from everyday experience when there has been no intention of recalling them later. On the basis of such facts one should expect recitation to facilitate learning and retention. A specific investigation of this program was undertaken by Gates (1917), whose experiments were carried out under classroom conditions. Forty to 45 children, from grades 1, 3, 4, 5, 6, and 8, were used. The materials to be memorized were lists of nonsense syllables and brief biographies. Each group memorized under each of the conditions of the experiment in such order that all factors other than the relative amounts of recitation and reading were equated. The total time given to memorizing nonsense syllables was divided between reading and recitation so that the percentages of reading were as follows: 100, 80, 60, 40, and 20. Reading comprised going over the material from the beginning to the end without repeating any unit except while looking at it. When recitation was called for, the child was instructed to look over the top of the card and repeat as many units as possible. Only when a unit could not be remembered was he to glance at the card while reciting. More material was given in a lesson than could be memorized in the time limit. A written recall was made after this limit had expired. The results obtained for memorizing of nonsense syllables appear in Table

1 See especially the case cited by Radossawljewitsch (1907, p. 127).

6.[1] Scores are relative, being derived from average scores by considering the average of each class for all five methods as 100.

TABLE 6

THE RELATIVE EFFICACY OF DIFFERENT PROPORTIONS OF READING AND RECITATION IN MEMORIZING NONSENSE SYLLABLES

Percentage Reading	100	80	60	40	30
Grade 8					
Relative score	65.40	92.23	99.69	105.45	137.26
PE	2.37	2.69	2.53	2.57	3.35
Grade 6					
Relative score	59.13	88.35	101.34	112.57	136.61
PE	2.74	3.78	2.70	4.09	4.81
Grade 4					
Relative score	63.42	80.53	108.05	113.75	134.42
PE	3.42	2.76	3.36	4.50	4.74

The same general procedure was followed in memorizing of short biographies. Grade 3 was allowed a total of 7 minutes and 30 seconds per biography, whereas grades 4, 5, 6, and 8 were allowed 9 minutes. Added to the proportions of reading and recitation used with nonsense syllables was a 10 reading–90 recitation percentage. Recall scores reduced to a relative basis are given in Table 7. Statistical analysis of these scores discloses that, for all grades, some degree of recitation is significantly superior to reading alone. Taking the average of all scores into consideration, Gates obtained the following relative scores for, respectively, no recitation to 90 per cent recitation: 83.71, 95.32, 101.63, 110.35, 106.67, and 102.30. Considering these data as a whole, it appears that 40 per cent reading and 60 per cent recitation give the best results for this type of material under these conditions.

1 Results for grade 1 are not included because, owing to differences in technique, they were not comparable with those of other grades.

Tests of retention given 3 to 4 hours after original learning showed trends similar to those found for immediate recall. Relative retention scores for nonsense syllables, averaged for all grades, were, for the successively greater amounts of recitation, as follows: 45.34, 72.96, 93.53, 119.13, and 169.17. Thus an increasing proportion of recitation, within the limits of zero and 80 per cent, led to increasingly better retention of nonsense syllables. For biographical material the comparable scores were: 73.31, 85.44, 110.23, 122.98, 115.65, and 110.82. As in the case of immediate recall, retention scores were highest with 60 per cent recitation.

In repeating these experiments with adults, Gates obtained results essentially similar to those mentioned. His analysis of the process of memorizing suggests that recitation enables the individual to develop with greater facility than is possible in reading alone the requisite "bonds" between items. Where these bonds must be built up by the learner himself, as in learning nonsense materials, recitation seems of most value. In general:

> Recitation leads to greater certainty of one's knowledge. It enables the learner not only to know but to be aware of how well he knows. Fewer blunders and erroneous recalls are made. The material is better organized; it is in more usable form (p. 101).[2]

2 Investigations on other aspects of economical memorizing in children have been carried out by Dell (1912), on position of items in a series and the relation of this position to ease of learning and recall; by Sullivan (1924), on development of attitudes concerning success and failure; by Meek (1925), on the most effective number of repetitions at different stages of learning; by Jensen and Schiodt (1936), on wording materials so as to bring them within the child's range of comprehension; by Forlano and Hoffman (1937), on the relative adequacy of guessing and telling methods in learning foreign words; and by Adams (1938), on the effect of correcting and repeating errors in serial rote learning.

TABLE 7

THE RELATIVE EFFICACY OF DIFFERENT PROPORTIONS OF READING AND RECITATION IN MEMORIZING SHORT BIOGRAPHIES

Percentage Reading	100	80	60	40	20	10

Transfer of Improvement in Memorizing. Does memorizing a particular kind of material increase a child's *ability* to memorize? Several investigators have sought an answer to this question.[1]

1 Although they do not concern memorizing *per se*, the following studies are somewhat relevant. Thorndike (1924) and Brolyer, Thorndike, and Woodyard (1927) investigated the transfer value of various high school subjects. Transfer was measured in terms of improvement in mental-test performance. The small apparent transfer of some subjects, such as mathematics, could be attributed to similarities between subject and mental-test material. The investigators claim that no general transfer occurred. Gordon's (1938) experiment on transfer of training within verbal tests is of interest in this connection. She found that a group of children trained on analogies for 8 weeks following initial tests had significantly higher final analogy scores than did a comparable group given only the initial and final tests. Transfer was probably in terms of an acquired "feeling" for analogy material and perhaps a technique. There is no implication that reasoning ability *per se* had been improved by the training with analogies. On tests which did not include analogies, the two groups performed with equal skill.

Winch (1908) had school children between 10 and 13 years of age memorize poetry on 1 day per week for 3 weeks, after which they memorized history and geography lessons. A control group, equated with the former in terms of initial tests and in terms of teachers' judgments of mnemonic ability, memorized the same lessons after doing sums for 3 weeks. The experiment was repeated with several different groups of children. As an example of the results obtained in these studies we shall cite the data of the initial one, which involved experimental and control groups of 17 children each. The average initial score of each group for memorizing history was 88. The average final score in memorizing history (another lesson of greater length than the first) was 121 for the experimental and 111 for the control group. All experiments yielded results in the same direction. Winch concluded that: "Im-

provement, gained by practice in memorizing one subject of instruction, is transferred to memory work in other subjects whose nature is certainly diverse from that in which the improvement was gained" (p. 293).

In a further experiment of the same general nature, Winch (1910) found that training in rote memory led to improvement in substance memory. Sleight (1911), who worked with both school children and adults, questioned Winch's techniques and the reliability of his data on transfer from rote to substance memory. Children averaging 12.8 years of age were divided into four groups of equal mnemonic ability as determined by a series of tests. One group learned poetry in rote fashion, one memorized tables, one learned the substance of prose selections, and the fourth, during the same period, did arithmetic problems involving no memorization. These activities occurred 30 minutes daily, 4 days per week, for 3 weeks. All four groups were finally required to memorize nonsense syllables, prose selections, the data of maps, and other materials. In two instances there was a statistically significant difference in favor of the trained group. In memorizing nonsense syllables, the groups which learned poetry and tables gained, respectively, 66 and 85 more points than their controls. The differences had a PE of 11. There was a statistically insignificant drop of 32 points in memorizing prose after learning nonsense syllables and a statistically insignificant increase of 21 to 31 points in going from training with prose to, respectively, literal and substance memorization of prose. Sleight concluded that, where transfer occurs, it is in terms of specific techniques. Subjects developed a procedure which served as well in memorizing one type of material as in memorizing another.

Winch (1911) presents data which seem to indicate transfer from memorizing to inventing stories having a different content. In each case there is a small, but probably insignificant, difference in favor of the trained group. Correlations between memory and invention scores run as high as .623, which is statistically significant.

Gates and Taylor (1925) and Gates (1928) report a transfer experiment involving digit span. Their subjects were 82 children separated into experimental and control groups on the basis of sex, age, intelligence, scholastic maturity, grade, initial memory span for digits, and other mnemonic performances. Children of the experimental group were given 78 days of practice in memorizing series of digits of differing length. The control group was tested for digit span only on the initial and final days of the experiment. The initial digit span of both groups was 4.33. During 78 days of practice the experimental group increased its average digit span to 6 40, a gain of 2.07. The control group had a final score of 5.06, a gain of 0.73. It is apparent that practice in memorizing digits increased the digit span. In a further test 4½ months later, however, both groups exhibited approximately equal spans. Gates assumes, therefore, that "the improvement brought about by training in this case is due to subtle techniques rather than to increased fundamental capacities" (p. 455). An interval of only 4½ months was apparently too long for the techniques to be retained. Both groups were given further practice 8 months after the final tests. On the first day of this practice period the scores of the experimental and control groups were, respectively, 4.73 and 4.83. Twenty-one days of training increased these scores to 5.73 and 5.92. It is again apparent that the 78 days of training 8 months earlier gave the experimental group no superiority over the control group at this later period.

On the basis of the above-mentioned experiments one must conclude that training in memorizing aids further memorizing only in so far as techniques acquired in one situation are applied to further situations. There is no evidence, in other words, that *memorizing ability per se* is improved by training.

Forgetting. Ebbinghaus (1885), who was his own subject, found that forgetting of nonsense syllables and poems learned to the point of 1 perfect repetition is at first rapid and then slow. Radossawljewitsch (1907), the first investigator to study forgetting in children, used 11 subjects whose ages ranged from 7 to 13 years. Nonsense syllables and poems were learned to the point of 2 perfect repetitions. These were relearned after intervals ranging from 5 minutes to 60 days. Comparison of the number of repetitions required to learn and to relearn gave an indication of the amount forgotten after each interval.[1] Adults learned and relearned the same materials. Radossawljewitsch found that both children and adults forgot much more slowly than Ebbinghaus. Results for children and adults did not differ in any consistent manner. Data obtained with children are summarized in Table 8. Some variation from interval to interval is probably due to the fact that relearning took place at different times during the day.

TABLE 8

PERCENTAGE OF NONSENSE SYLLABLES AND POEMS FORGOTTEN

Intervals	*5 minutes*	*20 minutes*	*60 minutes*	*8 hours*	*24 hours*	*2 days*	*6 days*	*30 days*	*60 days*
Syllables	9	15	23	37	28	32	43	66	94
Poems	3	11	23	39	21	29	42	75	85

An interesting forgetting experiment with 60 sixth-grade children has been reported by Klugman (1944*b*). Each child was shown a sheet of paper which was blank except for a dot. The dot differed in position from child to child and for different memory intervals, but each child served under each of the conditions of the experiment. Each child was asked to reproduce the dot in its proper position. With the dot in a given position, some children reproduced it after .5 minute, others after 1 minute, and others after intervals of, respectively, 2, 4, 8, and 16 minutes. To determine the amount of error, the experimenter superimposed the two sheets and drove a pin through each dot. The deviation was then measured in millimeters. In deriving the forgetting curve shown in Figure 18, Klugman deducted from the memory data the average error made in merely copying the dot from one sheet to the other. The children were equally divided with respect to sex. Half of them were Negro. No sex or race differences were apparent. The serial reproduction method used in this experiment is of only incidental significance. It guaranteed that the dot would be varied in position for each child.

Reminiscence. It is obvious that, when material is completely learned, either retention will be perfect after an interval or there will be decreased retention. Henderson (1903), Ballard (1913), Huguenin

1 Forgetting in children has also been measured in terms of recall. Under these circumstances, forgetting after only 10 seconds has been 17 per cent (Vertes, 1931). Experiments by Charles (1929) and Burtt (1932, 1937) have shown that material presented before the second year of life, although beyond recall 6 months (Charles) and 8 to 14 years later, is relearned with large savings in the number of repetitions required for new material. In Burtt's study the savings at 8 years was 30 per cent and at 14 years 8 per cent. Burtt (1941) found no savings at the age of 18. Recall in adulthood of fairy tales heard in childhood has been studied by Brenman (1942), but the results are reported only in a brief abstract.

(1914), and several later investigators whose subjects memorized material to a point short of perfection found *better* retention after an interval during which there was no experimental training than immediately after learning. Ballard called this phenomenon *reminiscence*. His re-

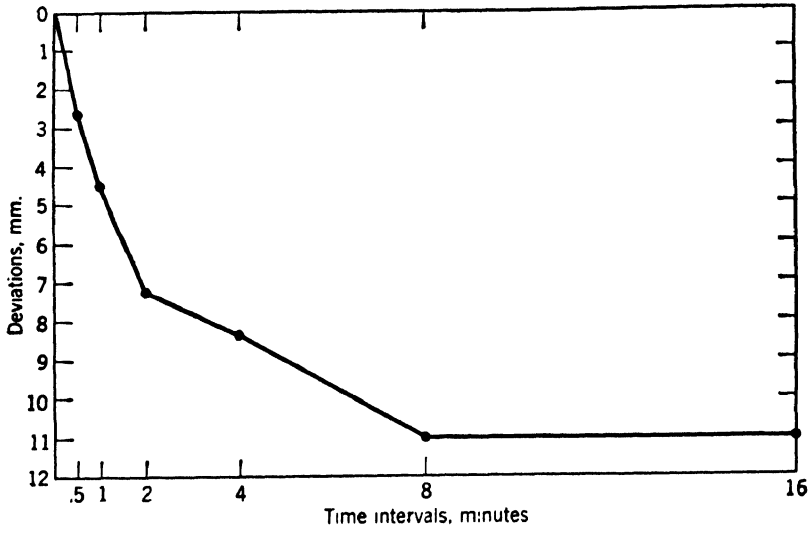

FIGURE 18. Forgetting curve for sixth-grade children, based upon memory for the position of a single dot on a sheet of paper. The copying error has been deducted from the memory error after the respective time intervals. (From S. F. Klugman, "Memory for Position, among Children, as Measured by Serial Reproduction." *British Journal of Psychology*, **1944**, *35*, p. 20.)

search has precipitated many further studies and much discussion.

Since reminiscence has been regarded as peculiar to children, and since most of the research has involved child subjects, it warrants careful consideration in any discussion of learning in children.

Ballard's subjects had an age range of 6 to 21 years. In one investigation, involving over 5000 school children, lines of poetry and lists of nonsense syllables were studied for shorter periods than would allow complete learning. A recall was given immediately after the study period and, as far as the subjects knew, there would be no further recall. The amount recalled immediately was taken to be 100 per cent. Different groups gave a further recall after intervals of, respectively, 1 to 7 days. Recall of poetry by 6-year-olds improved 38 per cent after the first day, 57 per cent after the second day, 60 per cent after the third day, and then began to decline. Only relatively slight improvement (10 to 20 per cent) was evidenced by 12-year-olds. Adults showed decreased rather than increased retention. The scores so far mentioned are based upon *averages* for the various age groups. Ballard also analyzed his data in terms of the *percentage of individuals* showing reminiscence at each age level. Reminiscence was present in 90 per cent at the 6-year level, 75 per cent at the 12-year level, and 30 per cent at the adult level. It is thus apparent that, although average scores indicated improved retention for children alone, some adults also

improved. Henderson (1903) likewise found improved retention in adults but greater relative improvement in children. Nevertheless, Ballard's results have been taken as evidence that reminiscence is peculiar to children and more evident in younger than in older children. His results suggest, furthermore, that reminiscence is more apparent for poetry than for nonsense material.

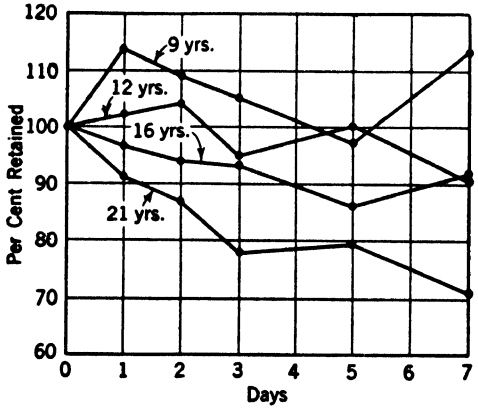

FIGURE 19. Retention of poetry after intervals of 1, 2, 3, 5, and 7 days. (From "A Study of the Phenomenon of Reminiscence," by O. Williams. *Journal of Experimental Psychology*, 1926, *9*, 373. By permission of the American Psychological Association, publisher.) Scores are for correct verbal reproduction of lines from "The Spider and the Fly."

Williams (1926) undertook to check Ballard's findings. Four groups, the average ages of which were 9, 12, 16, and 21, studied 40 lines of "The Spider and the Fly" for 5 minutes. They then recalled as much as possible immediately and after periods ranging, for different groups of 100 subjects each, from 1 to 7 days. Disconnected words were also partially learned and recalled. Recall was scored in terms of correct verbal reproduction, reproduction of sense, and reproduction of sense or partial sense. As in Ballard's research, immediate reproduction was scored as 100 per cent. Comparisons were entirely in terms of group averages. Data for retention of poetry by the four age groups after intervals of 1, 2, 3, 5, and 7 days are reproduced in Figure 19. It is apparent that, in terms of averages, reminiscence was exhibited only by the two younger groups. Also apparent is the fact that, even for the older groups, forgetting was initially less rapid than in the experiments of Ebbinghaus and Radossawljewitsch. Data reproduced in the table are for correct verbal reproduction. Other methods of scoring yielded essentially similar results. Scores

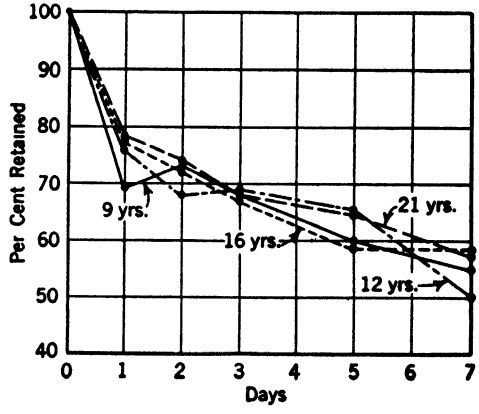

FIGURE 20. Retention of disconnected words after intervals of 1, 2, 3, 5, and 7 days. (From "A Study of the Phenomenon of Reminiscence," by O. Williams. *Journal of Experimental Psychology*, 1926, *9*, 374. By permission of the publisher.) Scores are in terms of correct verbal reproduction.

for retention of disconnected words are reproduced in Figure 20. They indicate no reminiscence and no consistent differences in the retention curves of the different age groups.

More recent studies of reminiscence have attempted to answer questions raised by the researches of Ballard and Williams. One question concerns the claim that reminis-

cence is more prevalent in children than in adults. Luh and Liang (1933) and McGeoch (1935*a*) found no satisfactory evidence in support of this claim. The former investigators used 11-year-old children and college students. Chinese poetry was studied, then recalled immediately and after an interval. There was no difference in the average amount of reminiscence exhibited by each group. However, a larger percentage of children than of students had scores indicating reminiscence. McGeoch analyzed the original data and found this difference to be unreliable statistically. Her own investigation involved 100 preschool children and 100 college students. Toy animals and common objects were exposed for 30 seconds and then covered.[1] Recall was given immediately and after 24 hours. Small differences in the number of each group reminiscing and in the number of items reminisced were in favor of adults. These differences, however, were not statistically reliable. Adults learned a greater amount of the material than did children; hence McGeoch (1935*b*) decided to determine whether the amount of material learned is in any way related to the degree of reminiscence. Materials comparable with those of the above-mentioned experiment were used. Adults and three groups of children learned, respectively, to the point where they could recall 71, 53, 42, and 29 per cent of the material. In a recall 24 hours later the following percentages of subjects showed reminiscence: 94, 89, 85, and 92. Thus the factor of initial learning did not appear to affect the frequency of reminiscence.

These investigations, and others in which adults have been used exclusively, show that the phenomenon of reminiscence is not more prevalent in children than in adults.[2] It will be recalled, in this connection, that some of Ballard's adults exhibited reminiscence but group averages obscure this fact. The same may be said of Williams's experiment. For this reason, McGeoch (1935*a*) claimed that the only valid measures of age differences in reminiscence are the percentage of subjects reminiscing and the amount reminisced by these.

May reminiscence be attributed to the effects of intentional review during the interval between immediate and delayed recall?[3] Ballard (1913) claimed that, although reviewing aids reminiscence, it does not account for the phenomenon. McGeoch (1935*c*) investigated this problem in a partial repetition of Williams's study. She used over 400 third- and fourth-grade children. They studied lines of poetry for 5 minutes. Recall was immediate and after 24 hours. After the final recall had been completed, each child was asked whether, before doing the experiment, he had ever heard or read the poem. Seventy-three per cent denied previous knowledge of the poem. They were asked whether they had thought of, or talked about, the poem between the first and second recall. It was made clear that such review was quite permissible and that they should not hesitate to tell about it. Data were then analyzed separately for those who did and those who

1 This method was earlier used with children by Nicolai (1922), who found it to yield higher scores in later than in immediate recall.

2 See the experiments of Ward (1937) and Hovland (1938*a*, 1938*b*) with adult subjects. Reminiscence (of nonsense syllables) was clearly evident in these studies.

3 Other approaches to the problem of review are (1) use of material which cannot easily be reviewed (e.g., a maze pattern); (2) use of organisms which, presumably, cannot review; and (3) interpolating activity which interferes with review. McGeoch (1937) found no evidence of reminiscence in maze learning by kindergarten children. On the other hand, Bunch and Magdsick (1933) found reminiscence in maze learning by rats. These studies differed markedly in technique; hence the discrepancy should not be attributed to a difference in subjects. Ward (1937) and Hovland (1938*a*), who used adult subjects, interpolated activity (color naming) between recalls, yet observed reminiscence.

did not report having reviewed. The percentage of subjects who exhibited reminiscence and the amount of material reproduced on the second recall did not differ significantly for the two groups. Scores for verbatim recall of lines were slightly in favor of the review group, whereas these scores combined with those for recall of substance favored nonreviewers. Thus McGeoch concluded that review between the first and second recall does not account for reminiscence or even influence significantly the degree exhibited.

A further question concerns the possibility that reminiscence is due to improvement resulting from the immediate recall. Recall constitutes a review of what has been learned. Even material not recalled immediately may be revived later as a result of an effort to recall it earlier.[1] In her study on maze learning in kindergarten children, McGeoch (1937) controlled this factor by equating the two groups on the basis of initial scores and requiring each to take only one further trial. One group had a further trial immediately; the other group waited for 24 hours. Scores on the last trial were compared to ascertain whether reminiscence had occurred. Reminiscence did not occur. This may be due to factors other than the control instituted, however, for Ward (1937) and Hovland (1938*a*, 1938*b*), using nonsense syllables and adult subjects, found reminiscence when similar controls were instituted.[2]

The phenomenon of reminiscence has been related to the fact that incompleted tasks are recalled more easily than completed tasks. Zeigarnik (1927) required 47 adults and 45 children to perform a series of 18 tasks. They were allowed to complete only one-half the tasks, which were distributed in random order among tasks the completion of which was prevented. Finally, the subjects were asked to recall tasks which they had performed. Significantly more interrupted than completed tasks were recalled. The memorial advantage of interrupted over completed tasks was 90 per cent for adults and 110 per cent for children. Thirty-seven adults and 36 children remembered the interrupted tasks better than the completed. Zeigarnik's results have been verified with children in studies by Pachauri (1935*a*, 1935*b*, 1936) and Abel (1938).[3] Martin (1940) reports, moreover, that interrupted tasks yield a greater degree of reminiscence than completed tasks. All his subjects were adults.

Reminiscence has as yet received no satisfactory explanation. Most commonly expressed is the view, first suggested by Ballard, that removal of stimulating circumstances allows neural activity to continue

1 On this point see Woodworth's (1938, pp. 66–68) discussion of research with adults.

2 Bunch (1938), who stresses the need for matched groups and only one recall by each, believes that the influence of an immediate recall is too small to account for all the improvement found in earlier experiments on reminiscence. In a study with adults, he found only 11 per cent improvement when a second recall was given immediately. A more recent study by Gray (1940) is relevant but inconclusive. Matched groups of children studied words, sentences, and a narrative. One group gave an immediate recall, whereas the other did easy problems in addition to control review. Both groups recalled 24 hours after learning. The first group evidenced an insignificant improvement in recall of the narrative after 24 hours. Otherwise all data for both groups indicated a loss in retention during the interval. Gray regards as important, however, the fact that there was a significantly greater loss in the group which had no immediate recall. This finding perhaps loses significance because the group in question did addition immediately after learning. Although the addition problems were easy, they may have inhibited to some degree what the children had just learned.

3 Related to this research are studies in which the relative retention of complete and incomplete words and figures has been investigated. A study from Nanking (1935) shows that children retain completed words and pictures better than incomplete ones. Tiernan (1938), on the other hand, finds a slight, but not statistically reliable, advantage for incomplete figures. This tendency was more marked between the ages of 7 and 11 than later.

and bring about further consolidation of what has been learned. Hovland (1938*a*), who presents an excellent critical examination of several theories, points out that reminiscence appears even when subjects are required to name colors during the period between learning and recall (in his experiment only 2 minutes). Color naming should, he claims, prevent continued activity (perseveration) of the neural traces involved in original learning. Ward (1937) and Hovland (1938*a*) both favor the view that a rest period after learning weakens "negative excitatory processes" (inhibition), thus facilitating recall. Referring to an apparent relation between reminiscence and distributed learning, Ward says:

> It may be that both phenomena are mediated by some more fundamental process or processes. For example, it would theoretically be possible that the different rates of dying out of correct responses or associations on the one hand, and of inhibiting or interfering associations and tendencies on the other hand, could account not only for reminiscence at very short intervals of time, but also for the greater relative economy of practice sessions distributed at intervals of 1 or 2 days. This type of explanation would require the additional assumption that once the interfering associations or tendencies are dropped out they will not return as rapidly with a continuation of learning as do correct responses and associations [p. 56].

It is of course not yet certain that all reported reminiscence phenomena have the same basis, since investigators have used different materials, methods, intervals, criteria, and age levels. Further research will be needed before many points mentioned in the above discussion can be clarified and a satisfactory explanation reached.

There have been several other experiments on retention and forgetting in children. Lyon (1916) and Gillette (1936) both demonstrated that children who memorize quickly tend to be slow forgetters. Gillette controlled the amount learned, as well as the factor of overlearning, yet the quicker learners still demonstrated superior retention. In an experiment with 1000 school children, Houlahan (1941) found retroactive inhibition to be greater immediately after learning than after an interval. She found that increasing the duration of a rest period before introduction of interpolated learning increased the retention score. Studies on the relative retention of pleasant and unpleasant associations have been reported by Rosenzweig and Mason (1934), Carter (1935, 1936, 1937) and Gilbert (1937). In general, such studies have shown that pleasant associations are more adequately retained. However, Carter found that unpleasant words tend to be retained better than indifferent ones. In Gilbert's study, there was equal retention of pleasant and unpleasant words.

Problem Solving

Every learning situation presents a problem of one sort or another. Escaping from a maze, buttoning a coat, hitting the correct keys of a typewriter, and memorizing nonsense syllables or poems are *problems* when confronted initially. As psychologists use the term, however, problem solving refers to activity at a somewhat higher psychological level than is necessitated in learning of sensorimotor and mnemonic skills such as those mentioned. The type of learning designated as problem solving involves attainment of some more or less specific goal under such conditions that observing relations, reasoning, generalizing, "getting the idea," or what the Gestalt psychologists call "insight," greatly facilitate the learning process. Solution of some problems may be achieved only after dis-

covery of an underlying principle, relation, or system of relations. Discovery of a principle is frequently the only immediate goal of the learning process.

Investigators of problem solving in children have utilized materials ranging in complexity from puzzle boxes to tasks calling for abstract reasoning. Many of the relatively simple materials have been patterned after those used in experiments with animals. The puzzle box tests of Healy and Fernald (1911), for example, are similar in principle to those used by Thorndike (1898) and Small (1900) to investigate problem solving in cats, monkeys, rats, and other animals. A large number of researches on problem solving in children take as their point of departure the similar experiments of Hobhouse (1901) and of Köhler (1925) on the use of tools by animals. In these studies the problem is to discover that tools may be used to attain otherwise inaccessible goals. More complicated still are the puzzles used by Lindley (1897) and Ruger (1910) to investigate problem solving in children and adults. J. Peterson's (1918, 1920) rational-learning and mental-maze tests represent another type of problem solving used in investigations with children as well as adults. These devices and several others which involve generalizing are of a predominantly verbal character.

How Children Attack a Problem Situation. Before discussing the solution of problems like those mentioned above it will be enlightening to consider Hamilton's (1911, 1916) observations on how children and other organisms attack insoluble problems. Children and adults were confronted by four doors, only one of which was unlocked. If a given door had been unlocked in one trial it was locked in the next. The problem was to escape from the enclosure. If the unlocked door had always been on the extreme right, on the extreme left, the second from the right or left, or the right on one trial and the left on the next, the problem could have been solved. Hamilton, however, purposely avoided following such principles. Which door would be unlocked from trial to trial was determined by chance. All subjects exhibited a variety of reactions which he designated as trial and error. Nevertheless, some exhibited a more "logical" trial and error than others. It seemed that they were using *hypotheses* as to the nature of the problem confronting them.[1] From the most to the least logical, the methods of attack were as follows: (*A*) trying the three inferentially possible doors—that is, those locked in the preceding trial—and avoiding the one previously unlocked; (*B*) trying all four doors once each in irregular order; (*C*) trying all four doors in regular order from left to right or right to left; (*D*) trying a given door more than once with intervening attempts to open some other door; (*E*) trying on two or more occasions to open a given door without intervening attempts at other doors, or persistent avoidance of a given door while trying all others. An infant of 26 months exhibited 15 per cent *A* reactions, 5 per cent *B* reactions, 20 per cent *C* reactions, 25 per cent *D* reactions, and 35 per cent *E* reactions. With subjects of increasing age, however, there was an increase in *A* and a decrease in *E* and similarly "illogical" reactions. Human adults exhibited 76 to 85 per cent *A* reactions and very seldom gave any *C*, *D*, or *E* reactions. The trial and error of young children was quite similar to that of infrahuman animals.

In his experiment with unicursal puzzles —that is, those in which a figure must be traced without lifting the pencil, retrac-

1 Hamilton did not use the term *hypothesis* in this connection. It was later (1932) used by Krechevsky in reporting his observations of similar trial-and-error behavior in rats.

ing, or crossing lines—Lindley (1897) also found that younger children exhibit a quite inadequate mode of attack. His subjects were from grades 3 to 8. The reactions of children in the lowest grade were, according to Lindley, characterized by lack of circumspection, conventional beginnings, slight and inconsequential variations from one attempt to another, frequent relapses into a former routine, and tardiness in profiting from errors. In older children, these characteristics slowly made way for "greater prevision, more adequate analysis of the design, less conventionality and automatism in procedure, more radical reconstruction of plan in successive trials, all of which led to greater promptness in profiting by mistakes" (p. 469). L. W. Gates (1938), using a multiple-choice situation, likewise observed increasing deliberateness of exploration with increasing age. The ages ranged from 5 to 10 years.

Other investigators of problem solving whose studies will be considered in the following discussions have also noted increasing appropriateness of attack as a function of age.

Puzzle Problems. A variety of puzzle situations have been devised to study problem solving in children. One of the simplest situations, from the standpoint of the psychologist if not of the infant, is the plate-glass test devised by McGraw (1942). Three situations are used. In the first of these the child is on one side of a 30-inch-high piece of plate glass and the lure (bell or other desirable object) is on the other side. The toy can be seen at all times that the child is facing the glass. A baby placed in this situation, if it responds at all, will usually try to reach the toy through the glass. It eventually learns that it must stand up and reach over the partition. In the second of McGraw's tests, the plate glass covers the right or left side of the play pen and the child must reach around it to obtain the object. The third test is illustrated in Figure 21. McGraw has described her data in detail, particularly pointing out the difficulty of quantifying the results and still doing justice to the process of problem solving. These situations, when applied to children between the ages of 6 and 27 months, elicit marked

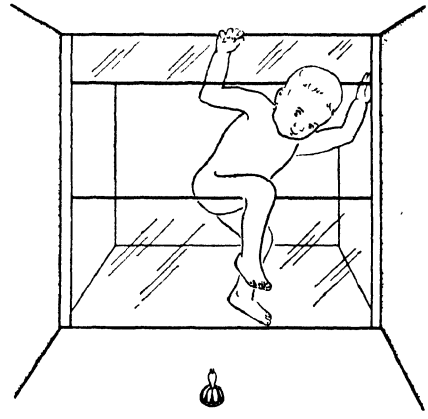

FIGURE 21. The lure is obtained by lowering the head and lifting the leg in order to climb between two pieces of plate glass. (From "Appraising Test Responses of Infants and Young Children," by M. B. McGraw, *Journal of Psychology*, 1942, *14*, 95.)

emotional reactions as well as trial and error and sudden insight.

The ability of infants to solve problems by utilizing such implements as rakes, sticks, chairs, boxes, and strings has been studied extensively. We shall shortly discuss these studies in some detail.

A puzzle box frequently used to investigate problem solving in older children was devised by Healy and Fernald (1911). The nature of the problem is illustrated in the diagram and legend of Figure 22. Healy and Fernald used the following instructions:

> *You see that this box opens by the lid lifting up. The glass is put in so that you can see the way to open it. You can work*

through the holes and use the buttonhook. Study the box, and if you do the right things in the right order, it can readily be opened. Do not break the string or glass. Open it as quickly as you can.

The problem is made more difficult by merely telling the child to open it, using the buttonhook. He then has to *discover* that the holes are his only approach to the rings and cords. After the box has been opened, the subject may be asked to close it.

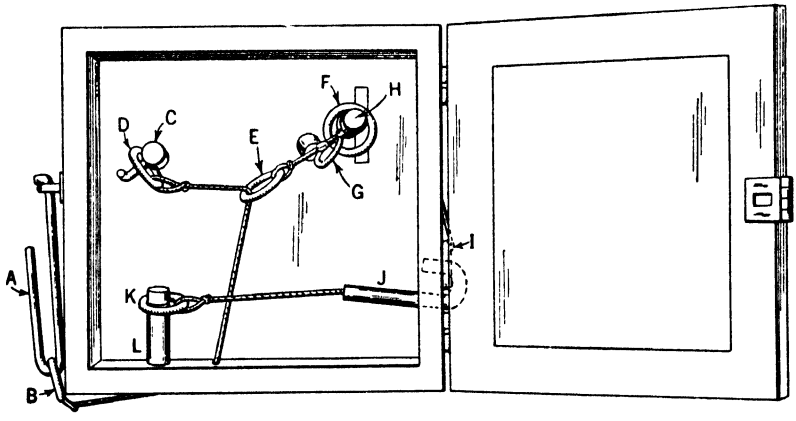

FIGURE 22. The Healy-Fernald puzzle box. (After W. Healy and G. Fernald.) Seven distinct steps must be followed if the box is to be opened. They are: (1) removing ring *K* from post *L*; (2) pulling out staple *J*; (3) removing ring *I*; (4) removing ring *F* from post *H*; (5) removing ring *D* from arm of post *C*; (6) removing ring *B* from hook *A*; and (7) removing hook *A* and opening box.

The typical mode of attack is by overt trial and error. Occasionally, however, an older subject surveys the internal mechanism carefully and, after some delay, opens the box with no overt trial and error. When questioned he says that he "figured out the correct moves." This probably means that implicit trial and error was the basis of solution.

Norms for the above problem are reported by Woolley (1926) and Bronner, Healy, Lowe, and Shimberg (1927). Woolley, who had over 400 subjects in each of her groups, gives the median time on the initial trial as 251 seconds at 15 and 153 seconds at 16 years for boys and 436 seconds at 15 and 212 seconds at 16 years for girls. These results indicate a difference in favor of the older individuals and the boys. Differences in mechanical skill rather than in problem-solving ability *per se* may underlie these differences. After the initial success, time curves drop precipitously and, within a few further trials, the box is opened in approximately the minimum time required for sheer manipulation. Time scores for closing the box are much higher than for opening it. Healy and Fernald report that the initial closing time is approximately twice that required to open the box.

The sudden drop in the learning curve for this problem is rather characteristic of problems the various aspects of which are all apparent to the subject. Gestalt psychologists claim that such sudden learning results from a more or less sudden grasping of relations, or *insight*. Where rela-

tions are not apparent, as in the usual maze problem, an individual is obliged to use overt trial and error, perhaps supplemented by implicit processes such as counting or other verbalization.[1] In situations like the present one, however, an individual may attack the problem as he would a maze, or he may, since opportunities are offered, observe the internal relations and so reach a quick solution with perhaps no overt trial and error.[2]

The ability of preschool children to solve puzzle situations without overt trial and error has been studied by Harter (1930). Each problem involved a solution requiring that one step be completed before the next. Overt trial and error would involve moving one part of the apparatus or another until the solution appeared. It was possible, however, to "figure out" the moves beforehand and thus to respond without error. A diagram of one of Harter's puzzle devices is shown in Figure 23. The nature of the problem is described in the legend of this figure.

Ability to solve such puzzles increased with CA and MA. Biserial *r*'s ranged from .54 ± .08 to .73 ± .06 for success and CA, and between .49 ± .09 and .57 ± .08 for success and MA. The amount of overt trial and error, as indicated by the average number of moves, decreased with age. Four yearly age groups from 3 to 6 made the following average number of moves, respectively, on the obstacle peg test: 36.0, 24.7, 20.4, and 17.6. Children who failed to solve the problems made more moves than did successful ones. Only 1 child out of 75 given the obstacle peg test solved it without making any error. Eighteen out of 75 solved a similar type of problem without error. In each case, the average age of the children achieving errorless solutions was much higher than that of those

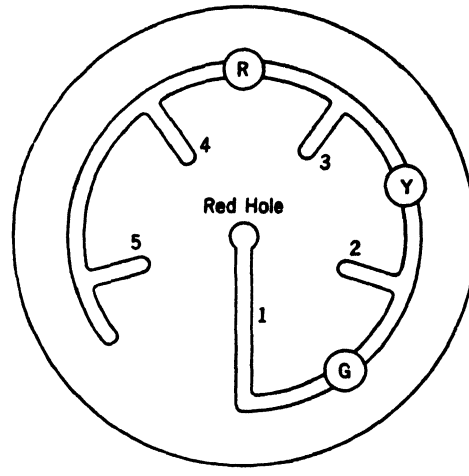

FIGURE 23. Obstacle peg test used to measure problem solving with or without overt trial and error. (From "Overt Trial and Error in the Problem Solving of Preschool Children," by G. L. Harter. *Journal of Genetic Psychology*, 1930, *38*, 362. By permission of the publisher.) A grooved path with side alleys 2, 3, 4, and 5 had red, yellow, and green pegs at the positions marked *R*, *Y*, and *G*. The pegs were modified styluses with a round knob at the top. They could be slid along the groove but not removed from the apparatus. The experimenter pointed to the red ball between 3 and 4 and told the child to put it in the red hole. If the child pulled at the red knob, he was told to push, not pull. Those who solved the problem used either of the following methods: (1) placing *G* and *Y* in the side grooves and then sliding *R* around to the red hole; or (2) moving the red peg into a side groove, pushing *Y* and *G* back to the blind end of the pathway, and then moving the red peg around to the hole. Ninety per cent of 40 adults and 74 per cent of 53 children used the first method.

1 Some investigators have used mazes, the entire paths of which are observable. In such instances insight may be apparent. See especially the study by de Sanctis (1931) of observational maze learning in normal and feeble-minded children.

2 For other studies of insight in puzzle solving by children, see Ruger (1910), whose research was primarily on adults but involved four boys, and Wunderling (1935), who used children from the first to eighth grades.

who solved with overt trial and error. On a repetition of the problems, solution was achieved with a marked decrease in moves and an increase in the number of errorless reactions. For instance, 32 out of 50 children given a second trial on the obstacle peg test solved it without overt trial and error as compared to 1 child out of 75 for the first trial. Adults who succeeded on the tests reacted like children who succeeded, but time was greatly reduced.

Problems Involving Utilization of Tools. Tool problems were used by Hobhouse (1901) with animals. Köhler (1925) revived and greatly extended the use of the method in his researches on learning in chimpanzees. It consists, essentially, of confronting the subject with some *lure,* such as food or a toy, which is inaccessible unless certain tools are utilized. These tools may comprise attached strings, a lever with lure attached, a stick sufficiently long to reach the lure if fitted together, a box or number of boxes to be stacked, or some other indirect means of obtaining the lure. The task which confronts the subject is chiefly to learn that the given objects may be used as a means of obtaining the lure.

Richardson's (1932, 1934) investigations dealt with infants between the ages of 28 and 52 weeks. Kellogg and Kellogg (1933) used tool problems with an infant ape and an infant human subject. Researches by Alpert (1928), Brainard (1930), Matheson (1931), Moriya (1937*a*, 1937*b*), Sawa (1937), Tagawa (1937), Sobel (1939), and Ling (1946) involved preschool children. Comparative investigations of normal and feeble-minded children have been carried out by Aldrich (1931), Aldrich and Doll (1931*a*, 1931*b*), and Gottschaldt (1933). Since several of these investigations have much in common, we shall describe in detail only the most representative ones. Results of related studies will then be summarized briefly.

Since Richardson's investigations deal with infants, they will be discussed first. The two studies were carried out concurrently and on the same infants. In the 1932 article are reported the reactions of 10 boys and 6 girls to string problems given at monthly intervals between the twenty-eighth and fifty-second weeks. The lure was a toy attached to a string. Although the end of the string was within reach, the lure was not. In some tests a barrier prevented the infant from reaching the table top on which the lure and string lay. In others the barrier was removed since, until the age of 44 weeks, it appeared to hinder solution of the problems. Representative string situations are illustrated in Figure 24. Each setting was arranged behind a screen. As soon as this was removed, the experimenter tapped the toy on the table, squeaked it, rocked it, or rattled it, depending on its nature. The reactions of the subject were then observed. If he pulled in the lure, he was allowed to play with it a short time before it was removed. Only settings such as that shown in Figure 24*A* were used at the earliest age level. Type *B* was added at 32 weeks. At 36 weeks, type *C* was added to the tests. From 40 to 52 weeks, all types were used.

The reactions of infants to the above situations suggested five types of *perceptive attitude.* They were: (*a*) interest in the string rather than in the lure, (*b*) interest in the lure and apparently accidental contact with the string, (*c*) awareness of both lure and string without evident purposive utilization of the string, (*d*) experimentation, and (*e*) definite utilization of the string as a means to bring the lure into reach. Richardson claims that *a* and *b* represent success without insight; *c* and *d*, success with incomplete insight; and *e*,

success with insight. The last type was associated with a marked drop in time. Types of response said to involve insight increased in frequency with age. The other types decreased as a function of age. Relative difficulty of the various situations appeared to be determined by the directness with which the dummy string or strings led to the lure. In terms of the percentage of children making initial correct choices, the relative difficulty was in the order shown from *A* to *E* in Figure 24.

second week, the percentage had increased to 83. Other criteria likewise indicated increasing ability to perform the problem as a function of age. Part of the improvement was undoubtedly due to greater mechanical ability and better motivation at the higher age levels. As in the string problems, several degrees of "perceptive attitude" or insight could be discerned, and the degree increased with age. Demonstrations failed to influence the infants' grasp of the nature of the situation although,

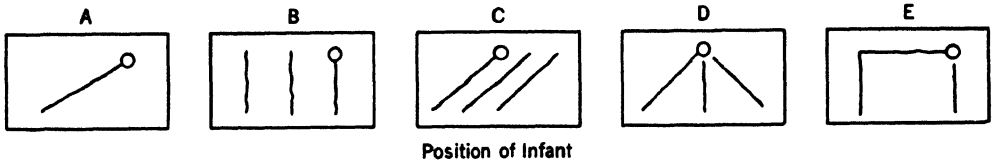

FIGURE 24. Representative string problems used with infants. (From "The Growth of Adaptive Behavior in Infants: An Experimental Study of Seven Age Levels," by H. M. Richardson. *Genetic Psychology Monographs*, 1932, *12*, 230. By permission of the publisher.) In other situations the position of the correct string was the reverse of that shown in these diagrams. The child sat in one half of a crib, and the top of the other half was covered to form a table top on which the settings of the strings were arranged. In some tests a barrier was between the child and the table top; in other tests there was no barrier.

Richardson's second report describes lever experiments carried out with the same infants and under the same general conditions. The experimenter rang a small bell and, while the infant watched, placed the bell on the end of a lever, the short arm of which was within the infant's reach. Turning the short arm of the lever a sufficient number of degrees brought the bell within grasping distance. Two positions of the lever, straight out in the median plane or oblique to the right, were used. A counterclockwise turn of, respectively, 90 to 45 degrees was thus required. If the child failed, a demonstration was given. This was followed by further tests and, if necessary, demonstrations. Between 40 and 44 weeks the percentage of infants succeeding at least once in securing the lure increased from 20 to 67. By the fifty-

after 44 weeks, they appeared to increase motivation.

In problem-solving situations the behavior of individual subjects is frequently more enlightening than group trends. The following protocol is presented by Richardson as representing development of insight in a 44-month infant.[1]

> As soon as the lever board is in place, B gets her hand on the short arm of the lever and tries to tug it toward her. She rotates it about 40 degrees in the counterclockwise direction.
>
> The lever is returned to its former position by E. The bell is rung. B reaches for it with her left hand as E moves it to the far side of the grill and sets it on the tray. Right hand is also active. B has

[1] Paraphrased from Richardson's (1934) protocols, p. 368.

turned the tray about 20 degrees before the bell is put on the tray. Left and right hands alternately approach short arm, turning it. She does not yet turn it more than 40 degrees in the counterclockwise direction, and occasionally turns it clockwise. As she rotates it back and forth with her right hand, she eagerly watches the bell in the tray. Once she turns the lever as much as 90 degrees, so that the stick is parallel to the grill. After *80 seconds* the tray, following trial rotations, is brought into contact with the grill, and B secures the bell.

E returns the bell to the lever in original position. B, with her right hand, turns the short arm about 40 degrees in the counterclockwise direction She brings up her left hand. With her right, in a steady movement, she rotates the lever so that *20 seconds* after the beginning of the situation the tray is near the grill. She secures the bell. The bell is removed and set again on the tray. This time the first turn of the short arm is greater. *Five seconds* after the beginning of the situation B has secured the bell and carried it through the grill.

Alpert's (1928) research is representative of those on preschool children. It is a repetition of several situations presented by Köhler to chimpanzees. Forty-four nursery school children 19 to 49 months old were confronted with situations like the following: An object suspended from the ceiling could be reached only by placing a near-by block beneath it in an appropriate position; an attractive toy too far from the play pen to be reached by hand could be obtained if a near-by stick was used to pull it in; a toy placed at a greater distance from the bars of the pen than was the former one became accessible only when two sticks were fitted together and used to angle for it.

The initial responses to such situations were usually of what might be called a trial-and-error nature. There was no grasping of the fact that the otherwise inaccessible lure could be obtained by the tools lying at hand, even when these were observed and, in some instances, played with. A good example is the behavior of Case 20, a girl of 42 months, in response to the suspended lure.

First exposure. S went up to objective, stared at it, and waveringly raised her left arm halfway up, looking at E; remained thus for 2 minutes, then indicated that she wished her coat taken off. While adjusting her sweater sleeves, caught sight of block, looked long and hard at it, then again partly outstretched her arm toward objective, looking at E, began to chew her nails, still staring at E.

Second exposure. S walked slowly up to objective and tried to reach it with her right hand, looking at E. S remained thus, with arm partly outstretched, gazing around, for 2 minutes. S looked at the block and took a few steps toward it, looking at E; alternated between a step toward block and attempt to reach up for objective; walked off, past the block, looking back at objective several times.

Third exposure. S looked at objective and at E, advanced slowly toward former, arm outstretched, reaching for object in an ineffectual manner as she gazed all around; saw block but continued to reach up. S began to amuse herself with the woodwork on the nearest wall.

Even with two further presentations of this situation, the subject failed to observe that the problem could be solved by using the block. Most children eventually solved the problem. A few solved it very quickly. An example is Case 15, a boy aged 39 months. Only one exposure of 30 seconds' duration was required.

S was much distressed when asked to come with E, but at sight of balloon—objective—he rushed at it trying to reach it with both hands. S turned around to complain to E, spied the block, and an-

nounced tearfully that he would get on it; dragged block under objective, got on, and reached up for it but found it rather a hard stretch; jumped off, turned block on its perpendicular side, got on, and swung objective with glee.

A good example of apparent trial and error followed by sudden solution is that or a girl of 38 months reacting to the two-stick problem.

First exposure. S examined one of the sticks and tried to reach objective with it over the top of pen; examined the other stick and used it in the same way, repeating, "I can't" over and over; tried out the stick between the bars, over the top of pen, finally striking it viciously against the floor; complained bitterly, and tried again to reach as before, stretching and straining; tried to climb out and whined, "I can't." E terminated exposure to avoid fatigue.

Second exposure. S reached for objective as above and in 10 seconds said, "Look, I can't," but continued her efforts; fitted sticks up against bars of pen, banged them together, etc. S tried to reach objective with her hand through the spaces, to force her way out, to shake the pen, etc.; said, "Dolly does not want me to get him."

Third exposure. As above, complaining intermittently and finally giving up.

Fourth exposure. S stretched for objective over top of pen, striking out angrily with stick, complaining and asking E to move object closer. S said, "Let's try big stick on little one," picked up the other stick, examined ends carefully and succeeded in fitting them, with a shout of "Bang!" S angled for objective, reached it exultantly, and repeated stunt several times.

Alpert found "exploration and elimination" to be the most frequent behavior of preschool children in responding to the problem situations. Where insight occurred, it tended to be immediate rather than gradual. It was apparent in varying degrees. Chance operated by bringing about "an optimum constellation of the elements" required for solution. The presence of an optimum constellation, however, did not guarantee that insight would appear. Brainard (1930) carried out similar experiments on a child of 2 years and 7 months whose IQ was 141. Insight was present for some situations but not for others. Similar results are reported by Ling (1946), who used an adaptation of Alpert's technique with 8 preschool children.

Matheson's (1931) investigation differed from the studies of Alpert, Brainard, and Ling in certain significant respects. The subjects were 28 children between the ages of 2 and 4½ years. One problem involved taking a ring off a hook in order to lower a basket containing the lure. Another was of the crossed-string variety, the child being required to pull in a longer string, alone of adequate length. A stick and a box-stacking problem somewhat like those used by Alpert were also involved. Matheson noted 15 types of reaction to these situations, all of which were called out to some extent by each problem. The most frequent of these were "manipulation" and "pointing and reaching," also designated as "trial and error." The rarest responses were "solution without previous manipulation" and "solution for the sake of solution." Only 14 per cent of the children exhibited such responses.

The percentage of children solving the problems went from zero at 2, to 62 at 4 years. The correlation between solution and CA was .464 ± .10; that between solution and MA, .422 ± .107.

Aldrich (1931) and Aldrich and Doll (1931*a*, 1931*b*) extended problems like the above to the idiot level of intelligence. The degree of insight attained in stacking boxes, combining sticks, using single sticks, and using a rake to reach a lure is reported to

be somewhere between that attained by Köhler's apes and Alpert's preschool children. The importance of strong incentives as a factor in achievement of insight is especially noted in these studies and in one by Sawa (1937) on normal children. Gottschaldt's (1933) investigation involved normal, moron, imbecile, and idiot children. Stick, string, and block-stacking situations were used. The chief contribution of this research is analysis of the behavior in terms of level of aspiration and in terms of field forces, following the lead of Lewin. Gottschaldt found a lower level of aspiration with decreasing intelligence. Feeble-minded children were satisfied with various substitute "solutions." The influence of vectors was brought out in stick problems of the following nature: A short stick lay near at hand and a long one was more distant. The long stick was alone adequate for reaching the lure. In some instances the short stick was secured and played with, the child seeming to forget the long stick and the lure. The presence of a toy near the short stick had a still greater influence upon the "attractiveness" of this inadequate instrument. Whenever an apparently easy, yet inadequate, solution appeared possible, the difficulty of the problem was greatly increased. Such "distraction" was more apparent in feeble-minded than in normal children. Similar principles are involved in detour problems used by Lewin (1935), Sawa (1937), and Tagawa (1937). Theoretical discussions of such problems have been presented by Lewin (1935), in terms of vector analysis, and Hull (1938), in terms of the goal-gradient hypothesis.

Moriya (1937*a*, 1937*b*) wished to determine whether preschool children achieve insight into the solution of problems involving the principle of a lever. Only the older of 29 kindergarten children evidenced insight in balancing objects on the flattened top of a pyramid. In a further problem involving removal of strings from a lever arm in such a manner as to leave it still balanced in the horizontal direction, no insight was evidenced. The author concludes that preschool children use trial and error predominantly in solving problems involving the principle of a lever. Lack of previous experience with levers is, however, probably the real explanation. G. M. Peterson (1932) used somewhat similar lever problems, but on a verbal basis. His subjects were children between the ages of 132 and 168 months. In these, as in many other problems, insight may involve transfer to the new situation of what has been learned previously in somewhat similar situations. The results of a preliminary investigation by Sobel (1939) is of interest here. Sobel found that some children between the ages of 18 and 48 months achieved immediate solution of tool problems. Others solved a given problem only after previous training which involved use of similar implements. The "insight" evidenced in the latter instances was thus known to be based upon transfer.

Solution of Problems by Learning a Principle. To the degree to which problems are solved as a result of implicit rather than readily observed overt activities, the solution is said to result from reasoning. The implicit activity involves "manipulation" of symbols, or substitutes for past stimulation. Such manipulation is often of a trial-and-error nature.[1] When solution of a problem involves learning a principle, we usually speak of the reasoning process as *generalizing*. Several investigations on learning in children have involved problems demanding generalization. Such problems will be considered in the present section.

1 For a more extensive discussion of the nature of implicit activity such as involved in reasoning, see Munn (1938), pp. 333 ff.

Heidbreder (1927, 1928) used three problem situations to investigate generalizing in 30 children between 2½ and 10 years and in 10 adults. Each problem involved a principle, the discovery of which was the chief task confronting the subjects. In Problem I the child was presented with two boxes, one of which contained a doll. The *right-hand box* always contained the doll, yet it might be closer than the left in one trial and farther away in the next. Problem II utilized plain and flowered boxes. Regardless of its position (right-left, near-far) with respect to the other box, the *flowered* one always contained the toy. Problem III involved boxes with plain figures and boxes with figures having perimeters with red dots. Two boxes of a given kind were used at each trial. If both had plain figures, the doll was in the farther box. On the other hand, if both had dotted figures, *the nearer box* contained the doll. Table 9 shows the number of solutions and number of reactions per problem for subjects at different age levels. One will note that children above the sixth year solved all three problems, and in relatively few trials. The first problem was solved by one 3-year-old and by six 4-year-olds. Whereas only two 3-year-olds solved Problem II, it was solved by all above this age. The youngest individual to solve Problem III was a 4-year-old. No children of the youngest age group gave a satisfactory reason for selecting a given box. When questioned, they sometimes said that the box was selected because they liked it. Only 5 per cent of the next age group verbalized their solutions. Above the age of 6 years, however, almost every solution was given an adequate verbal formulation.

TABLE 9

GENERALIZING AS A FUNCTION OF AGE *

Age	No.	Problem I		Problem II		Problem III	
		Solutions	Reactions	Solutions	Reactions	Solutions	Reactions
3	10	1	219	2	230	0	216
4	10	6	178	10	23	1	348
6–10	10	10	174	10	23	10	81
Adult	10	10	34	10	16	10	40

* From Heidbreder (1928), p. 525.

More difficult of solution than the above is the double-alternation problem used by Gellermann (1931) with 38 children between 3 and 13 years of age. The apparatus was a modification of one used by Hunter with rats and raccoons. Its main features are shown in Figure 25. This is called a "temporal maze" by Hunter to distinguish it from mazes of the spatial variety, that is, those in which the turn in each part may be elicited by stimuli peculiar to this part. The problem which confronted each of Gellermann's subjects was learning to turn *right, right, left, left,* in successive trials, upon reaching the point *X*. Since the stimuli in the central alley

were always alike, and hence could not give differential cues for right or left turns, the subjects were called upon to "figure out" the correct order of turns. They were given no instructions which would in any way suggest the solution. Unless they guessed it, as a matter of fact, the subjects did not at first know that a problem confronted them. They were merely invited to enter the apparatus and to keep moving. Incorrect responses were followed by the closing of a door which prevented

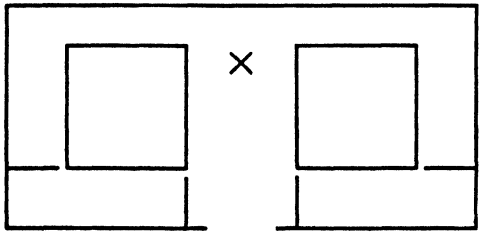

FIGURE 25. A double alternation maze.

progress in the incorrect direction. The subject was, on such occasions, required to retrace and take the correct turn. As soon as the *rrll* response had been made the child was allowed to leave the apparatus. It was readmitted after completion of a trial. This continued until 3 trials in succession without error had been completed. Finally, and without previous intimation, each child was required to give the response *rrllrrll*, that is, to repeat the series without leaving the apparatus. No questions were asked by the experimenter or answered by him while learning was in progress. After completion of the extended series, however, he asked these questions: "What did you think of it?" "How did you learn that [the solution]?"

Whereas adults learned this problem in an average of 6 trials children required an average of 15. Trials to learn ranged from 4 to 37. The average number of errors (incorrect turns) made by children was 30, almost twice that made by adults. The rank-difference correlation between CA and trials was only .28 ± .11. The two youngest (3- and 4-year-old) children, however, failed to master the problem. From 5 years on, the number of trials and the number of errors decreased with age. The two 5-year-olds failed to extend the series, even after 10 to 12 extension tests. Older children extended the series in 2 to 3 tests.

The nature of the problem which confronts the subjects is perhaps best indicated by their verbal reports. A 10-year-old boy who learned in 14 trials gave the following report:

> First I thought all the walls would close in, and you were going to test my nerve or something like that. Then I found the doors were open, and I kept on walking I thought there was something to it, because sometimes the doors were closed. After awhile I found you must go around each place twice.

Other reports were of a somewhat similar nature. At first there was no idea concerning what was to be expected, then came the idea that a *problem* was to be learned. Finally, the subjects formulated the problem in some such manner as *"twice to the right and twice to the left."*

The earliest age at which children solve the double-alternation problem has also been investigated by Hunter and Bartlett (1948). These investigators used a double-alternation box apparatus modeled after one earlier used by Gellermann in an experiment with monkeys. Their subjects had an age range of 2 years to 6 years and 9 months. The child sat before two boxes, one to the right and the other to the left. The experimenter, who sat behind the boxes and was hidden by a screen, placed candy in the boxes in the required order, a new piece of candy being placed after each response. Each series consisted of 8 responses

in the order *rrllrrll*. If the child opened the wrong box, it could then open the correct one and get the candy. The series was repeated, sometimes 8 times in 1 session. Most children who learned the problem did so within 2 sessions. The criterion of learning was 3 successive correct series, or 24 consecutive correct responses. After the criterion was achieved, an opportunity was given to extend the series from 8 to 12 responses.

The youngest child to achieve the criterion was 3 years and 7 months old. A few children above this age, but younger than 4, failed to reach the criterion. Of those children who failed to reach the criterion, some did perform short series of double alternations. At the earlier ages there was difficulty in controlling motivation. Thus some of the failure at earlier ages may have resulted from insufficient motivation.

There was a positive correlation between trials to learn and, respectively, CA and MA, but there was no correlation between trials to learn and IQ. This is related to the fact that some of the children with the highest IQ's were too young to learn. Children who learned the 8-response series extended the series. Adequate verbalizations were not found below 5 years.

The rôle of verbalization in development of generalizations by children has also been demonstrated in a multiple-choice type of experiment reported by Pyles (1932). Eighty children ranging in age from 2 to 7 years were confronted with 5 figures under one of which a toy was hidden. The instructions were: *"One of these shapes has a toy under it. See if you can find which shape has a toy."* The child tried this shape and that until the toy was discovered. Then the experimenter said, *"Where did you find the toy?"* The child indicated. The experimenter then said, *"Yes, that one had it."* Such comments were made on the first 3 and subsequently on every third trial, the aim being to maintain interest and to stress the importance of having the first selection correct. Three series of experiments were used, with rotation of matched groups to equate for order of presentation. One series had nonsense figures which were unnamed. A second series involved the same figures, but now given a name, "Bokie," or the like. In a third series, well-known animal forms were used. These were named spontaneously by the children. A series was regarded as learned when the child selected the correct figure 4 times in succession.

The results are summarized in Table 10. They indicate that verbalization is an aid to this kind of learning and that, the more familiar the material, the more rapid the learning. The correlation between trials

TABLE 10

COMPARISONS OF SCORES MADE ON THE THREE SERIES WITH ORDER OF PRESENTATION EQUATED

Groups	1–6	1–6	1–6

Percentage succeeding in 25 trials or less	54	72	96

* Omitting cases of complete failure. From Pyles (1932), p. 111.

and CA ranged from −.19 to −.72; that between trials and MA from −.21 to −.62. The highest correlations were for series *B*, involving the named nonsense figures.

Investigation of ability to respond to different situations in terms of a common principle was made by Roberts (1932) with 43 children between 2 and 5 years of age. The children were confronted by three doors above each of which a colored toy airplane was visible. The experimenter said, *"This house has three doors; all of them open, but only one makes an airplane fall."* Doors and airplanes differed in color. There was, however, always one door with an airplane of the same color above it. This was the correct door. All children solved this problem, but the youngest child giving a statement as to the principle involved was 3 years and 4 months old. At higher age levels there was an increasing frequency of generalizing. All but the 2-year-old subjects reacted appropriately to new situations involving the same principle.

In a second study which was similar, in general principles, to that described, Roberts (1933) used figures of various shapes or sizes instead of colors. In one situation, six lower doors contained squares. Above them, in order, were a triangle, crescent, square, semicircle, octagon, and figure with parallel sides and concave ends. The toy was always hidden behind the figure which matched that above, in this case the square. In some situations, both upper and lower figures differed, but there was always one above which matched the door below. The subjects were 21 children who were aged 4 years and 19 orphanage children between 4 and 8 years of age. These were separated into three matched groups which learned the problems in different orders. Learning of an initial problem was followed by learning of other problems involving different colors, figures, or sizes. The criterion of learning comprised 4 trials without error. In this study the chief aim was to discover whether a principle learned in one situation would be applied in others. Complete application of the principle would result in absence of errors in the solution of the next problem in the series. When the groups were equated in terms of MA, there was no difference in the learning ability of preschool and orphanage children. The correlation between trials to learn the initial problem and CA was $-.40 \pm .089$. The correlation with MA was $-.47 \pm .083$. With CA held constant, the correlation between trials and MA was reduced to $-.30$. The percentage of subjects making no errors in achieving the criterion increased with successive problems. On the first problem, for example, no subjects learned without errors; on the second problem, 71 per cent made no errors; on the third problem, 81 per cent made no errors. When the ninth problem was presented, 95 per cent performed without error. Although the children could solve these problems and thus make an overt generalizing response, they were unable to state the principle involved.[1]

J. J. Ray (1936) investigated generalizing in 6 dull, 6 average, and 6 bright 12-year-old children. Pictures were exposed, two at a time, in the aperture of a small

1 This difficulty is perhaps merely linguistic. Hazlitt (1930), in her investigation of concepts such as "exception," found that children between 3 and 7 years of age could *make an exception* in behavior although they did not understand what they were to do when *asked* to make an exception. A child was given a large egg into which various smaller colored eggs fitted. The series of eggs was opened before him and he was asked to put all back into the big egg except the *green* one. The younger subjects either failed to respond or put back all the eggs. When they were asked to put back all eggs *but* the red one, many more children responded correctly. See also Kreezer and Dallenbach (1939), on learning the relation of opposition; Hicks and Stewart (1930), on concepts of size; Graham, Jackson, Long, and Welch (1944), on the concept of middleness; and Lacey and Dallenbach (1939), on the cause-effect relation.

apparatus which was operated manually by the subject. Whenever a key under the *correct* picture was pressed, a green light went on. Pressure on a key under the *incorrect* picture lit a red light. Pressure of either key, in addition to connecting a light, also exposed the next pair of pictures. The child's task was to get a green light every time as soon as possible. Twenty series of problems were used and each involved twenty pairs of pictures. The pictures of a series were repeated until the child responded correctly to the whole series or verbalized the solution. In the simplest problem, the key under the *curved* figure () etc., always lit the green light while that under the straight figure

etc., always lit the red light.

Other series involved animate versus inanimate objects, tools versus playthings, quadrupeds versus nonquadrupeds, and the like. Ability to solve these problems was correlated with intelligence, the dull children solving few and the bright children many series. The nature of the problem confronting the child and some insight into the mode of solution are shown by verbalizations. The verbal responses of only two subjects can be presented here. Subject R responded to the quadruped versus nonquadruped situation, beginning with the eighth pair, as follows:

> "Animal." Next pair, "Wait a minute—might be animal with a tail." Second presentation of series, first pair, "I think—wait, let me go through one more time to make sure." Twelve pairs later, "If it's animal it's right, but I think something's wrong." Four series later, "If I'm not mistaken it's an animal that has legs." One pair later, "It's either the largest or a mammal. Wait a minute, let me go through once more." Two pairs later, "I think it's an animal with four legs. The thing that got me puzzled was the snake and the turtle. Couldn't see any difference hardly."

Thus an implicit trial and error is apparent. Subject K, responding to the animate versus inanimate series, gave evidence of trial and error punctuated with sudden insight. After five pairs had been presented he said:

> "I can't get this one." Ten pairs later he said, "I never get this one—I know." After the eleventh pair of the fourth presentation he said, "I believe I've caught on! (Great relief). It's the animal. Easy as pie when I caught on." [1]

Rational Learning. In solving J. Peterson's (1918) "rational learning" problem the subject is required to associate with each of a group of words a number which has been arbitrarily assigned to it. For instance, the letters *A*, *B*, and *C* may be numbered, respectively, 2, 3, and 1. The child is told that the letters *A*, *B*, and *C* are numbered from 1 to 3, but the *A* may not be 1, *B* may not be 2, and *C* may not be 3. He is then asked, *"What number do you think A has?"* He guesses numbers from 1 to 3 until the number 2 is given. Then he is asked to guess the number for *B*. When he says that it is 3, he is asked the number that goes with *C*. When he guesses this, the letters are repeated.

[1] Welch (1938, 1939*a*, 1939*b*, 1939*c*, 1940*a*, 1940*b*) and Welch and Long (1940*a*, 1940*b*, 1942) present a series of studies on development of concepts and generalizations in children. In some respects they are extensions of the early and much more limited studies of Munn and Steming (1931) and Gellermann (1933) on "form" discrimination in children. Limitations of space do not permit an adequate discussion of such investigations in the present chapter, where emphasis must be placed upon learning *per se*. The reader interested in development of concepts and generalizations will find the papers by Welch and by Welch and Long of great value. He should see Welch (1940*a*) also for an extensive bibliography of related studies.

When he repeats each number correctly as the letters are called, the child is given a longer list of letters.

This problem is believed to involve "rational" learning because, if the subject notes that a number which is correct earlier in the series cannot be used again in the same series, his learning is greatly facilitated. Repetition of an earlier correct number is designated a *logical error*. Likewise, learning will be facilitated if the subject does not repeat a given incorrect number while guessing the numbers which go with a given letter. Such repetitions are designated *perseverative errors*. In Peterson and Harrelson's (1923) study of rational learning in white and Negro children between 7 and 10 years of age, the letters *A* to *E* were used with the numbers 4, 2, 5, 1, and 3, respectively. Learning curves based upon data for 299 white and 314 Negro children were negatively accelerated and very similar to those obtained in learning of sensorimotor skills. Nelson (1936) presents several learning curves for problems involving rational learning of the above-mentioned type.

There was no sex difference for the learning of this problem. The mean score of white children was 1.69 PE units above that of the Negro children. A somewhat similar problem was later used by J. Peterson (1926) to investigate the limits of learning by trial and error in high school subjects.

Maier's Reasoning Problem Adapted for Children. In addition to those problems which involve solution of puzzles, use of tools, learning and application of a principle, and so-called rational learning, there are others not easily classified; Maier's reasoning problem is one of these.

Maier's (1936) investigation is based upon the view that the essence of reasoning is combination of past experiences in solution of a problem. He used the apparatus diagrammatically represented in Figure 26. The child was first made familiar with the entire apparatus. Then the experiment proper was conducted as follows: After another brief exploration of the apparatus the child was allowed to emerge through a door of one of the exit booths. This comprised *Experience I*. The child was then led around the apparatus by a devious route until another booth was reached. In this booth it was shown a

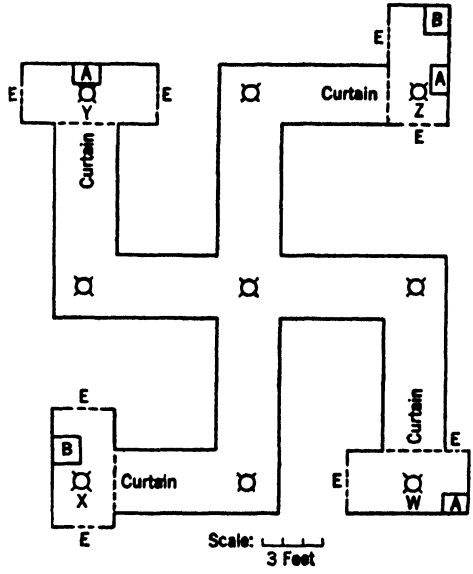

FIGURE 26. Ground plan of an apparatus for testing the ability of children to reason. (From "Reasoning in Children," by N. R. F. Maier. *Journal of Comparative Psychology*, 1936, *21*, 356. By permission of the publisher.) *W*, *X*, *Y*, and *Z* represent booths placed at the end of the pathways. *E* represents entrances to the booths. These entrances are covered by drop curtains. Similar curtains also separate the booths from the pathways. *A* represents an adult chair and *B* a nursery school chair. The position of 25-watt electric lights is indicated in the diagram. The apparatus is built of a wooden framework covered with black cloth.

toy house. When a penny was dropped into the house a tune played. This experience in a specific booth was *Experience II.* Both experimenter and child then left the booth to go in search of a penny by means of which the child could again play the tune. After the penny had been found and the child had been disoriented in the process, he was placed in a third booth and told to go and play the tune. In order to do this without trial and error he would have to utilize Experiences I and II. In other words, if the first experience had been in *Y* (see Figure 26), the second one in *X*, and the entrance from which he was to reach *X* in *W*, the child would have to think of the fact that *W* had a given position with respect to *X*. He could react in such terms only on the basis of his original exploration and the two specific experiences. The starting booth in each test was always the goal booth of the preceding test. Since the child had 3 possible goals in each trial, chance accuracy would approximate 33 per cent.

The subjects ranged in age from 42 to 112 months. They were arranged into groups having average ages of 47.6, 62.3, 70.1, 84.3, and 92.5 months. The size of the groups ranged from 4 to 12. There was an increase in the accuracy of response at successive age levels, the percentages being, respectively, 32.0, 43.6, 58.6, 73.3, and 82.5. The percentage of subjects giving 5 or more correct responses in 10 trials was, respectively, 20.0, 36.3, 71.4, 83.3, and 100. One will note that it was not until the age approximated 70 months that accuracy went far above what would be expected on the basis of chance. Maier says: "The ability to combine the essentials of two isolated experiences in such manner as to reach a goal is rather late in maturing. It is rarely developed in a marked extent in children below 6 years of age." When the data were arranged in terms of mental age groups, greater than chance accuracy was not apparent below a mental age of 6 years. Scores increased with mental age, as did the percentage of subjects making better than 5 correct responses out of 10.

Problem Solving in the Schoolroom Situation with School Materials.[1] Several investigators have studied problem solving under school conditions and in so doing have utilized arithmetic, geometry, and civics. Donovan and Thorndike (1913) report learning data on addition. Stevenson (1925) outlines some of the difficulties met by children from various grades in solving arithmetical problems. Monroe's (1928) investigation, which also deals with arithmetic, is more analytical than earlier studies. He stated the same arithmetical problems in technical terms, in everyday terms, or in relation to irrelevant material. Equated groups from the seventh grade were tested. Greatest success was achieved when the problems were framed in terms of everyday life. Monroe concludes, however, that a large percentage of seventh-grade children fail to reason in solving arithmetic problems. He claims that they depend upon habit for solution. Some corroboration for this view comes from Henry's (1934) investigation with geometric problems. Only 32 per cent of his group of college students gave evidence of insight in solution of such problems. In 285 test situations, responses of the "Oh, I see" type occurred but 17 times. Brownell (1938) reports that both repetition and insight are involved in learning arithmetic. Stump (1927) plotted curves for the learning of civics problems in terms of the number of "elements" learned. The subjects were high school seniors. Learning curves had a very gradual rise. Although the problems were logical ones, involving development and application of principles, there

[1] For a review of literature on factors which influence learning in school situations, see Stroud (1940).

was little evidence of higher processes than those involved in sheer memorizing. This may be due to the method of presenting the problems rather than to lack of insight in the students.

Social Learning

No doubt much of the learning that occurs in classroom situations at the early grades is motivated by the desire for recognition. The child who gets a star for superior performance is usually not interested in the star so much as in its actual or imagined effect on others. The efficacy of praise and blame probably stems from the same motivation.

The tendency to imitate, which some children learn quite early and which plays a very significant rôle in development of language as well as other skills, is also an important factor in classroom situations. Nor is it unrelated to desire for recognition, for the child tends to imitate those with prestige and not to imitate those with a less desirable status.

One of the most interesting features of the book by Miller and Dollard (1941) is its research on learning to imitate or not imitate. In the first of two experiments on learning to imitate in children, the investigators used 41 first-grade children. Two boxes were set up in a small room. One child (the imitatee) was shown the two boxes and told in which one candy was hidden. This box contained two pieces of which he was to take one. Before the imitatee responded, however, the imitator was brought into the situation. If this child, when told to get candy, copied the other, he also got a piece of candy. In other experiments, with different subjects, the extra piece of candy was in the box other than that in which the model found his piece. Thus the second child was rewarded for not imitating the first. The imitating and nonimitating situations were repeated until the second child always responded appropriately. Then the situation was changed so that there were four boxes. This was to see whether the imitative or nonimitative tendency already developed would transfer (generalize) to the new situation. Under these new conditions, 75 per cent of the imitators and 100 per cent of the nonimitators responded appropriately.

In the second of their two imitation experiments, Miller and Dollard (1941) investigated the effect on imitation or nonimitation of the "prestige" of the leader. For example, if the subject copied an adult he received a reward, but if he copied a child he received no reward. For some children this was reversed, copying a child being rewarded and copying an adult not being rewarded. Thus the "prestige" of the leader was determined by whether copying his response brought or failed to bring a reward. The subjects were 12 fourth-grade boys, and the apparatus involved a lever to be either rotated or depressed. The reward was candy. The boys soon learned whom to imitate, and they later generalized to a different problem involving different leaders with characteristics like those of the original training.

Learning in Children and Adults

Comparison of learning in children and adults appears especially relevant here, for at the beginning of the present chapter we noted the fact that educators and other students of child development have, until relatively recent years, treated children as though their learning process were in no fundamental way different from that of animals and adults. Were they correct in supposing that principles worked out with animals and adults are also applicable to children? Has the research on learning in

children disclosed anything not already apparent?

It should be evident, in the first place, that in so far as investigations on learning in children have been carried out in the classroom, or under similar conditions, they have disclosed the adequacy or inadequacy of given procedures in such situations, something which could not with any degree of assurance have been prognosticated from work with adults in the laboratory. To mention one example, the whole method has not worked nearly so well with children in classroom situations as with adults in the psychological laboratory. In the second place, conditions which serve to motivate adults and children, although alike in certain respects, are sufficiently different to warrant separate investigations. In the third place, so little is known about learning, despite the large amount of research, that we need information from as many sources and from as many levels of development as possible. Finally, it must be acknowledged that learning is dependent upon modification of neuromuscular mechanisms, mechanisms the development of which continues at a rapid pace during the early years of childhood. It is in terms of the growth of these mechanisms that we may expect the learning process in children and adults to differ most fundamentally.

The learning of infants is inferior to that of older children and adults chiefly because of neuromuscular immaturity. There is, of course, no sudden transition at any age level. The growth of learning ability is gradual, and one stage, if we may speak of stages, merges imperceptibly with the next. Nevertheless, when we compare the learning of an infant with that of a school child, the inferiority of the former is glaringly apparent. We see this inferiority in tardiness of development and instability of conditioned responses; in inability to acquire motor skills readily learned by the older child; in poor retentivity, especially in situations of the delayed-reaction variety; and in lack of ability to attack problems with sufficient effectiveness to allow solution. Not only is the infant handicapped by neuromuscular immaturity, but he is also devoid of the motives which are most effective in impelling the older child to learn, of the background of experience which may be applied to new situations calling for adjustment, and of an effective repertoire of words and other symbols with which external situations can, as it were, be implicitly manipulated.

As a child grows older we are confronted not so much by neuromuscular immaturity as we are by what might, for want of a better term, be called recalcitrance. It is clearly apparent in the conditioned-response experiment. From about the fifth year and thereafter the ease with which conditioned responses may be developed shows a continued decrease despite the fact that the child's nervous system is undergoing further development. As Razran has pointed out, although the child is more capable of modification than at an earlier age he *resists* such modification. He is no longer as docile as formerly. His naïveté has decreased, he has become increasingly critical of his surroundings, he has developed interests and attitudes of which those who would modify his behavior must take cognizance. After the relatively passive stage of infancy is passed, therefore, the psychology of incentives becomes increasingly important. Several investigations mentioned in this chapter have indicated the effectiveness of rivalry and of verbal and material rewards of various kinds in channelizing the efforts of children in learning situations. Lewin's concept of valences may yield fruitful results in this field.

In most of the learning situations considered in this chapter very little difference has been discovered in the modifiability of adequately motivated children and adults. Beyond the early years of childhood, when the handicaps of neuromuscular immaturity have largely been overcome, practically all differences in the learning of children and adults may be attributed to differences in motivation and in previous experience. Our discussion of motor skills, for example, demonstrated that, although older children and adults may begin with higher scores than younger children, the percentage of improvement resulting from a given amount of practice is alike regardless of age. Mnemonic processes show large differences in the ability of children and adults. The writer doubts, however, whether this represents true differences in modifiability and retentivity. In the first place, there is no way, even by use of nonsense syllables, to avoid the fact that increasing age brings increasing acquaintance with symbols and their manipulation. This is a factor of experience, not of neural growth. In the second place, it is difficult, if not impossible, to equate motivation in individuals at different age levels, especially when the levels are as widely separated as those between the first-grade child and the adult. Finally—and this is related to the two previously mentioned factors—mnemonic ability demands good observation as well as good modifiability and retentivity. Because of their wide range of interests and experience, adults are likely to be much better observers than children. Even reminiscence, which was once thought to differentiate child from adult forgetting, has been demonstrated to be prevalent at both levels.

The clearest case of a difference in the learning ability of children and adults could perhaps be made out in the field of problem solving. Even here, however, differences in motivation and in past experience, including familiarity with symbols and their use, rather than in problem-solving ability *per se*, may be the chief differentiating factors. Hazlitt (1930) has particularly challenged the view that a fundamental difference exists between child and adult reasoning. She attributes apparent differences to the type of factors just mentioned.

It seems apparent to the writer that the chief problems relating to learning in children are those of discovering the most adequate motivating conditions and the most effective procedures for the situations in which children must develop. The practical outcome of researches on learning in children will lie in these directions.

So far as discovering anything fundamentally new concerning the learning process is concerned, the investigations on learning in children have failed. One possible reason for this is that such investigations have from the first been patterned too much after the lines of earlier research with animals and adults in the laboratory. A more likely reason, however, is that the phenomenon of learning is fundamentally the same whether studied in the animal, child, or adult. Differences may be attributed to variations in neuromuscular maturation, in motivation, and in previous experience but not, apparently, to a different kind of learning process in each.

Chapter 8

THE MEASUREMENT OF MENTAL GROWTH IN CHILDHOOD[1]

Florence L. Goodenough

Historical Orientation

Up to the beginning of the second decade of the present century, the topic of mental growth and its measurement occupied an almost negligible place in psychological literature. Just before the turn of the century, it is true, a number of attempts had been made to relate individual differences in the ability to perform simple motor and perceptual tasks to the differences in scholastic ability that have baffled educators since schools were first established. From the time of his student days in Wundt's laboratory, Cattell's attention had been captured by the idea that the study of differences among individuals in their responses to the same stimuli might be of even greater psychological importance than the study of the typical effect upon people in general of a measured physical change in the stimulus itself. After his return to America, Cattell was one of the most energetic leaders in the development of these early tests. The first scientific use of the term *mental test* is to be found in an article by him that appeared in *Mind* in 1890, in which he described a number of tests of sensorimotor capacities which he was then using with his students at the University of Pennsylvania. The interest aroused by this article encouraged similar experimentation by a number of other leading psychologists, with the result that at the 1895 meeting of the American Psychological Association a committee, headed by Cattell, was appointed to consider the possibility of a cooperative effort to develop tests that would prove useful in gauging the probability of scholastic success among students entering college. A year later, Cattell and Farrand (1896) published a detailed account of the work of the committee in the form of a long series of tests which they planned to try out on Columbia freshmen.[2]

Although college students continued to make up the great body of subjects for these early experiments, tests for use with children were also devised. By far the most important of the investigations carried on during this period with children as subjects were those of Gilbert (1894, 1897). His studies are of special importance because of his attempt to validate his tests by comparison of the results with teachers' judgments of the ability of their pupils. Inasmuch as the tests used were made up of such items as physical measurements—height, weight, and lung capacity—speed of simple reaction, tonal memory, estimation of distance, sensitivity to pain, rate of tapping, and the like, the modern stu-

1 Grateful acknowledgment is due the Clark University Press for permission to reproduce herein a number of short sections from the writer's previous chapter. "The Measurement of Mental Growth" in *A Handbook of Child Psychology* (Carl Murchison, Editor), Second Edition. Revised, Worcester, Massachusetts, Clark University Press, 1933.

2 The results of the Columbia testing were later published by Wissler (1901). Correlations between college grades and standing on the various tests were consistently around zero.

dent will not be surprised to learn that, in spite of a fairly regular improvement with advancing chronological age in most of these functions, their relation to teachers' judgments of the ability of their students was negligible.

The interest aroused by the early tests was short-lived. It soon became evident that the results obtained by their use were of little or no practical value for the understanding and guidance of children. Although, because of Cattell's example, these measurements were commonly known as mental tests, they were evidently not measuring *intelligence*, either in the sense that the word is used by the layman or as it is understood by the psychologist of today. This was a disappointing discovery, which led to a general loss of interest in the problem and a virtual cessation of experimental work in testing in this country for almost a decade.

Meanwhile Binet, in France, had also become interested in the measurement of individual differences in mental ability. From the outset, however, his approach to the problem was radically different from that of most others of his time. Most of his experimental articles were published in the journal that he himself established in 1895, *L'Année psychologique*. A critical reading of these studies in their chronological sequence shows the steady trend of his interest away from the artificially simplified tasks of the formalized laboratory to the more complex and realistic problems encountered in life as it is lived. Over and over again he notes that differences between individuals become increasingly evident as one progresses from the relatively "simple" performances to those that are more complex, and that it is the latter rather than the former type of difference with which we are mainly concerned in everyday life. He admits that the simple mental functions or processes are easier to measure objectively, but insists that this is a secondary consideration, inasmuch as measurement degenerates into mere busy work unless the results are of some practical use. In this distinction between objectivity of measurement and the significance of the measures when made, Binet foreshadowed the discussions of *reliability* and *validity* that were to occupy so large a place in the literature on mental measurement a quarter of a century later.

Binet's first formalized scale for the measurement of intelligence was a direct outgrowth of his work as a member of the special commission appointed in 1904 by the Minister of Public Instruction in Paris for the purpose of devising means of selecting and segregating in special classes those children who were incapable of benefiting by the regular methods of instruction. This scale was published in collaboration with Simon in 1905. It consisted of 30 tests arranged roughly in order of difficulty. Age standards were not available at that time; as a matter of fact, although Binet, in his discussion of the scale, refers specifically to the desirability of comparing the performance of a child with that of others of his age, it seems improbable that the device of arranging tests in age groups for the purpose of ascertaining the mental age had as yet occurred to him. He does, however, indicate the levels of performance that divide the three classes of mental defectives—the idiots, the imbeciles, and the morons. Needless to say, the distinction as here used applies only to those who have attained their final level of development.

Crude as the 1905 scale was, it nevertheless proved to be sufficiently useful to encourage Binet and Simon in the feeling that they were on the right track. In 1908 they published a revision of the scale and in 1911 a second revision. The great feature of the two later scales lies in the fact that, instead of being arranged merely in

order of difficulty, the items are grouped according to the age at which they are usually passed.[1] The selection of items was also improved by the elimination of a number that had proved unsuitable and the addition of others that were more discriminative. The tests for idiots were also omitted as unnecessary in a scale designed for public-school children. The 1911 scale, published just before Binet's death, included tests for the mental age range from 3 years to the adult level.

Both the 1908 and the 1911 Binet-Simon scales were translated into English by Goddard (1910, 1911), with only such minor changes as were necessary to make them suitable for use with American children. After trying them out both with feeble-minded children in the institution at Vineland, New Jersey, and in the near-by public schools, Goddard became thoroughly convinced of the superiority of the new tests over all other methods of assaying the intelligence of children that had been tried up to that date. His many books and papers dealing with this topic were read with great interest by psychologists and educators throughout the country.

The extraordinary rapidity with which Binet testing was taken up in America can be traced to a number of conditions. Most important is the fact that the tests appeared at an opportune moment. In many states the period of compulsory school attendance was being extended, and compulsory attendance laws were being more strictly enforced. The immediate result was that large numbers of backward children who would formerly have dropped quietly out of school and been forgotten were being herded into the primary grades at small profit to themselves and at the cost of much wasted energy on the part of teachers. Ayres's *Laggards in Our Schools*, which appeared in 1909, did a great deal to arouse public interest in the matter of school retardation, and to point the need for more adequate methods of dealing with the problems involved.

Scientific interest in questions of juvenile delinquency also became active at about this period. The first juvenile court was established in 1910. Inasmuch as the question of individual responsibility for delinquent behavior has been a predominating feature of the public attitude for generations, it was but natural that the idea of utilizing the new instrument as a means of securing more valid information on the mental level of delinquent children should have arisen almost as soon as the tests were introduced into this country. The fact (afterward learned) that the Binet tests as revised by Goddard were incorrectly standardized at the older ages, with

[1] Binet was not the first to whom the general concept of mental age occurred, nor was he the first to adopt the device of arranging tests in age groups. It is not unlikely that crude comparisons between the behavior of backward adults and that of children have been made by laymen at all times just as today we often hear such expressions as "No more sense than a baby" or "Has to be looked after like a little child" even from people who have never heard of such a term as *mental age*. Reference to early medicolegal papers discloses a number of instances in which the same idea has been made more or less explicit. It is said that, as early as 1848 at the trial of one William Freeman, who was charged with the murder of four persons without provocation, a psychiatrist called as witness in the case stated that "in point of knowledge the accused was like a child of 3 years" (Hall, 1848).

In 1887 Doctor S E Chaille published a series of simple tests for children under 3 years of age. These tests are arranged in groups according to the age at which normal infants may be expected to succeed with them, in order, so the author points out, that parents and others who have to do with children may know whether or not a given child is developing as he should. Although Chaille does not use the term "mental age," it is clear from his discussion that this type of comparison was intended. However, Chaille's scale, which appeared in a medical journal of limited circulation at a date when few people were interested in the question of mental measurement, attracted little or no attention and was soon forgotten. It is Binet, therefore, to whom we are indebted for the development of the mental age concept as a practicable means of expressing test results in a roughly quantitative form.

the result that the mental ages obtained for adolescents who make up the great mass of juvenile delinquents were far too low, gave rise to astounding findings. Pintner (1931) has summarized the results of a number of the most striking of these early studies in which the proportion of "feeble-minded" among institutionalized delinquents is said to be as high as 50 to 90 per cent.[1] It was but natural to conclude that if the problems of mental deficiency could be solved the amount of juvenile delinquency would be greatly reduced.

Consideration of the cost of mental defect in terms of delinquency and of the special educational problems it presents led immediately to questions of causation and prevention. The rediscovery of the early work of Mendel by DeVries, in 1900, had by this time attracted the attention of a number of psychologists, among whom was Goddard. With characteristic energy, Goddard at once set about tracing the family histories of feeble-minded children in the Vineland institution in order to see if there might be evidence for the hypothesis that feeble-mindedness not only tends to "run in families" but is inherited according to strictly Mendelian principles as a "unit character." His three books, *The Kallikak Family* (1912), *Feeble-Mindedness; Its Causes and Consequences* (1914), and *The Criminal Imbecile* (1915) comprised what was then regarded by many people as a convincing body of evidence that a large proportion of all cases of mental defect is the direct result of biological inheritance of a defective nervous structure. Although Goddard's investigations, carried on as they were at a time when the technical aspects of the biological study of human beings were but little considered, have been severely and justly criticized,[2] their effect upon psychological thinking and upon social provisions for the care and training of delinquent and defective groups has been profound.

Another factor that gave impetus to the testing movement was the rapid increase of organized agencies for social welfare. Up to about 1910, family social work was largely in the hands of untrained volunteer workers from the various churches. With the appearance on the scene of the professionally trained worker, the coordination of records from different organizations, and the need for a better means of separating the cases for whom there was reasonable hope of rehabilitation from those who were unlikely ever to be able to "manage themselves and their own affairs with ordinary prudence,"[3] the importance of mental testing for improving the efficiency of social welfare work became increasingly apparent.

Two additional social changes that stimulated interest in testing need be mentioned. The first of these was World War I, when the possibility of testing large groups of individuals at one time was clearly demonstrated. The cost of administering individual tests has always proved

1 Although modern studies show a much smaller percentage of very low-testing cases, the relative number of young delinquents whose IQ's fall below 70 is many times as great as that in the population at large. Both Glueck and Glueck (1934) who used the 1916 revision and Merrill (1947) who used the 1937 revision of the Stanford-Binet tests report that approximately one-eighth of their subjects did not exceed this level. Other investigators have obtained similar results. The high figures reported by the early investigators can be attributed only in part to errors in the standardization of the tests used by them. Moreover, with increased awareness of the problems of the feeble-minded on the part of schools and social agencies, a greater number of such cases are identified and sent to institutions for the mentally deficient rather than to reformatories.

2 In *The Kallikak Family*, the entire case rests upon the unverifiable story of a casual intimacy alleged to have occurred at the time of the Revolutionary War between a Continental soldier of good family and a "feeble-minded" girl encountered in a tavern.

3 This is Tredgold's criterion for separating the feeble-minded from the normal.

to be a major stumbling block in the way of their application to the rank and file of individuals. With the advent of group testing, mental measurement as an aid to educational administration was at once put on a firm basis.

Finally, the cause of mental testing was materially advanced by the rise of the mental hygiene movement with its modern emphasis upon the establishment of behavior clinics for children. The determination of the mental level as a first step in diagnosis and as a partial guide to the kind of treatment most likely to be helpful rapidly became a part of the standard practice in organizations of this kind.

Looking backward along the path over which we have come, it is apparent that the development of mental testing, like many other scientific procedures of modern times, was by no means a result of the abstract curiosity of the "pure" scientist. First and primarily, mental tests as we know them today are practical instruments, devised to meet some specific and immediate social need. Their use as research implements has in practically all instances been secondary in time as well as in importance; it is only within comparatively recent years that new tests have been devised with the needs of the research worker rather than those of the clinician or educator primarily in mind. It is not unlikely that if the opposite condition had prevailed, if the demand for a practical working instrument had been less insistent, leaving the early workers more time to perfect their instrument before its pattern had crystallized into a tradition, the course of the testing movement might have been very different. In the white heat of early enthusiasm, many scientific blunders were made for which we are still paying the price in terms of mistaken concepts and conflicting practices. Nevertheless, these very blunders, with the spectacular conclusions to which they led, in many instances served to arouse public interest and support for the tests in a way that might never have been accomplished by an instrument designed for the service of pure science. Whether or not our present knowledge of the course of mental growth would have been greater had we postponed our studies until better techniques of investigation had been devised is at least an open question. We might have been better prepared to make such studies, but we might also have been less strongly urged to do so!

Be that as it may, it is of the utmost importance that students of mental growth continually bear in mind the fact that even the best of our present instruments for measuring mental growth are still fallible, although they have been shown to work surprisingly well in the practical situations for which they were designed. Even as tools for scientific research, they become extremely valuable in the hands of those who understand the basic principles by which they were constructed and their consequent possibilities and limitations, but they are by no means foolproof. That false as well as true conclusions have resulted from their use can hardly be attributed to the tests or to the test-makers, but rather, in great part, to the fact that their apparent simplicity has led many poorly qualified persons to apply them to the solution of problems that neither the tests nor their users were well equipped to handle.

The Present Status of Mental Testing in America

Within the few decades that have elapsed since the publication in 1910 of Goddard's translation of Binet's 1908 scale, the literature on mental growth and its measurement has become so voluminous that a mere

listing of titles requires an entire book. Hildreth's 1939 *Bibliography of Mental Tests and Rating Scales* covers 251 pages, exclusive of the indexes, and lists 4279 titles. Her 1945 *Supplement* brings the total that had appeared before October 1 of that year to 5294. Equally long listings have been assembled by South (1937) and by Wang (1940). These bibliographies, moreover, include for the most part only references to actual tests and scales. Had the theoretical and experimental literature dealing with these tests and with their evaluation been included, the number of titles would have been many times as great.

Through his work in the preparation of a series of selected bibliographies on tests and testing methods over a period of years, Buros became convinced that the spate of new tests appearing each year was so great that some method of selecting the wheat from the chaff had become well-nigh essential. He therefore decided that in place of his former series of unannotated bibliographies he would arrange to edit and publish a series of *Mental Measurement Yearbooks* in which each of the important tests that had appeared since the publication of the preceding *Yearbook* would be subjected to critical review and evaluation by at least two competent authorities. Three of these *Yearbooks* have now appeared (1938, 1940, and 1949 [1]).

It is obvious that nothing approaching an adequate covering of this enormous volume of literature can possibly be compressed into the number of pages in this chapter. All that will be attempted, therefore, is to direct the reader to some of the most useful sources for further reference. The remaining space will be devoted to a brief discussion of a few of the more crucial problems in the field of measurement.

1 The original plan for an annual volume could not be carried out because of financial limitations and the interruption incident to the war.

The most competent account of the early history of testing is to be found in Peterson's *Early Conceptions and Tests of Intelligence* (1925). In spite of its early date, Pintner's little book *Intelligence Testing* (1931) is particularly well adapted to the use of beginning students because of its clear presentation of material and its orderly arrangement. The more recent textbook by Mursell (1947) is written at a somewhat more advanced level with a wider covering of the literature. Many of the statements, however, are inexact or ambiguously worded, and the soundness of some of the discussions is open to question. Freeman's *Theory and Practice of Psychological Testing* (1950) is mainly bibliographical. It lists and describes a tremendous number of tests of all types, many of which are little known or used. It is designed to provide the student who is beginning his course in testing with a guide to the material available for his use. Gulliksen's *Theory of Mental Tests* (1950) deals chiefly with the mathematical theories and procedures underlying test construction with particular emphasis upon the determination of test reliability and validity and the importance of these factors for the interpretation and use of test results. Some knowledge of algebra, analytic geometry, and statistical method is presupposed. Goodenough's *Mental Testing; Its History, Principles, and Applications* (1949) is somewhat broader in scope than either of the two last mentioned, dealing, as it does, with each of the three aspects of the topic indicated by the subtitle. Kent's *Mental Tests in Clinics for Children* (1950) draws its material chiefly from her own long and rich experience in clinical work. It provides a refreshing first-hand view of the behavior of children in the test situation together with many practical suggestions as to methods of observation and record taking.

Annual reviews of the current literature in the field of intelligence testing by F. N. Freeman appeared in the *Psychological Bulletin* during the period extending from 1911 to 1920. The series was resumed by R. Pintner in 1926 and continued through 1935. Annual or semi-annual reviews with annotated bibliographies have appeared in the *Review of Educational Research* from 1932 to the present time.

From the beginning, mental testing has found one of its most important fields of usefulness in the public schools. Several books dealing with the application of test results to educational problems have appeared from time to time. Terman's *Intelligence of School Children* (1919) was one of the earliest. Later treatments of the same topic are to be found in Kelley's *Interpretation of Educational Measurements* (1927), Hildreth's *Psychological Service for School Problems* (1930), *Testing and the Use of Test Results* by Lincoln and Workman (1935), and *Measurement in Today's Schools* (revised edition, 1947) by Ross, as well as in a large number of monographs and periodical articles. Most college textbooks in elementary psychology also include one or more chapters on testing and the use of test results.

This tremendous volume of literature bears witness to the important place now occupied by mental testing in American psychology. As an aid to the objective study of human development and its aberrations and for the analysis and measurement of individual differences and their adaptation to the requirements of a complex social organization, the value of the mental test is well recognized. Not only in the practical guidance of individuals but also as a tool for fundamental research has the mental test amply proved its worth. It is doubtful whether any other psychological instrument is so widely used at the present time, for, regardless of the particular topic under investigation, unless the mental level of the subjects is known the findings may be hard to interpret. Reports of mental test results are therefore looked upon as a well-nigh indispensable feature of most experimental studies in the field of child psychology.

The Nature and Organization of Intelligence

Because the early use of intelligence tests was largely confined to the diagnosis of mental deficiency, little attention was at first paid to the question of what "intelligence" really is. Up to the middle of the second decade of the present century, attempts at definition were chiefly concerned with descriptions of individuals who were lacking in intelligence. As a result, we had many definitions of mental deficiency couched in terms of what the mentally defective person is like, but few attempts at defining or describing the trait in which he was alleged to be deficient. Although Spearman had formulated his "two-factor theory" of intelligence as early as 1904, it was not until much later, when, as a result of the extension of mental testing techniques to all levels of ability, the question of what the mental testers were actually trying to measure was brought clearly to the fore, that this theory became the matter of spirited controversy that it is today.

In 1921 a number of leading psychologists were asked to express their views on the nature of intelligence, and their replies were published (*Symposium*, 1921). Although at first reading the points of view seem rather diverse, a little consideration shows that in reality the differences are less important than they seem. Some emphasized the ability to profit by experience; others, the ability to adjust to new situations. But since the crucial test of the extent to which an individual has

profited by his experience is to be found in his ability to employ the knowledge thus gained in new situations, the two concepts reduce themselves to much the same thing in the end. Thorndike's practical suggestion that intelligence consists in the ability of the individual "to make good responses from the standpoint of truth or fact" is certainly in accordance with everyday practice, both in the judgment of intelligence from behavior and in the scoring of intelligence tests. However, it does not offer any clue to the types of behavior that make most demand upon intelligence. This, of course, is in line with Thorndike's general point of view that intelligence is not a unitary trait. Terman, on the other hand, makes the distinction very explicitly. According to Terman, "an individual is intelligent in proportion as he is able to carry on abstract thinking." Although some have regarded this definition as too academic, giving too little weight to the more practical and concrete aspects of behavior, nevertheless, as was shown in the early sections of this chapter, most investigators have found so low a correlation between the ability to respond to simple, concrete situations and the ability to handle abstractions, symbols, and relationships, as emphasized by Terman, that it seems doubtful whether anything but confusion can result from the attempt to embrace both within a single measure.

The above principle has been clearly recognized in selecting the material for inclusion in tests of intelligence designed for adults and older children. It is very probable that the low correlation universally found between the results of tests given at the early ages and those of tests of the same individuals at later ages is in large part due to the fact that the tests for infants and young children are so largely made up of simple motor and perceptual items that the type of ability measured by them may be very different from that measured later on by tests that conform more closely to Terman's definition. The latter tests, as, for example, following complicated directions, solving mathematical problems, or drawing analogies, show a fair amount of intercorrelation with each other. In contrast, even among young children the interrelationships of the abilities measured by such concrete motor performances as maze learning, ring tossing, and completing form boards are not high. Apparently, motor performances such as these are at all ages relatively specific, which means in effect that a test sample that includes only a few of them can by no means be regarded as a reliable indication of "general" ability. If the correlation of one measure with another is sufficiently high, only one of these need be used, since performance on the second can then be predicted from the score on the first with considerable accuracy. It is because the more abstract types of tests do show this characteristic of interlinkage, one with another, over a wide area of differential content that it has been found practically feasible to secure a reasonably dependable estimate of the general ability[1] of any individual by the use of a relatively small number of tests that require not over an hour's time for their completion.

Modern students of the nature of intelligence and of the organization of mental traits tend to lean much more heavily upon mathematical analysis for the verification of theories than did their forerunners. We are moving rapidly from the descriptive

[1] Needless to say, the term *ability*, as here used, has reference only to the area covered by the tests. A measure of *abstract thinking* will not predict standing on a specific type of motor performance any more effectively than the latter will predict the former. The advantage of the *abstract* test is that the mental area for which it affords a useful means of prediction is wide, whereas motor tests, generally speaking, have little or no predictive value for any functions outside the narrow limits of each particular item.

to the quantitative level, not only with respect to our attempts to assay individual differences in general ability but also, through mathematical examination of the interrelationships between various types of ability, with respect to our attempts to gain a more precise knowledge of the nature of mental organization. Space does not permit me to do more than touch upon the large body of experimental work centering about this problem. For a more complete account of the investigations and the conclusions that have emerged therefrom the interested reader should consult the brilliant review of the entire field by Thomson (1939). Here it must suffice to say that four somewhat different hypotheses as to the nature of mental organization have emerged from these studies. At one extreme we have the view expressed by Thorndike, which, briefly stated, is that each mental act is a separate element, to some extent independent of all others but also having features in common with many others. Certain acts have so many of their elements in common that we find it convenient to classify them into separate groups to which class names are applied, such as arithmetical reasoning or completing omitted portions of sentences.

Provided certain basic conditions of measurement are fulfilled, intelligence, according to Thorndike, is a simple aggregate of all the abilities underlying each of these separate acts. Symbolically, it may be regarded as a surface of which the height or *altitude* represents the difficulty of the acts that the individual is able to perform within a certain one of these closely related areas, such as completing analogies, while the *breadth* represents the range or number of tasks that can be solved at any given level of difficulty. According to Thorndike, correlation between performance on different mental tasks is not to be explained in terms of any generalized quality of "mind" but is purely a function of the number of common elements involved in their solution. This leads of necessity to the rejection of the whole concept of *general intelligence* and the substitution therefor of *specific intelligences*, the number of which is purely an arbitrary matter, depending upon how fine a classification is needed in any particular instance. He suggests that for many crude purposes a three-way classification under the headings of *abstract intelligence*, or the ability to deal with words and other symbols, *mechanical intelligence*, or the ability to deal with concrete objects and materials, and *social intelligence*, or the ability to deal effectively with people, will be found sufficient. Most of our modern tests of intelligence are based almost entirely upon the first, neglecting the other two. Thorndike regards this as a good thing as far as it goes, which is to say that he feels that only confusion would arise from mixing them. Better tests for the other forms of intelligence, rather than a combination of all three, are needed. He also points out that each of these may be divided almost indefinitely. This is illustrated in the case of abstract intelligence by his famous CAVD test (1926) in which each letter stands for a particular kind of performance.[1] These four tests, needless to say, are not to be thought of as covering the whole area of abstract intelligence; they represent only certain segments of it. However, because of the fairly high intercorrelation of all measures within this area, the remaining portions can be estimated from scores on the measured portion with a degree of accuracy that is sufficient for many purposes.

The other two types of ability may be subdivided in a similar manner. Social ability unquestionably varies with the age, sex, social status, intelligence, and so on,

[1] Sentence completion, arithmetic reasoning, vocabulary, following directions.

of the persons to be dealt with. Some people are very effective in handling children but are awkward and constrained in the company of adults; some get on well with their own sex but not with the opposite sex; some appear to be "born leaders," [1] others are happiest and most effective when someone else assumes the leading rôle. The limit of divisibility is reached only when the separate act can no longer be subdivided without losing its identity.

Moving upward in the organizational scale from Thorndike's view that the system of organization is external, inherent in the task rather than in the individual we come to the theory of orthogonal traits proposed by Kelley (1928, 1935).[2] By means of a statistical analysis of the intercorrelations between performances on many different kinds of tests, Kelley arrived at the conclusion that all the varying abilities of an individual can be accounted for on the basis of a relatively small number of independent traits or separate abilities that are completely unrelated to each other. In everyday life, as in test performance, a given act usually calls for the simultaneous exercise of more than one of these abilities, and in varying degree. It is because of the almost infinitely great number of combinations and permutations thus made possible that mental abilities appear to be so diverse, inasmuch as it is only by mathematical analysis that a given ability can be "purified" and known for what it is. Nevertheless, the principle, if true, is not devoid of its practical applications, for, if we once knew what these abilities are and, furthermore, if we were able to ascertain the kind of measurable acts in which a given ability exercises the dominant rôle, we should be able to develop a series of tests that would be more nearly exact measures of these separate functions even though they might not be completely freed from intermixture.

Thurstone (1938), whose theories rank next in our organizational scheme, has attempted to do that very thing. Like Kelley, Thurstone (1935, 1947) developed his theory of mental organization by means of a factorial analysis of tables of intercorrelation. His mathematical approach, is however, somewhat different, and, although, like Kelley, he emerges with a theory of separate and independent mental traits, he differs from Kelley in that he considers these traits to be ranked in order of generality and, hence, we may say, in terms of their importance in individual mental life. Mathematically speaking, these traits, or *factors,* as the mathematicians prefer to call them, are indeterminate, by which is meant that there is nothing in the nature of the analysis itself that tells what a given factor is like. They are simply Factor I (the most nearly general), Factor II, and so on. But it is possible to determine mathematically the part played by any single factor in determining the intercorrelations between tests. By comparing the subject matter of tests in which these *factor loadings* are markedly different, as, for example, tests that have a high loading for Factor I but a low loading for Factor II with those weighted in the opposite direction, hypotheses that are at least in accordance with common sense as to the probable nature of these factors may be drawn up [3] and the factors may then be named in everyday language.

1 This statement must, of course, not be taken literally. There is evidence that social abilities are at least in part the result of individual experience and training. The extent to which inborn characteristics may also be involved is unknown, though it is probable that they play some part in the matter. The expression is used here in the popular rather than the scientific sense.

2 Kelley's method is a modification of that proposed by Hotelling (1933). The results obtained are identical but the procedures differ.

3 The particular set of weights comprising the "factor pattern" for any given series of intercorre-

In the attempt to develop tests that are more nearly "pure" measures of these factors, or *primary mental abilities,* as Thurstone has named them, the procedure followed is essentially a cut-and-try matter in which the guiding principle is finding tasks that differ as much as possible from all those in which the loading for the factor in question is low, and most of all from those in which it is lowest, and which at the same time resemble most strongly those for which this loading is high. By repeating this process a sufficiently large number of times it should be possible, at least on theoretical grounds, to come out eventually with a series of tests by which all the abilities of an individual may be measured with a minimum of wasted time and effort. Within a somewhat less ambitious range,[1] this is what Thurstone has attempted to do in his Primary Abilities Test (1938). By means of a procedure essentially similar to that just described he arrives at the conclusion that individual differences in human mental abilities can be measured and described in terms of only twelve basic abilities, each of which may be possessed in varying degrees. Seven of these are tentatively named as follows: S = spatial abilities, P = perceptual abilities, N = numerical abilities, V = verbal relations, M = memory, W = words (that is, single unrelated words), and I = induction. With less certainty two others are named as follows: R = reasoning and D = deduction. For the remaining three he is not yet ready to propose names. Thurstone has also developed a battery of tests by which each of the first seven abilities may be measured separately. These tests were originally designed for use with college students and students in senior high schools. Later the procedure was extended downward to the 14-year age level (Thurstone and Thurstone, 1941) and finally to the ages of 5 and 6 years (Thurstone and Thurstone, 1946). Only five abilities were identified at these early ages: verbal, quantitative, perceptual, motor, and spatial. By means of the new series it is possible to draw up a mental profile for each child which will show his comparative proficiency along the following lines: verbal comprehension, word fluency, spatial relations, numerical ability, memorizing, and reasoning. Thurstone states that of these the reasoning or induction factor is most closely associated with the other aspects of ability (that is, is the most nearly general), whereas memorizing is the most nearly independent of the six factors studied.

Spearman, in a series of brilliant books and essays dating from 1904, expounded a theory that calls for an even higher degree of mental organization than that proposed by Thurstone. According to Spearman, all mental activity demands the exercise of a special attribute that he terms *mental energy* because in the realm of mind its place is analogous to that of physical energy in the world of physics. This attribute of mind he designates by the symbol *g*, or *general* factor, since it is pos-

lations is not, however, arrived at by any simple or unequivocal method. In order to obtain such a pattern, axes must be rotated until the resulting factorial structure is reduced to the simplest possible terms. Students of factor analysis are not in complete agreement as to the criterion to be used in determining when "simple structure" has been attained. Thurstone, whose methods are more widely used than those of any other authority, states on p. 181 of his *Multiple Factor Analysis* (1947) that, "If each test vector is in one or more of the coordinate planes, then the combination of the configuration and the coordinate axes is called a *simple structure.* The corresponding factor pattern will then have one or more zero entries in each row." For an account of the basic theory underlying this hypothesis, the reader should consult the original source.

1 Thurstone's primary abilities are not presumed to cover the complete range of human talent. They do not, for example, cover such specialized abilities as musical or artistic talent or motor skills. They involve only the abstract abilities needed for success in the conventional types of intelligence tests and in the academic pursuits of the classroom.

sessed by all individuals, though in varying degree, and enters into all mental activity, though to a varying extent. Because all are to some extent dependent upon *g*, all measurable forms of truly intelligent behavior, as, for example, the ability to solve arithmetic problems, to complete analogies, to perceive relationships among geometrical forms, or to understand long and complicated sentences, show some degree of correlation with each other. However, individual differences in ability are not wholly traceable to differences in the amount of *g* They are also dependent upon other factors, known as *s* factors, that are more or less specific to particular activities or situations, whereas *g* is common to all. Some activities involve the *g* factor to only a slight extent, being chiefly made up of *s* factors, and these will commonly show only low correlations with other mental acts. Others, in which the *g* factor is paramount, will intercorrelate highly with one another. Because this theory was the first to be proposed that was based upon mathematical demonstration (although in fairness it must be pointed out that there is not complete agreement among statisticians as to the interpretation of the results), it has attracted much attention and has stimulated a large number of important investigations. Indeed, it was largely the attempt to test Spearman's conclusions that led to the formulation of the three other hypotheses as to the organization of mind that have been described in the preceding pages.

In addition to the *g* factor, which is primarily intellectual in nature, since, according to Spearman, it involves mainly the "apprehension of one's own experience, the eduction of relations and the eduction of correlates," Spearman has obtained evidence of the existence of other general factors, some of which, as *w* (volition), appear to be related to what is commonly known as *personality*. Intermediate between these general factors that play a part in all mental activity and the decidedly specific *s* factors are others of less complete generality but nevertheless common to a rather wide range of mental acts. To these Spearman has given the name *group factors*. He suggests that musical ability and mechanical ability are of this type.

Inasmuch as all these variant hypotheses as to the nature of mental organization have been arrived at by means of different statistical methods applied to the analysis of tables of intercorrelations, it becomes pertinent to ask whether any one of them is more than an artifact of the method employed. This point has been ably discussed in a monograph by Thomson (1939), with which all who are interested in factor theory should be familiar. Because Thomson's treatment of the subject cannot be condensed into a few lines without danger of distortion, no attempt will be made to summarize his conclusions in this chapter. The interested reader should consult the original source.[1]

The Quantification of Intellectual Performance

For some years after the appearance of Goddard's translations of Binet's 1908 and 1911 scales the only way of expressing the amount of acceleration or retardation of an individual child was to state the difference between his actual or chronological age and his mental age. A child was said to "test" so many years "above age" or "below age." But, since the significance of a given number of years' acceleration

[1] For an able discussion of the use of factor analysis in the construction of a scale designed to measure "general intelligence," together with the detailed results obtained from a factorial analysis of the findings for the 1937 revision of the Stanford-Binet, the reader should consult Chapter 9 of McNemar's *Revision of the Stanford-Binet Scale* (1942).

or retardation varies with the age of the child, the use of the *intelligence quotient*, or IQ, first proposed by Stern and popularized by Terman in the Stanford revision of the Binet tests (1916), gained rapidly in popularity. The intelligence quotient, which is the ratio between the mental age and the chronological age, was at first assumed to have a constant meaning regardless of the age of the child. For this reason it was often spoken of as an *absolute* measure of intelligence. More recent work, however, has shown that this is not always the case. Unless certain constant relationships are maintained between the dispersion of test scores at each age and the averages or *norms* for the successive ages, the IQ cannot remain constant either for individuals or for groups. This point has been discussed by a number of different persons, and especially by Freeman (1930). For example, if the curve of mental growth from age to age is assumed to be a straight line, as is done when the tests are arranged in the form of a *year scale* with an equal number of tasks at each age, then the dispersion of mental ages must increase from age to age in a ratio that is proportionate to age. If at the age of 6 the standard deviation of mental ages is 12 months, then at the age of 9 it should be 18 months, at the age of 12 it should be 24 months, and so on. If this condition is not met, then an IQ of 120 earned at the age of 6 will not be comparable in meaning to one of the same apparent value earned at some other age. This is another way of saying that an IQ can have the same meaning at all ages only if its variability is the same at all ages.[1] The amount of error introduced by failure to conform to this rule increases with the extent of the deviation of a given score from the mean of the group. For example, Terman and Merrill (1937, p. 40) report the standard deviation of the IQ's obtained for Form L of the 1937 revision as 20.6 IQ points at age 2½, 12.5 at age 6, and 20.0 at age 12. For children whose IQ's differ from a constant mean of 100 by only a small amount,[2] say half a standard deviation, the errors introduced by the differences in IQ variability are small. Comparable figures at the three ages specified are 110, 106, and 110. But for those who greatly surpass or fall below the mean, the differences become appreciable. At +3.00 S.D. the 2-year-old would have an IQ of 162, the 12-year-old would rank at 160, and the child of 6 whose actual degree of superiority is identical with that of the other two would apparently rank much lower with an obtained IQ of only 137.5.[3] At −1.5 S.D., an IQ of 81 at age 6 has the same meaning as an IQ of 69 at the ages of 2 or 12 years. Differences in the intercorrelations and in the scattering of success on the items allocated to the several age groups afford the most probable explanation for the difference in variability.

The placement of the items in a year scale such as the Stanford-Binet is by no means a simple matter. The unsophisticated person may think that each item should be placed in the year group at which it is passed by approximately 50 per cent of the cases, but this would be true only if the intercorrelations of all the items at a given age were unity or (what amounts to the same thing) if there were but a single test item for each age. When there are

1 Inasmuch as the IQ is the ratio between the mental and chronological ages, it follows that, if the denominator of the fraction (the CA) is changed, the numerator (the MA) must undergo a proportionate change if the value of the fraction is to remain unaltered.

2 The means reported by Terman and Merrill also show small differences from age to age, but as the changes do not appear to follow a constant trend they can best be ascribed to irregularities of sampling

3 A table of corrective values for the IQ's obtained on this test has been incorporated by McNemar (1942) in his monograph on the standardization of the 1937 revision.

several items at each age level all of which must be passed in order to earn credit for the year and when, furthermore, the problem is complicated by the scattering of successes and failures over several age levels, the allocation of items in age groups becomes an extremely difficult problem, so much so that most constructors of tests who have followed the year-scale method have contented themselves with a cut-and-try procedure, in which items are shifted about from one age placement to another [1] until a satisfactory adjustment has been attained. In a brief but cogent article, Jaspen (1944) points out the issues involved and urges that test makers ascertain and utilize the statistical facts as a guide to the placement of items.

Examination of the available data for other tests indicates that there are relatively few for which the statistical requirements of the IQ technique have been adequately met. The uncritical use of this method for any and all tests for which age standards have been derived has been a regrettably common practice in the past but should certainly be discontinued.

An early study by Kuhlmann (1921), which was based upon a large number of retests of feeble-minded persons by means of his revision of the Binet scale, has been much quoted. In this study it was shown that the IQ's obtained for feeble-minded persons in institutions did not, as was then supposed, maintain a constant level from year to year either for individuals or for the average of the (feeble-minded) group. Instead, they tended to become lower with advancing age. This study was utilized by Heinis (1926) as a means of verifying his "law of mental development" first proposed in 1924. Heinis, at that time, had been greatly impressed by a series of tests developed by Vermeylen (1922), who had given the series to 10 children at each of the ages from 6 to 12 years. On the basis of Vermeylen's data together with the results obtained by Descoeudres (1921) for children of preschool age and certain unpublished figures of his own, Heinis worked out a curve of mental growth [2] that was presumably calibrated in equal units comparable to the feet and inches on a scale of linear distance. This curve showed marked negative acceleration with rapid growth at the early ages and comparatively small increments at the later ages. The standard deviations of the score distributions also decreased with age. From this curve Heinis derived a measure which he called the "personal constant" or, alternatively, the "personal coefficient" [3] (PC), for which he offers the following definition:

"The personal coefficient of any given individual is equal to the result of the intelligence examination divided by the normal degree of intelligence corresponding to his age, both measures being given in absolute graduation."

The values of the PC bear a superficial resemblance to the IQ but are not directly comparable with it because of the smaller variability, especially at the older ages. Heinis believed that the decreasing IQ's of Kuhlmann's feeble-minded subjects were a necessary consequence of the method of deriving the IQ, and that the IQ's of superior children would show a corresponding tendency to increase with age. He believed that

1 Binet himself observed that the allocation of items to the age at which 50 per cent of the subjects succeed with them results in too low a mental age value. By empirical trial he found that the requirement of 70 per cent passing results on the average in mental ages approximately equal to the chronological ages. This, of course, merely indicates the typical intercorrelation between test items, a factor that varies greatly from one item to another, rendering the adoption of any such general rule hazardous in the extreme.

2 The formula for this curve will be found on p. 478.

3 Kuhlmann, Hilden, and others have preferred the term "per cent of average" (P. Av.) as being more explicit.

the PC would yield more nearly constant results. When the new method was applied to Kuhlmann's data, this prediction appeared to be verified. Although Heinis considered this to be sufficient proof of the superiority of the PC over the IQ, not all who have tried the method have obtained equally favorable results. For example, Psyche Cattell (1933) found that the PC was more consistent than the IQ when used with feeble-minded or backward children but that the IQ was more uniform in the case of superior children. Kuhlmann, however, expressed himself as being definitely in favor of the method and made use of it in the final revision of his scale for individual mental examination (1939) published shortly before his death. The PC was also used for expressing the results of some of the earlier editions of the Kuhlmann-Anderson group test, but in the latest edition the IQ derived from the median of the mental ages earned on the ten subtests of which the scale is made up is the measure recommended.

Much of the apparent inconsistency in the attempts that have been made to compare the IQ with the PC has arisen from failure to realize that the units employed in the two measures are not equal in numerical value. As a matter of fact, examination of the tables for converting mental ages or IQ's into PC units prepared by Heinis (1926) or the more convenient arrangement by Hilden (1933) shows clearly that, particularly for ages above those of the primary grades, a given numerical change in the PC is of far greater significance than a similar numerical change in the IQ and that the greater apparent "constancy" of the former has been attained at the cost of lowered discriminative value. McNemar (1942) has given an excellent discussion of this and other factors connected with the Heinis coefficient with particular reference to Kuhlmann's reasons for preferring it.[1]

During the 1940's the *percentile method* of interpreting test scores became increasingly popular. The percentile score, or, as it is often called, the *percentile rank*, is expressed in terms of the percentage of a specified group, usually of the same age, whom the child in question surpasses. The fact that any group may be used for comparison gives the percentile method a degree both of flexibility and of specificity that the methods previously described lack. A mental age norm is always, supposedly, representative of children in general of the age in question. A little consideration, however, will show that it is rarely possible, in the actual standardization of a test, to secure the truly representative group that is implied by the term mental age. This difficulty has been recognized theoretically by practically all workers; nevertheless, the idea that the *mental age norms* which have been worked out in the course of the original standardization of a test have some kind of final or absolute value is implicit in most of the interpretations of results obtained for different groups by the use of various tests. Moreover, rarely are we actively concerned with a comparison between *individuals* in noncompeting groups. Ordinarily we compare college students with other college students, preferably of the same class. We are likely to be more interested in knowing how the 8-year-old daughter of a college professor compares with the 8-year-old offspring of other college professors or with the other children in her class at school than in knowing how she compares with the 8-year-olds in a backward mountain community or with

[1] The coefficient of intelligence (CI) proposed by Yerkes and Foster in 1923 is identical with the PC in method of derivation except for the important fact that the scale values were not calibrated in equal units. Like the PC, the CI was obtained by dividing the child's score by the average score of his age group.

the 8-year-old Negroes on a Louisiana plantation. Comparisons between contrasted *groups* of this kind are often interesting, but for this purpose other methods of quantifying test results are more suitable than the quotient methods so often used.

The percentile method has other very obvious advantages. It is easily understood even by the uninformed and is therefore particularly useful in explaining test results to parents, teachers, physicians, and others who may be interested. Since comparisons are made only between individuals of the same chronological age, the implications resulting from assigning equal basic scores to individuals of very different levels of physical maturity and life experience are avoided. An imbecile of 15 with a mental age of 3 is a very different kind of human being from a normal child of 3 years even though he may happen to pass the same number of items on a certain mental test. Even his test score, although it may count up to the same number of items, will usually show decided qualitative differences in the particular items passed and the kind of responses that are made to them. Cunningham (1927) has shown that, even with so carefully standardized a test as the CAVD, differences between the performance of adult imbeciles and normal children between the ages of 2½ and 6 years on the separate items of the test are in some instances as great as 10 times the standard error. Merrill (1924) found decided differences in the performance of gifted, average, and subnormal children of the same mental age on the different items of the Stanford-Binet. The groups also differed considerably in the amount of *scatter* on this test, that is, in the range which it was necessary to cover in order to meet the usual conditions of complete testing. Both the gifted and the subnormal groups "scattered" decidedly more than the group of average ability. Aldrich and Doll (1931) matched normal children of 19 to 38 months with idiot boys of corresponding mental ages and compared their performances on the Gesell developmental items and on the Merrill-Palmer series of performance tests. The idiots were markedly inferior to the normal children on all tests involving language but were superior in the tests involving experience and the use of concrete materials.

Although, when properly used and interpreted, the method of percentile ranks is a simple and valuable device for reducing test scores to meaningful quantitative terms, it must not be forgotten that, unless the distribution of test scores takes the form of a rectangle instead of the usual normal curve, the distances between successive percentiles cannot be equal. Instead, their values will increase steadily toward each extreme. This is easily understood if it is remembered that the percentiles are computed on the basis of the percentage of cases making each successive score, that is, in terms of the areas of successive segments above the base line of the curve. If the distribution of scores approximates the usual bell-shaped form, equal areas will subtend longer and longer segments of the base line as the extremes of the distribution are approached. The difference in score value between the ninety-seventh and the ninety-eighth percentile will be far greater than that between the fifty-seventh and the fifty-eighth. Percentile ranks, therefore, while they are useful methods for expressing individual standing within a specified group, should never be used as media for further computation. They cannot, justifiably, be added or subtracted or averaged. Neither do they lend themselves to the conventional forms of graphic expression such as bar diagrams or histograms. They are interpretative measures only.

Another method of expressing the test standing of an individual is in terms of the number of standard deviations by which he

falls below or surpasses the mean standing of his group. As in the case of percentiles, the group may be defined in any way desired. If age is taken as a basis for the definition, however, the range of ages used for determining the standard deviation should equal those used in defining the age of an individual child. That is, if the ages of the children are taken to the nearest month, then the standard deviations used in computing the scores should be calculated within the limits of dispersion shown by children whose ages vary only within a month's range. The point is a rather obvious one, and is mentioned only because it has frequently been disregarded when this method of expressing scores has been used.

The direct expression of test results in terms of untransformed standard deviation units has two practical disadvantages. Such scores involve the use of a decimal point, and they may be either negative or positive in sign. Both these factors make for errors in reading and recording. A device for overcoming this difficulty is rapidly gaining in popularity. It consists in setting the mean of every test or measure used at 50 and the standard deviation at 10. The score of each individual on any type of mental or physical measure thus becomes

$$\text{Converted score} = 50 + 10x$$

where x is the number of standard deviations (plus or minus) by which he deviates from the mean of his group.

Goodenough and Maurer (1942) have suggested a modification of this formula which is designed to make the numerical results correspond to the values which have already been made familiar through the use of the ordinary intelligence quotients. By a simple substitution of constants, the formula becomes

$$\text{Converted score} = 100 + 17.5x$$

This procedure has been used in the derivation of interpretative units for the Minnesota Preschool Scales. The values so obtained have been called IQ equivalents to distinguish them from IQ's obtained in the usual manner. It should be noted, however, that the significance of the two is the same, and the procedure itself is not subject to some of the criticisms often made of the intelligence quotient when calculated in the usual manner.[1]

The use of either percentiles or standard deviation scores (the latter are often called "sigma" scores) is based upon the implicit assumption that the items making up the tests are equally spaced for difficulty. But in few, if any, of the group tests in common use has this requirement been fulfilled. Generally speaking, all that has been done is to arrange the items in an approximate order of difficulty, and then count the number passed by each child. This procedure commonly yields very unequal steps, particularly at the extremes. The irregular overlapping resulting from the unequal spacing made it impossible that interpretative measures such as intelligence quotients or sigma scores calculated from these tests should have equivalent meanings at different levels, even within the limits of the same test. When different tests were used the discrepancies were likely to be even more glaring. A number of scaling procedures designed to overcome those irregularities have been worked out and applied both to the older tests first standardized on the basis of a simple item count and to newly devised tests. Thus far, scaling methods have been more generally applied to the educational tests for the measurement of accomplishment in the

1 In the Army General Classification Test used in World War II a similar method of deriving interpretative scores was used but with the variability constant set at 20. The formula thus becomes:

$$\text{Converted AGCT score} = 100 + 20x$$

different school subjects than to intelligence tests, but work on the latter is well under way, and it is to be expected that in the future the question of scaling will be given much more attention in the construction of tests of all kinds than has been done in the past.

Among the tests in present use for which norms are given in terms of scale values, the Arthur Performance Scale (1930) and the Minnesota Preschool Tests (Goodenough, Maurer, and Van Wagenen, 1940) may be mentioned. The procedure used in deriving the scale values for the Arthur tests is the so-called discriminative value method (D.V.) proposed by Arthur and Woodrow (1919). In scaling the Minnesota tests the C-score method used in a number of educational tests was used. Thorndike's work on the CAVD tests has already been mentioned. This is one of the most thoroughgoing pieces of methodological work that has appeared, and it merits careful study. In the same volume, scaled values for a number of the leading intelligence tests originally standardized on an item count basis are also given.

Although the question of scaling is so fundamental a problem in all attempts at mental measurement, there is as yet no general agreement as to which of the various methods that have been employed will yield the most consistent results. Thurstone (1925, 1928*a*, 1928*b*), who has developed a method of scaling based on the overlapping of scores at successive age levels, is very critical of any method which takes account of variability only within a single age group. His method results in scale values which appear to yield an approximately linear relationship between age and variability, a condition which, as was pointed out in an earlier paragraph, is necessary if quotients are to have the same relative significance from one age to another. Although the true linearity of this relationship has been called into question by Holzinger (1928), the error appears to be much smaller than that which would result if scores derived from a single age group were used as the basis for scaling, as Holzinger recommends.

Since the values derived from the so-called absolute scaling methods will vary according to the method employed and the extent to which the empirical data correspond to the assumptions under which these methods have been worked out, it is evident that at best the equality of spacing that these methods are presumed to yield is only approximate.[1] It is undoubtedly an improvement over the old item-count method, but much further work needs to be done before we can be certain how and to what extent the results are affected by variations in the conditions of testing and in the sampling of subjects upon whom the test was standardized. All methods of scaling derive their units from the proportion of children at each age who pass each test item. Although the matter has not been adequately tested, it seems highly improbable that scale values can maintain their equality of spacing except for groups that are reasonably similar to the one on which the values were derived. This point has been recognized to some extent. Thurstone (1928*a*, p. 178), for example, specifically states that "the social and intellectual factors of selection must operate more or less uniformly for the several age-groups" if the conditions requisite for his method of scaling are to be observed.

Thorndike (1926) has pointed out additional sources of error. The ordinary criterion of test difficulty is the relative frequency with which an item is passed. A test that is passed by few children at a given age is regarded as more difficult than one which the majority can answer. The frequency of passing, however, is deter-

[1] See the discussion of this point by McNemar (1942, Chapter XI).

mined not only by intrinsic difficulty but also by the extent to which the fact in question has become a matter of general knowledge, that is, the likelihood that all or most of the children will have had opportunity to become acquainted with it. The word "broccoli" is not intrinsically more difficult than the word "spinach" or "cabbage," but until the last few years at least it would unquestionably have been classed much higher in a vocabulary test. Whether or not the concepts of elementary algebra are intrinsically more difficult than the concepts of long division is uncertain, but because most schools teach long division before elementary algebra more children will succeed with division problems than with algebra problems. Probably more city children than country children of the same age will be able to give a correct answer to the question. "What must you do if you are going some place and miss the streetcar?" but if the question were, "What must you do if the cows break into the wheatfield?" the opposite tendency might be shown. Sherman and Key (1932) report that many of the mountain children whom they studied were unable to give their family name, identifying themselves simply as " 'Lizy's Tom" or "Moses' Joe." Giving the family name is a test for 3-year-olds in the 1916 Stanford revision of the Binet, but if the 3-year-olds upon whom this test was standardized had been asked to give their father's or their mother's first name, they might have been no more successful than the mountain children were in giving the family name. The difficulty of a task for any group is in part a matter of its familiarity or strangeness for that group. It follows that *scale values*, though they may be equally spaced for a particular group, are likely to be quite unequally spaced for another group of similar intelligence but different experience.

No matter what method of quantifying test results is used, the standards obtained cannot safely be applied to other groups unless it has been shown that they are reasonably similar to the standardization group in all matters that may be expected to affect the relative value of the scores. In order that such comparisons may be made, it is essential that the main characteristics of the group used in standardization be defined as exactly as possible. This means that some information about the home background of each child needs to be obtained. Although elaborate social case histories are usually out of the question and would be difficult to handle in any event, a few simple facts such as paternal occupation and residence (city, town, or rural) are easy to ascertain. If these were uniformly classified and reported as a part of the routine information concerning every test that is worked out, many of the discrepancies that result from the use of differently standardized tests could be explained and the suitability of a particular test for use with a given group of children could be more safely judged. The relationship between socio-economic status and mental test standing will be considered further in a later section.

Mental Growth Curves

A natural outgrowth of the attempts to calibrate mental tests in truly equal units is the plotting of the results thus obtained in the form of growth curves. Inasmuch as there is as yet no general agreement as to the method best suited for calibrating the items making up the tests, it is not surprising to find that even when the same procedure is used for plotting the growth curves the "form of the mental growth curve" derived from one test may be radically different from that derived from another test. Dissimilarity of test content, not only from

one test to another but also at successive age levels within the same test, also confuses the picture. Dissimilarity of the sampling of subjects used, particularly when the selective factors resulting in a biased sampling have differed from one age level to another, is a further complicating factor.[1] And, finally, there is the fact that the statistical procedures used for plotting the growth curves have varied from one investigator to another.

Courtis (1930) believes there is no single type of growth curve that can adequately express the pattern of growth represented by a conglomeration of items varying irregularly as to both kind and level of difficulty, such as in included in the usual mental test. Such curves lack stability of form because they do not measure a uniform function in a uniform manner. Courtis insists that any adequate plan for the study of mental growth must take its origin from a consideration of the developmental progress in the performance of a single act. After plotting curves for many forms of biologic growth, ranging from the growth in weight of a pumpkin to the increase with age in the percentage of men who are married, he derived a unit called the *isochron*, which is defined as the percentage of the total period of maturation that has been attained by any individual at any time. Isochronic units, so Courtis thinks, have uniform significance for all forms of growth whether of structure or function. The idea is an interesting one but requires further confirmation.

Most present-day students of human development accept the theory that mental growth proceeds most rapidly during infancy and early childhood. This is equivalent to saying that the curve of mental growth is negatively accelerated. No general agreement has been reached, however, as to the most nearly correct formula for this curve. Gesell (1928) assumed a logarithmic form. Thurstone (1928*a* and *b*), after applying his method of scaling to the items of a number of well-known intelligence tests, found that the resultant curves varied with the tests from which they had been derived and (presumably) with the character of the groups to whom the tests had been given. However, when the various curves were extrapolated at the lower end, he found that for all the tests examined the point of "zero" intelligence was located at birth or shortly before birth. Heinis, whose study was mentioned in the preceding section, by applying a logarithmic transformation to Vermeylen's data, derived the following formula which he believed to be an absolute expression of the law of mental growth:

$$Y = 429(1 - e^{x/6.675})$$

where Y = the height of the curve at the age in question.
x = the chronological age.
e = the base of the natural logarithm.

Though the principle involved is arbitrary, since no one knows whether or not mental growth actually conforms to a logarithmic scale, the curve itself is not out of line with modern hypotheses and observations concerning mental progress. The constants used, however, were derived from so few cases (10 at each age) as to render their validity open to serious doubt.

According to Heinis, the midpoint of mental growth is reached at the age of 5 years. Thorndike *et al.* (1926), utilizing the data and the scaling procedure of the CAVD test, arrived at the conclusion that the curve for CAVD altitude is parabolic in form, rising from zero at birth to a mid-value around the age of 3 years and attaining its final height at about the age of 21.

1 This point is discussed by Anderson in Chapter 1 of this book.

It is interesting to note that, although independently derived, this curve shows fairly close agreement with that for growth in brain weight. Although at first thought the idea that one-half of an individual's ultimate mental stature has been attained by the age of 3 years may seem a bit startling, the following exercise which the writer has repeatedly tried both with university students and with laymen may put the matter in a somewhat different light. The instructions given are:

> First, try to forget all that you may have learned about mental tests.[1] Think only of children as you have known them.
>
> Now try to get the clearest picture that you can of a newborn baby. Go over his abilities and inabilities in your mind in considerable detail. (A few moments' time should be allowed for this.)
>
> Now turn your mind to the adults whom you have known. Consider in detail the things that they are able to do, especially the things that we commonly think of as indicating "intelligence." (Pause.)
>
> Now go back once more to the newborn baby. Holding in mind these two points of reference—the newborn and the adult—move slowly up the age scale, asking yourself at each point, "Is the typical child of this age more nearly like the adult or the newly born infant in respect to the things he is able to do?" Continue this process until you reach an age at which, in your judgment, the resemblances and differences are so evenly balanced that you can no longer come to a decision. If your judgment is sound, that age will fix the halfway point in postnatal mental growth.

1 This caution is necessary because of the strong tendency on the part of those who have been taught that mental maturity is attained at some specified age, as 16 years, to assume that the midpoint of growth in ability would of necessity correspond with one-half the time span covered between birth and maturity. This, of course, is circular reasoning. The mere length of time required to accomplish something tells nothing whatever about the evenness or unevenness of the rate of accomplishment.

When this exercise has been tried with fair-sized groups who have thoroughly grasped the idea that what they are seeking is a point of balance, equally far removed from the two terminal points in the matter of resemblance, the mean estimate is, as a rule, not far from that set by Thorndike. The distribution of judgments tends to be skewed toward the lower ages, which is, of course, just what would be expected if the true form of the growth curve were parabolic in shape.

The Prediction of Later Status from Earlier Status

The idea that mental tests not only provide a measure of the present mental level of the individual but also yield some indication of his potentialities for further development has from the outset been implicit in the uses to which they have been put. Shortly after the IQ method of expressing test results had been popularized by Terman, the extent to which this measure tended to remain constant for the individual child became a popular subject of investigation. Until the late twenties, however, these studies dealt almost exclusively with children of school age. The few studies based upon younger children that had appeared up to that time usually included only a small number of cases, with little or no attempt at experimental control either of the sampling of subjects or of age at initial and final testing. Sometimes even the results from different tests were thrown together in a single grouping. Only within comparatively recent years have sufficient data been accumulated to provide a tentative answer to this important question: With how great a degree of assurance may we predict the mental level likely to be attained by any child at maturity (or at any other specified age) on the basis of tests given at some stated earlier age?

Both the empirical evidence and the underlying theories on this topic have been summarized by Anderson (1939). His conclusion is essentially the same as that expressed by the writer in Murchison's *Handbook of Child Psychology* (1933, p. 322). Briefly stated, the conclusion is that, *the younger the child at time of first testing, or the longer the interval between tests, the less accurate will be the prediction of later status from earlier status.*

Findings for the Minnesota Preschool Scales by Goodenough and Maurer (1942), however, make it appear that the effect of interval between testings may be actually far smaller than that of the age at first test. The reason for this apparent exception to the results of other investigators is not clear. It may be a function of the particular scale used or of the unit of measurement employed. On the other hand, it is possible that certain functions of the human mind, although measured with very unequal accuracy at different ages, nevertheless remain relatively constant from early childhood to maturity. This hypothesis would be encouraging if true, but much further evidence is needed before we can be warranted in accepting it at its face value. No study that has yet appeared has shown more than a moderate relationship between the results of tests given before the age of 6 and those administered in later childhood or at maturity. Bradway (1944) in a carefully controlled study of the predictive value of the preschool tests in the 1937 Stanford-Binet re-examined 138 of the children used in the original standardization of the scale 10 years after the initial testing. Fifty-two of the subjects had been under 4 years of age when first tested; the remaining 86 had been between 4 and 6 years. Correlations between original and later IQ's on the same scale were +.66 for the younger and +.67 for the older group. This difference, however, is greater than appears from the *r*'s since the younger group was more variable, the SD's being respectively 17.1 and 14.1 IQ points. The mean change in IQ was 12 points for the younger and 10 points for the older group. Changes of 15 points or more occurred in approximately one-third of the younger and one-fourth of the older subjects. Bradway's conclusion that "an individual IQ obtained prior to the age of 6 years must be interpreted with discretion" seems well justified.

In a later study (Bradway, 1945), an attempt was made to identify factors related to IQ change. Few of the items studied proved to be reliably associated with the differences found.[1] The highest relationship was for a "measure of ancestral intelligence" based upon a composite of such factors as mid-grandfather's occupational status and mother's vocabulary. This, as Bradway correctly points out, may have operated either as an environmental influence or as a hereditary factor not completely realized at the time of the first test. Of possible significance, however, is the fact that the cases for whom large changes in IQ occurred were usually those whose initial IQ's had shown large deviations from the values to be expected on the basis of ancestral intelligence.

Bayley (1933), Honzik (1938), Furfey and Muehlenbein (1932), Shirley (1933), and others who have followed the development of infants from early infancy up to the period at which mental tests show reasonable stability of results from one testing to another, all report an absence of relationship between mental test standing

[1] It should be noted that the significance of the differences found by Bradway is less than she reports inasmuch as the statistical methods appropriate for large samples rather than the small-sample techniques were employed throughout the study.

before the age of 18 months and later test performance. After the appearance of speech, the tests begin to have predictive value, although the amount of confidence that can be placed in the results as indices to the child's ultimate level of development continues to be small up to the age of 6 or 7 years. Both Goodenough (1933) and Anderson (1939) have pointed out that the amount of overlap between earlier and later testings is a factor of major importance in determining the degree of relationship between the results of successive testings of the same individuals.

In an article of basic importance for all students of mental growth, Bayley (1940) has shown that, when the same individuals are retested at regular intervals over a period of years, characteristic differences appear in the rate and pattern of their mental growth. Out of a total of 48 cases who were followed over a period of 9 years, 8 maintained fairly constant positions near the mean of the group as a whole throughout the entire period; 8 showed relatively slow rates of growth, with continued tendency to lose in standing when compared with the other members of the group; 8 showed the opposite tendency with continued gain in test standing as age advanced; 8 displayed a tendency to lose in standing during infancy and early childhood but later shifted to an accelerated rate whereby the early loss was regained; and, in contrast to these, another group of 8 cases showed early rapid growth with subsequent loss. The growth curves of the remaining 8 were not classified as to form, since the patterns appeared not to fall into any easily recognized class. These findings are in fairly close general agreement with those obtained by Goodenough and Maurer (1942) in a 12-year study carried out at the Institute of Child Welfare at the University of Minnesota.

Relationship of Intelligence Test Standing to Other Factors

That more than chance relationship exists between the scores made by a given individual on standardized tests of intelligence and his scores on many instruments designed to measure other mental and physical traits is well known. In many instances, however, it is not wholly clear to what extent the relationships found may be ascribed to biological or social factors and to what extent the issue is in reality a matter of semantics. We know, for example, that practically all measures of language development, such as size of vocabularly, mean length of sentence used, and complexity of sentence construction, show fairly high correlation with measures of intelligence. Whether this relationship between *scores* indicates a genuine tendency for two *different* aspects of mental development to vary together or is merely a necessary result of measuring the same thing twice by slightly different instruments and calling the results by different names, is a question about which opinions differ. When greater agreement with respect to factorial procedures has been attained, an answer may perhaps be reached. For the present we shall avoid the issue by specifying that, in the discussion to follow, we are dealing only with relationships between the results of tests *designed* to measure general intelligence and those of measurements *designed* for other purposes.

Although in many instances the correlations are too low to have practical utility, it is nevertheless true that standing on recognized tests of intelligence is positively related to standing on practically all other measurements of socially desirable traits. Even physical measurements such as height and weight have been found to conform to the general rule, although the relationships are not high and in many of the reported

studies heterogeneity of race and the inclusion at the lower end of the intelligence scale of special clinical types such as Mongolian imbeciles have operated to make the apparent relation higher than would be the case had a truly representative selection of subjects been used. (See Paterson, 1930.)

That performance on intelligence tests varies according to the social class from which the subjects are drawn has been recognized since the days of Binet. That the relationship is not one of simple cause and effect is demonstrated by the fact that every level of intelligence can be found within each social level, though not in equal proportion. A greater percentage of the very bright come from families of superior socio-economic status, whereas the frequency of backward children is proportionately greater among the lower social classes. The relationship is sufficiently marked to bring about a difference of 20 to 30 IQ points in the mean test standing of children of college professors and those of day laborers.

This relationship between socio-economic status and intelligence must always be kept in mind when considering statistical findings on the correlation of intelligence test scores with other factors such as juvenile delinquency, social behavior, standing on the pencil-and-paper "tests" of emotional stability, and the like. Undoubtedly, children of the upper social classes have fewer incentives to delinquent behavior than those who live in the slums. Undoubtedly, too, their offenses are more likely to be handled privately by cooperation between parents and police than are corresponding offenses by children from homes where little parental assistance can be expected. All this makes for a greater percentage of low-testing individuals among institutionalized delinquents than among children not classified as delinquent, but in all probability a large share of this difference is attributable to the socio-economic factor rather than to intelligence *per se*.

Likewise, the finding that children of superior intelligence are on the average more popular with their mates than those of low intelligence might be considerably modified if the socio-economic factor (which, particularly among older children, involves some degree of prestige, as well as the means for providing little treats or toys for group use) were made equal for all. In the paper-and-pencil tests designed to measure various nonintellectual traits, the almost uniformly positive correlations between scores on these tests and scores on intelligence tests may be interpreted in either of two ways. There may be a true relationship between intelligence and the social or emotional traits presumably measured by these tests, or, on the other hand, the obtained correlations may result wholly or in part from the greater ability of bright children to select the more socially acceptable responses.

The question of sex differences in intelligence has been a matter of active controversy for many decades. That there are differences in the type of intellectual skills in which each sex excels has been thoroughly established. At all ages, males outrank females in general information, especially along scientific lines. They also have better insight into mathematical and mechanical relationships. Females excel in linguistic and perceptual skills and in certain types of rote memory. As might be expected, intelligence tests will therefore show some advantage of one sex over the other according to the kind of items with which they are most heavily weighted. In the standardization of most tests, however, particularly those intended for use with school children, items have usually been so chosen as to keep the sex differences at a minimum. On the average, girls make slightly better school records than boys and are

more often ranked superior in intelligence by their teachers in the elementary grades, but it is likely that greater docility and better application to their studies, rather than a genuine difference in ability, are responsible.

That males greatly exceed females in the number who achieve fame is an incontrovertible fact. More males than females are also found among the inmates of institutions for the feeble-minded and in the special classes for mentally retarded children in the public schools. This raises the question of a possible sex difference in intellectual variability. Regardless of the equality of the means, if one sex is more variable than the other, that sex will show a greater proportion at the extremes of the distribution. Because of social and industrial conditions that make it difficult or impossible to examine large and equally representative groups of adults, the answer to the question can best be sought among children.

Perhaps the most crucial data thus far available, as far as the upper extreme is concerned, are to be found in the records of the Stanford University study of intellectually gifted children, which was initiated by Dr. L. M. Terman in 1921. Later careers of well over 95 per cent of the subjects have been studied by means of follow-up tests, interviews, and mailed questionnaires up to the present time. Children were originally chosen for inclusion in the study if their Stanford-Binet IQ's were 140 or higher. In spite of the fact that the method of selecting the children for testing [1] was such as might possibly favor the girls, the actual sex ratio among the 1070 elementary school children selected on the basis of their standing on the Stanford-Binet was 116.4 boys to 100 girls. Among the 428 high school children who were given the Terman Group Test, the sex ratio of 163.2 boys to 100 girls is even higher [2] (Terman and Oden, 1947).

Unquestionably the most nearly perfect sample of the abilities of a specified group that has ever been obtained comes from Scotland (Macmeeken, 1939), where *all but one* of the 875 children born in Scotland on 4 selected days of the year 1926 and who had survived until the age of 10 were located and tested by means of the Stanford Revision. The mean IQ of the boys was found to be 100.5; that of the girls was 99.7. The corresponding SD's were 15.9 and 15.2 respectively. Although these differences appear small, they would nevertheless, if valid, result in large discrepancies in the proportion of the sexes found at the extremes. Terman has calculated that the sex ratio among those who attain an IQ of 140 or higher would, under these circumstances, be approximately 158 boys to 100 girls, or, if the small difference in the means is disregarded and variability alone considered, the ratio would be 134 males to 100 females.

Data on the sex ratio among the feeble-minded also show an apparent excess of

1 Lack of sufficient funds made it impossible to examine all the school children in the California cities covered by the survey. Teachers were therefore asked to name the two or three children in their classes whom they thought to be most intelligent. The name of the youngest child in each class was also called for. These children were then given a group intelligence test, and all who attained a certain standing were later given an individual Binet test. Since the initial selection was based on teachers' judgments of ability, the possibility that the excess number of boys among those who qualified might be due in part to sex favoritism called for investigation, even though the difference in this case ran contrary to the usual finding. The crucial test of bias is the sex ratio among those named who failed to qualify. This ratio was found to be 103.7 boys to 100 girls, which compares with a ratio of 104.5 boys to 100 girls in the elementary school population as a whole. This difference is too small to be reliable, but at least it does not suggest that biased selection can account for the greater proportion of boys in the gifted group.

2 These figures do not correspond exactly to those given in Vol. I of the Stanford report (Terman *et al.*, 1925) because of different classification of the groups.

males. These figures, however, are subject to a number of sources of misunderstanding that operate little or not at all at the upper extreme. Certain organic factors, such as cerebral birth palsy, are very unequally distributed between the sexes. Sociological and economic conditions are also influential in placing a greater number of males than females in institutions for the feeble-minded. Financial pressures bear most heavily upon the boy, who is expected to become an active breadwinner, whereas the moron girl who is docile and industrious can often satisfy all requirements by helping about the home. Eventually marriage may provide her with some degree of economic security. For her brother, on the other hand, marriage merely adds to his economic responsibilities. The greater aggressiveness of the male is another factor, since it often leads him into difficulties that expose his mental backwardness. These and other circumstances of a similar nature are in all probability partially responsible for the large excess of males over females that has been reported by most institutions for the feeble-minded, but a genuine difference in variational tendency may also play a part.[1]

Considering all the evidence, the hypothesis that the distribution of male intelligence has a wider spread than that of females is a reasonable one, even though it has not yet been definitely established as fact. If verified, such an assumption would account for many of the established facts concerning sex differences, including the greater number of males who attain eminence as well as the greater number found in institutions for the feeble-minded. Although the importance of the standard deviation has frequently been pointed out by students of sex differences, the extent to which even a very small inequality in the variance of the sexes can affect the proportions at the extremes has not, as a rule, been completely realized. The majority have centered their attention upon the means of the groups, rather than upon their relative dispersion.

The question of racial differences in intelligence, like that of sex differences, is still a controversial issue in spite of the large body of data that has been accumulated on the subject. Differences in interpretation, rather than the figures actually obtained, are in the main responsible for the variant opinions that have been expressed, since the test results reported in most of the published investigations are in fair agreement with one another. In spite of many brilliant exceptions to the rule, Negroes and immigrants to this country from the south of Europe and the Spanish-American countries, together with their children, have been found to rank distinctly lower, on the average, than North American whites on tests designed for the latter. Whether this reflects a genuine biological difference in the distribution of intellect among the races or whether it results wholly or in part from the use of measures that are poorly suited to the appraisal of the mental capacity of subjects whose experiential background differs in many ways from that typical for those upon whom the tests were standardized is uncertain. It is also possible, as some believe, that the growth of intelligence is dependent upon environmental stimulation, and that the members of the groups in question are likely to be truly unintelligent, not because they were originally incapable of intellectual development but because they lacked the opportunities and incentives that make for mental growth. Perhaps future investigators will devise some really crucial tests

1 Although there is evidence that the distribution of intelligence conforms fairly closely to the normal curve, it is by no means certain that the correspondence is exact or that it is identical for both sexes. The small differences in variability that have been reported could be the result of differential skewing at one or the other extreme.

of these hypotheses, but the attempts that have been made so far leave so much room for biased interpretation and conclusions that not much weight can be assigned to them.

Studies of racial differences are particularly liable to bias in the selection of subjects. That immigrants to this country are not representative of the total population of the parent country is more than a possibility. It is likely, too, that the factors leading to emigration have differed from country to country and at different periods of time within the same country. The evidence on these points has been ably reviewed by Tyler in Chapter 5 of her *Psychology of Human Differences* (1947) and will not be repeated here. Her conclusion that the difficulties involved in racial or nationality studies are great and that many of the published studies are of little or no worth because of the want of essential information with respect to the sampling of subjects, the use of unsuitable tests, and other technical faults is certainly well grounded.

The Modifiability of Intelligence

Few, if any, questions relating to mental growth crop up so persistently or have provoked more intensive study than those relating to its possible modification. The obvious practical importance of the problem and the occasional, though by no means universal, improvement in mental level that has been brought about through thyroid treatment in cases of cretinism or by other types of glandular therapy in analogous conditions of endocrine malfunctioning have served as constant examples of the mental gains that can be accomplished when the basis for the original deficiency is once understood. It is but natural, therefore, that theories on the etiology of mental differences should lead by the shortest possible route to theories as to the extent and manner by which these differences may be modified. Because the most obvious indications of mental superiority or inferiority have to do with the learning process, it is not strange that many should question whether differences in learning ability have any constitutional bases at all, or whether they might not better be ascribed to lack of opportunity or stimulation to learn, or to the failure to acquire proper techniques of learning.

Two of the *Yearbooks of the National Society for the Study of Education* (1928, 1940) as well as a large number of separate articles and monographs have been devoted entirely to a consideration of this topic. As yet, however, no general agreement on the basic question involved has been reached, although the weight of evidence when all the large number of investigations reported in the *Yearbooks* and elsewhere is taken into account certainly does not support the view that the intellectual development of children is as readily modified by experience as many wishful thinkers would like to believe. Woodworth (1941) has given us a painstaking and eminently fair critique of the evidence available up to that date, with particular reference to that dealing with the development of twins separated in infancy and of children reared in foster homes. Like many others he noted that, in a number of the studies which have apparently shown that marked changes in intellectual status have resulted from an altered environment, the conclusions reached have been based upon the faulty results of erroneous statistical techniques.

That children reared from infancy in environments where intellectual opportunity is not lacking and where the incentive to intellectual achievement is high are likely to reach a higher level of achievement than others of equal original endowment for

whom both opportunity and incentives are poor is conceded by practically all who have considered the matter. But this is not equivalent to saying that either opportunity or incentive will bring about charges that go beyond the limitations set by the germ plasm. "Men do not gather grapes from thorns nor figs from thistles." Such amazing results as those reported by Schmidt (1946) on the changes brought about in the intellectual status of a group of low-grade feeble-minded subjects by means of a not unusual type of educational program should be viewed with considerable skepticism, particularly when the large number of arithmetical errors in her published tables and the questionable accuracy of her original data as investigated by Kirk (1948) are taken into account.

The principle involved may be stated as follows: In respect to every human or animan trait, whether physical or mental, heredity sets limits to individual variability. For some characteristics the range of possible variation for the individual is wide, approaching that for the race. In most cases, however, it appears to be more or less restricted. Just how far the latitude extends in the case of intellect we do not know, nor are our present instruments sufficiently free from inherent sources of error to permit a final answer to the question, for a given change in measured IQ does not always and of necessity connote a similar change in the trait that the test is presumed to measure. If it did, a relatively small amount of coaching on the items of an intelligence test, which may temporarily raise the obtained results by as much as 20 to 30 IQ points with some residual effects as much as 3 years later (Greene, 1928), would richly repay the time and funds required for it! Greene also showed that training on material similar to but not identical with that included in the tests also had a measurable effect upon the results. That changes such as these are superficial rather than genuine indicators of intellectual differences can hardly be doubted. They suggest, however, that divergences in the IQ's of children reared under varying conditions of opportunity and training may likewise result wholly or in part from the fact that the intelligence tests in present use are indirect rather than direct measures. They deal with the results of learning, from which capacity to learn is inferred. When opportunity and incentives have been reasonably similar, the inference is sound, but its validity may well be questioned when a comparison is to be made between two or more groups for whom these factors have been markedly different. Failure to take account of the possible effect of a specified type of experience upon the validity of *test scores* as indicators of the kind of ability which they are presumed to measure may perhaps account for some of the differences in the opinions reached by those who have attempted to study the effect of experience upon mental capacity.

An additional source of disagreement is unquestionably to be found in unclear thinking about the real nature of the point at issue. In the scientific world it is idle to ask the cause of a present condition since causes lie in a past that cannot be reinstated. Our knowledge of causal factors is always derived by inference; we check the accuracy of these inferences by instituting anew the conditions or factors that we hypothesize as necessary antecedents of the present facts and wait to see whether similar consequences result. Because of the exceedingly complex nature of most biological phenomena, modern scientists are wary of accepting at their face value any etiological theories that fail to meet the following generally accepted criteria:

1. Have the experimental conditions necessary for testing the hypothesis been de-

scribed with sufficient detail and accuracy to enable others to make the same tests? That is, is the hypothesis susceptible of experimental validation?

2. When independent tests are made, are similar results obtained?

Whether it is theoretically possible *by any conceivable means* to modify the course of mental growth to any specified extent is an unanswerable question since no one knows what scientific discoveries the future may bring. Whether a method has now been found that can be described in such terms that others may profit by its use is a question that permits a straightforward answer. It is the second rather than the first question that the reader of the literature on this highly controversial issue must hold steadily in mind if he is to avoid becoming hopelessly entangled in a web of conflicting figures. The question involved is not, as many have been led to think, determining the factors that caused the present differences in mentality that we observe in children. That question cannot be answered because too many unknown variables are involved. The question is: has a practicable method been discovered by which the course of a child's mental development can be materially altered? And, if so, *in precisely what respects does this method differ from others that have proved ineffective?* To date, no useful description of such a method has been given us.

Concluding Discussion

In the treatment of this topic more emphasis has intentionally been placed upon the inadequacies and imperfections of our present methods of mental measurement than upon their positive values. These values have been thoroughly demonstrated. In spite of minor inaccuracies, in spite of disagreement as to exactly what it is that we are trying to measure and uncertainty as to what units we shall employ for expressing the results of our measurement, the fact remains that for most purposes and in most cases the tests work amazingly well. In the schoolroom, the behavior clinic, the offices of the vocational counselor, the juvenile court, or the child-placing agency, their practical value has been shown repeatedly.

In one sense it may be said that in the success with which they have been used lies their greatest weakness, for too often this successful use has engendered a blind faith in all test results to which some kind of numerical score is attached. Figures are likely to have a hypnotic effect upon most of us. Although we may know that the significance of a test score varies with the test used, the conditions under which it is given, and the age of the child tested, even the well-informed are often far too prone to feel that, once it has been calculated, an IQ is an IQ with fixed and absolute meaning. This attitude has led to two unfortunate errors in thinking. On the one hand, we have those who, on the basis of a single test, even when given at a tender age, are ready to "diagnose" the child's present mental level, make predictions as to his future, perhaps even take action with respect to matters of vital importance for his future. On the other hand, we have those who, with equally naïve confidence in the accuracy of the tests, regard every fluctuation in standing as indicating a "real" change in the child's mental level. Even a casual reading of the experimental literature on the extent and frequency of changes in IQ upon retesting children of different ages and after varying intervals of time should demonstrate the lack of scientific basis for either of these extreme views. Fortunately, the number who still adhere to them appears to be diminishing. A critical examination of the literature that has appeared since the

publication of Goddard's translation of Binet's 1908 scale shows an encouraging shift from the wholesale production of new and half-tried testing devices to the critical examination of the significance and accuracy of those already in use. Improved statistical methods have been applied to problems of scale construction as well as to the investigation of sources of error in measurement. The day is past when a simple statement of the "reliability" and "validity" of a test was thought to provide sufficient information as to its effectiveness.

Chapter 9

LANGUAGE DEVELOPMENT IN CHILDREN

Dorothea McCarthy [1]

Introduction

The amazingly rapid acquisition of an extremely complex system of symbolic habits by young children is a phenomenon which has increasingly attracted the attention of child psychologists as well as linguists in recent years. This area of child development is one of the most important for the child psychologist, not only because the possession of the ability to speak is one of the distinguishing characteristics which sets man apart from the lower animals, but also because of the intimate relationship which exists between language and thought. The increased interest in language development since 1925 appears to be due to the realization of the valuable insights which can be gained into the content of the child's mental life through the study of his linguistic expression, to the dependence on some form of verbal expression in introspective technique as well as in the adequate measurement of intelligence and other psychological traits, and to a recognition of the limitations of psychological observations of infancy, when language responses are not a part of the child's observable repertoire of behavior. There has also been in more recent years an increasing recognition of the important clues that can be gained as to the nature of an individual's personality adjustment from a study not only of the content but also of the manner of his speech and the form of his verbal expression both oral and written.

The word *language* has a wide variety of meanings, but in the present review emphasis will be placed on the ontogenetic development of spoken language in normal children. Some attempt will be made to show the setting of this aspect of language development in its broader relationships and to show the relationships of normal speech development to the acquisition of the secondary forms of language development in reading and writing and to personality adjustments. Only brief mention will be made of the fields of speech pathology, the physiology of speech, phonetics, linguistics, and semantics, which are much too highly specialized areas for any detailed treatment in the present review.

Excellent discussions of the various definitions of language are to be found in DeLaguna (1927), Pillsbury and Meader (1928), Esper (1935), McGranahan (1936), Eisenson (1938), Lewis (1948), and Miller (1951). In general, the various theories that have been advanced place the emphasis on different aspects of this tremendously complex process, and some recognize its plurality of function. Wundt (1901, 1911–1912) emphasized the expression of mental content, including both ideas and feelings, through language and considered that communication was only a secondary function of language. Pillsbury and

1 The writer makes grateful acknowledgment to her husband, Robert T. Rock, Jr., for invaluable bibliographical assistance and encouragement in the preparation of this chapter.

Meader (1928), however, stress the function of communication in language. In 1927 DeLaguna, after seriously criticizing Wundt's point of view, claimed that a fresh conception of speech as an essential activity of human life was needed. She thereupon advanced a social-behavioral view of the nature of language which has become rather popular with the increasing emphasis on the function of language in the total stimulating situation. J. Dewey (1926) also pointed out that "the heart of language is not 'expression' of something antecedent, much less expression of antecedent thought. It is communication; the establishment of cooperation in an activity in which there are partners and in which the activity of each is modified and regulated by partnership" (p. 179). Esper (1935) states: "The exclusive preoccupation with 'ideas' which are held to be 'expressed' by speech leads to a neglect of the behavior and concrete environment to which the speech is related."

K. Bühler (1934) distinguishes three functions of spoken language: representation, expression, and appeal. McGranahan (1936) points out that a speech phenomenon may be considered (*a*) in relation to the person who produces it, (*b*) in relation to the person or persons who hear it, and (*c*) in relation to the objective fact represented by it. Although Bühler recognized these three aspects, he was more interested in the speech phenomenon itself than in the social-psychological situation. Gardiner (1932) emphasizes four factors: the speaker, the listener, the words said, and the things referred to or spoken about. Much theory has been concerned with the speaker and with the words, but little attention has been paid to the listener and the things spoken of.

Linguists, who in the past have been concerned chiefly with descriptive and historical accounts and comparative details of the grammar of various languages, have become increasingly interested in problems of phonology and semantics. When the linguist thus raises the question of meaning he is led directly into the field of psychology, for he finds that meaning must be explained in terms of the situation in which the word is used. E. Horn (1942) considers that significant trends which have emerged in theory involve a greater recognition of the importance of language in all human culture, rejection of the view that language is the external reflection of psychical processes, as well as an acceptance of the fact that verbal symbols have a predominant function in thinking. Newman (1939) emphasizes the affective aspects of language and considers that they supersede in importance the intellectual and social aspects which continue to be stressed in the literature, especially by Lewis (1948) in his volume entitled *Language and Society.*

In order to realize the importance of language in the psychological development of the child, one needs only to consider the comparative mental vacuum in which the young deaf-mute lives before any means of communication have been established (Baldrian, 1940) and to compare his mental state with that of the normal child who not only can acquire a wealth of information through his understanding of the language of others but also can use language to express his ideas, needs, and wants, as well as to influence the behavior of others. The intimate relationship which most writers claim exists between language and thought is further evidence of the importance of this aspect of the child's development. Language, although perhaps not essential for all thinking, is so frequently involved in thought, and especially in making abstractions and fine distinctions and shades of meaning, as well as in communicating to others the results of one's thought

processes, that a certain basic level of attainment in linguistic skills is practically an essential prerequisite to the child's formal education. Vigotsky (1939) makes very provocative distinctions among external or vocalized speech, inner speech, and thought, and concludes that "Without a correct understanding of the psychological nature of inner speech there is no way of explaining the relation of thought to words in all its complexity," and that "thinking and speech are the key for understanding the nature of human consciousness" (p. 37).

As will be shown in this review, a basic mastery of spoken language is normally acquired very rapidly during the preschool years usually between the ages of 1 and 5 years, and the child whose language development is seriously delayed for any reason labors under an almost insurmountable handicap in his social and academic relationships. The earlier a child can acquire facility in linguistic expression, the sooner he is free to reap the benefits of the use of this valuable tool in all his social and intellectual pursuits.

Characteristics of the Literature

As in all aspects of child psychology, the study of language development began with the rather casual observation of isolated cases which were reported in the early biographical literature. Because linguistic development lends itself so readily to the method of direct observation without the use of instrumentation, it played a large part in the studies of the period of the child study movement in the 1890's. Most of these early biographical studies were concerned chiefly with the acquisition of vocabulary from the time of the appearance of the first word up to the fourth or fifth year, when the data tended to become unwieldy. A few dealt with the prelinguistic utterances of early infancy, usually without benefit of phonetics; and others attempted analyses of all-day conversations extending into the fourth and fifth years of life. Although this wealth of observational material proved stimulating and suggestive for later research workers, it has little scientific merit, for each of the studies employed a different method; the observations were for the most part conducted on single children who were usually either precocious or markedly retarded in their language development; the records were made under varying conditions; and most of the studies were subject to the unreliability of parents' reports. Since the 1930's there has been a revival of interest in the biographical method, with the employment of more refined techniques and special safeguards of objectivity (Lewis, 1951; Low, 1936; Grégoire, 1937, 1947; and Leopold, 1939, 1947, 1949*a*, *b*).

Since the 1940's there have emerged two main types of studies, first those dealing with the vocalizations of infants and utilizing phonetics and recording devices, and secondly those in the clinical literature emphasizing the genetic approach to language disorders; so that there seems to be a merging of the clinical and the genetic points of view. Studies of language deviates have become more concerned with the total personality and the dynamics of the disorders. They have ceased to treat symptoms and are more concerned with total syndromes and the search for causes. Thus, once more in this field there is evidence of the study of the abnormal throwing light on the course of normal development.

Previous Reviews. The literature in the field has been brought together from time to time by various authors. In 1833 Feldmann reviewed the reports of the vocabularies of 33 children, and in 1883 Sikorski gave a brief review of studies in foreign languages. In 1899 Franke surveyed about 200 titles for the German *Handbook on Education,* edited by Reins. Preyer (1889*a*)

compared his son's progress in speech with that reported by Sigismund (1856), Lindner (1882), and others. Tracy (1893) presented an excellent summary of the studies of children's language up to 2 years of age, and Meumann (1908) discussed the early anecdotal accounts in the foreign literature with emphasis on the work of Lindner (1882), Ament (1899), and Gheorgov (1905). In 1907 appeared the classic volume, *Die Kindersprache*, by Clara and William Stern, in which they presented detailed observations on their own 3 children and compared their studies with those previously reported in the literature. Between 1907 and 1920 tabular summaries of vocabulary studies were published by Doran (1907), Pelsma (1910), Grant (1915), Gerlach (1917), and Magni (1919). Doran (1907) compiled a summary table of the vocabularies of 98 children between 8 and 72 months of age, and Bateman (1917) summarized all the published reports on the first word. Dale (1949) classified 1855 titles of vocabulary studies and recognized 25 categories. His list is very exhaustive and cites many unpublished studies. In 1948 Lewinski published a review of studies dealing with vocabulary and mental measurement. Leopold (1952) has published an annotated bibliography of child language containing approximately 1200 titles. It combines references from several areas principally from the linguist's and the psychologist's points of view. The psychological references are borrowed with acknowledgment chiefly from the 1946 edition of this manual.

The *Twenty-eighth Yearbook of the National Society for the Study of Education* (1929) included abstracts of 123 published studies on language development in preschool children and 20 researches in progress at that time. The May, 1929, issue of the *Psychological Bulletin* was a "Special Language Number," but it placed little emphasis on linguistic development in the early years. In 1933 a special volume of the *Journal de Psychologie* consisted of a symposium by a number of well-known French psychologists and linguists on "Psychologie du Langage." Most of these articles, however, deal with theoretical problems of the origin of language and of the relationship between thought and language, as well as with problems of imagery and phonetics. Only two, those by Grégoire and Cohen, deal with the acquisition of language by children. The former is concerned primarily with phonetics in the first 2 years and the latter with the effect of infantile speech on the history of a language. McCarthy (1929*b*), reviewed the reports on infants' vocalizations up to and including the appearance of the first word, and later published more extensive reviews in the *Handbook of Child Psychology* edited by Murchison in 1931 and 1933. A rather comprehensive review of 162 titles by Decroly was published posthumously, about 1934. E. Dewey (1935) devotes about 40 pages of her survey of the literature on the period of infancy to a discussion of studies of language development which appeared between 1920 and 1934. Arsenian (1945) summarized investigations on bilingualism, and Eames (1950) reviewed 24 studies dealing with the relationship of reading and speech difficulties. Some of the more recent investigations on infant vocalizations are summarized in Thompson (1952).

Whereas in 1930 scarcely more than an isolated paragraph or two on language was to be found in textbooks in psychology, nearly all the textbooks in child psychology which have appeared since then include a major chapter on this aspect of the child's development. Some of the best chapters on language appear in textbooks by Stoddard and Wellman (1934), Brooks and Shaffer (1937), Munn (1938), Goodenough (1945), Jersild (1947), Breckinridge and Vincent

(1949), Merry and Merry (1950), Miller (1951), and Thompson (1952).

Irwin (1941*a*) summarized literature dealing with the speech sounds of the first 6 months of life, and Irwin and Chen (1943) presented a comprehensive review of studies of speech sounds occurring in the first year. Fifty-five titles dealing with children's questions have been summarized by Fahey (1942), and Leopold (1948) has presented a highly critical, but not too informative, review of studies dealing with infant bilingualism with emphasis on German studies and those employing the case study method. A fairly comprehensive annotated *Bibliography of Speech Education* by Thonssen and Fatherson appeared in 1939. It is restricted to materials written in English and directed primarily toward the interests of those in the field of speech education. Part IV, however, deals entirely with language and phonetics, and one section of this part is devoted to references on language development. Froeschels (1948) edited a brief and rather superficial handbook for speech correctionists called *Twentieth Century Speech and Voice Correction* in which scattered bits of information on language development appear.

Quantitative Studies. The years since 1925 have seen the appearance of a series of interesting major studies on large numbers of children, which have employed scientific controls in the observation of more nearly representative groups. M. E. Smith (1926) standardized a vocabulary test for preschool children on 273 children ranging in age from 8 months to 6 years. She employed test words selected from the Thorndike (1921) word list which she elicited by the use of objects, pictures, and questions. In another part of this same study, she analyzed sentence structure in 1-hour records of the conversations of 88 children taken in free play situations. Her vocabulary test was revised by Williams and McFarland (1937). Another vocabulary test by Van Alstyne (1929) measured only the understood vocabulary of 3-year-olds.

In 1930 the writer published a study based on the recording of 50 consecutive verbal responses from each of 140 children ranging in age from 18 to 54 months. A representative sampling of the population was secured by using paternal occupation as a criterion of selection. The data were subjected to four major types of analysis according to (1) the length of response, (2) the complexity of sentence structure, (3) the function of the response, and (4) the proportions of the various parts of speech. Each of these analyses was carried on in relation to age, sex, paternal occupation, mental age, and age of associates. This monograph was condensed and appeared as Chapter 7 in Barker, Kounin, and Wright (1943), *Child Behavior and Development.*

A major investigation by Templin is nearing completion at this writing. Its purpose is to provide normative data over the developmental period from 3 to 8 years on the interrelationships of language skills. Data are being obtained from 480 representative subjects on vocabulary, sentence structure, length of sentence, and articulation of speech sounds. The same investigator is conducting a longitudinal study of articulation following the same children from 2½ to 6 years of age.

The general plan and methods used by McCarthy (1930) have been followed with minor variations by Day (1932), who duplicated the study on 80 pairs of twins, and by E. A. Davis (1937*a*), who extended the work to higher age levels, and who compared single children with siblings, twins, and only children. Fisher's (1934) study of 72 children of superior mental ability uses larger samples of conversations, but her analyses have much in common with the approaches of the above-mentioned studies. Later studies by M. E. Smith

(1933*b*, 1935*a*, 1939), Young (1941), and Shire (1945) also yield data which are fairly comparable with these investigations.

Piaget (1924), who attempted to study the child's thought processes through a study of his language, pointed out that the child's language was largely egocentric. His stimulating approach served as a point of departure for the functional analyses employed in these major American studies. His claims have not been verified by most of these studies when his method was taken literally. Much interest has centered around the interpretation of, and the attempt to harmonize, these apparently conflicting findings.

Some of the most valuable material on the development of the language sequence has appeared in the longitudinal studies of infant development by Shirley (1933*a*, 1933*b*) and by Bayley (1933). The normative studies of Gesell (1925, 1928), Gesell, Thompson, and Amatruda (1934, 1938), Gesell, Halverson, Thompson, *et al.* (1940), and those of C. Bühler (1930), C. Bühler and Hetzer (1935), and Cattell (1940) have also yielded significant findings regarding linguistic development. These observations made under standardized conditions on large numbers of cases have superseded the earlier biographical reports because of their greater scientific value.

The most elaborate attempt to study the development of articulation in young children was made by Wellman, Case, Mengert, and Bradbury (1931). Tests of language achievement were developed by Descoeudres (1921) in France, and more recently Williams (1937*a*) and his associates at Iowa (Little and Williams, 1937) have developed a language achievement test and have attempted to discover something of the interrelationships of the various aspects of linguistic development. A study by Young (1941) presents the results of records of 360 minutes of conversation per child on 74 children in four different situations. Half of the subjects were from families on relief and half were from upper socio-economic levels. Analyses are conducted on length of response, amount of talking, and the proportions of the various parts of speech. Rigorous grammatical rules, formulated by Jespersen (1933), were employed in the parts-of-speech analysis, and the results are related to the findings of six other similar studies.

An excellent study of written composition was conducted by LaBrant (1933), who used over 1000 subjects ranging from fourth-grade children to adult scientific writers. Although primarily interested in a comparison of deaf and hearing children, Heider and Heider (1940*b*) give data for a hearing group of 817 children, ranging in age from 8 to 14, which constitute one of the most valuable contributions on children's sentence structure in written language.

Goldstein's (1948) *Language and Language Disturbances* is concerned chiefly with problems of aphasia. Only about 10 pages are concerned with language development, and articulatory defects and stuttering are merely mentioned.

As will be seen in the next section, when appropriate allowances are made for selective factors as well as for differences in method and classification, a remarkable degree of uniformity emerges from these research projects regarding most of the important developmental sequences and group differences.

Developmental Stages

From the mass of data which has been collected on children's development during the past two decades in the various research laboratories, it seems as if it should now be possible to sketch an adequate picture of the child's linguistic development.

The various major longitudinal studies mentioned above were much broader investigations and observed language as only one aspect of the development of the whole child. They yield data on language, however, which are of considerably more value than the materials previously available. In the first place, they all involve fairly large numbers of cases (from 25 to over 100) per age level. There is some attempt to have moderately representative groups of children; the observations have all been made under identical conditions within each study; and the authors have in each case been consistent in the criteria which they have employed for the various items at different age levels. Furthermore, all these observations have been made by trained observers who were unrelated to the children examined and who could presumably be objective about the observations. In all the above respects, then, these data are far superior to the earlier isolated biographical studies.

On the other hand, a careful analysis of the material which emerges from such a group of comprehensive studies reveals a number of shortcomings. Since language development was only one aspect of the development observed, it has not been studied at regular intervals throughout the developmental period except by Gesell, who includes language items at all levels. Many writers leave gaps of several months, during which they evidently were more interested in motor, sensory, social, or emotional aspects of the children's development, and for which no language items appear in their scales. It is only by dovetailing the results of several studies, as the writer has done in compiling Table 1, that it is possible to fill in the developmental sequence for language during periods when this aspect of development is probably being obscured by some other aspect which is developing in a more spectacular manner and thus attracts the attention of observers. On a few points many writers have reported data which are apparently in marked agreement. Many items were noted by only one author and hence cannot be compared with the results of other investigations. On other items there is considerable agreement, but, since most of these studies were carried on almost simultaneously, it was not possible for later writers to adopt the terminology of earlier ones and to make their data comparable. The reader is thus confronted with a confusion of terms which appear to be similar but which do not guarantee that the various observers were actually noting the identical behavior in similar situations.

In this table the writer has assembled 126 items of linguistic development which have been reported in eight major infant studies covering the first 2 years. All items which involve vocalization on the part of the child have been included, as well as responses to the human voice, responses to verbal commands, and all responses which are indicative of the comprehension of spoken language. A few items listed by the authors as linguistic were omitted either because they were negative items, such as the report of absence of vocalization or because they did not involve vocalization on the part of the child and could just as reasonably be classified in a social development sequence. The entries in the table have been retained in the terminology of the original authors, and all ages have been converted into months to render them directly comparable. The items are arranged roughly in the order of their appearance. Tentative groupings, which seem reasonable on the basis of similarity of terminology have been made and are indicated by the horizontal lines which mark off groups of items describing almost identical behavior noted by different authors at about the same period. It will be seen that the range in months reported for the different

items is rather narrow within the horizontal lines. Occasional items noted by only one author appear in isolation in their proper chronological place. The few exceptions, in which items which appear on logical grounds to belong together but where there is considerable divergence in the age at which the behavior is reported, have been cross-referenced. Such discrepancies can usually be understood if one examines the criteria employed by the various authors for crediting the particular items.

Although the writer holds no brief for the tentative groupings which have been indicated in this table summarizing data on the language sequence, the table appears to have some interpretative value in suggesting possible groupings for future investigators who may be able to employ more uniform terminology and criteria in order to clarify this still obscure picture. Additional items are available up to 60 months of age in this group of studies, but they consist largely of the familiar intelligence test items, such as naming parts of the body, naming objects, naming objects in pictures, picture vocabulary and action-agent tests, as well as repetitions of sentences of various lengths. The objects and pictures employed take on variety so that the increasing numbers of things named have little or no significance from one investigation to the other. These difficulties begin to appear in the latter part of the table, but, as the first few items named are probably more nearly comparable from study to study, and since several authors have data up to 24 months of age, it was arbitrarily decided to terminate this analysis with the last group of items for which the earliest entries occurred in the twenty-fourth month.

At first inspection of the array of items in this table the reader may be impressed with the length of the list and the amount of detail. If, however, he will mentally cross out all the items which are apparently duplicates, and list on a single line many of the items between pairs of horizontal lines, the amount of available information on the language sequence from the major normative studies will shrink appreciably. The reader will probably be impressed also with the striking degree of uniformity which is noticeable for the age at which similar items are reported in many instances where more than one author has observed the same or similar behavior with the same or almost the same criteria. Items 1 to 8 are, in general, descriptive of the utterances and syllabic vocalizations observed by most of the authors in the first few months. From the second to the fourth month are clustered all the reports of the infant's response to the human voice; the group of observations of cooing appears during this same time. Observations of vocalizations expressive of pleasure are reported by Bayley[1] and Gesell from the third to the sixth and seventh months, and of recognition in the seventh and eighth months. Variety in syllabification is heard apparently from the fourth to the sixth months and some rudimentary imitation of sounds from the sixth to the tenth months. Interjectional vocalizations are reported at the eighth month and listening to familiar words from the eighth to the ninth months. Response to gestures and to "Bye-bye" occurs from the ninth to the twelfth months.

The greatest discrepancies appear in the group of items from 57 to 60, in which the behavior is described in rather vague terminology and in which the various investigators may have employed different criteria for what constitutes "expressive sounds" and what constitutes "jargon." Differential responses to different words are reported by both Bayley and Gesell in the ninth and tenth months, and C. Bühler and Bayley agree in noting imitation of syllables and

[1] For bibliography references in this section, see headings of Table 1.

words in the eleventh month. Only two of these studies, those by Shirley and by Cattell, report data on the first word. Here, there is an apparent discrepancy, for Cattell notes a vocabulary of 1 word at 11 months, whereas Shirley notes it at 14 months. Shirley, however, recorded only words actually spoken in the presence of the examiner, although the mothers heard the first words considerably in advance of the time at which they were elicited during the examination. Cattell, however, accepted the mothers' reports of the occurrence of the first word. With the exception of C. Bühler,[1] all investigators report responses to commands of various sorts from the tenth to the twelfth months. Two words or more are reported quite uniformly at the twelfth month, with the third and fourth words following very shortly. The naming of single objects and pictures appears quite consistently in the latter half of the second year, as do responses to questions. According to the data available from this group of studies, children begin to combine words in the last quarter of the second year, and, as the vocabulary increases and the child enters upon the naming stage, there is a steady increase in the number of items named and objects pointed to in pictures on verbal request. Such items, numbered 104 to 126, are all clustered from the twenty-first to the thirty-sixth months with the majority of the reports occurring at about 24 months. The first phrases, sentences, pronouns, and prepositions occur in the twenty-third and twenty-fourth months and round out the most advanced accomplishments of the second year of life.

It is somewhat surprising that the same sequence of behavior should be described so differently by these authors, and even by the same author from time to time. It is also surprising that some items which are readily observable and which one might expect to find reported by all investigators as landmarks are so often overlooked. Inspection of Table 1 for single entries reveals an amazing number of items on which only one of the writers reports data. Inspection of vertical columns of this table also reveals that it is entirely possible for writers to conduct apparently very thorough studies of infant behavior of the inventory type and yet to have serious gaps of several months without the notation of a single language item. For example, Bayley does not have any language items from the twelfth to the seventeenth months, Shirley has none between the ninth and fourteenth months, and C. Bühler has none from the sixth to the ninth months or from the eleventh to the fifteenth months.

Another limitation of this group of normative studies is that none of the observers was trained in phonetics or employed any kind of recording aids, and none gives data on the reliability of observation.

Lewis (1951) working in England and Grégoire (1937, 1947) in France used the phonetic approach to the problem of infant speech, employing the International Phonetic Alphabet and a comparative case study method. Their techniques overcame the earlier difficulties of spelling notation and the use of diacritical marks, but still they dealt with only a few selected infants.

In her review on the period of infancy, in which the section on language is based largely on Decroly's (c. 1934) survey, E. Dewey (1935) states:

> The literature is in general agreement that the first sounds of the newborn infant are the overt elements from which speech develops; that vocalizations are used as means of communication before words proper are used; that comprehension appears before the use of words; that the normal child has a repertoire of a very few

[1] Bühler's group was definitely underprivileged and probably was a retarded group of infants, living in institutions.

words by one year of age; that development is slow in the first months of the second year, but that toward the end of that year a great increase in the speed of progress appears; that words are first used in a generalized sense, and that their use for specific meanings is a developmental process; that name words appear first, verbs and adjectives later, relational words still later, and pronouns are just beginning to be used by the most advanced children by the end of the second year; that the first words have the force of a phrase or sentence, and combinations of words do not begin for some time [p. 251].

Prelinguistic Utterances of Infancy

Students of child development have always recognized the tremendous importance of the period of infancy, which is perhaps most often described as the period preceding the assumption of the erect posture. Strictly speaking, however, the word *infancy* means the period *without speech*, since the word itself is derived from the Latin words *in* (meaning without) + *fari* (to speak). The derivation was pointed out in 1880 by Schultze, but this interpretation of the meaning of the period of infancy is rarely encountered in the modern child development literature, and one finds that the derivation of the word is overlooked and emphasis placed on the more dramatic and more readily observable change in motor behavior which happens to occur at about the same time as the onset of speech.

Research in this period when utterances are incomprehensible is fraught with many methodological difficulties, described by McCarthy (1929*b*). There is the problem of hearing correctly the fleeting meaningless sounds and of using phonetic notation correctly in order to record them accurately. Although much progress has been made in mechanical and electrical recording, little has been done to apply these techniques in the study of infant speech.

The most promising of the more recent developments in apparatus for use in this work are the spectrograph and Sonalator developed by the Bell Telephone Laboratories and described by Koenig and Rappel (1948), Kersta (1948), and by Koenig, Dunn, and Lacy (1946). These devices are sufficiently sensitive to give differentiable graphic records of consonant sounds, but practical research on infant sounds apparently will have to await development of motion-picture recording from the Sonalator.

Carmichael (1946) cites Minkowski's report of faint sounds uttered by a 5-month-old fetus (280 mm.) on exposure to the air as the earliest sounds observed in the human organism. Weak cries and spontaneous movements, more feeble than those of an infant born at term, were reported in a fetus of 330 mm. by Bolaffio and Artom (E. Dewey, 1935, p. 50). Thus, although the mechanism for the production of vocal sounds is ready to function considerably before birth, it is necessary to have the auditory and environmental social stimulation for language itself to emerge.

The Birth Cry. The birth cry is of significance for the development of language because it constitutes the first use of the delicate respiratory mechanisms which are to be involved in speech. Its function is entirely physiological, having to do with the establishment of normal respiration and the oxygenation of the blood. It is also the first time that the child hears the sound of his own voice and, as such, has significance for language development. The earlier interpretations of the child's first cry as having intellectual or emotional significance have largely been discarded and are now no longer held in the scientific literature.

Palmer (1940) reports briefly on a project involving the recording of the birth cry and of further recordings in the first 2 weeks of life. He found that children damaged at birth or prenatally have cries different from the cases delivered normally in pitch, rhythm, accentual character, and volume. Lynip (1951) reports the first graphic recordings of 2-second samplings of the birth cry of one child by means of a "sound spectrograph" developed by the Bell Telephone Laboratories. His pilot investigation on one infant involved taking weekly recordings for the first 13 months. Graphic records of selected utterances were obtained covering only 2.4 seconds' duration. These then require elaborate statistical analysis (not done in this study) of pitch fundamentals, resonances, intensities, etc. The method is an important step forward but needs considerable refinement before large-scale investigations will be feasible. The works of Cowan (1936) and of Hanley (1951) offer promising leads on methodology in this connection.

Later Sounds. It is almost universally agreed that the first utterances of the child are vowels of some sort. Observations in support of this are presented by Taine (1876), Preyer (1893), Tracy (1893), O'Shea (1907), Blanton (1917), Gesell (1925), Bean (1932), Shirley (1933*a*, 1933*b*), Lewis (1951), Irwin (1941*a*), Fisichelli (1950), and Lynip (1951), but from this point on there are divergent reports as to the order of appearance of the various speech sounds. The cruder observational studies were almost unanimous in reporting *m*, *p*, and *b* as the first consonants to appear and to modify the early vowel sounds into syllables.

Schultze (1880) states that the evolution of *lallation* is subject to the law of least physiological effort and that infants' phonetic utterances evolve from labial phenomena to sounds requiring greater effort, namely, guttural sounds. Ombredane (1935), however, disagrees with this early observation and, in harmony with Irwin, points out that development proceeds from phenomena involving strong muscular tension (the glottic) to those having weak tension but which are uttered by the lips, the most mobile speech organs. He considers that the pre-eminence of the labial phenomenon marks the beginning of cortical functioning and the approach of the period of imitation.

In spite of the former general acceptance of the early appearance of labial sounds which have been said to be formed quite naturally when the child closes his lips while uttering a vowel sound, there is an accumulation of evidence which seems to indicate that the front consonants probably are not the most frequent early sounds.

Lewis (1951), who presents one of the most detailed phonemic studies based on only one child, but carefully integrated with earlier reports of infant vocalizations, is also in substantial agreement with the findings of Irwin and his associates. Lewis makes the interesting distinction between sounds uttered in comfort and sounds uttered in states of discomfort. He groups all the back consonants of g, *x*, *g*, *k*, and *r* as the early consonants uttered in comfort and the front consonants, both nasal and oral, as later consonants which are usually uttered in comfort. With regard to the front consonants Lewis (1951) states:

> Many observers have noted the occurrence of the characteristic labial and dental consonants. In Stern's summary of the records we find that they appear after the back consonants and that the nasals (*m* and *n*) occur chiefly in states of discomfort [p. 26].

Lewis (1951) traces an interesting relationship between the child's movements which are characteristically made with the

vocal apparatus in typical states of comfort, usually after feeding, and in states of discomfort, usually in anticipation of feeding. The back consonants, which appear early and are said to be typical of periods of comfort, are associated with the swallowing and belching movements which usually follow feeding. In the prefeeding period the child typically makes mouthing movements with tongue and lips in anticipation of feeding which are most likely to result in the later *m*, *p*, and *b* sounds. It is obvious, however, that the infant needs some weeks of preliminary experience in the feeding situation in which to learn to make these anticipatory movements. It is probable that the earlier writers, who claimed that these labial and dental sounds appeared first, did not make their observations early enough in the neonatal period to get the first utterances. Hazlitt (1933) points out that no crying occurs in a state of comfort and that babbling occurs only in states of comfort. In general, the phonetic grouping of sounds for purposes of research in infant vocalizations appears promising. The reader who is interested in more detailed accounts of the phonetics of infant babblings should consult the works of Lewis (1951), and Grégoire (1937, 1947), Leopold (1947, 1949*a*, *b*), Fisichelli (1950), and Lynip (1951).

After the first acquisitions of sounds, there seems to be a rather rapid increase in the variety of sounds, so that by the third month most observers of infant behavior report cooing and babbling, which continue until about the end of the first year, when the first words are heard. K. C. Moore (1896) reports that her son had used all the sounds which occur in English by the fourth month. Lewis (1951) maintains that the child's first comfort sounds are really expressive and that they are subsequently transformed into playful babbling, that is, sounds uttered for the mere delight of uttering them.

Major experimental contributions to language development of infants have been made by Irwin and his associates at the University of Iowa. This reviewer has been able to locate a total of thirty articles by these writers scattered in various journals. Typically they consist of two- or three-page presentations of one or two facts, with emphasis on mathematical curve fitting and with a minimum of interpretation or discussion of the relation to child development or theory of language development. Four of them are reviews of the literature on infant vocalization (Irwin, 1941*a*; Irwin and Chen, 1943; Irwin, 1946*b*; and Irwin, 1949).

The most popular presentation appeared in the *Scientific American* in 1949, and the most technical of these reviews appeared in the *Journal of Speech Disorders* in 1943. At that time the authors concluded that it was quite obvious that a systematic knowledge of speech-sound status throughout the first year of life had not yet been achieved, and they characterized the literature as "spotty, meagre, and unscientific." Summarizing the reports for the first 6 months, they stated that during the second quarter of the first year of life infants produce most of the vowel elements and about half of the consonants. Contrasting the results of this period with the reports for the first month of life in which only about half of the vowels and very few consonants are present, they noted that a great expansion in the mastery of sounds occurs in the first 6 months of life (Irwin and Chen, 1943).

Three of their studies are concerned primarily with methods and the reliability problem (Irwin, 1941*a*; Irwin and Chen, 1941; and Irwin, 1945), and two are concerned entirely with variability (Irwin, 1947*b*, *c*). These authors use the International Phonetic Alphabet to transcribe the

speech sounds uttered during 30 breaths. The respiration unit was found more satisfactory than time units or speech samples of specified length for this type of research (Irwin and Curry, 1941). They use either consecutive or nonconsecutive breaths, during which crying occurs, in the studies of the newborn. Noncrying sounds are reported to be rare in newborns. It cannot be determined from the reports whether the "speech sounds" attributed to older children are also heard during crying or not, and in none of these reports do they give any information as to how long a time was required to secure vocalization during 30 breaths. The descriptions of method are so brief that it is difficult or impossible for others to duplicate the procedure. No descriptions are given of the conditions under which the observations were made.

Irwin was able, after taking all the phonetics courses offered at Iowa, and after considerable intensive training in phonetics under several phoneticians, and by keeping in practice himself, to train Curry and Chen to agree with him in the recording of the vowel utterances of newborn infants with percentages of agreement over 90. This was based on the speech sounds collected in 30 breaths for 18 infants. Continued observational practice did not improve observer reliability appreciably. It should be pointed out that the reliability data presented in the 1941 studies were limited to *vowels* in the *crying of newborn infants*. It is not surprising that high observer reliabilities can be obtained in the newborn period, when there are so few sounds to be discriminated, when the data are limited to vowels which have greater duration than consonants, and when crying, rather than noncrying, sounds are used, in which the sounds are sustained. A further study on the reliability of speech sounds, both vowels and consonants, appeared in 1945. This, however, deals with odd-even reliability and with different samples, and not with observer reliability. The reliabilities are very high, from .93 to .99 for vowels and from .88 to .97 for consonants, indicating high internal consistency when very wide age ranges contribute to the heterogeneity of the data.

The measures used in the Irwin studies are: (1) simple frequencies of the occurrence of each of the vowel and consonant phonemes, counting duplicates; (2) "types" of vowels and consonants, i.e., number of different sounds, or variety; (3) ratios of consonant to vowel frequencies; (4) ratios of consonant to vowel types; (5) type-token ratio (TTR), which is the ratio of the variety of sounds to the frequency of use; and (6) two indices based on the difference between the number and percentage of phonemes in infant and adult speech. In addition, some of these studies utilize a profile technique (Irwin, 1941*b*) in which a series of single phonemes or groups of phonemes, such as labials or dentals, are arranged along a base line and histograms are erected to indicate their frequencies in per cent. Comparisons of such profiles from age to age or from group to group are helpful and informative.

The earlier articles (1941) are based on 40 infants in the first 10 days and on some small groups of 10 to 15 infants in the first 6 months. The later articles (1946–1948) are all different analyses of the same basic data from 95 children in the first 30 months of life. The original plan was to visit each child twice a month in a longitudinal study, but owing to the war many cases were lost. There are many retests of the same babies in the data. The largest number of subjects at any bimonthly age group is 80, and the numbers dwindle after 20 months, the smallest number, 19, occurring at the 29–30 month age level. The number of records per age level ranges from 27 to 181. The

basic data from seven articles are summarized in Table 2. The articles themselves present growth curves for each of these functions, together with the mathematical equations for the curves. In evaluating the data it must be kept in mind that these studies are not independent but are based on the same records from the same babies, observed by the same workers, with similar training, who worked together.

The main points of developmental significance in the data of these studies are: (1) The frequency of vowel sounds is greater than that of consonant sounds in the first 30 months. (2) There is a steady increase in the frequency of vowel sounds until 2 years of age, but then there is a rapid spurt in the curve for vowel frequency as soon as real speech emerges. (3) In early infancy vowel sounds are about 5 times as frequent as consonant sounds. (4) The curve for consonant frequency in this period is parabolic. (5) Consonant frequency does not equal vowel frequency until about 2½ years of age. (6) In the first 2 months children used on the average 4.5 different vowel sounds and only 2.7 different consonants. (7) The number of vowel types exceeds the number of consonant types throughout the first year, but at this time, when the first words usually emerge, the two curves for vowel and consonant types cross, and the number of consonant types exceeds the number of vowel types at all later ages observed. (8) By 2½ years the child uses practically all of the vowel sounds, but only 16, or about two-thirds, of the consonants he will use as an adult (Irwin and Chen, 1946*a*; and Chen and Irwin, 1946*a*). (9) During the first 2 months the child's phonemic repertoire consists of 7.5 different phonemes, and by 29–30 months it includes 27 of the 35 phonemes present in adult speech (Voelker, 1935), the progress being greater in the first year of life than in the succeeding year and a half (Irwin and Chen, 1946*a*). (10) Sex differences do not emerge until the 26–27 month age level when, at about the age for the onset of true speech, the curve for the girls forges ahead of that for the boys. (11) When consonants are considered from the point of view of manner of articulation, the nasals show a marked increase with age, and the fricatives decrease with age in the first 30 months. (This may conceivably be related to the shift from the lying to the erect posture which occurs during the age span covered.) (12) When consonants are considered according to the place of articulation, back consonants, especially glottals, predominate at first, constituting 87 per cent of the consonants. These and the velars account for 97 per cent of the few consonants used in the earlier months. As the other types of consonants made with the forward parts of the oral cavity, namely the post-dentals, dentals, and labials, emerge the glottals drop to only 8 per cent of the consonants by 30 months of age. (13) When vowels are analyzed according to place of phonation a reverse situation is observed, for the front vowels decrease from 72 to 47 per cent and the back vowels increase from 2.3 to 37 per cent by 2½ years of age. (14) Initial consonants yield a linear curve in the age range studied and exceed medial and final ones. (15) Final consonants are negligible in the first ½ year and are then mastered at an accelerating rate, though they never exceed the initial or medial consonants.

In an unpublished doctoral dissertation under the writer's direction Fisichelli (1950) obtained high-fidelity tape recordings of ½-hour vocalizations of 100 institutionalized infants. There were 20 children at each of five discrete age levels from 6 to 18 months. In general her findings in regard to consonant development agree very well with Irwin's investigations although

TABLE 2

SUMMARY OF BASIC DATA IN SEVEN IRWIN STUDIES

Age in Months	No. of Subjects	No. of Records	Mean No. of Phonemes [1]	Mean No. of Vowel Types [2]	Mean No. of Consonant Types [2]	Mean Vowel Frequency [3]	Mean Consonant Frequency [3]	Mean Ratio of Consonant Types [4] / Vowel Types	Mean Ratio of Consonant Frequency [4] / Vowel Frequency	Type-Token Ratio in 100 Sounds [5]	Relative Frequency of Vowel Sounds Classified by Place of Articulation [6]			Relative Frequency of Consonant Sounds Classified by Place of Articulation [7]

the institutionalized children showed retardation in comparison with his subjects living with their own families. Fisichelli, too, found regular increases with age in consonant/vowel ratios. When the aspirate *h* phoneme is omitted (some phoneticians class it as a vowel) she also found a decline in back consonants and an increase in front consonants with increase in age. These measures seem to be of real developmental significance. Vowel data from this study and from the Irwin investigations are, however, more difficult to harmonize. This is probably due to differences in phonetic transcription. The Iowa workers observed the babies directly and undoubtedly were influenced in their notations by lip-reading techniques, whereas in the Fisichelli data transcriptions were done directly from the tape recording so that only auditory cues were used. Then, too, the dialects spoken by middle westerners differ from those of the eastern-seaboard transcribers probably so as to affect the vowel notations especially. Subsequent work by Curry (1950) and by Siegenthaler (1950) shows the difficulties involved in correct identification of vowels without the aid of context, as is necessary in dealing with the utterances of infants. Future workers in this field would do well to heed the warnings stated by the famous linguist Sapir (see Mandelbaum, 1949) in an article entitled "The Psychological Reality of Phonemes."

A few additional points in the Irwin studies concerning relationships to intelligence, socio-economic status, size of family, and institutional experience will be discussed in the appropriate sections. It is to be hoped that these authors will some day integrate this material in monograph form with suitable interpretation and that their promising techniques can be mastered by others, so that such basic investigations can be verified and the findings related to other aspects of child development. Thompson (1952) is the first to summarize these studies in a major text.

As more objective and more refined observations on the vocalizations of infants begin to appear in the literature it is possible to fit various aspects of the puzzle together and to see an emergent pattern in the prelinguistic utterances. Much of the confusion in the literature is undoubtedly due to the tendency of authors to speak of "sounds" and not to differentiate between vowel and consonant sounds, which Irwin's investigations show have directly opposite developmental trends. Another difficulty is attributable to failure to distinguish between sounds uttered in crying and non-crying vocalizations. In the Irwin and Curry (1941) study approximately 50 per cent of the consonants of newborns were the aspirate sound *h*. It occurred in their data 4 times as often as the next most frequent consonant. Other writers who report *h* as among the earliest sounds are Blanton (1917), Fenton (1925), Bean (1932), and Shirley (1933*a*, *b*). Lewis (1951) also gives an explanation of the early appearance of the *h* sound, which he says "is the sound heard if the voice is momentarily withheld in the act of uttering any vowel" (p. 30). It must be remembered in interpreting observations such as this that the organs used in speech are also used for respiration, which biologically is their primary function, and only later are they used for speech, for the essential accomplishment of the newborn, if he is to survive, is breathing. It should not be surprising, therefore, that the young infant, whose breathing is just becoming established, and whose early utterances are almost all in crying states, should have the most frequent consonant sound designated by the letter *h* which in its Greek origin meant "rough breathing." The frequency of occurrence of this aspirate sound, *h*, and its classification as a consonant, contributes

heavily to the generalization that consonant development proceeds from back to front, in contrast to the front to back development of the vowels.

Evidence has been mounting in the direction of what Goldstein (1948) aptly terms an "organismic" approach to language development, as opposed to the earlier conceptions which he characterizes as "atomistic" theories. He considers that "every individual speech performance is understandable only from the aspect of its relation to the function of the total organism in its endeavor to realize itself" (p. 21). He stresses the importance of the meaningfulness of sounds uttered in each situation. In order to understand the organismic concept of language development it is well to keep in mind some of the principles of organismic development as they have emerged from studies of physical and motor development (McCarthy, 1952*c*). Certain of the more recent theories in the literature seem to fit in with the laws of developmental direction, that the development of the organism proceeds from anterior to posterior parts of the body and from medial to more peripheral organs. The ideas on language development seem to harmonize also with the theory of motor development proceeding from mass activity through control of gross muscles to the finer muscular coordinations, and these concepts, in turn, enable interpretation in terms of the total organism and make possible an understanding of the triple functioning of the organs of speech in breathing, eating, and speaking (McCarthy, (1952*c*).

Shohara (1935) points out that both food-getting movements and speech movements serve the same purpose of advancing the general welfare of the organism through facilitating its direct or indirect integration with the environment. The thesis is presented that speech movements of oral and pharyngeal structures are modifications of the various movements involved in eating, namely, sucking, swallowing, and chewing. Shohara claims that aside from the articulatory movements, no movements of oral and pharyngeal structures are known to exist which cannot be shown to be concerned with providing food, including gaseous food or oxygen. This author goes so far as to state that in the articulation of the various consonant sounds the specific action of each muscle or muscle group bears "a close resemblance to, or even identity with, sucking, swallowing, and chewing." It is interesting to note that speech does not emerge in the normal child until after breathing is well established and has become automatic, the child has assumed the erect posture for most of his waking time, and has had some experience with solid food which affords exercise of jaw muscles in chewing (McCarthy, 1949*c* and 1952*c*). Shohara points out further that over 80 per cent of the consonants in Indo-European languages are made with the lips and tip of the tongue, and then traces the origin of consonant development from movements of the tongue in sucking, chewing, and grinding. In vowels, however, an opposite situation is noted as they are formed by the contraction of the muscle fibers in the posterior part of the dorsum and root of the tongue, which are the muscle groups used in swallowing. Is there not a parallel here between this theory of Shohara (1935) and Irwin's findings that vowel development proceeds from front to back of the oral cavity and that consonant development proceeds from back to front? May there not be a parallel between the mass activity of the newborn and vowel development? Vowel sounds are made by the stream of breath passing over the vocal cords into an oral cavity of varying shapes at varying times. This oral cavity is smallest when front vowels of *i*, *I*, etc., are be-

ing made, and these are the vowels which appear first. Then the cavity gradually becomes larger as the mouth is opened wider and the tongue is retracted, for after birth the child no longer needs to use it as a valve to keep out amniotic fluid and is able to live in the medium of the air. This probably is the raw stuff out of which more specific speech sounds, particularly syllables, are individuated.

The consonants however, which result from control of tongue and lip movements, particularly in the anterior regions, develop later, and this development progresses from the back of the oral cavity toward the front. The aspirate *h* and the guttural and velar sounds are first among the consonant group when the young infant is just establishing breathing and when he is learning to suck and to swallow. Vowels predominate during the early months while the infant is still a nursling and remains in a dorsal or prone position most of the time. This theory, it seems, could eventually be harmonized with the observations of regular sequences in the appearance of the various phonemes (Grégoire, 1937, 1947) and with Jakobson's (1941) contributions on comparative linguistics, which show, as Goldstein (1948) puts it, a "constancy in the sequence of the occurrence of sounds [which] indicates that we are dealing with a fundamental phenomenon characteristic of man." Goldstein (1948), however, was not familiar with the Irwin investigations and, going only on the cruder observations of the biographical studies, found it necessary to omit the babbling period in order for his organismic point of view to hold. He rightly points out that Schultze's law of least physical effort is difficult to validate because we do not know which movements are "easier" to make than others. It seems highly probable that in the near future all these points of view can be harmonized to include the babbling period in the developmental sequence.

As McCarthy (1952c) points out, there are five important changes which occur in infancy before the onset of true articulate speech involving syllabic utterances which combine vowels and consonants in meaningful units. After the survival of the infant is fairly well established by the successful maintenance of respiration and ingestion of food, the two primary uses of the organs of speech, he assumes the erect posture. He sits up at about the time he enters into the babbling stage. This postural change must affect the shape of the oral cavity, especially by affecting the normal position of the soft palate, which undoubtedly accounts at least in part for the forward movement of the control of muscles involving the later-appearing consonants. Two other changes, which follow shortly in the last quarter of the first year of life, are the experience with solid food, which stimulates chewing and exercises jaw muscles, and dentition. As chewing activity increases and nursing and suckling activity decrease, the sucking pads in the cheeks of the infant become absorbed, which again alters the shape of the oral cavity. He also acquires front teeth, usually 4 upper and 4 lower ones by the end of the first year, which give a new front wall to the oral cavity and make possible dental and postdental consonant sounds. It is only after respiration has been satisfactorily established, after the child has assumed the erect posture, has ceased to be nursed, has begun to use solid food, and after the frontal incisors have erupted, that the onset of true speech is observed. As control of tongue and lips proceeds and dentition provides the frontal wall of the oral cavity, cortical control of speech sounds begins, and the infant voluntarily imitates the speech of others and imitates his own speech sounds. According to Berry and Eisenson

(1942), "The spinal cord subserves speech directly only in breathing." Swallowing, sucking, and chewing are innervated chiefly through the medulla, and many writers have attributed cortical control to the tongue tip and lip movements involved in the later-developing front consonants. Thus, the gross features of infant behavior, involving the use of the musculature of the organs of speech, appear to follow a neurological sequence from lower to higher centers of the central nervous system.

Other aspects of early infantile experience in oral activity, which should be mentioned for a full appreciation of the significance of this early period, are that the mouth is pre-eminent in the domain of touch in the newborn and that during this early period everything is explored with the mouth, when the palate is extremely sensitive. Also, hand-to-mouth reactions are one of the main ways in which the infant explores his environment. This oral exploration does not wane until after voluntary reaching and grasping and eye-hand coordinations are well established. It is possible that further study of some of these relationships may reveal facts of importance in the genesis of handedness and eyedness which are often found to be disturbed in cases manifesting clinical syndromes of language disorder at higher ages. Of interest in this connection is the fact that hand preference usually begins to be manifested at about the same age as the onset of true speech.

T. K. Davis (1938) stresses that the primitive sounds are not only action but emotion in action, and Ribble (1943) emphasizes the importance of the pleasure value of the sucking activity which relieves tension and establishes a vital relationship with the mother as the giver of this pleasure. Ribble considers that the sucking activity alone is satisfying and pleasurable to the child whether much food is ingested or not. T. K. Davis points out that the organs of the oral cavity have developed from the embryological "primitive gut" and that sounds have greater vital significance the closer their activating organs are to the visceral regions. He considers that the lips which are the most peripheral of the organs of speech and which have already been indicated as probably being under cortical control dominate the expression of ideas rather than the expression of emotions. These suggestions have interesting implications for the study of the emotional tone of many of the child's early sentences (McCarthy, 1930) and for the importance of the mother-child relationships in many of the language disorders (McCarthy, 1946, 1947, and 1952c).

Sherman (1927) showed that adults had little success in judging the emotional accompaniment of infants' cries when the stimuli were not known. Interpretations of the cries were most often based on what was known regarding the stimulating situation and not on any peculiar characteristics of the cries themselves. Blanton (1917), who was the first to observe as many as 25 babies during the first month of life, states: "There were differences of vowels and consonants, of timbre and degree, but no one was used as response to one set of circumstances that was not at the same time used to others—the cry of colic was the one exception." She also states that the other cries of the infant in the first month of life in response to hunger, pain, and cold differ from each other only in intensity.

Lynip (1951) in his spectrogram analysis of the "hunger" and "attention getting" crying of one girl infant states that it was impossible to find sound values corresponding to the interpretations attributed to the various "types" of crying. The designations of "hunger" and "attention" given the cries by the mother and the experi-

menter were in terms of probability favoring one designation over another because it preceded or followed a feeding period. This author reports that "crying samples differed even though the observable stimuli remained the same" and, further, that "there was some partial resemblance in certain crying when stimuli differed."

Most writers agree that children's speech sounds are much less precise and definite than those of adults, and that during this preliminary babbling period of infancy there occurs increasing definiteness of utterance of various syllables. The often-reported observations that young infants at first use only a few vowels and later add more and more sounds to their verbal repertoire, and the frequent observation of the persistence of baby-talk which is gradually outgrown, have led many writers to assume that the speech sounds are acquired very gradually and that the complex sounds are built up from the simple ones. A number of articles, however, tend to bring this theory of the learning of language into question, for many writers have indicated that they find a tremendous variety in the vocal repertoire of the infant and that they hear many sounds which defy spelling in our alphabet.

McGranahan (1936) says that there are two main types of theories of the evolution of language. One which was popular in the nineteenth century conceived of the development of language as a building-up process involving the progressive combination and integration of a number of elementary units called *roots*. The other more recent theory championed by Jespersen (1922) considers the process of evolution to be one of progressive differentiation of a number of primitive mass units. McGranahan (1936) further points out:

> These two theories of linguistic development have interesting counterparts in modern physiological and psychological theories of development. The root theory, for example, corresponds to the reflex theory of behavioral development, according to which more mature and complex behavior results from the combination and integration of a number of elementary reflexes; and the mass theory to the modern psychological conception of behavioral development as the progressive differentiation of original mass activity.

Children whose mother tongue is to be English, and who are hearing only English, often use sounds resembling German umlaut sounds, French guttural *r*'s, and a wide variety of sounds which it is difficult or impossible to describe. These phenomena are usually attributed to the plasticity of the child's speech organs; and, since any child regardless of his parentage learns the language which he hears spoken by those in his environment, it is claimed that the sounds needed for any particular language which the child is to learn are selected from this extensive repertoire and are singled out for practice because they are heard so frequently. Latif (1934) states that out of this astonishingly rich and varied repertoire of sounds those which are used by the child's elders are reinforced and become habitual and others cease to be uttered. He goes on to state:

> Almost as soon as sounds begin to be produced at all they begin to be repeated rather slowly and monotonously. . . . This *repetition*, or *reduplication*, may well be considered the final step in that process by which the mere vocalizations become organized into language. It is here that explanation of the development of language must begin [p. 62].

Children's babbling often consists of repetition of identical or similar syllables so that the first vocal utterances to acquire meaning are usually reduplicated monosyllables such as *mama, dada, nana, bye-bye,*

tick-tick, choo-choo, and the like. Writers who hold to slow acquisition of sounds and the building-up of the repertoire of speech sounds by imitation, and the gradual perfection of each, stress the difficulty of the sounds from the motor aspect and claim that the sounds which are late in appearing are more difficult to execute. As Goldstein (1948) brings out, however, we do not know the relative difficulty of executing the various speech sounds. It has to be inferred from the time of their appearance.

Others, who see extreme variety in the plasticity of the vocal organs, take the point of view that the child can make the various sounds necessary for the acquisition of any language at a very early age, but they stress the sensory and perceptual difficulties of the acquisition of speech. E. Dewey (1935), in summarizing the literature on this point, says:

> There are a number of theories as to the way in which speech develops from the early vocalizations. In general, two opposing points of view appear: one, that learning goes on by a very gradual process of building up the complex from the simple; the other, that the original phonetic equipment of the individual is very large and that learning takes place by a process of adjusting, and eliminating, the sounds used to the language learned. . . . Grégoire, on the other hand, believes that the sound repertoire of the young infant is phonetically great and that a particular language evolves by the elimination of some sounds. The first sounds the infant makes are uncoordinated, and precision is gained gradually. In the beginning, the infant tries hard to express himself without awareness of trying to use words. He usually ends by crying. Later, about the ninth month, the combination of syllables begins. This sounds in its rhythm like an imitation of adult speech, and in the tenth month he begins to imitate the rhythm of the language of his country. Before the question can be decided we must have more exact, complex, and phonetically correct records of all sounds made by infants, from the time of birth to the appearance of speech [p. 252].

If Grégoire's theory of the beginnings of speech is substantiated by further investigation, it will be interesting to relate it to the known facts about the development of the gross motor skills in which there occurs individuation of specific movements from the random mass activity manifested by the newborn child. Irwin's researches summarized above appear to be the first steps in the demonstration that some such individuation occurs in the motor responses involved in the development of speech. McCarthy's (1952*c*) organismic interpretation attempts to relate some of Irwin's findings to certain physical and motor development patterns.

Grégoire (1937, 1947), Lewis (1951), Irwin and his associates, and Fisichelli (1950) have done the most extensive work using the International Phonetic Alphabet. Lynip (1951) questions the validity of this approach, however, for he claims that crying utterances of infants "cannot be expressed in sound values used to describe an adult's language sounds" and that "there exist no symbols representative of sounds made by infants before they learn to talk." He finds only "dim outlines of future sound forms in the spectrograms of babbling." This he attributes to the differences in size and shape of the articulating mechanisms of the child and of the adult. He finds a "similarity" of child utterances to adult speech sounds, but says that they are "lacking in clarity." He found in the child he observed that "a series of changes took place in the infant's sound production until, at the thirteenth month, a remarkable similarity could be observed between the infant's utterances and those of its mother." These sounds, however, were only approxi-

mately the equivalents of adult vowels and consonants.

The Rôle of Imitation. The mere fact that the child learns the language of his environment is evidence of the importance of imitation. Children imitate all aspects of the behavior of others. This is especially apparent in motor and verbal areas. The fact that the congenitally deaf child does not learn to speak because he is deprived of the opportunity to imitate others also bears witness to the important rôle of this factor. Imitative behavior is reported most often after the ninth month and is especially prominent around the end of the first year and the beginning of the second year when language proper is just beginning to emerge. Champneys (1881) said, "From 9 months the child distinctly imitated the intonation of the voice when any word or sentence was repeated several times." C. Bühler (1930) reports some elemental imitation of sounds as early as 6 months, whereas Cattell (1940) reports imitation of words as a test item at 9 months, and Gesell (1928) at 10 months. C. Bühler (1930) reports imitation of syllables such as *mama, papa,* and *dada* at the eleventh month and Bayley (1933) finds her group of infants imitating words at 11.7 months. Shirley (1933*a*, 1933*b*) reports the first imitative word heard in the presence of the examiners in the fourteenth month, although the mothers of the children in her group had reported such behavior considerably earlier. (See Table 1.)

The term *imitation* has been used in several different ways in the literature. Decroly (*c.* 1934) distinguishes the following forms of imitation (p. 88):

1. Imitation with and without intention to imitate which is sometimes designated as spontaneous or voluntary imitation.
2. Imitation with or without comprehension.
3. Immediate or deferred imitation.
4. Exact and inexact imitation.

It is over the last of these that so much controversy has centered. The most limited use of the term refers only to exact mimetic reproduction of the identical sounds said to the child as a model. Although this sort of reproduction undoubtedly does occur, it is much more rare than the second type, by which is meant the attempt to reproduce sounds heard, regardless of the accuracy of the accomplishment. Most present-day psychologists seem to agree with the opinion of Taine (1876) that new sounds are not learned by imitation of the speech of others, but rather that they emerge in the child's spontaneous vocal play as a result of maturation, and that the child imitates only those sounds which have already occurred in its spontaneous babblings. This view holds that imitation of the speech of others serves only to call attention to new combinations of sounds already used.

Curti (1938) also states:

> By repeating to the child other sounds which he has already spontaneously practiced, adults may evoke the sounds again and again and thus lead to facility in their use. No sound, however, will be thus repeated which the child has not already used [p. 261].

Shirley (1933*a*, 1933*b*) calls attention to the fact that there is a marked tendency to imitate the intonations and inflections of the voice regardless of the specific sounds.

Valentine (1942) distinguishes two types of imitation noted in his observations of his 3 children; first, the imitation of sound-making in general, which he called a "talking back" stage, occurring at about 2 months, and the later type consisting of distinct efforts to imitate specific sounds. He stresses "readiness to imitate" and describes efforts on the part of 2 of his chil-

dren "to imitate difficult words—combinations of sounds which they probably had not uttered spontaneously *as* combinations." An excellent discussion of the problem of imitation appeared in Guillaume (1925), which is well summarized in French by Decroly (c. 1934) and in English by Lewis (1951).

Lynip (1951), who was the first to obtain graphic recordings of an infant's utterances, states that as one listens to recordings of early imitations they appear to match the mother's sounds, but that "although there is a similarity, there is a lack of clarity to the infant's utterances." He states that exact mimetic imitation was not found, but neither was the child observed to produce the same sounds heard in previous weeks. The tendency to echo adult sounds was found, but the infant's utterances were constantly changing, successive modifications tending to approximate adult sounds more and more closely. The subject of his investigation did not produce any vowel or consonant sounds comparable to those of adults until the thirteenth month, and even then only approximations of adult sounds were noted.

When the child accidentally, and later purposefully, reproduces sounds which he himself has made, the adults in the environment usually say a real word which the child's sounds appear to approximate. This tends to give auditory reinforcement to the sounds the child has just made, at the same time making for more precise perception and rendition of the approved sound groups. Thus there occurs a progressive elimination of errors and a selection of movements which give the best approximation to the real word heard in the speech of adults. Continued practice thus results in the fixation of the sound groups, which come to be uttered habitually.

Basing his point of view largely on Guernsey's (1928) intensive study of 200 children between the ages of 2 and 21 months, Lewis (1951) outlines three stages of imitation. He cites the child's tendency in the first 3 or 4 months to respond to human utterance by making sounds as a rudimentary form of imitation. Most writers do not classify this early vocalization as imitation, but Lewis points out that it is really a question of the criterion of imitation to which one subscribes. He then notes a pause during which there is a "diminution, if not an entire cessation, of the vocal responses to speech typical of the first stage." The third stage which he recognizes is that which most writers report at about 9 months of age. He says: "There can be no question that in the second and third months children normally respond vocally to speech as speech." He argues for the imitative nature of these early sounds, which have been reported in the literature, on the grounds that "first, they most readily occur when the child is attentive to the speaker; secondly, the child's utterance is specially evoked by hearing adult speech; and, thirdly, this utterance consists of his own familiar sounds" (p. 73). He cites the Sterns (1907), the Hoyers (1924), Guillaume (1925), Valentine (1930), and C. Bühler (1931) as showing similarity of phonetic form between the vocalizations of the first 2 or 3 months and sounds spoken to the child by adults. He points out, however, that sometimes the child's responses do not resemble what he hears either in intonation or phonetic form and concludes:

> It would appear, then, . . . that the child's vocal response to adult speech in his earliest months consists of his own familiar sounds; when he hears a sound drawn from his own repertory, his response may occasionally resemble it in intonational and phonetic form.

Three different explanations of the phenomenon of imitation have been advanced

in the literature and are well summarized by Lewis (1951) as follows: "First, that there is an innate tendency for the child to respond to speech by speech; secondly, that the child responds by expression to expression; and, thirdly, that vocal responses to speech arise from intervention of the adult into the child's activity of babbling" (p. 76). In discussing the third of these explanations, Lewis points out that this is J. M. Baldwin's (1895) hypothesis of *circular reaction,* which has been accepted by such writers as the Sterns (1907), Bekhterev (1913), F. H. Allport (1924), Koffka (1924), Guillaume (1925), and McDougall (1931), and Allport's description of the circular reflex, which has been followed by Markey (1928), Lorimer (1929), and many others.

The general principle is that "in the course of repetitive babbling, a pattern of alternating hearing and utterance is set up; if an adult repeatedly imitates one of a child's own sounds while he is babbling, the heard sound becomes a part of the pattern of alternation, so that ultimately it remains effective in evoking speech which may resemble the stimulus both in phonetic and in intonational form" (p. 79). Lewis (1951) goes on to point out, however, that Baldwin's (1895) hypothesis which has been so widely accepted cannot by itself account for the child's learning of language through imitation, for the Sterns (1907), Koffka (1924), Guillaume (1925), and McDougall (1931) "have found it necessary to supplement Baldwin's (1895) principle by accepting at the same time the principle of a general tendency to respond to speech by speech."

Lewis (1951) believes he is the first, however, to point out that "the actually observed facts of early babbling and imitation demand that Baldwin's principle shall be modified and supplemented." He concludes then that "our only alternative is to recognize that the hearing of the adult word can merely stimulate the child to the utterance of his *own* babbling sounds and that from this the child may become trained to respond with a particular sound to a particular heard sound" (p. 80).

Training experiments in language presuppose imitation as a basic factor. One of the most conclusive experiments on this point was made by Strayer (1930) in which one member of a pair of identical twins was given intensive training in naming objects, etc., for a period of 5 weeks, whereas the other twin was deprived of all opportunity to hear language during that period. After this initial experimental period, similar training was given to the other twin. The author concludes:

> A maturational difference of even 5 weeks has a definite influence on the relative effectiveness of training. . . . Not only was training which was begun with a maturational advantage of 5 weeks more effective than earlier training, but the pattern of response was more mature. Training cannot transcend maturational level.

She adds that the typical stages in the learning process were strikingly alike for both children. Sommer (1932), who found a 28 per cent improvement in an untrained kindergarten group in articulation, also tends to show the influence of maturation, although her trained group showed a 57 per cent improvement due to the effects of both maturation and the training given in articulation.

Decroly (*c.* 1934) calls attention to a controversy in the literature on the problem of the relationship between imitation and comprehension of language. He points out that Compayré (1896), Sully (1908), and Meumann (1908) consider that vocal imitation comes before true language but that Preyer (1900) contends that imitation does not precede comprehension. His son

did not imitate the word *papa* until about the second year although he gave considerable evidence of understanding language in the period from 12 to 18 months. The Sterns (1907) are cited as pointing out, in contradiction to Preyer (1900), that sound groups are imitated long before the appearance of comprehension and that the imitation observed in their 3 children at about the ninth month was only imitation of gestures, inarticulate sounds, and intonations of the voice. Imitation of the combinations of articulate sounds did not appear until the end of the second year, at which time many words were understood and some pronounced correctly. As E. Dewey says:

> Decroly (c. 1934) concludes that auditory differentiation must precede speech and is a necessary element in imitation, and that development of comprehension and auditory perception are inseparable. He says that words do not have a purely tonal or musical interest for the child, and that he distinguishes only those to which he gives a meaning. Therefore, imitation cannot precede understanding, for function must not only be within the capacity of the individual, it must also serve some individual need or interest [p. 260].

Leopold's (1949*a*) third volume on the language development of his bilingual daughter is replete with illustrations of what he terms "mechanical imitation" especially in the use of interjections and in the 1-word-sentence stage. He stresses, however, the selectiveness of the child's imitation and points out that imitation is not a passive process but requires active cooperation on the part of the child and that the child is the one who chooses what he will imitate.

Language Comprehension. Most writers agree that the child understands the language of others considerably before he actually uses language himself. Abundant evidence for this appears in the anecdotal accounts in the early biographical studies indicating children's responses to commands and questions. Some of these incidents are subjective and are inadequately reported without complete description of the circumstances in which the utterances were made. From the normative studies included in Table 1 it would seem as if the child usually gives objective evidence in his overt behavior of his comprehension of the speech of others at about the end of the first year. There may, however, be a dawning comprehension at about the ninth month, when the child is reported as paying close attention to words and making differential responses to them.

Decroly (c. 1934) begins the discussion of the problem of language comprehension with a consideration of the child's earliest responses to sounds, especially to the sound of the human voice, and agrees that the first influence of heard words is affective in nature. He also discusses the problem of the length of the interval between the child's first comprehension of language and his actual use of linguistic expression. The Sterns (1907) are cited as maintaining that there is a relatively short interval between the time when the child first shows that he comprehends speech and his actual use of speech. Schäfer (1921), who took up this problem in detail, claims that most children show an interval of about 3 months between linguistic comprehension and expression.

Bean (1932) states that long before his child could pronounce a word he knew the meanings of a great many words. As a training method, he attempted to converse with the child in single words or short phrases at this period and secured 3 repetitions per item as evidence that "association links" had been formed between 152 words and phrases and the objects or acts to which they belonged. The process of

training in the comprehension of language is outlined by Lewis (1951) as follows:

> The child responds affectively both to the intonational pattern of what he hears and to the situation in which he hears it. And at this very same time he hears a phonetic pattern, inextricably intertwined with the intonational pattern and—in many cases—linked expressively or onomatopoetically with the situation. Then his affective response fashions a new whole out of these experiences, this new whole including the intonational pattern, the situation, and the phonetic pattern. When at last the phonetic pattern acquires dominance so that irrespective of the intonational pattern it evokes the appropriate response from the child, we say that he has understood the conventional word. Finally, there comes a time when the child on hearing the particular word refers to a particular object [p. 122].

Gesture Language

It is quite generally agreed that the child understands gestures before he understands words and, in fact, that he uses gestures himself long before he uses language proper. He looks for objects he has dropped, he reaches for objects, etc., long before he can ask for them. These and other overt bodily movements which are used as means of early expression and communication are often accompanied by early vocalizations. It has been claimed that words constitute substitutes for actual gross motor activity. The extreme point of view in this direction is represented by the behaviorists, who hold that the laryngeal movements involved in speech are actual substitutes for overt bodily movements.

An interesting analysis of gesture language is presented by Latif (1934), who says: "It is through the intervention of its elders that the general movements and postures of an infant gradually pass into symbolic gestures." He describes the hungry child seeking his bottle as manifesting "*whole-body* language, since the attitude and activity of its whole body convey meaning to an onlooker," but he goes on to point out:

> This whole-body language of the infant soon comes to be abbreviated, through the solicitous participation of the mother. As soon as the infant shows a nascent attitude of food-adience, the mother brings the bottle and thus cuts short the adient efforts of the infant. Whenever it stretches out its hand toward an object, the attentive mother is there to put the object in its hand. Such cooperation on the part of the mother soon reduces the whole-body language of the infant to mere ("conventional") gesture, in which *only a part* and that the earliest part of an action is substituted for the entire action. The responses of the infant thus become merely symptomatic, i.e., symbolic [pp. 76–77].

It is evident that just as the child's gesture may become reduced from the whole-body language to the merely conventional gesture, so those actions which are originally accompanied by vocalization may drop out entirely and the reduction of effort may limit the child's activity to only the vocalizations which come to have symbolic meaning. Latif (1934) also points out that "the child's understanding of the behavior of others does not begin with its appreciation of words; it begins with an appreciation of its elders' actions and gestures" (p. 79). And he states further: "As vocal language (tonal or verbal) develops, the gesture language recedes into the background. But not even at the highest levels of vocal communication do gestures ever entirely disappear" (p. 81).

Witte (1930) conducted some interesting experiments on gesture language in which he attempted to determine what are the limitations of gestures. He finds that con-

crete ideas and things within the visual field can readily be expressed in gestures, as can commands, questions, and negations. Many verbs and adjectives he finds can be gesticulated, but equality and similarity, the pronoun *it*, and auxiliary verbs are difficult to express in this way.

Much of the literature is obscure on the comprehension of adult gesture and language by children, for so much of it involves notation of the child's responses to commands. Often it is not stated whether the commands are accompanied by gestures or not. As may be seen in Table 1, C. Bühler (1930) specifies in items 75 and 76 that the commands were accompanied by gestures. Other investigators, however, report responses to commands at much earlier ages than she does, and they do not specify that gestures accompanied the commands, although it is rather likely that some gestural cues were employed; undoubtedly the authors would have specified any artificiality introduced into the situation by experimental controls. In all probability the discrepancy in ages is due to differences in the selection of cases.

Studies on the use of gesture language have appeared by Critchley (1939) and by Schäfer (1934). The latter author conducted several experiments in which he instructed children to communicate ideas by gesture only. Children described as of normal intelligence, and presumably normal hearing, interpreted the gestures correctly 67 per cent of the time. Children described as of retarded mentality and assigned to special classes, however, interpreted the gestures of their classmates 86 per cent of the time. As some older children were included in the retarded group, however, and as nothing is given regarding their hearing, caution must be taken in interpreting the author's conclusion that the lower the intelligence the greater is the tendency to use gesture. He considered that normal children inhibit gesture in favor of spoken communication. Valentine (1942) also claims that the part played by gestures in communication seems to be very slight in intelligent children who are encouraged by their parents in the use of speech. Since the essence of communication is the conveying of ideas to others, these findings if corroborated by more carefully controlled investigations may have interesting implications for education which characteristically places such a premium on verbal communication. Perhaps the use of more gesture and pantomime in the instruction of those less well endowed with verbal ability would prove helpful.

In discussing gesture theories of the origin of language, McGranahan (1936) says that kinesthetic experience is often proposed as the basis of natural representation, and he cites Paget's (1930) theory which claims that the origin and development of all language are based upon certain positions and movements of tongue, jaws, and mouth which instinctively imitate the events and objects of the outside world. The speech sound which comes from a particular imitative oral gesture is claimed to evoke the same gesture in the hearer and thereby to symbolize the referent of which the gesture is an imitation.

Lewis (1951) takes issue with the Sterns' (1907) view that "the early responses of the child to heard speech are fundamentally built up on natural gestures, whether of the speaker or of the child himself," and he says that "the child responds first to a gesture, then to the gesture accompanied by words, finally to those words in themselves." Lewis (1951) considers that such a description leaves out of consideration the child's early responses to the human voice, for it is evident that the child is quieted by talking and that he distinguishes between friendly and angry talking, and in general is responsive to affective intonations

of the voice long before he gives evidence of understanding gestures or of showing differential response to phonetic patterns of words.

Whereas the Sterns and others have accepted the point of view that it is easier for the child to understand the gestures than the language of others, Lewis points to the findings of Bühler and Hetzer (1935), who report that before 6 months of age no child observed by them responded to coaxing or threatening gestures and that an additional 2 months of maturity seemed necessary before such response could be elicited, but that specific responses to differences in the intonation of the voice were definitely established in these same children as early as the sixth month. Lewis (1951) concludes, therefore:

> What we cannot accept is Stern's suggestion that the response to gestures is prior to the response to the intonational patterns of speech. The child responds to both; each indeed may facilitate the effect of the other. Together they evoke an affective response from the child, initiating or inhibiting his acts [p. 121].

The First Word

Although it might seem as if it would be very easy to determine the actual onset of speech by noting the child's first word, there are a number of difficulties surrounding the determination of the exact age at which the child uses his first word. The first use of sound with meaning is usually considered to constitute the child's first word. This event is so eagerly anticipated by parents that they often read meaning into the child's early babblings which happen to coincide with the presence of certain persons, objects, or events in the environment. If the child habitually uses *da-da* in his babbling, and sometimes uses it in the presence of his father, when can it be said that "Daddy" is uttered to designate his father? If the criterion of using the word to mean only one person, and not using it in any other situation, is accepted, it is necessary to observe over a period of time, to note consistency of usage, and to see that the sounds are not used in other situations. This is rather a negative way of establishing the fact that the word is used with meaning, and it does not indicate positively the *first* time the word is *used with meaning*.

Other criteria are accompanying gestures which may make the interpretation of the child's usage more certain and observation over a period of time for recurrences of the sound in similar situations. Some observers consider the child's first word to be his first spontaneous utterance of a word with meaning (meaningfulness being inferred by the adult with little or no objective evidence as to the correctness of the inference); others consider it to be the first word that the child gives evidence of understanding; and still others consider it to be the speaking of a word in imitation of an adult's speech. With such varying criteria it is necessary to employ caution in interpreting data which have been reported on the appearance of the first word.

As Lewis (1951) puts the same problem:

> To discover how reference develops, we have to notice, by considering the child's behavior at times when he is speaking or responding to words, what is the function of a given sound-group both before and after he first appears to attach it to a given object. In other words, we have to judge of the meaning of a word by noticing its place in the child's activity.

Lorimer (1929) points out that "because of the variety of factors involved in the origin of words it is rather artificial to attempt ever to say exactly what is the child's 'first word.'"

Leopold (1939, 1947, 1949*a*, *b*), a linguist, who has written four volumes on the acquisition of speech by his daughter, gives four possible ages (8, 9, 16, and 17 months) as the age of her first word, stating: "The hesitation concerning the starting-point (of the 1-word sentence stage) arises from the question whether the interjection listed as the first word 0:8 is recognized as a word or not" (Vol. III, p. 2).

Earlier sections on imitation and on language comprehension have already indicated the chief points of view which have been set forth as to how the child's utterances come to have meaning for him. There is a tremendous psychological gap which has to be bridged between the mere utterance of the phonetic form of a word and the symbolic or representational use of that word in an appropriate situation. As Sapir (1921) says in speaking of sound elements in speech: "What distinguishes each of these elements is that it is the outward sign of a specific idea," and again: "The mere phonetic framework of speech does not constitute the inner fact of language" (p. 43).

As may be seen from inspection of Table 1, only two of the authors (Shirley and Cattell) included in this group attempt to assign an age level to the stage of linguistic development characterized by the use of a single word. Cattell (1940), who accepts the mothers' reports for this item, places it at 11 months, and Shirley (1933*a*, 1933*b*), who reports on the first comprehensible word spoken in the presence of the examiners, places it at the fourteenth month. She states, however, that most of the mothers reported that the babies had a vocabulary of 2 or 3 words at 1 year, but that speech did not occur so early during the tests as it did spontaneously in the presence of the mothers. Thus these two studies are probably in fairly close agreement that the first word actually does occur shortly before the end of the first year of life. C. Bühler (1930) reports the imitation of syllables such as *mama*, *dada*, and the like at 11 months, and Bayley (1933) reports imitation of words at 11.7 months.

In Smith's (1926) study none of the 13 children studied at 8 months had begun to talk. The 17 children whom she observed at 10 months had an average vocabulary of 1 word, and 52 children at 1 year of age had an average vocabulary of 3 words. Castner (in Gesell, Halverson, Thompson, *et al.*, 1940), however, points out that Smith's group was probably somewhat precocious.

The scattered reports on the appearance of the first word in the biographical studies have been collated from time to time by various writers. Feldmann (1833) gave statistics on 33 cases in which the mode for the appearance of the first word was at 16 months. Bateman (1917) summarized 35 cases, 18 of whom were English-speaking, 12 German-speaking, and 5 Polish and Bulgarian. Since all these cases were children whose parents were sufficiently interested to write articles on their linguistic development for scientific journals, it is probable that they represent a highly selected group. The age range in this group is from 8 to 15 months, with 43 per cent of the cases using the first word between 10 and 11 months of age. The boys usually reached this stage somewhat later than the girls, and the English-speaking children somewhat in advance of those speaking other languages, with the Polish and Bulgarian children considerably later than other nationality groups. The Sterns (1907) also summarized 26 biographical reports, but most of these are included in Table 3, taken from C. Bühler (1931), who presents data on 49 cases. The 3 cases reported as not using the first word until 20 months of age are reported by Bühler to be definitely pathological. Decroly (*c.* 1934) reproduces this table of Bühler's with the addition of an-

TABLE 3

TABULATION OF AGE OF APPEARANCE OF FIRST WORD

(After C. Bühler, 1931)

Age in months	8	9	10	11	12	13	14	15	16	17	18	19	20
Number of cases	3	7	13	6	5	5	4	1	1	1	0	0	3

other case at 11 months. For these data on children drawn largely from superior socio-economic backgrounds the mode for the use of the first word is at 10 months. The median for all cases is at 11 months of age. This agrees with the average age of talking reported by Terman *et al.* (1925) for his gifted group. His data were collected from the parents in retrospect after the children had been located as gifted children in school. Mead (1913), using rather crude techniques of parents' retrospective reports, gives the average age for beginning to talk as 15.3 months for normal children and 38.5 months for a group of feeble-minded children. The significance of these findings will be discussed in the section on the relationship between language development and intelligence.

In regard to the form of the first word there is rather striking agreement in the literature that it is usually a monosyllable or a reduplicated monosyllable such as *bye-bye, mama, dada, bebe, tick-tick,* and the like. Certainly the commonest words heard in the nursery of the child who is just beginning to talk are of the reduplicated monosyllable type. Perez (1889), the Sterns (1907), Kroeber (1916), and Shirley (1933*a*, 1933*b*) are among the many writers who call attention to this phenomenon. The frequently occurring syllables, which are heard again and again in the child's babble, readily become the familiar appellations of babyhood as soon as adults begin to note the child's consistent use of them in specific situations and begin to use them in talking to the child. The Sterns (1907) also point out how often these words are of an onomatopoeic character, having a natural connection between sound and meaning, such as *moo-moo* and *tick-tick*. Shirley (1933*a*, 1933*b*), who terms these "childish imitative words," states that they are apparently picked up from parents or older children in most cases rather than invented by the babies themselves.

Lewis (1951), after making a phonetic analysis of the first words of the 26 children reported on by the Sterns (1907) and observing his own son, states:

> The great majority of the earliest words are of a definite phonetic form: they consist of single or duplicated syllables in which the consonants are either labials (*p, b, m, w*) or labio-dentals (*f, v*) or tip-dentals (*t, d, n*); they are made with both lips or lip against teeth or tongue-tip against teeth (or gum ridge). . . . No less than 83 out of 110 (or 75 per cent) contain only front consonants, while 12 per cent contain one front consonant. Further, 85 per cent of the total are either monosyllabic or reduplicated (39 per cent of the former and 46 per cent of the latter) [p. 125].

These observations, it may be noted, agree with the data from the Irwin investigations and with the idea that sounds made with lips and tongue tip are associated with the onset of true speech and with the development of cortical control.

It is difficult to say exactly what part of speech the first words usually are since they are used in isolation for lack of supporting vocabulary. Frequently these words function as 1-word sentences (Lukens, 1894; the Sterns, 1907; Pelsma, 1910; Koffka, 1924; Bean, 1932; Brigance, 1934; and Leopold, (1949*a*). However, if only the form of the words is considered and the most frequent occurrence of the forms noted, the first words are characteristically nouns or interjections. Markey (1928) and Leo-

pold (1949*a*) give detailed accounts calling attention to the verbal function of many of the early nouns. By the use of gestures and intonations of the voice the child often uses a single word to convey a variety of meanings in different situations. The single word "ball" may mean "There is the ball," if uttered in the presence of a ball, accompanied by a pointing gesture; or it may mean "Where is the ball?" or "I want the ball," if uttered with a questioning or demanding inflection and accompanied by searching behavior. Meumann (1908) has stressed the point that first words are strongly affective and that they express wishes, feelings, and needs. He claims that if these early words do designate object names at the same time, such function is secondary to that of expressing the emotional relation between the child and the object.

The Growth of Vocabulary

After the appearance of the first few words used consistently with meaning in appropriate situations, there occurs a rapid increase in vocabulary as the child acquires the raw material of language which he is to utilize later in various combinations to express all degrees and shades of meaning. Many of the early biographical studies began with the appearance of the first word and proceeded to list cumulatively all new words as they were first heard in the child's speech. This method has proved moderately satisfactory for studies of the earliest stages of vocabulary growth, but soon the vocabulary becomes so extensive that the lists become unwieldy and adults find it increasingly difficult to detect the new words. Most such records have been kept on precocious children, and the various authors have not employed the same methods in counting plurals, inflections of verbs and adjectives; some counting the root word only once and others counting all derivatives as separate words, so that comparisons of the total vocabulary counts are almost impossible to interpret correctly. Other difficulties of interpretation arise, as Dale (1931) has pointed out, from the facts that various writers use different lengths of observation periods and employ different criteria for considering that a child "knows" a word. Some investigators recorded only words heard in spontaneous conversation, others recorded "words understood," some kept running cumulative accounts, others recorded all words heard within a week of the child's birthday, and some excluded words which had been in active use a few months before, but which appeared to have dropped from active use according to the latest sample.

The studies of vocabulary may be grouped into several types: (1) estimates of total vocabulary at specified ages (usually of single children); (2) analyses of total vocabularies according to parts of speech; (3) analyses of total vocabularies for subject matter; (4) analyses of the occurrence of the various parts of speech in samples of conversation; (5) analyses of the occurrences of the various parts of speech in compositions; (6) estimates of total vocabularies of groups by the use of the free association technique; (7) estimates of total vocabularies by the use of vocabulary tests; and (8) word frequency counts. The vocabulary tests have all been devised by employing different methods of sampling, so that serious methodological problems are raised. Some of the tests require the actual eliciting of the words, whereas others involve merely pointing to pictures and thus reveal only understood vocabulary.

Summaries of the vocabulary studies of preschool children have been attempted by Tracy (1893), Doran (1907), the Whipples (1909), Waddle (1913), M. D. Horn (1926–

1927*a*), and others. Outstanding among individual vocabularies recorded are those by Deville (1890), the Gales (1906), the Whipples (1909), Boyd (1914), Bateman (1914), Nice (1915, 1917), the Brandenburgs (1916), Haggerty (1930), and Brigance (1934). Dale (1949) has published an exhaustive bibliography of vocabulary studies. Attempts at complete enumeration of vocabulary have of necessity been confined to the preschool period, and at higher ages some form of sampling has been employed in the efforts to ascertain total vocabulary.

These studies indicate that there are marked individual differences in the size of vocabulary at any age. Shirley (1933*a*, 1933*b*) reports that on the average each baby in her group had spoken 36.9 different words in the presence of the examiners by the age of 2 years, the range being from 6 to 126 words. These figures are undoubtedly low estimates, for the sampling secured during the periodic visits of the examiners was probably much smaller than mothers would have reported for these same children had they kept complete records. Although tabular summaries of reported vocabularies have been compiled by some, they are not presented here because of the lack of comparability of the data from one study to another. For estimates of the probable normal vocabulary at various preschool ages the reader is referred to Table 4, from Smith (1926), in the section on vocabulary tests (p. 533).

The vocabulary appears to increase rather slowly at first, then quite rapidly throughout the preschool period, and then more slowly at least until mental maturity. It probably never stops increasing, as the individual is constantly learning the meanings of new words and learning new usages of familiar words throughout life. The age at which the rapid increase in vocabulary occurs is probably related to the age of walking in individual children, for Shirley (1933*a*, 1933*b*), Brigance (1934), and others report that there seems to be a plateau in language development during the mastery of a new motor skill, especially that of walking. Although there is enormous variation in the age of onset of both developmental phenomena, most normal children begin to walk before they talk. In many cases, however, especially among girls and among children who are more precocious in their intellectual development, talking precedes walking. In such cases there is likely to be observed a slowing-up of rate of improvement in vocabulary while the child is devoting most of his attention to mastery of the skill of walking. After such a plateau, rapid progress in vocabulary is likely to be made. (See section on relation to motor development, pp. 597–598.) Drever (1915–1916), Brigance (1934), and others report rapid vocabulary development associated with a vacation or trip to the seashore. With the broadening of the child's experience through travel there appears a marked increase in vocabulary. (See section on effect of environment, pp. 584–597.)

This is undoubtedly the same sort of thing that progressive educators attempt to do when they broaden the experiences of primary children in order to develop reading readiness. (See Strickland, 1951; and the National Council of Teachers of English volume, *The English Language Arts*, 1952.) Behrens (1939) stresses conditioning as the essential element in the acquisition of meaning and brings out the importance of supplying the child with a rich variety of experiences in order to increase his knowledge of meanings.

Analyses of vocabularies for content or for listing concepts known to children at various ages are of some value at early ages, but at later ages selective factors are probably operative to such an extent that generalizations based on such data are of little value. One of the most interesting

studies of this type is by Shirley (1938), in which verbatim records were made for 336 children from 2 to 5 years during a play period of 30 to 45 minutes. It was found that the four most common concepts related to the mother, home, father, and siblings. The eleven most frequently used word concepts all seemed to carry an emotional tone for the children. At least half the concepts seemed to arise out of common needs of children and another 20 per cent were largely expositional. These findings are of interest when the affective nature of infants' vocalizations is recalled as well as the high frequency of interjectional speech in the earliest words. It tends to emphasize the importance of the function of language to express feelings, wants, and desires.

The study of vocabulary is fraught with methodological problems. Some of the difficulties inherent in vocabulary research may be appreciated from a consideration of Vigotsky's (1939) comments to the effect that a word deprived of meaning is not a word but only an empty sound. Meaning he considers to be a basic constituent criterion of the word itself. He stresses, however, that meaning is not a static property of words but that the meaning of words develops. Werner and Kaplan (1950) have published an interesting experimental study which demonstrates with nonsense "words" how words acquire meaning through usage in various contexts.

Three basic difficulties which have contributed much to the confused state of the literature on children's vocabularies may be mentioned. The first is the difficulty of deciding on the proper criterion for *knowing* a word. Dale (1931) points out in reference to this matter that *know* is a relative term, since there are accretions to the meanings of words throughout life. He argues, therefore, that the *knowing* of a word should be defined in terms of the specific reactions one is able to make to a word. For example, is the child able to understand the word when he hears it spoken, or is he able to use it in his spontaneous speech, or is he able to read it? How many different shades of meaning does he know for the word, and in what variety of situations can he use it? Is he able to define the word, and, if so, how well can he do it? Such questions about the degree of *knowing* a word are carefully brought out in the study of Bear and Odbert (1941). They serve to show the psychological artificiality which enters into all vocabulary tabulations.

The second basic difficulty in vocabulary measurement, which has been stressed by Seashore (1933), Seashore and Eckerson (1940), and M. K. Smith (1941), involves failure to define *the word* as a unit of measurement. Seashore cites particularly in earlier estimates such as those by Kirkpatrick (1891), Brandenburg (1918), and Holley (1919) the failure to distinguish adequately: (1) among spoken, written, and recognition vocabularies; (2) between root and derivative words, which he says occur in the proportion of 1 to 3.4 words; (3) between commonest and multiple usages of words; as well as (4) among differences in policy regarding inclusion of special terms such as proper nouns, technical, foreign, obsolete, and provincial terms; and (5) among differences associated with various criteria of knowledge of a word. Seashore states that methods of sampling word lists from dictionaries gave very stable proportions of each type of word. Seashore and Eckerson estimated by the use of a four-choice recognition vocabulary test, considering the commonest meaning as correct, that the average college undergraduate recognized 35 per cent of the common basic words in the sample, 1 per cent of the rare basic words, and 47 per cent of the derivative words in the test which was

based on a numerical sampling of the items in the Funk and Wagnalls unabridged dictionary. The total vocabulary of college undergraduates, therefore, would be estimated at 155,736 words, the range being from 112,100 to 192,575 for the group studied. Comparisons of the various criteria employed to indicate different degrees of knowledge of a word showed high intercorrelations and yielded estimates of total vocabulary for a group within a range of 8 per cent.

On the third issue basic to the methods of vocabulary studies, Williams (1932) sounds a much-needed and wholesome note of warning to the makers of vocabulary tests regarding the methods of selecting words from the dictionary. Since all vocabulary estimates at higher ages are based on prediction from small samples, it is important that great care be exercised in the selection of the words to be used in the test. Williams points out that all available vocabulary tests have selected the test words by the page method, that is, by taking the last word on alternate pages or according to some such plan. He determined the expected frequency of children's words in the International Kindergarten Union (1928) list of 2500 words and found that the actual number of words of high frequency selected by the page method greatly exceeded the expected proportion. He also found that the larger the dictionary used in the selection the greater was the likelihood of the selection of these very common words for vocabulary tests. He attributes this phenomenon to differences in spatial allotment which favor the words in most common use and those which have the greatest richness of meaning. Naturally such words receive relatively more space in large than in small dictionaries. Williams recommends that the selection of test words in future vocabulary tests be based on the actual counting of ordinal position in the dictionary, taking every fifth or every tenth or every hundredth word. This appears to be a fundamental criticism of all previous vocabulary tests with the exception of the one just mentioned by Seashore and Eckerson (1940). Their change in sampling method, as well as their use of an unabridged dictionary, undoubtedly accounts for the unusually high, but probably more nearly correct, estimates.

The Seashore-Eckerson vocabulary test published by the authors at Northwestern University is available for grades 1 through 12. Norms have been established on 867 children by M. K. Smith (1941), who devised special adaptations of procedure for the lower grades. The odd-even reliability for this test was above .90 for grades 5 to 9, inclusive, but was less satisfactory at higher and lower ranges. For grade 1 the average number of words in the total vocabulary was 23,700 with a range of 6000 to 48,800, and for grade 12 it was 80,300 with a range of 36,700 to 136,500.

Although the estimates of total vocabulary obtained by Seashore and Eckerson (1940) and M. K. Smith (1941) are much larger than those previously noted in the literature, Hartmann (1941) in his critique of the common methods of estimating vocabulary size considers that even these may be gross underestimates by as much as 100,000 words. He used four lists of varying lengths from a single dictionary and found that all members of a group of normal-school graduates had vocabularies in excess of 200,000 words.

Part I of the Seashore-Eckerson test was given to all 16-year-olds in a typical midwestern community by Schulman and Havighurst (1947). Their results agreed closely with those reported by M. K. Smith (1941). Lovell (1941) and Odbert (1948) both report multiple-meaning vocabulary tests. Lovell (1941) concludes that intensity or richness of vocabulary is fairly closely re-

lated to knowledge of single commonest meanings.

Bear and Odbert (1941) studied the degree of insight which pupils have into their knowledge of words and found the often-used method of checking known or unknown words unsatisfactory as pupils identified as unknown fewer than half the words they missed on a vocabulary test. Those having the poorest vocabularies had least insight into their own limitations.

Another vocabulary test for grades 3 through 8 was devised by Gansl (1939). It consists of 100 items of the sentence type of multiple-choice questions. It has a reliability of .94 for 190 eleven-year-old boys, and norms are based on 3306 children. Items were carefully selected from among those of 22 current vocabulary tests; frequencies were determined on the basis of the Thorndike Word List (1931–1932), and the order of difficulty was empirically determined. The author seriously questions "the naïve acceptance in many former tests of the frequency ratings as measures of difficulty," which she found to be wholly unwarranted. The test yields raw and derived, or "D scores," but no estimates of total vocabulary. The curve for vocabulary growth from age 8 to 13 was approximately a straight line with a tendency toward negative acceleration from 12 to 13 years.

Recognition of the multidimensional nature of vocabulary has been revealed in several studies. Feifel and Lorge (1950) published a qualitative analysis of the responses of 900 children ranging from 6 to 14 years of age to the vocabulary test of the Stanford-Binet Form L Scale. The younger children more often employed the use, description, illustration, and demonstration types of definition as well as inferior explanation and repetition responses. Older children significantly more often used synonym and explanatory responses. The younger children were found to perceive words as "concrete" ideas, whereas older children stressed the abstract or "class" features of a word. Similar tendencies were brought out in regard to the Wechsler-Bellevue vocabulary scale by Gerstein (1949).

Parts of Speech. In the analyses according to the various parts of speech three approaches have been used which yield quite different results. The first, which is suitable only for the vocabularies of very young children where there may be some reasonable expectation of approximating the total vocabulary, is to calculate the proportions of the total number of words in the entire vocabulary, however defined, which belong in each category of the various parts of speech. This method always yields a very large proportion of nouns, merely because nouns are predominant in the language and hence are most numerous in any dictionary. The samples taken for very young children also yield an unusually high proportion of words usually classified as nouns, because during the early acquisition of vocabulary the child goes through the naming stage in which, after making the important discovery that everything has a name, he asks many "what questions" in order to learn the names of the various objects in his environment. As has been pointed out above, however, merely because a word used by a child has the form of a noun does not mean that it always functions as a noun in the child's usage, for he may use what appears to be a noun with a variety of meanings, and it may actually function as a verb, an adjective, an interjection, or even as a whole sentence in itself. (See Leopold, 1949*a*.) Thus it is difficult, if not impossible, to arrive at a satisfactory answer as to the relative proportions of the various parts of speech in a child's total vocabulary, first because of the difficulty of determining when a child *knows* a word, second because of the difficulty of determining the total vocabulary, third be-

cause of the difficulty in classifying the word according to the part of speech it actually functions as in the child's usage, and fourth because of the difficulty of classifying the same word form according to different functions.

In the second type of study of the parts of speech, no attempt is made to determine total vocabulary, but a fairly long sample of running conversation (or sometimes compositions or letters) is taken, and an attempt is made to determine the relative importance of the various parts of speech in the child's running language. After the child has passed beyond the naming stage and has ceased his early use of interjections, about the end of the second year, and when he has begun to combine words into sentences, the relative proportions of the various parts of speech are determined to a large extent by the limitations imposed upon the speaker by the conventional forms of sentence structure. Thus, whereas a child may have a high percentage of nouns in his "total vocabulary," roughly 60 per cent perhaps, at 2 years of age in the first type of analysis, in this second type of analysis he will probably have only about 20 per cent of the words in his running conversation consisting of nouns. This does not mean that he does not have the variety of nouns in his vocabulary, but merely that because he is speaking in sentences he does not need to draw heavily on his store of known nouns, since each simple sentence requires only one noun for the subject. In order to say anything about that noun, however, it is necessary for him to use a verb, and perhaps an adjective or an adverb; at least for every clause involving one noun he is forced by the rules of sentence structure (which he comes to know by the example of others) to use other parts of speech with it. It is also obvious that since such figures are relative, and are expressed in percentages, any change or trend in one part of speech will upset the balance, and there may be an apparent trend in some part of speech which is really only an artifact and a reflection of the tendency already noted in another part of speech. Which trend is more significant psychologically is usually a matter for interpretation.

The third type of analysis according to parts of speech is that which is based not on the total number of words in a given sample of running conversation or writing but upon the total number of different words appearing in such a sample. A comparison of this method with that of the previous one immediately reveals the fact that the great bulk of language is made up of a small number of frequently recurring words, and that there is relatively infrequent use of the great majority of words in the total vocabulary. Zyve (1927), who recorded the conversations of third-grade children during a 15-minute story period for about 3 months, used both these methods of tabulation and obtained strikingly different results with the two procedures. Nouns constituted 51 per cent of the number of different words and only 15 per cent of the total number of words used. Verbs represented 22 per cent of the number of different words, and they amounted to 27 per cent of the total number of words used. Pronouns also show a striking difference when tabulated by the two methods, as they equaled only 1.5 per cent of the number of different words and 17.2 per cent of the total number of words used. Like the nouns, the adjectives showed a decrease, but the adverbs, prepositions, and conjunctions all showed relative increases when considered according to the total number of words used. The tabulations for the articles bring out clearly the striking artificiality of these methods. There are only 3 different articles in the English language and all 3 of them are

used by very young children, yet they represent only 0.1 per cent of the number of different words. These same 3 words recur so frequently in conversation, however, that in Zyve's (1927) data they constituted 7 per cent of the total number of words employed.

Uhrbrock (1936) reports interesting data on this point based on a sample of 24,000 words dictated into an Ediphone by a little girl during the 6 weeks immediately preceding her fifth birthday. He found that three-quarters of the dictated material involved the use of 141 different common words, each of which occurred 20 times or more in his sample. Forty per cent of the total number of different words (750) occurred only once. Separate samples of 1000 running words of dictation never contained fewer than 258 different words or more than 331, with the average number of different words at 290 per 1000 words dictated. Some idea of the difficulty of determining total vocabulary for a 5-year-old may be seen in Uhrbrock's report that 52 new words, not previously encountered in the data, appeared in the twenty-fourth thousand.

Another approach to this problem has involved the "type-token ratio" or TTR. W. Johnson (1944) and his co-workers at Iowa reported several studies employing this measure, which is the ratio of the number of different words (types) to the total words (tokens) in a sample of language. It was also applied to infant vocalizations by Chen and Irwin (1946*b*) (see Table 2). This measure is sometimes considered to indicate degree of variability or flexibility of language usage. Chotlos (1944) who applied it to extensive samples of the written language of 108 children considers that this index shows the greater differentiation of language structure in older and more intelligent children.

Jersild and Ritzman (1938), using extensive samples of the conversation of a group of very superior preschool children, report that there is a tendency for younger children to use a higher proportion of different words in relation to the total number of words spoken. Roughly every fourth word in their data was a "new" word, and one 3-hour period yielded only about half as many different words as three periods of 3 hours each.

Vocabulary Tests for Preschool Children. The first serious attempt to devise a vocabulary test for young children was made by M. E. Smith in 1926. In this test 203 words were selected by a systematic sampling of the Thorndike (1921) 10,000-word list which had been checked against the vocabularies of a large number of children in order to eliminate words which these young children were almost certain not to know. Most of the words were elicited from the child by means of pictures, although no standard pictures were provided. It is quite likely that the materials gathered by other investigators in attempting to elicit the words of the Smith battery differ widely from those used in the normative work. If the child failed to say the word in response to the appropriate pictures and questions, the examiner then asked another type of question in which the test word was used in such a way that the child could not answer the question unless he understood the word involved. Credit for "knowledge" of the word was allowed if the child responded by using the word in the first type of test, or if he answered the second type of question correctly. Thus the score on the test was made up of a composite of items, on some of which credit was allowed for recalling and speaking the word in the test situation, and on others of which credit was allowed for mere indirect evidence that he "understood" the word. On quite a large number

of the test words no second form of the question is provided, however, and the word actually must be said by the child before credit is allowed. Smith reported a split-half reliability of .97 for a 2-year level with this test. On the basis of the fact that actual known total vocabularies were predicted fairly accurately by multiplying the total score by an appropriate multiplier, she argues that total vocabulary can be estimated with this test.

Williams and McFarland (1937) point out, however, that such estimates are really only fair predictions of the total number of known words in the Thorndike list of 10,000 words rather than accurate estimates of total vocabulary. M. E. Smith (1926) reports correlations of +.88 and +.84 with Descoeudres' (1921) tests of language and Cobb's (1922) rearrangement of the Stanford-Binet vocabulary test as evidence of validity of the test. The figures given by Smith as the total vocabularies of 278 preschool children ranging in age from 8 months to 6 years are widely quoted as the best available material on vocabulary estimates at these ages, although it must be remembered in interpreting them that they are subject to the above-mentioned limitations. (See Table 4.)

TABLE 4

INCREASE IN SIZE OF VOCABULARY IN RELATION TO AGE

(From M. E. Smith, 1926)

Age			Average	Number	
Years	*Months*	*N*	*IQ*	*of Words*	*Gain*
	8	13		0	
	10	17		1	1
1	0	52		3	2
1	3	19		19	16
1	6	14		22	3
1	9	14		118	96
2	0	25		272	154
2	6	14		446	174
3	0	20	109	896	450
3	6	26	106	1222	326
4	0	26	109	1540	318
4	6	32	109	1870	330
5	0	20	108	2072	202
5	6	27	110	2289	217
6	0	9	108	2562	273

M. E. Smith's vocabulary test was revised by Williams and McFarland (1937), who overcame a number of these limitations. It is now known as the Smith-Williams Vocabulary Test, and materials are available for two equivalent forms of 42 words each. It has been applied in several of the investigations reported later in this chapter. The revision considerably reduces the administration time, yet a satisfactory reliability of +.96 is reported by the authors between Forms I and II for 359 children from 2 to 6 years of age. The procedure has been modified to make for more rigid control of the recall method, and the test is given first as a recall test and later as a test of verbal recognition. This separates the administration of the two methods for the same word by the length of the test. Results are reported for 242 children who attended the Iowa preschool laboratories and for 64 orphanage children, but, since the authors emphasize that the original and also the revised tests are only relative measures and do not yield absolute figures on total vocabulary, no figures comparable with Smith's data are provided. The two groups tested could hardly be considered adequate normative samples since they had mean IQ's of 124 and 84. Grigsby (1932), using apparently a prepublication edition of the Smith-Williams Vocabulary Test on 83 subjects between the ages of 2 years 8 months, and 6 years 4 months, reports the mean vocabulary at 3 years as 1507, at 4 years, 2148, at 5 years, 2527, and at 6 years, 3054. These estimates are somewhat higher than those reported by M. E. Smith (1926).

Another approach to the measurement of vocabulary was made by Van Alstyne (1929). This test, which takes 15 minutes to administer, is entirely a picture-vocabu-

lary test involving a series of pen-and-ink drawings with four items to a card. It is limited to 3-year-olds with regard to norms, and if children of other age levels are tested with it interpretations have to be made in terms of the 3-year-old norm. The child is expected only to point to the one object out of the four on each card which is named by the examiner and is not expected to speak the words. The test is thus limited to "understood" vocabulary. The reliability reported by the author is +.87 for split halves after using the Spearman-Brown prophecy formula.

Ammons and others (1948, 1949*a*, *b*, 1950*a*, *b*), basing their work on Van Alstyne's (1929) technique, published a series of studies presenting the standardization of a "full-range picture vocabulary test." It is available from the author in two forms which are reported to have high reliability (from .93 to .987). Norms were based on 30 representative cases per age level from 2 to 17 years from both urban and rural areas. Ammons, Larson, and Shearn (1950*b*) reported vocabulary figures for a group of adults with this same test. Although responses were entirely nonverbal the results correlate .83 to .85 with the vocabulary test of the Stanford-Binet Form L.

Word-Count Studies. Closely related to the general problem of vocabulary are the various word-count studies and frequency lists of words which have been published for various purposes. The most widely used is Thorndike's *Teacher's Word Book*, which as originally published in 1921 listed the 10,000 words most frequently encountered in extensive samplings of adult writing, including large samplings of children's literature. This list was revised and extended in 1931–1932 to include 20,000 words. The tables indicate in which thousand the words fall, and, in the first 5000 words, whether they fall in the first 500 or the second 500 of each 1000.

In 1944 Thorndike and Lorge published an extension to include the 30,000 most frequently occurring words using five different samplings covering a count of 120 juvenile books such as are approved in schools and libraries. The occurrences of these words were tabulated as they appeared in written material of various sorts and were not those actually used by children as in the International Kindergarten Union List. However, as Gansl (1939) and others indicate such lists serve as guides to the relative difficulty of the vocabularies in various materials and have become standard research tools. Wesman and Seashore (1949) point out that there is a great difference between frequency of occurrence of words as revealed in the Thorndike-Lorge word list and the difficulty of the concepts involved in such vocabulary tests as those of the Stanford-Binet and the Wechsler-Bellevue scales.

A valuable list by Eaton (1940) has appeared, the *Semantic Frequency List for English, French, German, and Spanish.* It is based on the first 6000 concepts, rather than word forms, in frequency lists which have been compiled for the four languages separately and then combined. It was issued by the Committee on Modern Languages of the American Council on Education.

Other word lists which have been devised especially as spelling lists include the lists of Ayres (1915), E. Horn (1925), and many others. Of greatest interest to the child psychologist, however, are: the list of M. D. Horn (1926–1927*a*), sometimes spoken of as the International Kindergarten Union List, which is based on words actually used orally by children before entering the first grade; Fitzgerald's (1934*b*) list, based on the letters written by elementary school children in life outside of school; and Rins-

land's (1945) list of over 25,000 words used by children in the first 8 grades in their conversations and compositions. Perhaps the most useful single source book on frequency word lists is that by Buckingham and Dolch (1936) called *A Combined Word List,* which presents data showing the degree of overlapping and disagreement on the frequencies of words in seven different word-count studies. A comparison of the Dale, Dolch, and Rinsland word lists has been published by Hildreth (1948).

Zipf (1935) in his *The Psycho-Biology of Language* points out that the words which occur most frequently are quite short and that longer words are much more rare. After elaborate word-count investigations he proposes a theory of linguistic change based on economy of time and effort. He has subsequently (1942) analyzed the records from Fisher's (1934) study as well as Uhrbrock's (1936) data and finds that his theory is substantiated in the oral language of young children. Skinner (1936) confirms Zipf's law with his use of the verbal summator, which has interesting possibilities as a projective technique. Carroll (1938) suggests that the diversity of a small vocabulary sample has a definite relation to the total vocabulary.

Hockett (1950), a linguist, considers that the fundamental speech habits of the individual are firmly established by the age of puberty and that the most important force shaping the dialect is the speech of other children. He believes that phonetic change occurs in a language through the continuity of tradition in successive generations of children. He indicates that the earliest speech of the child consists of a phonemic system much less fully differentiated than that of the adult, and that it develops by splits and contrasts until a reasonable facsimile of the adult phonemic system heard in the environment is attained. He finds a loss of linguistic flexibility at puberty when the sounds of one's own language sound "right" or "wrong" according to how closely they resemble those used by the peer group. If these claims are correct the implications for bilinguals and for foreign language teaching are indeed far reaching.

Baker (1950) studied the pattern of various languages, and, in harmony with Zipf (1935), found that the more frequently words are used in a language the shorter they become. He also showed that the shorter the words the greater is the number of meanings they acquire. Thorndike (1937, 1938), while agreeing in general with the correctness of Zipf's (1935) observations, questions some of his interpretations G. W. Allport (1936) in his review criticizes the saving of time and effort theory and feels that the more universal process of cue reduction in learning is more important. He considers hearer needs rather than ease for the speaker to be the more important factor. Although he is not satisfied with Zipf's interpretations, he admits that psychologists have nothing better to offer as interpretations of the mental counterparts of linguistic change.

Of the studies which employ the free association technique those by Dolch (1927) and by Prescott (1929) are typical. Elementary school children were asked to write all the words they could think of in 15 minutes. The Prescott study showed an increase in the average number of words given from 35 at 7 years to 157 at 13 years, whereas the Dolch study showed a steady increase from 73 words for the average second-grade child to 191 in the eighth grade. Shambaugh and Shambaugh (1928) used 400 stimulus words with 50 children in each grade from the fourth to the eighth inclusive. The stimulus words were chosen because of their close association with the daily lives of the children. The words were arranged in lists of 50, and no group of children responded to more than one list

of words. In all, 1851 children participated and were asked to write in 4 or 5 words which they associated most closely with the stimulus word. The total number of words given ranged from 32,905 in grade 4 to 46,505 in grade 8, a total of 230,631 being given in all grades. The number of different words listed ranged from 2102 in grade 4 to 3017 in grade 7, there being a marked drop in the eighth grade probably due to selective factors. In all grades a total of 4515 different words was given, 1309 of which were common to all grades. Interesting comparisons are made with the Thorndike and Horn lists. For example, 51 per cent of these 1309 words common in the free associations of all grades from fourth to eighth were not found in Horn's first 3000 words. Shambaugh and Shambaugh (1928) also found 98 words which occurred in their data with a frequency of 500 or more, 61 of which did not appear in Thorndike's first 500 words, 15 of which were not in his first 1000, and it was necessary to go into the third 1000 of the words most frequently used in the Thorndike 10,000 word list to include all 98 words which occurred with a frequency of 500 or more in the free association data. This study is cited in detail to illustrate the elusive nature of frequency word lists and the difficulty of making valid comparisons among them. Tinker, Hackner, and Wesley (1940) found that those who have higher vocabularies also have more rapid word associations. There was a correlation of +.83 between the quality of the associative response and vocabulary score.

This type of approach appears in a more modern version in the "Studies in Word Fluency" by Gerwitz (1948*a*), who constructed a series of eight tests for word fluency involving rhyming, alliterations, thing names, word output, etc.

Comprehensibility of Speech

Adults usually have considerable difficulty in understanding the speech of young children. The degree of comprehensibility of the speech varies with a number of factors, especially with the child's accuracy of sound reproduction, his voice quality, the hearer's familiarity with children in general and with the individual child in particular, as well as with the stage of the child's linguistic development, and with the amount of baby-talk used by adults in the child's environment, which often makes for perseveration of infantile speech habits. This means that there are varying amounts of children's speech which either go unrecorded in the studies which employ longhand or stenographic accounts of oral language, or that varying percentages of the flow of language are subject to separate treatment, owing to incomprehensibility. On the other hand, in spite of very poor pronunciation, there is much in children's speech that can be understood and interpreted correctly by adults who are familiar with children.

Since most of the major investigations of children's spoken language have been made by longhand recording, the degree of comprehensibility, as well as the speed and accuracy of the recorder, is a vital problem in methodology. Day (1932) obtained quite high coefficients of correlation for most indices among the records made by three examiners who noted children's speech simultaneously. These satisfactory degrees of agreement were obtained for indices based on samples of 25 responses. Even though the recorders did not always record the identical responses, errors, which were chiefly those of omission, did not appear to be constant and did not appreciably affect the measures used which were based on the total sample. Betts (1934), however, using the strict criterion of an elec-

trical record of grade-school children's oral compositions compared the relative completeness and accuracy of four types of recording: that of court reporters, longhand recorders, shorthand recorders, and phoneticians. Although the court reporters made the most complete records, they obtained only 80.4 per cent of the material. This was secured with an accuracy of 84.9 per cent. Shorthand reporters had the next most complete records with only 53.3 per cent of the material, and their accuracy was 82.9. Longhand recording yielded only 32 per cent of the flow of speech, but the accuracy remained high (83.9 per cent). Phoneticians had the most incomplete records, but the most accurate, as they noted only 14.9 per cent of the material with an accuracy of 87.6 per cent. The incompleteness of all these types of record is probably very significant from the standpoint of methodology. It is all the more important when it is remembered that the oral compositions were by fourth-, fifth-, and sixth-grade children whose speech undoubtedly was much more comprehensible than that of preschool children, and that the compositions had common content, being based on a short motion picture which the children had seen in school. The greater length of the sentences found at this age level, however, probably operated to reduce the completeness and accuracy in comparison with records on younger children.

Some investigators of children's language development do not mention the incomprehensibility of children's speech, yet from the percentage of incomprehensible responses reported by other authors at the same ages it seems unlikely that any investigators could have understood 100 per cent of what the children said. Such studies should probably be interpreted as having recorded only comprehensible responses. Shirley (1933*a*, p. 293) states that "incomprehensible vocalization attained its highest frequency in the period between 12 and 18 months; after 82 weeks it reached a low level and thereafter (up to 2 years of age) varied around 10 per cent." McCarthy (1930) found 26 per cent of the responses of her 18-month-old children were comprehensible, 67 per cent of the responses of the 2-year-olds, 89 per cent at 2½ years, 93 per cent at 3 years, and practically all responses from 3½ years on. At most age levels the speech of the boys was much less readily understood than that of the girls. Day (1932) found about 35 per cent of the responses of the 2-year-old twins incomprehensible and only about 7 per cent of the responses of the 3-year-olds. Fisher (1934) reports that 8.1 per cent of the responses of her superior group, ranging in age from 18 to 60 months, consisted of "non-verbal speech." Young (1941) reports her data in terms of the mean number of comprehensible words spoken per 10-minute period. The results are in close agreement with Smith's (1926) figures, showing increases from about 20 words at 30 months to about 70 at 54 months.

Articulation. Wellman, Case, Mengert, and Bradbury (1931) report a correlation of +.80 between age and the ability to give sounds correctly in their very detailed examination of 204 preschool children. They report that at 2 years approximately 32 per cent of the total number of sounds were given correctly, at 3 years 63 per cent, at 4 years 77 per cent, at 5 years 88 per cent, and at 6 years 89 per cent. The most marked increases in accuracy of articulation of all types of sounds appeared between 2 and 3 years of age. E. A. Davis (1937*a*) used a crude seven-point rating scale in conjunction with her very extensive investigation and reports that 75.7 per cent of the 5½-year-olds, 90.9 per cent of the 6½-year-olds, and 90.4 per cent of the 9½-year-olds

had "perfect articulation" in a representative group of 173 singletons with siblings.

Poole (1934) tested 140 preschool children for the ability to articulate 23 consonant sounds in words by evoking isolated words as responses to objects, pictures, and questions, but she does not describe the test itself or supply the materials and questions. She reports that the sounds that the child uses most often in his everyday conversation are the ones in which he shows the greatest ability in articulation. Slightly over 64 per cent of the sounds that appear most often in the words of these children's conversations are articulated correctly before the age of 4½ years. The median child at 6½ years articulated all 23 consonant sounds correctly. Poole states that a normally developing child should be able to articulate all sounds by at least 8 years and that failure to make notable progress in articulation at 6 years indicates that a speech therapist should be consulted. In another briefly reported study by Templin and Steer (1939) an apparently good articulation test was used, although the vocabulary load cannot be determined since the test words are not published. It tests for 84 sounds with one sound per word being tested. The test takes from 7 to 40 minutes to administer and was given to 93 children ranging in age from 1 year 11 months to 4 years 9 months.

Approximately 2000 children in grades 1 to 6 were tested for 66 consonants and consonant blends with a modification of the Detroit Articulation Test in a study by Roe and Milisen (1942). The mean number of errors per child dropped markedly from 13.30 in grade 1 to 7.62 in grade 4, but showed no significant change from grades 4 to 6. Single consonant sounds arranged from most to least difficult were: *z*, *ʍ*, *θ*, *dʒ*, *d*, *s*, *g*, *ð*, *v*, *t*, *b*, *tʃ*, *r*, *k*, *ʃ*, *f*, *p*, *l*, *ŋ*, *w*, and the most difficult consonant blends were, in order, *st*, *str*, *sk*, *dr*, and *fl*.

Sayler (1949) carried the work of Roe and Milisen (1942) through grades 7 to 12 testing individually 1998 children with a test of 56 sentences which were read orally. She found very little improvement in articulation in grades 7 to 10, some improvement in grades 10 and 11, but articulation in grade 12 was no better than in grade 11. More boys than girls made articulatory errors in all grades but the twelfth. Consistent improvement was noted in the *f*, *d*, and *t* sounds. The phonemes showing the most improvement were the *ð*, *f*, *z*, and *t*.

A group of 207 children from 18 to 54 months was studied by Metraux (1950) using phonetic transcripts. She found vowel production to be more than 90 per cent correct by 30 months of age, but this level of correctness was not attained in consonant production until 54 months. She gives splendid brief descriptions of the speech of a typical child at each of seven age levels, treating pronunciation, voice, repetitions, relation of language to activities and to other people, as well as manifestations of tensional outlets and illustrative excerpts.

Spriestersbach and Curtis (1951) summarized several unpublished M.A. dissertations done under their direction at Iowa which involved detailed testing for the discrimination and articulation of certain speech sounds in approximately 400 children from kindergarten to sixth grade. They conclude that children who misarticulate speech sounds do so inconsistently and that the inconsistencies can be accounted for on a lawful basis. Sound discrimination errors were only about one-third as frequent as articulatory errors. Older children tended to be more consistent in their misarticulations than younger ones.

A speech-defective group was found by Metraux (1942) to be inferior in the oral reproduction of consonant sounds heard on a record, whereas there was no difference

between them and a group of normal speakers on reproduction of the vowel sounds. Boys had a higher auditory memory span than girls in this study. Sheridan (1945), who studied the speech of 650 children under 5 years of age, believes that articulatory defects are due to auditory confusions and not to muscular incoordination.

Templin (1943), testing more than 300 elementary school children on speech sound discrimination, found practically no correlation with degree of hearing loss. Correlations of approximately −.20 with various measures of achievement were obtained. In all grades more errors occurred with sounds in the medial and final positions than in the initial position. Sheridan (1945) reported that initial consonants appear before central and terminal ones. Reid (1947), using similar techniques, concluded that the ability to distinguish between speech sounds is the outstanding factor related to articulatory defects and to the responsiveness to special speech training.

In Templin's elaborate cross-sectional study the mean per cent of correct articulation scores yielded steady growth curves and increased from 56.6 [1] at 3 years to 94.8 at 8 years. Most of the improvement was in the consonants, especially in the consonant blends. She too found that initial consonant sounds were mastered first and final consonants were perfected last.

The most elaborate attempt to test for all the phonetic elements in all positions is by Wellman, Case, Mengert, and Bradbury (1931). This test, however, is extremely long, involving 583 sounds to be tested for by eliciting 352 test words with a variety of unstandardized pictures and questions. Only 75 per cent of the test words occur in the first 2000 words of the Thorndike Word List, and 7 per cent of them are not listed in Horn's 2500 words most commonly used by children of kindergarten age. Many of the sounds tested for are of rare occurrence in the language and hence are relatively unimportant as far as a child's articulation is concerned (McCarthy, 1935). Similar criticisms can be made of the West Test (1933), the Detroit Test by Stoddard and Langum (1934), the Voegelin-Adams Test (1934), and to a lesser extent of the Blanton-Stinchfield Test (1926), which tests for 100 sounds with 100 test words with standardized pictures.

Henrikson (1948) criticized Wood's (1946) articulation test which he says assumes that the various consonants occur in the three positions with equal frequency. He finds that this assumption is only approximately satisfied for no more than three infrequently occurring phonemes. Significant variations from the expected frequencies occurred for all other phonemes.

As part of the development of their language achievement scale, Little and Williams (1937) modified the speech sounds test originally devised by Wellman and her collaborators (1931). They eliminated the testing for all sounds in medial positions and included only those sounds which occur in the first 1000 of the International Kindergarten Union List. The revised list of speech sounds was divided into seven steps according to level of difficulty as established by Wellman *et al.*, and a child was given 1 point for any 3 sounds pronounced correctly at each of the seven levels of difficulty, with 7 the maximum score. They also devised a measure of intelligibility of children's speech by securing a sample of 50 syllables which Williams had previously found had a predicted reliability of +.94. The child is assigned a score of 2 points for each syllable pronounced correctly, 1 point for each syllable mispronounced but intelligible to an observer not familiar with the child's idiosyncrasies, and 0 for syllables not intelligible to an observer who was not

[1] From prepublication data made available through the courtesy of Dr. Templin.

accustomed to the child's speech. Data are presented on 285 cases in which rapid improvement in speech sounds and intelligibility scores were found up to the forty-eighth month, at which time there occurred a leveling-off of the curve for both these functions when the children had attained almost maximum scores.

McCarthy (1935) made a preliminary report on the development of an articulation test for young children designed to overcome many of the difficulties of previously published tests. It is based on the frequency of English speech sounds as they occur in the count of 100,000 words by G. Dewey (1923), who employed the Fonetic Key Alfabet approved by the Simplified Spelling Board. It is designed to elicit 46 test words which include 95 test sounds accounting for 94 per cent of the total number of sounds in the Dewey sample of adult language and for 90 per cent of the sounds occurring in the Horn list. All the test words are taken from the first 1000 words used by kindergarten children, and hence should not place a serious vocabulary burden on children of 3 and 4 years.

A so-called "nondiagnostic articulation test" devised by Templin (1947*b*) appears to have considerable promise. It tests for 50 sounds, selected as important for articulatory development, in 40 words or in 19 sentences. Reliabilities obtained by the retest and intertest methods were all above .89. Correlations with CA were +.64 and with MA +.71. The test is still in the process of standardization.

There has been considerable difference of opinion among workers in this field as to whether articulation tests should employ the method of eliciting the words in the child's spontaneous manner by showing pictures or asking appropriate questions, or whether the examiner may pronounce the test words for the child in an effort to elicit them. Most writers have scrupulously avoided saying the word for the child, fearing that immediate imitation might occur which would fail to reveal habitual faulty sounds. Morrison (1914–1915) and others, however, have reported that when the children are asked to repeat sounds as well as they can in imitation of the examiner, practically none of the sounds are pronounced correctly simply from hearing the correct form.

Templin (1947*a*) administered an articulation test to 100 preschool children. She found no difference in measured articulation scores when words were uttered spontaneously and when they were repeated in imitation of the examiner. She also found that it made little difference what word was used to test for a specific sound. It appears, then, that if the child habitually mispronounces a sound he will give only his own approximation to the sound in the test situation, even though he has just heard the correct form. Certain forms of careless speech might be eliminated in such a method, but if the child is actually unable to pronounce the correct forms or habitually fails to use them, the imitative method should reveal such defects just as readily as the eliciting of the child's natural way of saying the word independent of the immediate example of the examiner.

In general, all these tests are very long and they test for rarely occurring sounds with words which involve an excessive vocabulary burden for young children. The two exceptions to this appear to be those devised by Little and Williams (1937) and one reported by Templin (1947*b*).

Fairbanks *et al.* (1949*a*, *b*) studied voice breaks in oscillograph recordings of the voices of 7-, 8-, 10-, and 14-year-olds. They found 1 voice break for every 14 words. The pitch levels were about one octave above the usual level for adult males. The voice breaks occurred in girls as well as in boys and appeared in the

voices of both pre-adolescents and adolescents.

Studies of the incidence of speech defectives vary greatly in that they all employ different criteria of what constitutes a speech defect. Some are concerned only with articulatory difficulties exclusive of stuttering; others emphasize cases of stuttering to the exclusion of other problems. The methods of determining whether or not the child has a speech defect vary greatly, and much depends upon teachers' sensitiveness to such matters. Some teachers are much more aware of minor speech difficulties than others, and this results in percentages varying from about 2 to 25 per cent. Many of the studies report only the total number of speech defectives located without giving the size of the population from which they were drawn.

The whole area of speech defects is such an important, extensive, and highly specialized field that no attempt can be made within the compass of this chapter to treat it adequately. However, one very important problem which arises for the child psychologist is determining whether a child is or is not a speech defective, and when the aid of a speech therapist is indicated. As has already been shown, the vast majority of children go through a period of baby-talk. For many children this is relatively brief and the articulatory imperfections are comparatively unimportant, for the children usually develop correct speech habits quite early. On the other hand, a fairly large number of children have quite marked articulatory defects in their baby-talk which for various reasons persist for some time, even well into the elementary school period. It is an important practical problem for the clinician to be able to distinguish between the children who are likely to outgrow their infantile speech patterns at a reasonably normal age and those who need speech training from a specialist in order to overcome their articulatory defects. Too early introduction of formal speech training of young children who may outgrow their infantile speech without help, or whose speech infantilisms are only a symptom of general emotional immaturity, may make these children speech-conscious and result in their refusal to talk. With such children, practice in talking may be more essential than drill on correctness of articulation for a time. Gain in self-confidence, increased independence, and social contacts often do much to improve the speech difficulties.

For the few children whose speech is so defective that they are not likely to overcome the difficulty without special training, it is desirable to have a measuring instrument to evaluate and diagnose the seriousness of the articulatory defect. A study by Sommer (1932) indicated that group training was quite effective with nursery school and kindergarten children. Her experimental group which received training improved 57 per cent, as compared with the control group which improved 28 per cent without training. This shows that, whereas in a group of children certain improvement occurs with maturation alone, speech training such as Sommer gave brings about twice as much improvement.

Springob (1930) selected as speech defectives children whose errors as detected with the Blanton-Stinchfield Articulation Test were 20 or more after the age of 4 years. A plot of the number of speech errors against age shows a distinct dropping-out of errors in his 5- and 6-year groups with a few exceptional cases persisting in a large number of errors at these ages. These apparently are the children in need of therapy. Town (1921), after analyzing the speech of 42 children for speech defects, states:

> It was found impossible on the basis of the examination results to divide the class into two groups, one of which contained children with perfect speech, and the other of which contained children with defective speech. In speech, as in other abilities, the transition is so gradual from normal performance to defective performance that it does not permit of an absolute dividing line.

However, 10 of her 42 cases were judged to have sufficiently defective speech to need corrective work.

Fuller (1936) showed that when kindergarten children with foreign-language handicaps were given speech training there were fewer failures of promotion in the early grades and that IQ's were apparently increased as much as 10 points by two semesters of speech training.

It appears, however, that speech correction with children of functional articulatory defects operates on the level of treating symptoms rather than causes. If the basic causes are still operative, little will be accomplished in the way of permanent cure. If results are not evident fairly promptly, group or individual psychotherapy and general improvement of the child's mental health should be undertaken. (See the study by Wood (1946) in the section, "Language Disorder Syndromes and Personality Development," p. 608.) The field of speech correction was summarized for educators by W. Johnson *et al.* in *Speech Handicapped School Children* (1948). A more popular presentation for parents of speech-defective children is *Speech Problems of Children* (1950) also edited by W. Johnson.

Quantitative Measures

There are two types of studies which undertake to determine only quantity and rate of speech output without reference to the quality of the expression or to any details of the complexities of sentence structure. These studies are limited in scope but have the advantage of objectivity. Studies of the amount and rate of talking are involved here as well as studies presenting data on length of response. The latter, however, are usually more elaborate studies in which length of response is only one aspect of linguistic development measured.

Amount and Rate of Talking. Gesell (1925) reported on the results of a complete 24-hour record of the vocal activities of a 6-month-old child who spent 3 per cent of its waking time in vocal activity. He says: "There were 104 separate moments of vocalization during the day, varying in complexity from 1-letter sounds to 32 repeated syllables; 75 sounds and combinations of sounds were used." The Brandenburgs (1919) reported on a child who at the age of 40 months used 11,623 words in a day, or an average of 950 words per hour, and by 52 months of age this same child used 14,930 words in a day. They compare these data with a study by Nice (1917) in which a child of 63 months used 10,500 words in a day and with one by Bell (1903) in which a child at 3½ years used 15,230 and another at 4 years used 14,996 words in a day. These are undoubtedly reports on children who were very precocious in linguistic development and who were undoubtedly encouraged to converse freely at home, but they serve to show the important rôle that conversation can play in the life of a young child.

There are very marked individual differences in loquacity, for McCarthy (1930) found that among 140 children observed under similar conditions the time required to record 50 consecutive responses varied from 7 to 50 minutes. Fisher (1934), who recorded the responses of a group of 72 children with a mean IQ of 132.6 for 9

hours of free play, found that the average number of remarks per hour ranged from 23 to 192, with a mean at 92. There was a correlation of +.56 between CA and the number of remarks per hour. M. E. Smith (1926) recorded children's responses for 1 hour during free play. This measure showed a steady increase from a mean of 78 words per hour for 2-year-olds to 400 words per hour at 4 years of age, with practically no change from 4 to 5 years. She states:

> The average total number of words used to the hour shows a regular increase with age; but the variability is too great from child to child for it to be an adequate criterion. In fact, this number ranges from 0 to 1100 words for the entire group studied. The length of sentence, that is, the number of words to the sentence, seems to be a much better measure [p. 17].

A study by Olson and Koetzle (1936) presented a technique for securing a quantitative statement of the amount and rate of talking. The groups they used were small and highly selected, so the study is chiefly of value from the methodological standpoint. It involves the use of a mechanical hand tally and a time-out stop-watch in a modification of Olson's (1929) short-sample technique of observation. Records were made for two 1-minute periods per day for 15 days. The examiner actuated the counter for each word heard and started and stopped the stop-watch as the child talked until a whole minute of continuous talking had elapsed. Measures of rate of talking were made in similar fashion, using 6 samples of 30 seconds each distributed over 6 weeks. Observers checked the reliability of the method against reading aloud and found a correlation of +.99 between the number of words recorded and the actual number of words in the passages read from a book. The mean error was 1.4 words in 12 samples of 144 words each, and the errors were in the direction of omission. The reliability of the amount records as measured by comparison of odd and even observations was +.93 after application of the Spearman-Brown prophecy formula. Rate samples were quite unreliable, but the authors believe that the reliability could be made satisfactory by increasing the number and length of the observation samples. It was found that the child who talked most talked seven times as much as the child who talked least, and that the most rapid talker spoke 1.4 times as fast as the slowest. Amount scores correlated +.40 in the nursery school and +.73 in the kindergarten with teachers' ratings of the quantity of the child's verbal output as measured on a five-point graphic rating scale. Amount scores showed a correlation of only +.14 and rate scores a correlation of only +.02 with IQ on the Kuhlmann-Binet. The two types of scores correlated only +.13 with each other.

Jersild and Ritzman (1938) reanalyzed the same data used by Fisher (1934) with the addition of 16 more cases. They state that the increase in sheer quantity of speech is perhaps the most obvious indication of the rapid development of language in the early years of childhood. They also note a decelerating rate of increase around 4 to 5 years. The average half-yearly increase in amount of talking between 24 and 48 months for these bright children was 66 per cent.

Young (1941) determined the number of comprehensible words spoken per 10-minute period. This measure showed a steady increase up to 60 months of age and reflected all the group differences, such as difference in sex, socio-economic status, and situation which were revealed in the other analyses in her study.

Gerwitz (1948*a*, *b*) measured "word fluency" in a group of 38 children 5 and 6

years of age by means of a free association technique. As might have been anticipated, he found a higher relation to MA than to CA, substantial correlations (.67) with other measures of vocabulary, and low insignificant correlations with a wide variety of other measures. As the numbers were small and reliability was determined on only one variable, the elaborate statistical treatment hardly seems warranted.

Length of Response. As noted earlier, the child uses his first words as whole sentences, but with the increase in vocabulary which soon follows he begins to combine words in varying numbers. One of the most objective and easily determined indices of language growth is the increase in length of response which has been reported by most investigators. A number of the studies on speech development in preschool children have employed similar methods and hence have yielded fairly comparable results, which are shown in Table 5. In general this table reveals quite striking agreement among a variety of workers, each employing a different group of subjects and slightly varying methods. Most of the discrepancies which appear can be accounted for in terms of known selective factors or by differences in the methods of recording and analysis.

The data reported by McCarthy (1930), those on E. A. Davis's (1937*a*) singletons, and those reported by Templin (1953*a*) are the most comparable since they were selected so as to be representative of the population on the basis of paternal occupation. Fisher's (1934) group, being a gifted group intellectually, yields much higher mean length of response at all ages. Day (1932) found that her twins, selected by the same criteria as used in the McCarthy study, were seriously retarded in this aspect of language development, and Howard (1934) found a group of 5-year-old triplets also seriously retarded in language development. In this connection it is interesting to note that the reports available on the language development of the Dionne quintuplets reveal that they were more seriously retarded in language development than twins and perhaps more so than triplets. It is indeed unfortunate that the data were not recorded and reported in such a manner as to make the results on the quintuplets directly comparable with this accumulated body of knowledge. (See section on effects of environmental factors, pp. 584–597.)

The results from the McCarthy (1930), Day (1932), Shirley (1933*a*), E. A. Davis (1937*a*), and Shire (1945) studies, and the data from the adult situation in the M. E. Smith (1935*a*) study, as well as from the Hahn (1948) and Templin studies, were taken when the child was alone with the examiner. In the M. E. Smith (1926) study, the Fisher (1934) study, the child-child situation data from the M. E. Smith (1935*a*, 1939) studies, and in the Young (1941) study all records were taken while the children were engaged with other children in free play situations in nursery schools. As may be seen by a comparison of the adult and child situations (Smith, 1935*a*), children appeared to use somewhat longer sentences when alone with an adult than when engaged in conversation with other children, but since different numbers of cases were used in the two groups the comparison is obscured. The situation is reversed, however, when the children have an audience of other children, as in the first-grade "show-and-tell" classroom situation of Hahn's (1948) investigation. The same children used sentences averaging 10.4 words before a group but only 6.9 words per sentence on the average when conversing with an adult.

The data reported by Shirley (1933*a*) are really longitudinal and represent the same measures taken on the same group of chil-

dren at successive ages. All the other studies are of the cross-sectional type. In the E. A. Davis (1937*a*) twin group quite a number of the cases at 5½ and 6½ years are the same cases used at an earlier age by Day (1932), although the exact amount of overlap is not specified. In some of M. E. Smith's studies the same children have contributed records at various ages, but it is difficult if not impossible to determine the number of overlapping cases from age to age. In Fisher's (1934) data 10 of her 72 records were obtained by having two records on the same cases about 1 year apart.

In M. E. Smith's (1926) study data were based on 1-hour conversations in the free play situation. In Fisher's (1934) study the data represent 9 hours of recording of spontaneous conversation during free play taken in 3 periods of 3 hours each, and in Young's (1941) study they are based on 28 periods of 10 minutes each distributed over four different types of situations in the nursery school. These two studies may be thought of as the most intensive since they have the largest samples of conversation per child. The McCarthy (1930), Day (1932), Shirley (1933*a*), M. E. Smith (1935*a*, 1939), E. A. Davis (1937*a*), Shire (1945), and Templin (1953*a*) studies employed 50 responses which have proved to be a sufficiently reliable sample for most purposes, provided the situation remains constant. Young's study was primarily concerned with a comparison of relief cases and privileged nursery school children, so her data are necessarily broken according to socio-economic level. It should also be mentioned at this point that the Davis, Day, McCarthy, and Smith (1935*a*) studies found marked and consistent differences in length of sentence with change in socio-economic level. This matter will be discussed in more detail in a later section. (See pp. 586–587.)

The Templin investigation has data on the largest number of children over the widest age range of any of the major language investigations. Furthermore, it provides data on vocabulary, articulation, and sentence structure for the same children. The study by Anastasi and D'Angelo (1952), reported in Table 5, is significant as it is the first study giving data on length of sentence by Negro and white children equated in age, sex, socio-economic status, and intelligence. In this study 60 responses were recorded for all subjects and the results were based on the last 50 because McCarthy's (1930) data showed that the first 10 responses were slightly shorter on the average than later groups of 10. The findings will be discussed in more detail in the section on racial differences. (See pp. 586–587.)

Shire (1945), in an unpublished doctoral dissertation at Fordham University, studied 300 first-grade parochial school children having an average IQ of 108 at an average age of 6½ years. Her method of gathering data for measuring language maturity in the prediction of success in first-grade reading was comparable to that of McCarthy, Day, and Davis. Shire's procedure differed from that of Davis's in that she used play materials of equal interest value to both boys and girls. It may be seen from Table 5 that Davis's and Shire's data are in close agreement in regard to length of response, although in this measure and in others Shire's group seems somewhat advanced in comparison with Davis's and appears more like an upward extension of the McCarthy (1930) data. Templin's group seems even more accelerated in length of response. A possible explanation may lie in the greater permissiveness and lessened rigidity in parental methods of child care in recent years. It is probable that Davis's penalizing of the girls in her choice

* Figures made available by the courtesy of Dr. Templin. When complete study is published data will be presented for 480 cases from 3½ to 8 years.

† Means for total groups combined computed from data supplied in Anastasi and D'Angelo (1950).

of toys lowered her averages for the total age levels.

In general, it may be seen that the child of 18 months is still essentially in the 1-word-sentence stage and that he is just beginning to combine words. A year later, sentences of 2 or 3 words are most typical, and by 3½ years complete sentences averaging about 4 words each are used. By 6½ years the mean length of sentence is about 5 words, and by early elementary school years it appears to level off at about 7 words. Note should be made at this point regarding sex differences in length of response in favor of girls which appear fairly consistently in Table 5. More detailed discussion of this problem will be presented in the section on sex differences. (See pp. 577–581.)

The measure of sentence length was first suggested by Nice (1925), who described four stages of sentence development. The complete sentence stage, she said, did not appear until after 4 years of age. Nice pointed out that the complete sentence usually consisted of 6 to 8 words and was characterized by mastery of inflections. These conclusions, based on observations of only a few children and made before any of the quantitative studies had appeared, afforded a fairly accurate forecast of what was in store for later investigators.

This same measure has been applied to written language as well as to spoken language. The best available data on the length of sentence in written compositions are supplied by Heider and Heider (1940*b*) who present data for 817 normal cases aged 8 to 14 years who wrote compositions based on a short movie they had seen. It is interesting to compare these figures with those by Stormzand and O'Shea (1924) based on 10,000 sentences collected from children's compositions and letters in various grades as well as with length of sentence in adult writing as represented by the works of such writers as Macaulay, Stevenson and others (See Table 6.)

TABLE 6

MEAN NUMBER OF WORDS PER SENTENCE IN WRITTEN COMPOSITIONS BY AGE AND SCHOOL GRADE

Age Grade	8 3	9 4	10 5	11 6	12 7	13 8	14 9	10	11	12	College Freshmen	College Upper Classmen	Adults
Heider and Heider	10.2	10.9	11.1	11.1	12.8	13.7	13.9						
Stormsand and O'Shea		11.1		12.0	13.5	15.2	17.3	17.8	18.0	19 3	19.9	21.5	20.9

J. E. Anderson (1937) also reports data on sentence length for 150-word samples from the compositions of college students; he obtained a mean length of written sentence at the college level of 20.4 words. He reports, however, that such short samples do not yield adequately reliable measures.

Apparently, then, sentence length is a measure which continues to show increase in normal children until maturity. The use of the measure has been criticized by some writers, and a few substitute measures have been suggested, but none seems to have superseded the mean length of sentence for a reliable, easily determined, ob-

jective, quantitative, and easily understood measure of linguistic maturity.

LaBrant (1933) used the mean length of clause in her study, for she argued that division into sentences may be rather arbitrary, especially in the compositions of children who have not mastered punctuation and who may write several run-on clauses as a single sentence. LaBrant argues that the counting of predicates is easier, more objective, and psychologically more sound. The length of clause she found remains fairly constant in grades 4 to 12, although the subordination index, or ratio of subordinate to coordinate clauses, shows an increase. Apparently length of clause is somewhat controlled or restricted by the structure of the language, and whatever increase in sentence length occurs at higher age levels is brought about largely through the addition of more subordinate clauses. J. E. Anderson (1937) determined subordination indices for samples of 150 words each, taken from four different compositions written by college students, and found very low reliabilities averaging only + 07. Subordination indices based on two successive samples of this length taken from the same compositions correlated only +.23. The mean number of words to the sentence yielded reliabilities of only +.31 and +.35 when similarly treated E. A. Davis (1941) found that the index of subordination was slightly higher in written than in oral products.

E. A. Davis (1937*b*) also compared the relative merits of the longest sentences with the mean length of all sentences. The measures of the longest sentence and that of the five longest sentences she found exaggerate developmental trends and group differences and tend to throw them into relief. Although they undoubtedly are a better indication of the child's maximum linguistic capacity at the time than the mean of all the sentences, they do not afford as reliable measures, especially at lower ages, as the mean length of all sentences. The longest sentence and the mean of the five longest sentences in a sample have the advantage of ease of computation, but there is considerable sacrifice in reliability when either of these short-cut methods is employed, which is more serious at younger age levels. Davis advocates the use of the mean of the five longest sentences, but the writer is of the opinion that the use of this measure should be restricted to rough group comparisons.

Sentence Structure and Grammatical Form

Most students of children's language development have been concerned not only with the quantitative approach in terms of length of responses, but they have also attempted some form of qualitative analysis to reveal the improvement in sentence structure which takes place as the child develops.

Emphasis has been placed on sentence structure because of the necessity of guiding children's writing and because of the rôle of grammar in the school curriculum. Symonds and Daringer (1930) state:

> Sentence structure in a language is a key to the logic and structure of thinking, inasmuch as the sentence is the smallest complete unit of thought. Growth in the power to form complete, concise, balanced, consistent sentences is an index of the growth in clear and accurate thinking.

The biographical studies usually give anecdotal accounts of the first sentence, but make little or no attempt to trace sentence formation further. According to a summary of these observations in the *Twenty-eighth Yearbook of the National Society for the Study of Education,* the time of the appearance of the first sentence is reported from the fifteenth to the twenty-

sixth month by Moore (1896), Bateman (1914), Drummond (1916), Nice (1925), Guillaume (1927*a*), and Stern (1930). Nice (1925) reports the average age of the appearance of the first sentence for 20 children as 17.5 months. Shirley (1933*a*, 1933*b*) calls attention to the marked perseverative tendency which is apparent in the first sentences and suggests that possibly the variety of sentences would afford a better measure than the total number of sentences at the earliest stages. More detailed analyses of sentence structure are reported by Pollock (1878), Moore (1896), Boyd (1913), and Nice (1925). Nice outlines the various stages in sentence formation as follows: (1) the single word stage from 4 to 12 months; (2) the early sentence stage from 13 to 27 months, with an average at 17.5 months, lasting from 4 to 7 months, and characterized by a preponderance of nouns, lack of articles, auxiliaries and copulative verbs, prepositions, and conjunctions; (3) the short sentence stage, which consists of sentences 3.5 to 4.5 words in length and having the same characteristics as the preceding stage, but to a lesser degree; inflections are not yet mastered, and only 1 or 2 sentences out of 50 are compound or complex; (4) the complete sentence stage, which appears at about 4 years and consists of sentences of 6 to 8 words, characterized by greater definiteness and complexity as shown by an increased use of relational words and a fairly good mastery of inflections.

The studies which have presented the most elaborate analyses of sentence structure, and which used almost comparable classifications, are those by McCarthy (1930), Day (1932), E. A. Davis (1937*a*), Shire (1945), Hahn (1948), Anastasi and D'Angelo (1952), and Templin (1953*a*). Day's figures are somewhat different from McCarthy's because of the general retardation which Day found in the language development of twins. The construction analyses of five of these studies are compared in Table 7. Davis's (1937*a*) groups represented an extension to higher age levels using similar samples from the same geographical area. Shire (1945) and Hahn (1948) supplied additional data for comparison with Davis's 6½-year age level. Considering the variation in method explained in the footnotes there are a number of close parallels. Apparently Shire secured greater spontaneity and had fewer elicited responses than the other authors, as remarks which have to be elicited often fall in the functionally complete category. It is particularly interesting to note the increase in complexity of sentence structure that Hahn's first-grade children used when in an audience situation in the classroom. In spite of her more strict criterion for elaborated sentences her first graders said more elaborated, compound and complex sentences when speaking to other children than when speaking to an adult, even more than Davis's 9½-year-olds used with an adult.

Other studies which have been concerned with construction analysis cannot be compared with this group of studies for various reasons. Fisher's (1934) data are presented only for her total group and are not separated by age levels. In the series of studies by M. E. Smith (1926, 1935*a*, 1939) totally different classifications are employed, so that the figures are not comparable. In work of this sort change in one category affects the percentages in other categories if the authors have used classifications that account for 100 per cent of the responses. Smith reports on the percentage of complete sentences, simple sentences, and "yes" and "no" only; and the rest of her classification in all three studies is based on the functional classification of sentences into declarative, interrogative, imperative, and exclamatory, which makes the

TABLE 7

MEAN PERCENTAGES OF TOTAL RESPONSES IN EACH CONSTRUCTION CATEGORY AT VARIOUS AGE LEVELS IN THREE COMPARABLE STUDIES

* Figures from Day have been estimated from graphs.

† Hahn uses only the category of "non-sentences" which probably includes both incomplete sentences and functionally complete ones here classed as functionally complete.

‡ Hahn's elaborated sentences involved two or more independent units with one or more subordinate clauses. Cf. McCarthy's definition (1930, p. 44).

data more comparable with the functional analyses of many of the other studies. She does not provide a classification for incomplete [1] or fragmentary responses which often occur in records of conversation, so it is difficult or impossible to determine whether or not her classification covers 100 per cent of the data. If various types of sentences have merely been counted without necessarily accounting for all sentences, it is difficult to ascertain what was used as the base in determining percentages. Young's (1941) study, which in many respects is comparable with the group of studies in Table 7, does not attempt any analysis according to sentence structure.

Shire's (1945) figures, which are comparable with those of Davis on 6½-year-olds, agree closely with hers in the percentage of simple sentences and in the percentage of incomplete sentences. The greatest discrepancy was in the category of functionally complete although structurally incom-

1 Incomplete sentences were considered "grammatically wrong." Imperatives not requiring a subject in adult language were not counted incomplete. (Personal communication to the writer.)

plete sentences, which were only half as frequent as in Davis's study. This factor may have been due, at least in part, to differences in quality of rapport. Shire (1945) found almost twice as high a percentage of simple sentences with phrases, 3 per cent more compound and complex sentences, and 3 per cent more elaborated sentences.

Hahn (1948) reported on construction analysis of data from 116 first-grade children, who probably represent a more highly selected group than those in the other studies included in Table 7. She used two situations, one an adult-child situation comparable to those of the other investigators. In examining Table 7 for developmental trends the data of Hahn (1948) should be interpreted with caution for two reasons. In the first place her samples are much smaller than the 50 sentences employed in the other studies, as her median sample in the adult situation was only 70 words, or about 10 sentences, and only about 4 sentences in the class situations. Thus, a shift of 1 or 2 sentences from one category to another would make a large shift in percentages, and the data are less dependable because of the small sampling. The large percentage of compound and complex sentences in her data in comparison with the other studies might be due to the fact that approximately 80 per cent of her cases came from upper and middle class homes. Considering the different sampling and slight differences in classification, her figures are in remarkable agreement, however, with those of Davis (1937*a*) and of Shire (1945), who also report on 6½-year-old children. The greatest discrepancy is in the "compound and complex" category. This is probably due to her more strict interpretation of the elaborated sentences.

Examination of Table 7 for developmental trends reveals that in general there is a decrease in the functionally complete but structurally incomplete sentences, although even at the 9½-year level they continue to constitute about one-third of the speech of the children studied by E. A. Davis (1937*a*). Simple sentences without phrases show an initial increase, followed by a decrease as the more elaborate forms of sentence structure begin to appear. Simple sentences without phrases constitute 9.6 per cent of the comprehensible sentences at 18 months, and they practically double in number every half-year up to 2½. They appear to reach a peak in the latter part of the preschool period and then decrease. The decrease is much later among twins in accordance with their general linguistic retardation, as this peak is not reached by twins until 6½ years of age. Phrases are first reported in small numbers—about 1 or 2 per cent—at 2 years, and show a steady increase with age in both twins and singletons, although they never exceed about 10 or 11 per cent even by 9½ years of age except in the Shire and Hahn data, where they are found in about one-fifth of the sentences of 6-year-olds. Phrases are comparatively infrequent in the speech of twins until after school age.

Compound and complex sentences also first appear in very small numbers at 2 years of age. Among singletons they quickly rise to 6 and 7 per cent of the total number of comprehensible sentences between 3½ and 4½ years and remain at about this level in the speech of the 9½-year-olds. The extremely high figures for this category in Hahn's data are probably due to the highly selected group and to the stricter definition of elaborated sentences. The emergence of compound and complex sentences appears to be considerably slower in the preschool period for twins, but they seem to catch up in the use of the more complex forms after exposure to the school environment. The category of elaborated responses, first sug-
