This arrangement has several important consequences. First, the temporal bundles are assembled in greatest numbers at two points along the temporal margin of the papilla, approximately corresponding to between 7 and 8 and 10 and 11 o'clock, in an upright view, or between 4 and 5 and 1 and 2 o'clock, in an inverted view, in the right retina when seen ophthalmoscopically, for example. When interrupted by a block in one of these two localities, the entire or almost the entire upper or lower nasal quadrant of the corresponding field of vision may be affected. In such a case the blind and the unaffected quadrants may be accurately separated by the horizontal meridian. The reason is a cleavage line or "seam" (*raphé*) by which the optic nerve fibers, arising from the upper temporal quadrant of the retina, are separated from those originating in the lower temporal quadrant.

If a lesion is limited enough to interrupt only a small portion of fibers close to the optic papilla, corresponding to a sector of one quadrant, the field defect corresponds to a sector-shaped portion of a quadrant (Fig. 382, *5*, right side). The base of such a triangular field defect extends as far as the limit of the field of view. Since, however, the point of convergence of all retinal optic nerve fibers is not the central fovea but the optic papilla, the apex or pointed end of the blind sector is not at the fixation point, as in injuries to the supranuclear portion of the visual pathway, but a few degrees away from it (*cf. also* Figs. 392, 393).

This is true only of the lesions situated in the nasal portion of the retina and therefore of the cuneate field defects in the temporal half of the field of view. A different situation is found when a small focus along the temporal margin of the optic papilla interrupts a small fiber bundle or segment. In this locality the optic nerve fibers form arches above and below the foveal excavation in order to avoid it (*see* Fig. 162; and chap. VI, 2, 3). The fiber area eliminated here by a focus will necessarily resemble a curved wedge or sickle, and the resulting field defect will be an arcuate or sickle-shaped scotoma, mostly in the nasal half of the field of view (Fig. 382, sketches *5*, *6*). The base of such an arcuate scotoma is either in the periphery of the upper or lower nasal field quadrant or somewhere along the horizontal meridian, depending on whether the interrupting lesion is farther away from, or closer to, the horizontal meridian at the papilla.

Only in the case of a minute focus placed in the horizontal meridian between the papilla and fovea, does the blind zone or belt extend to the fixation point, or even beyond it, and may also spread beyond the horizontal meridian. If a minute focus situated along the temporal edge of the papilla interrupts completely numerous fine fiber bundles arising from the fovea and its immediate vicinity, the central vision in the corresponding field alone is interfered with, producing a central scotoma.

The preceding schematic presentation of the various field defects caused by an interruption of small fiber bundles at the optic papilla needs to be further qualified. First, those lesions located close to the papilla, if nasal to the fovea, without, however, involving foveal fibers proper, are bound to produce arcuate field defects whose broader end terminates on the nasal side of the fixation point along the horizontal meridian, with or without extending to the field periphery. Also, and for the same reason, all larger defects on the nasal side of the field are bound to extend beyond the vertical meridian and may also involve the entire central portion of the field. Conversely, the analogous small lesions situated along the nasal edge of the papilla must produce wedge-shaped or cuneate field defects in the temporal quadrants, with their pointed extremity falling short of the fixation points (Fig. 382, sketches *5*, *6*).

The quadrantic defects on the temporal side of the field of vision caused by lesions in the nasal half of the retina likewise will not necessarily extend to the vertical dividing meridian, if the zone of the retina between this meridian and the vertical line passing through the optic papilla remains intact. In other words, the wedge-shaped field defects of retinal origin tend to terminate with their sharp ends in the blind spot and not at the fixation point. In this respect the sector defects in the field of view caused by retinal pathology differ from those caused by partial damage to the striate area or cortical visual center, which, if complete, terminate at the fixation points, besides being hemianopic in character.

When several small lesions interrupt a number of separate fiber bundles in various localities of the retina in the same eye, the result is a combination of defects in the same field. When appropriately combined, this produces so-called annular or ring-shaped scotomas, often of bizarre shape, encircling the central portion of the field from all or almost all sides. Such scotomas are especially characteristic of glaucoma. The underlying pathological process in this disease interrupts more or less symmetrical fiber bundles encircling the fovea above and below the horizontal meridian. The ends of the resulting two small arcuate field defects merge, producing an annular, circular, or ring-shaped scotoma. (*Cf.* Traquair 1946; F. B. Walsh 1947.)

More extensive lesions of the retina, such as those found in luetic chorioretinitis, when limited to one nasal or one temporal half, may produce a field defect in either the temporal or the nasal half. When in the homonymous halves of both fields, they may approximate or simulate one of several forms of homonymous hemianopia, for example, a superior or an inferior quadrantic of a complete or incomplete type; or, when in the symmetrical halves of both fields, they may appear as a binasal or a bitemporal hemianopia (Fig. 382, sketch *15*). In such cases the field defects usually are incongruous (Wilbrand 1930).

2. Visual field defects caused by lesions of the optic nerve.—The exact arrangement or location of functionally different fiber bundles on a cross-section through the optic papilla and optic nerve are even now only imperfectly known. Hence only a preliminary interpretation of visual field defects found in the pathology of optic nerves can be made at this time.

The first difficulty arises in the interpretation of the formation of the optic papilla. If the fibers from the various peripheral, intermediate, and central zones of the retina, as they converge upon the papilla, rigidly observed their relative topographical arrangement, bundles from the extreme retinal periphery would assume a position in the very center of the nerve, those arising from the region around the optic papilla would become most peripheral in the nerve, with fibers originating from the intermediate retinal belts filling seriatim the belts of the nerve between the central and the peripheral fibers. Such an arrangement in the nerve, with the ora serrata in the center and the fovea in the periphery, would reverse the zonal topography of the retina. This, however, as experiments and clinical cases with partial degeneration of optic nerve fibers—for example, of the foveal or "papillomacular" bundle—clearly show, is not the case. Only in the distal portion of the nerve, close to the eyeball, does this bundle preserve its original peripheral position, becoming gradually more central in the proximal portion of the nerve close to the chiasma. (*Cf.* chap. VI, 7, 11, and Figs. 201, 202.)

The foveal-macular fibers, in order to penetrate into the center of the optic nerve, have already assumed an advantageous position in the retina. They pour over the temporal brim of the papilla toward its center, pushing upward and downward those fibers that stream from more peripheral, extrafoveal portions of the temporal and the adjoining zone of the nasal retinal halves (Fig. 162). The foveal-areal fibers preserve this peripheral position along the temporal margin along most of the length of the optic nerve, becoming definitely central only in a section of the nerve close to the chiasma. The peripheral or extrafoveal fibers must also undergo certain rearrangements, in order to permit those from the more distant retinal zones to come to the surface and those from the zones closer to the papilla to assume a more central location. Since the fibers from the far periphery,

while within the retinal fiber layer, are necessarily situated close to the vitreal surface of the retinal membrane, during their passage through the cribriform lamina or shortly before or behind it they probably intertwine with and cross the deeper fibers that arrive from the more centrally located retinal regions in order to reach the periphery of the optic nerve.

The result of all this shifting and changing is an arrangement of the foveal and extrafoveal quadrants on a cross-section of the initial segment of optic nerve next to the eyeball that closely corresponds to the topographical arrangement in the optic papilla, gradually resembling more and more the arrangement in the retina as the optic chiasma is approached. But in spite of the considerable displacement mentioned, there are reasons to think that the individual bundles of optic fibers that originate from small adjoining territories of the retina remain neighbors along the entire optic nerve, as well as in the chiasma and the optic tracts.

The relatively simple arrangement of the various bundles composing the optic nerves, because of their small size and compact structure, manifests itself in rather global symptoms in the pathology of the nerves. A complete severance of a nerve is, of course, followed by a loss of function, or amaurosis, of the corresponding eye (Fig. 382, sketch *1*). The inflammatory and toxic processes and also the infiltrating and enveloping tumors first affecting the superficial fibers of the nerve, provided that they are not located close to the eyeball, may initially manifest themselves by impairment in the peripheral zones or a more or less concentric contraction of the visual field (sketch *11*). When a process spreads into deeper layers of the nerve and also affects the foveal-areal or "macular" bundle, central vision suffers. In toxic degeneration of this bundle, central vision may be affected more or less independently (sketches *2*, *3*). Scotomas and hemianopic defects, in general rare, do not show regular boundaries typical of the lesions of parts of the visual system above the chiasma (sketches *7–10*).

3. Visual field defects in lesions of the optic chiasma: unilateral temporal or nasal and bitemporal or binasal or heteronymous hemianopia.—The most important fact about the chiasma of the optic nerves is that it contains fibers originating from both the nasal and the temporal halves of the retinae of both eyes. The clinical and experimental evidence shows that the line of separation between the crossed nasal and the uncrossed temporal fibers follows the vertical dividing meridian, passing through the fixation points. This is as true of the fovea and of the rest of the central area as it is of the extra-areal periphery of the retina (*see* chap. VI, 6 [4]).

The details of how the crossing of the individual bundles is accomplished have been disclosed in different ways: indirectly with the help of clinical evidence and by direct anatomical investigation (*cf.* chap. VI, 6 [2]). The consensus is that the separation of the ipsilateral from the contralateral fibers is already beginning to take place in the optic nerve as it approaches the chiasma. The fibers from the nasal portion of the retina begin to separate from those coming from the temporal portion. It was further demonstrated that in the chiasma itself not all fibers take the shortest course to the contralateral optic tract but in the distal segment of the contralateral optic nerve form more or less extensive loops and detours, called the "anterior knee"; however, no detours, or only slight ones, are present in the initial portion of the contralateral optic tract (*see* Figs. 193, 194, 195, 198, 199).

The important problem of the identity, course, and location of the foveal-macular fibers in the chiasma has been variously answered. One view, based upon purely circumstantial clinical evidence, insists upon a central location both in the chiasma and in the optic tracts (Henschen 1910, and others; *see* chap. III, 9 [8, 9]). Another and a more recent view prevalent among modern clinical neurologists assumes that the foveal-macular fibers are located in the posterior margin of the chiasma, which would account for the frequent appearance of central and paracentral scotomas of a bitemporal type in chiasmal pathology (Cushing 1930; Traquair 1946; F. B. Walsh 1947).

The clear-cut evidence furnished by the experiments with monkeys presented in chapter VI, 7, shows both views to be at some variance with the experimentally determined facts. According to these facts, the foveal-macular fibers

are in approximately the upper half of the chiasma, located immediately beneath the hypothalamus. The lower third of the chiasma next to the sphenoidal bone is entirely occupied by the extrafoveal peripheral fibers. In the longitudinal sense, the foveal-areal fibers occupy about the intermediate third of the chiasma, leaving free the anterior-oral and the posterior-caudal third of that structure. The monocular-crescentic fibers, as the same experiments with monkeys and the study of human pathological specimens show, are most ventral in the chiasma and, after crossing, form the inner, ventral margin of the contralateral optic tract. The extrafoveal or peripheral binocular fibers are arranged serial fashion between these two, also forming the anterior and posterior thirds of the longitudinal extent of the chiasma. (*Cf.* chap. VI, 6 [2], and especially 7 [2], and also the accompanying figures.)

The visual field changes caused by an interference with the chiasma play an important role in neurosurgery, since they are commonly caused by tumors of the pituitary gland or hypophysis and by pathology of the hypothalamus of the brain (*see* Walker & Cushing 1918; Cushing 1930; Bailey 1933; Traquair 1946). These have been extensively studied especially with respect to the progress and recession of the illness. The two types of field disturbances characteristic of the chiasma are temporal and nasal hemianopia and its variations.

Temporal or *bitemporal hemianopia* is blindness of both fields of view caused by an interruption of the two sets of decussating optic nerve fibers which form the connecting link between the two optic nerves or tracts, which is the intermediate, bridgelike portion of the chiasma proper (Fig. 382, sketch *12*). When an interruption is complete, the dividing lines separating the normal from the blind halves of the fields of view coincide with the vertical dividing meridians.

Since in the intermediate, bridgelike portion of the chiasma the decussating fibers alone are present, defects in the temporal halves of both fields may be complete without the nasal halves being appreciably affected. In such a case the two nondecussating systems of fibers may remain intact and are merely pushed aside. If, however, the causative factor, usually a tumor of the hypophysis or pituitary gland, a gummatous infiltration and exudation, and the like, expands in one or in both directions and also compresses or interrupts the uncrossed or ipsilateral bundle of one or of both sides, blindness extends from the temporal halves beyond the vertical division line into one or both nasal halves of the fields (Fig. 382, sketch *17*).

If pressure is exerted first upon the basal bundles of the chiasma, compressing fibers related to the periphery of the inferior nasal retinal quadrants, a contraction of the fields may involve the upper temporal quadrants before the lower ones are affected, and the reverse order is observed in the process of recovery (Cushing & Walker 1915; Josefson 1915; Wilbrand 1930). If, on the contrary, a tumor presses from above, from the side of the optic recess, the first fibers to be affected are the foveal-areal or "macular" bundles, functionally manifested by an impairment of the central portions of the fields of view in their temporal halves.

Nasal or *binasal hemianopia* is blindness in one or both nasal halves of the two fields of view (Fig. 382, sketch *14;* Fig. 384). Such a defect is caused by an interruption of, pressure upon, or interference with, the blood supply of the ipsilateral or uncrossed optic nerve fibers of either the right or the left side in the region of the chiasma. The cause, usually a tumor, gumma, luetic basal meningitis, or atheroma of the arterial circle of Willis, initially compresses one set of the uncrossed fibers of the chiasma from the temporal side, producing a more or less pure unilateral nasal hemianopia. However, owing to the proximity of the nondecussating to the decussating fibers, a clean-cut nasal, unilateral or bilateral, hemianopia is hardly ever present. The reason is obvious: an expanding pathological process, in its further growth toward the center of the chiasma, gradually encroaches upon the crossed fibers from the ipsilateral and the contralateral nerves, impairing vision in the ipsilateral temporal and then in the contralateral temporal halves of the fields of view. If the process progresses to a point of interference with the contralateral nondecussating fibers of the opposite optic nerve, the nasal half of that field also becomes blind.

A bilateral lesion affecting the nondecussating bundles of both sides in a more or less sym-

metrical way and causing a binasal hemianopia, usually of an incongruous type, is a rare occurrence and therefore of small practical importance (Fig. 382, sketches *14*, *15*). The reason is that on rare occasion only will there be two pathological processes impinging upon both lateral margins of the chiasma to the same extent. In this case, too, owing to the mingling of crossed fibers with uncrossed, there will be a partial loss in the temporal halves, in addition to the more or less complete blindness in both nasal halves of the fields of view.

It is remarkable that such a combination may be caused on occasion by apparently a lowermost plane of the chiasma and form the innermost margins of the optic tracts, it is possible that on occasion they may be interfered with on one or both sides separately, causing a unilateral or bilateral crescentic hemianopia (Fig. 383, sketch *12*). A crescentic defect may be an initial symptom, gradually spreading over the binocular temporal part of one or both fields, as the causative pathological process gradually involves crossed binocular fibers of the same side and finally those of the opposite side.

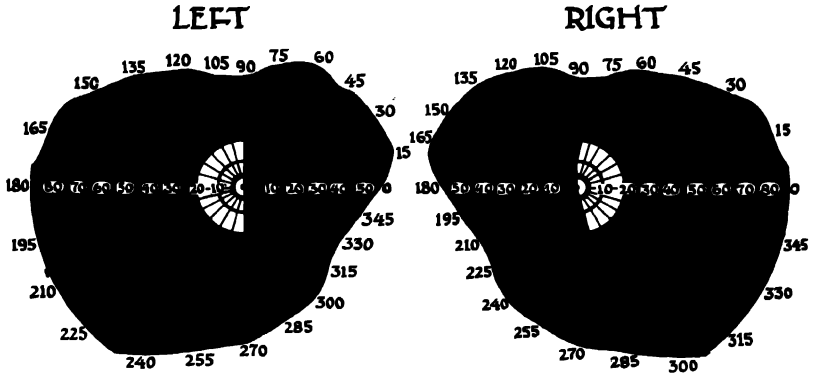

FIG. 384.—Case of a complete binasal and incomplete bitemporal hemianopia, with much reduced fields, caused by pressure on the chiasma due to an internal hydrocephalus, in consequence of a traumatically induced cerebral hemorrhage in and around the lateral ventricle, with an obstruction of the cerebral aqueduct by a blood clot. From K. H. Bouman, Monatsschr. f. Psychiat. u. Neurol., v. 25, p. 387, 1909.

single lesion, as, for example, an expanding internal hydrocephalus of the third cerebral ventricle (Bouman 1909; *see* Fig. 384). Other combinations may appear, depending on the location, spread, and multiplicity of the pathological process. Such is a tractus hemianopia associated with a contralateral temporal hemianopia caused by a compression of the uncrossed fibers on the opposite side of the chiasma (Fig. 382, sketch *17; see* Wilbrand 1930). A binasal hemianopia of an incongruous shape, such as that shown in sketch *15*, may be caused by a retinal pathology (see par. 1, this section).

Since the two decussating systems containing fibers from the monocular crescentic segments of the nasal retinal halves are located in the

SEC. 3. DISTURBANCES OF VISION CAUSED BY SUPRACHIASMAL PATHOLOGY OF THE VISUAL SYSTEM

1. GENERAL REMARKS ON HOMONYMOUS HEMIANOPIA.—The visual field disturbance called homonymous, vertical, or lateral hemianopia is a functional loss in either the right or the left homonymous halves of both monocular fields of view (Fig. 383, sketches *1, 2;* Figs. 385, 386, 387). It is a defect characteristic of unilateral lesions of the visual pathway anywhere from the chiasma of the optic nerves to and including the striate areae of the occipital lobes of the brain. (For uniocular hemianopias *see* Lutz 1923.)

Homonymous hemianopia is a pathophysiological manifestation of the partial decussation of the optic nerve fibers (chap. VI, 6, 7). In such a partial decussation, the fibers originating in the nasal half of the retina cross in the chiasma to join the contralateral optic tract, whereas those arising from the temporal retinal half proceed in the tract of the same side to the subcortical visual center. In other words, whereas, in the optic nerves, fibers both from the nasal and from the temporal halves of the respective retinae remain together, in the remainder of the visual system above the chiasma and as far as the visual centers in the occipital cortex, each cerebral hemisphere contains fibers conducting impulses both from the right and from the left homonymous halves of both retinae (*cf.* Fig. 259).

Because of this arrangement, the functional and pathophysiological character of the suprachiasmal portion of the visual pathway differs profoundly from that of the eyes and optic nerves. Whereas each optic nerve is anatomically and functionally related to its own eye and each retina to its own field of view, each tract, lateral geniculate nucleus, visual radiation, and striate area is related to the ipsilateral homonymous halves of both retinae.

In the fields of view, because of the "dark-chamber effect" of the eyes that makes the right retinal halves see to the left and vice versa, the relationship is reversed: whereas each eye or retina sees both halves of its own field of view, each optic tract, lateral geniculate nucleus, visual radiation, and striate area sees the contralateral halves, nasal and temporal, of both fields of view.

Concretely, the right tract, geniculate nucleus, radiation, and striate area see the nasal half of the right monocular field of view and the temporal half of the left, whereas the left tract, geniculate, radiation, and striate area see the nasal half of the left monocular field of view and the temporal half of the right. In the combined binocular visual act, the right side of the suprachiasmal portion of the visual system sees the left half of the common binocular field of view, the left side of the system sees the right half. (*See* Figs. 180, 225, 259, 260, 361, 439.)

The intrinsic organization of the visual sys-

tem being as described, any massive unilateral lesion of the visual pathways and centers, from any point above the chiasma and as far as the striate areae, necessarily affects both monocular fields of view. The affected halves of the fields are either the right or the left ones and always on the contralateral side of the site of the lesion. A right homonymous hemianopia, for example, is caused by damage to either the optic tract, lateral geniculate nucleus, visual radiation, or striate area of the left side, and a left hemianopia by damage to the same structures of the right side.

Since the location, extent, and many other features of the causative process vary in each individual pathological case, the functional pathological manifestations also vary in a great many ways. The different types of hemianopia and the underlying pathological processes are discussed in more detail in subsequent paragraphs of this section and in the following sections of this chapter. In all cases one basic factor concerns anatomical mechanics: topographic organization of the visual pathways and the distribution of the blood vessels, both varying from level to level. The other essential factor is pathophysiological dynamics: the nature of the underlying pathological process which may be either a trauma, a nonexpanding encephalomalacia, a thrombosis or embolism, a temporarily expanding hemorrhage, or a progressively expanding tumor. In the first, dramatically exemplified by traumatic war injuries, the frequently observed outcome of an initial complete or almost complete amaurosis that gradually subsides is homonymous hemianopia as a residual symptom (Uhthoff 1915, 1916, 1922; Wilbrand & Saenger 1917; Szily 1918; Foerster 1929). In the latter cases the initial hemianopia may be gradually transformed into complete amaurosis.

The strictly unilateral lesions of the suprachiasmal portion of the visual system, owing to the fact that the two pathways of this system are at some distance from each other, produce strictly unilateral field defects. This simple situation may be complicated either by the presence of additional foci or by an expansion of a single focus. In the case of processes involving tracts, the most likely structures to suffer, because of proximity, are the chiasma and the ipsilateral optic nerve, followed by the contralateral tract and nerve. In processes located in one occipital lobe, the most likely path of interference is by way of the splenium of the corpus callosum. The course largely depends on the nature of the pathological process. In case of a simple encephalomalacia, thrombosis, embolism, or arterial spasm, an initial unilateral hemianopia may become a complete or almost complete amaurosis when the unilateral process spreads to the opposite brain hemisphere, eventually interfering with the contralateral pathway.

2. Lesions of the optic tracts.—The constituent nerve fibers and nerve cells of the suprachiasmal portion of the visual pathway, unlike those of the optic nerves, are sufficiently spread out along the greater portion of their course to permit selective damage by lesions of limited size. This is least evident in the optic tracts, which are flat, compact bands attached to the base of the brain (Fig. 183). Unilateral interference with these structures may more likely be complete, hence causing a complete and absolute homonymous hemianopia on the side contralateral to the lesion.

In rare cases, however, superficial injury, such as a hemorrhage, encephalomalacia, superficial inflammation, abscess, edema, aneurysm, small tumor arising from the adjoining hippocampal gyrus, or a restricted traumatic lesion, may interrupt or exert an effect upon only a portion of the tract, affecting only a part of the opposite fields of vision. Also, for a short stretch next to the chiasma, the crossed contralateral and the ipsilateral fibers are partly segregated, permitting a selective injury.

In by far the longer portion of the tract, certainly close to the lateral geniculate nucleus, both sets of fibers intermingle, until in that nucleus the individual bundles, representing "corresponding points" of both retinae which in the binocular visual act are more or less simultaneously stimulated, come to lie very close together. The injuries in this part of the tract are likely, therefore, to produce disturbances in both fields of vision of a character congruous in shape, size, and location.

The segregation of the tractal fiber bundles according to quadrants and belts, in spite of a

compact arrangement, is sufficient to make their separate damage possible. For example, a limited injury may independently interrupt fibers related to a part, or to a whole, of the monocular crescent or of the upper or lower binocular quadrants, of parts of these or of the central portions of the fields of view. The facilitating factor in producing congruity is the adjustment which the "corresponding bundles" undergo in order to assume their final place at the point of entry into the lateral geniculate nucleus. The most superficial fibers in the ventromedial corner of the optic tract, for example, are those conveying impulses from the monocular portion of the contralateral retina.

Conversely, the most dorsolateral on a cross-section through the tract are the foveal or "macular" fibers of both hemifoveae and central areae around the fixation point (*f*). The remaining fibers related to the greater intervening portion of the upper and lower binocular quadrants of the homonymous halves of the two retinae are placed in the dorsomedial and ventrolateral segments of the tract (*see* Fig. 225, *r. opt. tr.*, *l. opt. tr.*; Fig. 259, *OT*).

The field defects, except in complete tract hemianopia, would rarely exhibit the straight linear boundaries encountered in deep lesions of the occipital lobes involving the radiations. The incongruity of the homonymous defects in the tractal lesions is also considered more frequent. Finally, the lesions which are low enough to affect the chiasma, complicate with their special features the simple picture of a unilateral tractal syndrome.

3. Lesions of the lateral geniculate nuclei.—In the lateral geniculate nucleus the "corresponding" or syndynamical retinal bundles have a location similar to that in the adjoining portion of the optic tract. The crossed monocular fibers enter into the ventralmost zones of the geniculate nucleus on both sides of the hilum; those related to the hemifoveae into the intermediate wedge-shaped segment; those from the upper homonymous retinal quadrants into the medial segment; those from the lower homonymous quadrants into the lateral segment (*see* chap. VI, 7, 11, and Figs. 225, 259, *LGN;* Fig. 260, *LLGN*, *RLGN*). An isolated injury to any of these segments, because of their small dimensions, however, may rarely occur. In such a case a functional defect would be confined to the corresponding quadrants and would bear a hemianopic character (thus in cases described by Henschen 1897–98; E. Vries 1913; and Winkler 1913). A hemianopic atrophy of both optic papillae has been described by Wilbrand (1930).

4. Lesions of the visual radiations and of the striate areae.—In the visual radiation the two sets of fibers, arising from the ipsilateral and contralateral layers of the lateral geniculate nucleus and carrying impulses from the homonymous halves of the right and left retinae, are so intimately intermingled that a selective injury seems unlikely (Fig. 259, *VR*, *LSA*, *RSA;* Fig. 260, *LVR*, *RVR*, *LSA*, *RSA*). This, as is assumed by some, is more probable when the initial portion of the radiation in the temporal lobe is affected, where a slight degree of anatomical discrepancy is believed to be present. In this way small incongruities of the right and left field defects may be explained (Harrington 1939; Sanford & Bair 1939). Outside of this, the unilateral lesions of the visual radiation or of the striate area, as a rule, produce hemianopic defects which are nearly absolutely congruous in shape, size, and location (an exception is, of course, the monocular portion).

The relatively large spread of the visual radiation on a cross-section through the posterior portion of the cerebral hemisphere and the large surface that the striate area represents offer the greatest chance in the entire visual system for partial damage and for an appearance of small defects in the corresponding homonymous fields of vision (*cf.* Figs. 228–33, 235, 236, 267, 269, 278, 289, etc.).

When a portion of the visual radiation is interrupted or a fraction of the striate area destroyed, field defects may be produced, ranging all the way from a complete quadrantic hemianopia to minute bilateral homonymous, or unilateral crescentic, scotomas or small blind islands or gaps in the visual fields. The size, shape, and location of the defects depend entirely on the size, shape, and location of the lesion. Extremely small lesions, especially multiple, affecting portions of the visual radiation or of the striate area, may produce such elusive

impairment of vision that it cannot be determined by perimetric methods but is merely manifested in decreased function, such as lesser acuity, dim color vision, blurring of the shape of objects, and the like. If such zones or areae with a reduced function are situated in the periphery of the visual fields, they may cause no appreciable, or only slight, subjective discomfort. Conversely, even minute lesions, single or multiple, if close to, or in, the fixation points, may cause much subjective discomfort and reduction of vision.

The character of a hemianopic defect is either that of amblyopia or of amaurosis or absolute and permanent blindness for all vision in case of a complete interruption or destruction of one optic tract, lateral geniculate nucleus, visual radiation, or striate area. Or it is a temporary phenomenon when the impairment is indirect, as, for example, in a more or less distant pathological process such as compression by a slowly expanding tumor, thrombosis or embolism in an adjacent territory, a distant hemorrhage, an infectious focus surrounded by a collateral edema and infiltration, or a trauma to the adjoining parts of the brain. In such cases, after the removal or disappearance of the causative factor —e.g., collateral edema or compression or relaxation of a spastically contracted artery causing an ischemia—vision may be restored completely, sometimes dramatically, within minutes or hours, or else the rehabilitation of function may be incomplete. In the latter case portions of the hemianopic fields may remain permanently obscured in various degrees, with normal function returning to the remainder of the same fields. Or perception of light only, of light and cruder forms, or of finer details returns, leaving permanent impairment of color vision only.

A particular type—a transient hemianopia—appearing in brief attacks of only a few minutes' duration, often many times a day, and frequently terminating in absolute hemianopia or in scotomas of various shapes and location, was named by Hughlings Jackson "epileptic amaurosis." The basic underlying process appears to be the same as in scintillating scotoma (*see* chap. X, 8 [3]; *cf. also* sec. 7, this chapter).

The subjective experience in homonymous hemianopia, as in blindness of peripheral origin, is of the absence of visual perception, that is, the inability to see objects in the affected parts of the fields of view. It is contended by some observers that, in contrast to impaired vision caused by damage to the eye, retina, optic nerves, chiasma, tracts, and visual radiation, neither the loss of function in the blind parts nor the division lines separating the latter from the normal parts are subjectively noticed in blindness of central origin, where either the striate cortex or the near-by parts of the visual radiation are affected (Siegfried 1880; Anton 1898, 1899; Redlich 1907; Redlich & Bonvicini 1907, 1908; Wilbrand & Saenger 1918; Z. Bychowski 1920; Pick 1920; Pinéas 1926). The hemianopically blind halves, just like the space beyond the normal field limits, are simply nonexistent in subjective experience.

While this opinion is to some extent correct, the actual situation is much more complex. First, the boundary lines or, more correctly, zones are not absolutely sharp but have a certain width, wider in the periphery of the field and narrower when closer to the fixation points. Even quite close to the axis the transition from the amblyopic to the seeing territory is not quite sharp, amounting at an approximate distance of 5–6 degrees from the fixation point to as much as 1–2 degrees, and in the periphery to several times that much. This is hardly due entirely to diffraction and dispersion of light within the eye but must be caused to some extent by a margin along the defect separating the cortex still functioning in a normal or nearly normal way from the absolute cortical defect. In this transitional marginal zone there still remain enough functioning nervous structures to act as an anatomical substratum for a rough perception of light and movement ("protopathic vision" of Parsons) but not enough for an appreciation of finer details and of hues ("epicritic vision").

Subjectively, a reduced function of the zone adjoining the amblyopic parts of the fields of view is experienced as an uncomfortable "blur," especially felt in moving objects. In fact, the appreciation of "movement" in this zone is intensified during the first days and weeks after the insult and appears to be the essential factor underlying a subjective feeling of a "gelatinous transparency," especially marked in early

stages and in smaller scotomas where the opposite borders are not far apart. And it is this zone wherein the "scintillation" or "flicker," often intermittent and of but a few seconds' duration, is subjectively experienced with gradually decreasing intensity, frequency, and duration in the early stages after a cerebral trauma. Hypothetically, these phenomena may be interpreted as an anatomical and physiological upset in the normal relations and function of the neuronal complexes populating the marginal zone along the focus of complete destruction of the nervous substance.

Another phenomenon much discussed and misrepresented is the "reorganization" of vision in hemianopia and a displacement of the "centers" or fixation points outside the anatomical fovea ("pseudo-fovea"). Unfortunately, there is, according to our own personal experience, nothing in support of the fantastic "gestaltist" or "configurationalist" concept assiduously propagated by Goldstein and his school (Goldstein, Gelb, W. Fuchs, *et al.*). In fact, no matter what part of the striate area and of the visual radiation is destroyed, the remainder, in our subjective appreciation, tries by will power to restore normal function in the remaining part, with the help of functional space values of the visual system inherent in it.

5. BASIC TYPES AND COMPLICATIONS IN HOMONYMOUS HEMIANOPIA.—There are two basic types from which other varieties of homonymous hemianopia may be derived. In complete hemianopia, blindness in the affected homonymous halves of the two fields of view extends to the vertical meridians (Fig. 383, sketch *1;* Fig. 385). In an incomplete hemianopia, more or less extensive territory around the fixation points in otherwise blind halves is spared (Fig. 383, sketch *2;* Fig. 386).

The character of the impairment in both types may be either that of an absolute scotoma, in which all perception is lost, or of a relative scotoma, in which some perception is still possible.

Homonymous hemianopia may be present either alone or associated with field defects in the opposite functioning halves, such as absolute or relative scotomas of different shapes, sizes, and locations.

In many cases there are at some time complications of various kinds—somesthetic, auditory, motor, and psychic—in addition to a field disturbance. These are related to the concomitant damage of the nervous system during or prior to the onset of visual disturbance, caused by the same basic factor. Such complications often appear during the initial or acute period; or they may appear any time in the course of the illness; or they emerge during the terminal phase.

At all events, these complications indicate a spread of the causative process to parts of the brain other than those strictly concerned with the perceptive functions of vision. Undoubtedly, such symptoms are a warning signal. Their appraisal, in the examination of a given case, requires a thorough clinical and pathophysiological experience in neuro-ophthalmology and a careful, balanced evaluation of many factors. In this evaluation, both a detailed examination and analysis of the visual disturbance and a careful appraisal of the general state of the case, including metabolism, are necessary to determine what further developments may reasonably be expected and, most important, what medical help can be offered.

Whereas in many cases extensive hemianopia is a threatening sign, much can be accomplished by expert medical care. An optimistic note is further introduced by such cases as the one reported in the following chapter of a dormant scotoma lasting for more than three decades, which in no appreciable measure interfered with the activity of a distinguished microscopist (*see* chap. XII, case MALLORY).

The principal means of determining the presence and character of a homonymous hemianopia and of other forms of visual field defects is field plotting with the help of a perimeter, introduced by R. Förster (*see* chap. IV, 1 [2]). Subsidiary tests or signs by which a differential diagnosis between the infra- and supranuclear lesions may be aided in hemianopic disturbances, in addition to the presence or absence of an atrophic optic disk, are as follows. The first is the "hemianopic pupillary reaction," meaning an inability to elicit a pupillary light reflex in the hemianopic halves of the fields in case the seat of the injury is in the optic tract or lateral geniculate nucleus (*see* chap. VI, 10 [3]). An-

other indicator is "Lauber's symptom," consisting of the presence of optic nerve fibers observable ophthalmoscopically in infrared illumination in supranuclear lesions, and the absence of the same fibers in infranuclear ones, in the retinal halves corresponding to the affected hemianopic halves of the fields of view (Lauber 1927; Kolmer & Lauber 1936). For other symptomatology consult textbooks on ophthalmology and neuro-ophthalmology, especially R. L. Rea (1941) and F. B. Walsh (1947).

SEC. 4. TYPES OF HOMONYMOUS HEMIANOPIA AND THEIR ANATOMICAL BASIS

1. Complete homonymous hemianopia with division lines passing through the fixation points.—In this form of hemianopia the blind defects take the entire territory of the corresponding homonymous halves of the monocular fields of view, with the dividing lines

passing exactly through the points of fixation (Fig. 383, *1;* Fig. 385). The dividing lines are almost always straight and coincide with the vertical meridians. In rare cases the dividing lines are oblique or uneven or differently oriented in the two fields, producing incongruous, asymmetrical defects (Fig. 383, *3*). Whether this is caused by a genuinely faulty separation of the nerve fibers in the chiasma or rather by some inadequacy of testing or by other as yet unknown factors is not always clear. Another possible source of error is in the sector rests (the portions of sectors in which vision remains) on the blind side, caused by a peculiar localization of damage or damages, associated with blind other cases; *also* case AMES in the following chapter). Since the pathological agent interfering with the tract is usually a tumor or a similar expanding process which before long affects the chiasma also, a tractal hemianopia is usually complicated by loss of vision in the ipsilateral homonymous half or in both halves of the fields of vision.

It is entirely possible and probable that the seemingly infrequent occurrence of complete homonymous hemianopia of occipital origin is merely the result of inadequate testing and that a more careful examination would eliminate some of the artificial sparing of central vision. (*See* secs. 8 and 9, this chapter.)

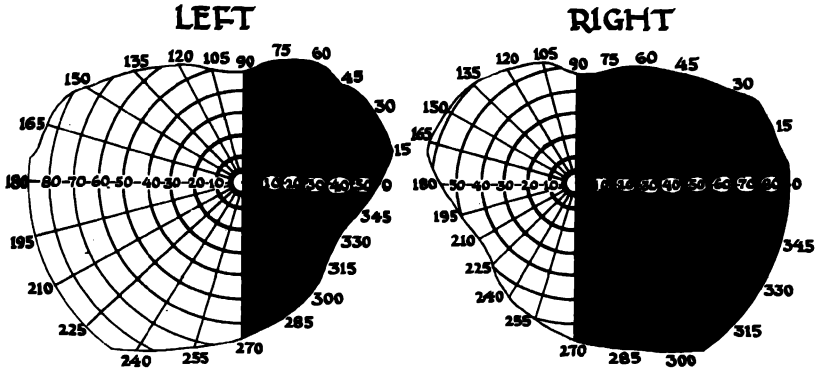

FIG. 385.—Typical complete homonymous hemianopia of the right side, with the dividing meridians passing through the points of fixation.

sectors in the opposite normal halves of the fields, the first decreasing the hemianopic loss on their own side of the vertical meridians, the latter expanding the hemianopic loss on the other side, and in this way merely simulating obliquity of the dividing lines.

A complete homonymous hemianopia is a rather frequent result in cases of a unilateral complete interruption of the optic tract or destruction of one lateral geniculate nucleus (somewhat less than half of all cases, according to Wilbrand 1930). It is more rare in unilateral injuries to the visual radiation and to the striate area of the occipital lobe (Bjerrum 1881; Dejerine 1892; Ziehl 1895; Wilbrand & Saenger 1917, p. 136; Foerster 1929, case *1*, even though his interpretation is inadequate; *see also* his

2. INCOMPLETE HOMONYMOUS HEMIANOPIA WITH PRESERVED CENTERS OF THE FIELDS OF VIEW.—This impairment is characterized sometimes by a slight, and in other cases by a large, sparing of the central or foveal-areal portions in the hemianopic halves of the two monocular fields of view: a "surplus hemianopia" (Fig. 383, *2;* Figs. 386, 387). Central sparing, in turn, is caused by a peculiar organization of the visual radiation and of the striate cortex and also by a multiple blood supply of the foveal-macular portion of the striate area, owing to which the foveal-macular portions of the visual apparatus are spared, while the extrafoveal portions are eliminated. (*See* chap. X, 8 [4]; and secs. 8, 9, this chapter.)

Whereas in a complete homonymous hemi-

anopia the dividing lines, coinciding with the vertical meridians, pass exactly through the two fixation points, in the incomplete type the lines encircle the fixation points on the blind side. Since in clinical parlance the "central" and "macular" portions of the fields of view, or "central vision," are synonymous, it is customary in cases of an incomplete homonymous hemianopia to speak of "macular sparing" or "sparing of the macula" or of "central sparing" or of a "surplus or overshot field." The spared portions of the hemianopic fields, as discussed in sections 8 and 9 in this chapter, usually coincide more or less with the opposite homonymous halves of the two central foveae and areae.

In carefully tested cases the central surplus fields are usually of the same size and shape. Not infrequently, however, owing to inadequate testing or to fatigue of the tested person and possibly also to inaccurate apposition of the ipsilateral and contralateral fibers in the brain, an incongruity between the right and the left fields is found. True sparing, it is alleged by some investigators, is characterized by smooth outlines, whereas the "rests" of the visual fields tend to have uneven boundaries. Also, in the former, the boundaries for colors and for white are the same, or almost so.

In other cases more than small central areae around the fixation points are spared. Occa-

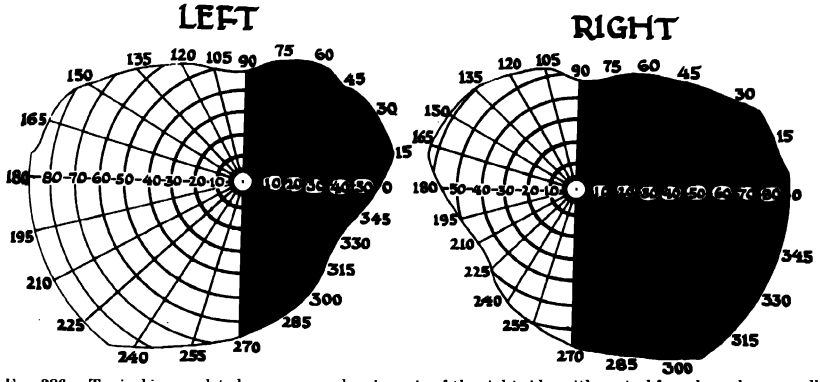

FIG. 386.—Typical incomplete homonymous hemianopia of the right side, with central foveal-areal, or so-called "macular," sparings of 5° around the points of fixation.

The extent of central sparing varies in individual cases and according to the investigators. Usually it does not exceed ½, 1, 1½, 2, or 3 degrees beyond the fixation points. In other cases it is much larger. In one case Heine (1900) computed the size of central sparing to be 2 mm. on the retinae and 7–8 degrees in the fields of view. Along the horizontal meridians central sparing measures from 5 to 10 degrees according to Morax (1919), and only 2 degrees according to Wilbrand (1930). Sparing is also more extensive along the horizontal than along the vertical meridians. In advanced age, sparing amounts to from 10 to 15 degrees, more rarely from 5 to 20 degrees, according to Schiff-Wertheimer (1926). In the first case the spared portions of the fields would approximately correspond to the central areae of the two hemiretinae.

sionally the spared or "surplus" portions of the fields are represented by narrow zones along the vertical meridians, either above or below the horizontal meridians. In still other rare cases such narrow zones of approximately equal width extend along the entire length of the vertical meridians. Again, on other occasions, the spared zones have the greatest width in the horizontal meridians, tapering along the division lines toward their upper and lower extremities (Wilbrand & Saenger 1917; *see also* cases STRAUSS, DYKSTRA, and HOLT, in chap. XII).

In still other cases considerable portions of the extrafoveal-areal homonymous field halves are spared, in addition to more or less well-preserved central or "foveal-macular" portions (thus in case DYKSTRA, early stage; *see* following chapter). Such field defects have been ob-

served in most varied combinations, for example, in a quadrantic homonymous hemianopia associated with larger or smaller scotomas in the less affected quadrants of the same side, with sector or zonal defects of various shapes, sizes, and locations, some or all extending to the field periphery, with or without central sparing, though incomplete, damage to the visual system in one or both cerebral hemispheres (*cf.* Figs. 388, 389, 392).

Central acuity in the majority of cases of homonymous hemianopia, both complete and incomplete, is found to be normal. Where there is subnormal acuity, it is usually accounted for

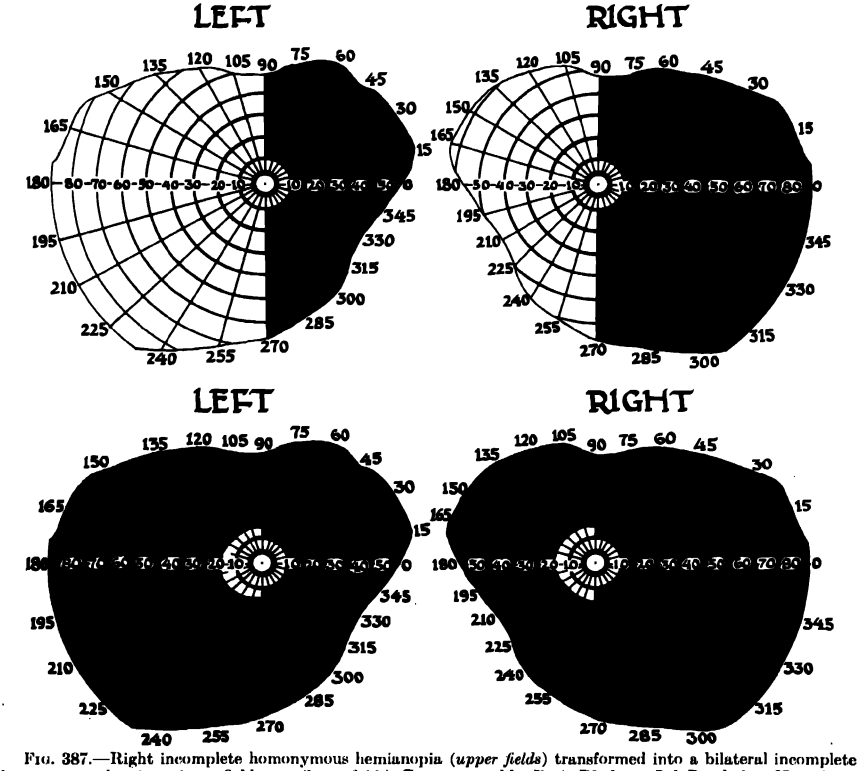

FIG. 387.—Right incomplete homonymous hemianopia (*upper fields*) transformed into a bilateral incomplete homonymous hemianopia, or field rests (*lower fields*). Case reported by R. A. Pfeifer in J. f. Psychol. u. Neurol., v. 40, 1930: a male patient, age sixty-two, interval between two plottings, six weeks; cause of visual disturbance, local defects induced by an obliterating endarteritis in the medial calcarine fissures, on right side less extensive; the right occipital pole was entirely spared, while the left pole was spared only slightly. Surrounding para-peristriate areae of both occipital lobes were not affected, nor were there any pronounced psychic symptoms registered.

or with only partial sparing in certain meridians. Such defects may be either absolute or relative or both, and may be combined with similar more or less complex defects in the opposite homonymous halves of the fields. It is only fair to say that such irregular, complex field disturbances are indicative of complex, even by secondary factors, such as pathology of the eye or optic nerve or damage to the spared foveal-macular portion of the striate area. Stereopsis usually is also found to be normal.

3. COMPLICATIONS IN HOMONYMOUS HEMIANOPIA.—An injury to the central visual mech-

anism may be either unilateral or bilateral. A lesion in one occipital lobe involving the visual radiation or striate area or lateral geniculate nucleus of one side always produces symptoms of a homonymous character, no matter what the extent and location of the lesion or what the particular quality of the disturbed visual function (an exception being the monocular temporal crescent). The loss of function is always confined to the homonymous fields opposite the site of the injury. An involvement of the ipsilateral damage to the contralateral cerebral hemisphere. However, it may happen that a damaging agent in one hemisphere simultaneously damages the opposite hemisphere also, as is frequently observed in trauma, especially in war injuries.

A bilateral injury to the visual system may most readily occur in those localities where the right and the left halves of that system are close together. Of all parts of the visual system, excepting the chiasma, the place where such an

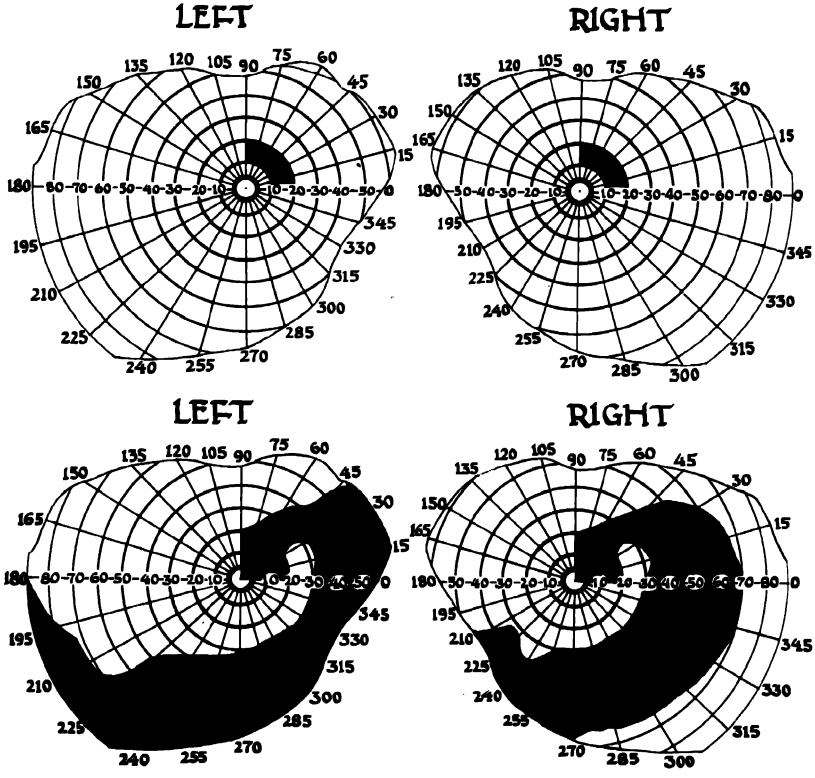

FIG. 388.—Visual field defects of a hemianopic zonal type caused by an infantry rifle bullet lodged in the left occipital lobe, verified radiographically. Point of the bullet (French type) facing anteriorly toward the sagittal plane and also 40° upward, probably beyond the mid-sagittal plane. No cerebral symptoms, except epilepsy. Operative removal of the bullet resulted in an extension of field defects on both sides of vertical meridians, especially in the upper field halves, corresponding to the operative approach. Note sparing of the right monocular temporal crescent, involvement of the lower half of the left temporal crescent, and destruction of the right upper quadrants as far as fixation points formerly preserved. B. Fleischer, Klin. Monatsbl. f. Augenh., v. 57, p. 140, case 2, 1916.

lobes. Here the two striate areae lie close together, being separated by only a thin dural partition called *falx cerebri* or "sickle" (Fig. 228). A bilateral injury caused by a single lesion may occur here more easily than elsewhere. Such an injury, because of the toughness of the intervening dural partition or falx cerebri, takes place less frequently in peacetime activities, where the applying force of trauma is less violent or where the cause is a degenerative or other type of pathology. (*Cf.* R. Förster 1890; H. Sachs 1895; Laqueur & Schmidt 1899; Laqueur 1904; R. A. Pfeifer 1930; G. Holmes; *see also* Fig. 392.)

and partly to the accident of trauma or pathological process, the centers of both fields of view are preserved for a few degrees around the points of fixation alone, as in some of the above-quoted cases. This, especially in the war cases, may frequently be preceded by complete blindness, which, within a few days or weeks, gives way to partial restoration, almost always involving the centers of the fields of view, with a resultant "tubular vision" as a residual condition (Fig. 397).

The cases of bilateral injury are of special interest, since the symmetrically organized visual pathway, given favorable circumstances,

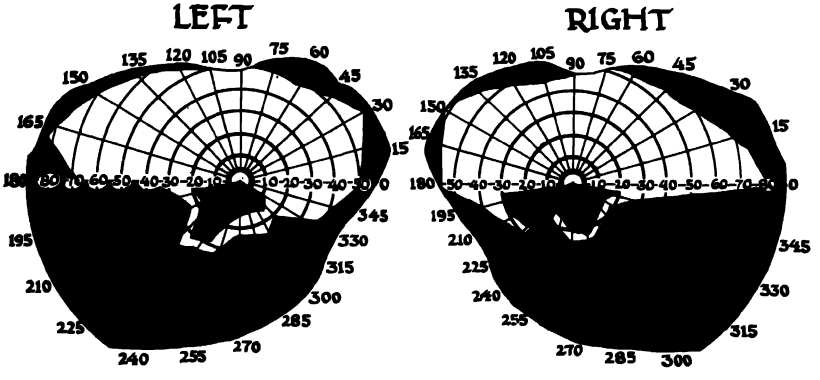

FIG. 389.—Inferior horizontal or altitudinal hemianopia of bizarre shape, with beltlike sparings, inclosing central scotomas spreading to horizontal meridians and points of fixation. Beltlike sparings apparently caused by spared strips of striate cortex lining deep secondary pockets of the calcarine fissures close to the occipital poles. A war case, Miert: rifle shot in the occiput at a level of occipital protuberance. From Wilbrand & Saenger, *Die homonyme Hemianopsie*, etc. (v. 7 of *Die Neurologie des Auges*), Fig. 134, 1917.

Bilateral damage, penetrating the dural partition is more frequent, however, in war injuries, where modern high-powered missiles easily pierce the dural falx, causing not only direct damage to the substance of the opposite hemisphere but also a complicating hemorrhage. Such bilateral lesions may cause a loss of visual function in a great many combinations (Figs. 388, 389, 390, 395).

The field defects in the right and left homonymous halves usually are not symmetrical, as they are caused by different damage to both striate areae and both visual radiations.

Occasionally, owing partly to a peculiar anatomical organization of the supranuclear portion of the visual system and its blood supply

produces symmetrical visual field defects on both sides when the causative agent impinges upon symmetrical portions of the visual system in both cerebral hemispheres. Asymmetric lesions, in turn, and for the same reason, when affecting both halves of the central visual apparatus, produce an infinite variety of visual field defects, depending upon their location, size, shape, intensity, individual anatomical peculiarities, and other factors. In particular, in war injuries the course of the channel made by the bullet in the two hemispheres is of importance, because it, together with the secondary factors such as hemorrhage, compression, and ischemia, is responsible for a particular form of disturbance in each individual case.

If the lesion is sufficiently large and if the destruction of the cerebral substance, including concussion, compression, and other interference by hemorrhage, edema, or thrombosis, damages and shuts off completely both occipital lobes, the result is complete blindness. This may be, however, merely an initial symptom, gradually receding within the first few days or weeks, with vision subsequently restored either completely or partially. Such a course of development was observed especially in traumatic injuries exemplified by the numerous war cases, where it almost seems to be the rule (Szily, Uhthoff, Wilbrand & Saenger, Morax *et al.*). In these cases intensive swelling and edema, associated with abundant hemorrhage, caused by laceration of the brain substance and very likely also by damage to the cerebral veins but especially to the arteries—primarily to the calcarine artery and its subsidiaries—often produce a general effect upon the entire brain, irrespective of the shock or commotion.

In some pertinent cases vision was eliminated completely and permanently. In other cases initial complete blindness was gradually relieved, giving way to incompletely restored function, with most variedly expressed residual partial field defects, to be discussed later. The reason for the relatively benign character of the traumatic injuries, especially in war, is the fact that the blood vessels are only a secondary cause of blindness, which, with the usually youthful and healthy state of the traumatized tissue, explains the speedy recovery of parts not directly destroyed by the trauma.

A considerably different situation is found in many cases met with in peacetime practice. Here the outcome is frequently not so favorable, because the underlying pathology is usually of a vascular, progressive character. Hence an incomplete right or left homonymous hemianopia may variously expand and sometimes become double or bilateral, occasionally leaving preserved only the centers of the fields of view, unless even these are engulfed in the general process of vascular degeneration, as may happen especially in advanced age. (*Cf.* case HOFFMANN in chap. XII; *see also* Fig. 387.)

In a number of cases, homonymous hemianopia is the only clinical symptom that indicates an organic pathology of the brain. Such monosymptomatic hemianopia is especially characteristic of the nonexpanding processes confined to the occipital region (*cf.* cases MUNSON and MALLORY in chap. XII). Contrasting with this are the lesions located in and close to the internal capsule, which directly or indirectly interfere with the lateral geniculate nucleus, optic tract, and the initial portion of the visual radiation. In such cases the clinical symptoms necessarily indicate an interference with one of the sensory or motor systems, including the cranial nerves.

In numerous other cases a simple sensory visual field defect may be accompanied by symptoms indicating disturbances of a "higher" order. Such are visual agnosia, or inability to recognize familiar objects and their use by sight; alexia, or inability to understand the meaning of written words which are otherwise seen; and especially disorientation in space, or the inability to find one's way about in formerly familiar territory (loss of mental formulas of space). Such "psychic" complications are symptomatic of more extensive organic damage to the cortex of the occipital lobes outside the striate area and to the near-by portions of the parietal and temporal cortex or to their association and projection fibers. (*Cf.* cases AMES, DYKSTRA, HOLT, and HOFFMANN in chap. XII; *see also* Figs. 274, 275.)

A rather frequent complication of right homonymous hemianopia is some form of impaired speech, sensory or motor. The underlying anatomical basis is the common blood supply of the cortical speech centers in the temporoparietal and frontal regions of the left hemisphere and, in particular, a common dependence of the visual radiation and other subcortical fiber systems upon deep branches of the middle cerebral artery (*cf.* chap. X). In some cases these symptoms may also be of a temporary nature, leaving a slight residue or none.

SEC. 5. PARTIAL HOMONYMOUS HEMIANOPIAS AND THEIR ANATOMICAL BASIS

1. QUADRANTIC HOMONYMOUS HEMIANOPIA, QUADRANTANOPIA, OR TETRANTANOPIA.—These terms designate a more or less complete loss of vision either in the upper or in the lower quadrants of the two homonymous fields of view (Fig. 383, sketches *4*, *5*). Again, as in other field defects, loss may concern all functions, such as the perception of light, form, and color, resulting in an absolute quadrantic scotoma or amaurosis. Or perception of colors alone may be lost, resulting in a relative quadrantic hemianopia or achromatopia. Or perception of forms may also suffer in various degrees, causing a quadrantic amblyopia.

The limits of the quadrantic defects usually coincide with the horizontal and vertical meridians, more or less (see case MUNSON, late phase, in chap. XII). The field defects may extend to the fixation points (Fig. 383, sketch *4*), or the central vision may be spared in a varying degree (sketch *5*). In some cases a zone along either the vertical or the horizontal meridians, or both, may also be spared (cases DYKSTRA and HOLT in chap. XII). Occasionally this zone may have the shape of a wedge or a sector, with its sharp end at the fixation points. Or the zone may extend more or less parallel to one or both meridians, or, finally, it may be of an irregular shape and location.

In an incomplete quadrantic hemianopia the field defects may be of various shapes and extent: wedge-shaped sectors or circular belts or a combination of both; or they may be irregular.

A quadrantic hemianopia may, in addition, be associated with defects in other quadrants of the same side (*see* cases MUNSON and DYKSTRA, early phases). These may disappear in the further course of the illness (case MUNSON, late phase); or, on the contrary, they may expand, producing as a final result an incomplete or complete homonymous hemianopia (case DYKSTRA, late phase).

An initial quadrantic homonymous hemianopia, on the other hand, may be temporary, improving later and even disappearing completely, with vision more or less restored to normal. Such changes depend on the nature of the causative process and on other concurrent factors.

Of the two possible types, the inferior quadrantic hemianopia is more frequent than the superior variety. The rarity of the latter, as of the upper altitudinal or horizontal hemianopia, particularly in war injuries, is to be explained by the small chance of survival because of the proximity of the vital centers in the brain stem and the damage to the large venous sinuses by a missile taking a course necessary to destroy

the lower lip of one or of both calcarine fissures. (*Cf.* Figs. 228, 269; Fig. 383, sketch *10;* and *see* par. 9, this section; for an interesting case caused by an infantry bullet arrested by the cerebellar tentorium, illustrated with an X-ray figure, *see* Szily 1918, p. 87.)

2. THE ANATOMICAL BASIS OF QUADRANTIC HOMONYMOUS HEMIANOPIA.—The anatomical cause of homonymous quadrantic hemianopia is a unilateral interruption of either the upper half of the visual pathway above, or the lower half below, the horizontal meridians anywhere above the chiasmal junction. Such a selective injury occurs more readily in a locality where the two quadrants are at some distance from each other, as they are in the visual radiation, than it does where they are close together, as in the tract and in the lateral geniculate nucleus.

In the visual radiation the fibers are arranged in a broad but thin lamina, each segment of that lamina representing a definite zone or belt of a quadrant in the two homonymous fields of view (Figs. 228–33, 235, 236). The most important single anatomical-mechanical factor that makes possible an elimination of one homonymous set of quadrants, the upper or the lower, by a single focus is the peculiar organization of the visual radiation. According to this, the extrafoveal-areal portions of the upper homonymous retinal quadrants are represented in the upper segment of the visual radiation, the lower quadrants in the lower segment or branch, with the foveal-areal, or "macular," fibers forming the intervening vertical segment of the radiation, filling the "gap" or "interval" of Gordon Holmes and Monbrun (*see* chap. IV, 7 [6]; chap. VII, 4, 5, 6; Figs. 259, 260).

This anatomical mechanism permits selective injury by a single agent of either the upper or the lower homonymous quadrants, without injury to the other quadrant on the other side of the "gap" (case MUNSON in chap. XII). The striate area, which also is potentially a favorable locality, owing to an individually varying blood supply, produces quadrantic hemianopias of its own that are less regular in shape.

The physiopathological agents responsible for the quadrantic hemianopia are as varied as those causing other visual field disturbances of central origin - trauma, hemorrhage, ischemia or thrombosis due to arteriosclerosis, embolism caused by a heart ailment or by one of the kidneys, the various tumors, syphilis, infectious foci, and so forth. In agreement with the prevalent vascular etiology, the onset is usually sudden (case MUNSON in chap. XII). In the further course the symptoms, after an initial period, may recede more or less, leaving as a residue a permanent, stationary defect (case MUNSON). This sometimes happens in pathology of vascular origin and in trauma. Frequently, however, the illness is progressive, and the field defects increase in size and intensity. This occurs in the vascular disturbances of advanced age and in expanding tumors (cases DYKSTRA and HOLT in chap. XII).

As in other visual field disturbances, a quadrantic homonymous hemianopia either may be the only cerebral symptom or may be associated with other signs indicating more or less widespread cerebral pathology. Such possible complications are hemianesthesia of the same side, Jacksonian epileptic seizures, hemiplegia, and various monoplegias. Manifestations of the higher order—e.g., visual agnosia, alexia, and agraphia; the various speech disturbances, such as aphasia, paraphasia, and so on—may also be present, frequently only temporarily. Spatial disorientation may likewise appear in benign cases, as a transient impairment. Visual hallucinations in the remaining fields of the same side have also been recorded. Scintillating scotomas and photisms of various kinds may be a prodromal or an initial symptom preceding partial or complete blindness. Or they may be residual manifestations persisting for a while after a cerebral insult. In still other cases a quadrantic homonymous hemianopia of an absolute character may be associated with a relative hemianopia in the other quadrants of the same side (case HOLT in chap. XII).

3. THEORETICAL INTERPRETATION OF QUADRANTIC HOMONYMOUS HEMIANOPIA.—The importance of quadrantic homonymous hemianopia is great in understanding the intrinsic organization of the visual pathways. A functional field defect of such definite character must obviously be caused by some definite anatomical arrangement.

Of the several striking features deserving at-

tention in a complete or almost complete quadrantic hemianopia, the first is the *straight boundary*, by which the affected quadrants are separated from the normal quadrants of the same side. This boundary coincides with the *horizontal meridian* and is a straight line, whether central vision is spared or not (Fig. 383, *4*, *5*). A classical example is case MUNSON (chap. XII; *see also* case HOLT). Strict observance of the horizontal boundaries is understandable only by assuming a mechanical-anatomical factor in the visual pathway, which, when involved, always manifests itself in precisely the same way. The straight boundary along the vertical meridians is, of course, caused by a separation in the chiasma of the nasal from the temporal fibers, which is responsible for the phenomenon of homonymous hemianopia in general.

The next noteworthy feature is the *sector defects* in cases where blindness does not extend to the vertical and horizontal meridians, or does so along only one of them (Fig. 383, *8;* Figs. 390, 391). Here the other boundary of the blind sector coincides with any one of the many possible meridians between the vertical and the horizontal meridians. The affected sectors always turn their broad base toward the periphery of the fields of view, while their pointed ends are directed toward the fixation points, which they frequently reach. The sector-shaped remnants or rests found in cases of unilateral or bilateral incomplete homonymous hemianopia behave in exactly the same way (Fig. 392). This almost stereotypical mechanical repetition found in numerous cases, especially traumatic, again indicates an anatomical segmental arrangement in some part of the visual pathway, be it in the bundles of the visual radiation or in the visual cortex, a mechanism which permits individual interference with the sector-shaped portions of the visual fields.

There is still a third feature, the *zonal* or *belt-shaped defects* or *sparings*, not rarely found in cases of incomplete homonymous hemianopia, requiring an explanation (Fig. 383, *9;* Fig. 388). In such field defects or sparings the boundaries coincide with concentric circles whose centers are the fixation points. Such narrow or broad blind belts, or remnants, may stretch from the vertical to the horizontal meridians, or they may stop at any one of the intermediate meridians. Also, they may be bounded on one side by the periphery of the fields of view, or they may be located anywhere between the periphery and the fixation points.

The regularity of outline of these beltlike defects or sparings likewise indicates the presence of a special anatomical mechanism which per-

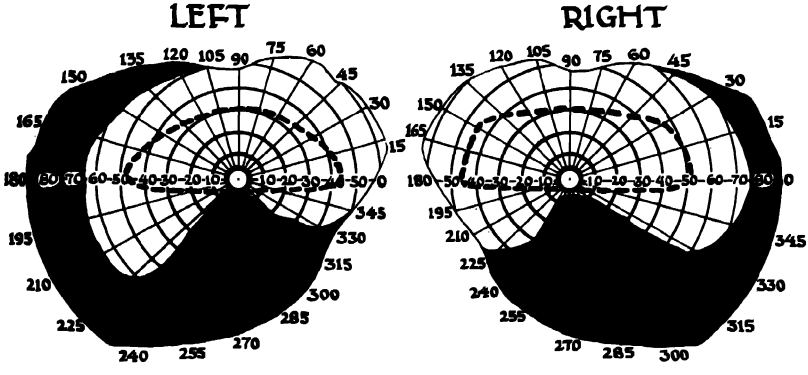

FIG. 390.—A wedge-shaped additive scotoma in lower halves of the fields of view along vertical meridians, of almost symmetrical shape, with central sparings, associated with blindness in both monocular temporal crescents. Lower relative horizontal hemianopia for colors. A war injury. Probable mechanism: partial destruction of both calcarine fissures along the cuneal margins, with additional damage, probably by thrombotic clotting, in both calcarine fissures in front of the two cunei. From A. von Szily, *Atlas der Kriegsaugenheilkunde*, etc., case 30, 1918.

mits an isolated interference with its constituent parts, corresponding to the beltlike zones of the hemiopic fields of view.

The necessity of explaining this triple mechanism, responsible for all varieties of quadrantic and partial quadrantic field defects, appears urgent in view of the fact that the sectorial and zonal defects especially appear to be mutually exclusive, in spite of their frequent occurrence in the same cases.

4. QUADRANTIC HEMIANOPIA AND THE ORGANIZATION OF THE VISUAL RADIATION.—A lesion that would cause more or less complete homonymous quadrantic blindness bounded by the horizontal meridians could a priori be thought of as being anywhere between the optic chiasma and the visual cortex, or within the latter (*see* Fig. 180).

On closer examination it seems improbable, however, that it could be in the optic tracts or the lateral geniculate nuclei, because of the compact arrangement and proximity of their fiber bundles and cellular segments related to the upper and lower retinal quadrants. This is, of course, possible, although it would be difficult to imagine a lesion of such small size, precise form, and proper location as would be required to eliminate either the upper or the lower quadrants exactly in such a way as to produce almost mathematically accurate horizontal boundaries (in such a case the large intermediate foveal-areal segment would play the role of a "buffer").

The same argument is valid against the striate area also: its large, irregular surface in the calcarine fissure and at the tip of the occipital lobe would work against this. Its multifarious blood supply also varies from case to case and follows a different pattern in each hemisphere of the same brain (as pointed out in chap. X, 5–8; *see* Figs. 369, 370, 372, 373, 374).

These obstacles would hardly allow a single lesion to extend precisely along the crooked line representing the straight horizontal meridians in the depth of the fissures. In cortical lesions it is more likely that a focus, limited, for example, to the upper calcarine lip, would partly spread over the lower lip of the calcarine fissure or that a part of the striate cortex in the upper lip would remain intact, resulting in an uneven boundary line either above or below the horizontal meridians or crossing the meridians at an angle (thus in the early phases of the cases DYKSTRA and MUNSON, in chap. XII).

By a process of elimination, the only probable structure of the visual system in which a single, relatively small lesion could readily produce homonymous quadrantic blindness appears to be the visual radiation. Here the fibers

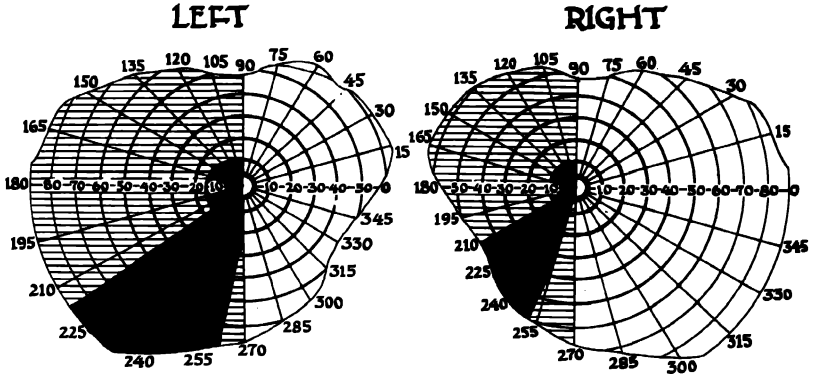

FIG. 391.—A combined left homonymous hemianopia without central sparings, consisting partly of absolute sector-shaped scotomas, but mostly of amblyopic reduction of vision (*shaded areas*). A war case, probably a combined cortical and subcortical injury. From Wilbrand & Saenger, *Die homonyme Hemianopsie*, etc. (v. 7 of *Die Neurologie des Auges*), Fig. 93, 1917.

lated to the upper quadrants of the ipsilateral homonymous hemiretinae, and the one below related to the lower quadrants. In fact, however, no "axial" segment of the external sagittal fiber lamina can be identified with a narrow stripe, which, in the homonymous fields, would coincide with the horizontal meridian, since every small fiber segment of the radiation represents a complete field belt curving between the vertical and the horizontal meridians in the respective homonymous quadrants.

Assigning to an "axial" segment of the radiation the role of representing the horizontal meridians means solely that a "virtual axis" separates the bulk of the fibers related to the upper quadrants from those related to the lower quadrants of the two ipsilateral hemiretinae or contralateral hemiopic fields of view.

6. THE REPRESENTATION OF THE WEDGE-SHAPED SEGMENTS AND BELTLIKE ZONES IN THE VISUAL RADIATION.—The representation of the homonymous sector defects in terms of anatomical arrangements is difficult to interpret (*see* Fig. 383, *8*). It would be necessary to assume that each small segment across the thickness of the radiation contained fibers corresponding to a narrow wedge-shaped sector in the ipsilateral homonymous retinal quadrants. This, however, is contrary to the concept of the organization of the visual radiation expounded in paragraphs 4 and 5 (this section), well founded upon experimental and pathological evidence (*cf.* chap. VII, 4, 5, 6; and Figs. 259, 260).

In order to explain homonymous sector defects and field rests, it would be necessary, in addition, to hypothesize that each small segment of the radiation comprises fibers of a particular field sector all the way from the fixation point to the periphery of the field. Such an organization alone would explain field defects and rests with a pointed end at the center and a blunt end at the field periphery, if a small segment of the radiation was interrupted.

This would also necessitate assuming that each small segment contains both "central" and "peripheral" fibers; for example, the axial segment would also contain extrafoveal fibers, and the upper and lower segments would also contain fibers representing the central fovea. Such an interpretation, however, cannot possibly harmonize with anatomical and clinical observations.

This forces one to the view that all hemianopic sector defects and field rests are strictly of cortical origin (thus Fig. 393). A corollary of this is the belief that the anatomical basis of sector defects and rests is essentially cortical-vascular. The uneven outlines of most of the sector defects and rests confirm this (Figs. 391, 393, and case HOFFMANN in chap. XII; *see* especially the case presented by G. Holmes 1934 and Fig. 392, this chapter).

The linear boundaries of the zonal or beltlike defects or sparings, on the other hand, coinciding with semicircles that may be drawn around the fixation points (Fig. 383, sketch *9*), agree well with the organization of the visual radiation, where each small segment on a cross-section corresponds to a quadrantic belt stretched between the vertical and horizontal meridians. According to this concept, each successive segment of the radiation, beginning with the axial-foveal and following seriatim toward the extremities of both upper and lower horizontal branches of the radiation, represents a parallel belt or zone encircling the adjoining zone closer to the fixation points, and so on as far as the periphery of the fields.

Each fiber segment of the radiation represents a complete belt or zone stretching from the vertical to the horizontal meridians in the contralateral homonymous field quadrants. The width of the blind or spared zones or belts would depend entirely on the size of the interrupted fiber segment of the radiation.

While this is easy to understand, the reason why in some cases the belts do not stretch from the vertical to the horizontal meridians, but stop short of these, must still be explained (thus in Fig. 388, lower fields; *also* Fig. 393). To assume the presence of a complicating cortical lesion is unsatisfactory for the reason already mentioned in connection with the sector defects: the difficulty of imagining lesions in the striate cortex with straight lines and a position exactly coinciding with a theoretically postulated zone or belt.

Considering the factors just mentioned, it may be assumed for the time being that most beltlike homonymous field defects or field rests of central origin are caused either by an inter-

lated to the upper quadrants of the ipsilateral homonymous hemiretinae, and the one below related to the lower quadrants. In fact, however, no "axial" segment of the external sagittal fiber lamina can be identified with a narrow stripe, which, in the homonymous fields, would coincide with the horizontal meridian, since every small fiber segment of the radiation represents a complete field belt curving between the vertical and the horizontal meridians in the respective homonymous quadrants.

Assigning to an "axial" segment of the radiation the role of representing the horizontal meridians means solely that a "virtual axis" separates the bulk of the fibers related to the upper quadrants from those related to the lower quadrants of the two ipsilateral hemiretinae or contralateral hemiopic fields of view.

6. The representation of the wedge-shaped segments and beltlike zones in the visual radiation.—The representation of the homonymous sector defects in terms of anatomical arrangements is difficult to interpret (*see* Fig. 383, *8*). It would be necessary to assume that each small segment across the thickness of the radiation contained fibers corresponding to a narrow wedge-shaped sector in the ipsilateral homonymous retinal quadrants. This, however, is contrary to the concept of the organization of the visual radiation expounded in paragraphs 4 and 5 (this section), well founded upon experimental and pathological evidence (*cf.* chap. VII, 4, 5, 6; and Figs. 259, 260).

In order to explain homonymous sector defects and field rests, it would be necessary, in addition, to hypothesize that each small segment of the radiation comprises fibers of a particular field sector all the way from the fixation point to the periphery of the field. Such an organization alone would explain field defects and rests with a pointed end at the center and a blunt end at the field periphery, if a small segment of the radiation was interrupted.

This would also necessitate assuming that each small segment contains both "central" and "peripheral" fibers; for example, the axial segment would also contain extrafoveal fibers, and the upper and lower segments would also contain fibers representing the central fovea. Such an interpretation, however, cannot possibly harmonize with anatomical and clinical observations.

This forces one to the view that all hemianopic sector defects and field rests are strictly of cortical origin (thus Fig. 393). A corollary of this is the belief that the anatomical basis of sector defects and rests is essentially cortical-vascular. The uneven outlines of most of the sector defects and rests confirm this (Figs. 391, 393, and case Hoffmann in chap. XII; *see* especially the case presented by G. Holmes 1934 and Fig. 392, this chapter).

The linear boundaries of the zonal or beltlike defects or sparings, on the other hand, coinciding with semicircles that may be drawn around the fixation points (Fig. 383, sketch *9*), agree well with the organization of the visual radiation, where each small segment on a cross-section corresponds to a quadrantic belt stretched between the vertical and horizontal meridians. According to this concept, each successive segment of the radiation, beginning with the axial-foveal and following seriatim toward the extremities of both upper and lower horizontal branches of the radiation, represents a parallel belt or zone encircling the adjoining zone closer to the fixation points, and so on as far as the periphery of the fields.

Each fiber segment of the radiation represents a complete belt or zone stretching from the vertical to the horizontal meridians in the contralateral homonymous field quadrants. The width of the blind or spared zones or belts would depend entirely on the size of the interrupted fiber segment of the radiation.

While this is easy to understand, the reason why in some cases the belts do not stretch from the vertical to the horizontal meridians, but stop short of these, must still be explained (thus in Fig. 388, lower fields; *also* Fig. 393). To assume the presence of a complicating cortical lesion is unsatisfactory for the reason already mentioned in connection with the sector defects: the difficulty of imagining lesions in the striate cortex with straight lines and a position exactly coinciding with a theoretically postulated zone or belt.

Considering the factors just mentioned, it may be assumed for the time being that most beltlike homonymous field defects or fi[illegible]s of central origin are caused either by [illegible]

ruption of, or by sparing, a small segment or bundle of the visual radiation. This may be especially plausible in instances of defects and sparings of equal width and regular, smooth outlines, stretching from the vertical to the horizontal meridians. The wedge-shaped sector defects and field rests and incomplete belts, on the contrary, may all have their origin in purely cortical lesions in the striate area of one side. This may be so in spite of the difficulty of visualizing such accurately outlined lesions. More careful plotting may yet show the outlines of the wedge-shaped defects and rests to be less straight than presented in the routine charts.

7. COMBINED CORTICAL AND SUBCORTICAL LESIONS AND COMPLEX FIELD DEFECTS PRODUCED BY THEM.—It is in the nature of the various pathological processes and equally in that of traumatic lesions to inflict irregular damage as they spread through the various brain structures serving vision. The same agent may, for example, destroy parts of the afferent fibers of the visual radiation and segments of the striate cortex. Since the bundles of the radiation and the striate cortex are spread in a tridimensional space, each in its own pattern, the resulting nonidentical or asymmetrical defects in the fields of view will equal the combined damage in the visual radiation and the striate area. It requires a thorough knowledge of the cerebral visual mechanism and a very detailed histopathological analysis of a given specimen, to interpret such complex cases in terms of anatomy and to understand the significance of each particular feature of the clinical visual disturbance in each particular case.

A good example of the difficulties is a case of incomplete hemianopia presented by G. Holmes (1931), here somewhat reinterpreted (Fig. 393). The conspicuous feature in this case was the shape of the scotomatous area. In the field periphery this area spread along almost the entire circumference, including in the left field most of the monocular temporal crescent. Toward the center it tapered along the horizontal meridian in the form of a wedge, terminating with a sharp end at the point of fixation.

According to what was said in the preceding paragraphs, the sector-shaped defect should be interpreted as of cortical origin. Instead, however, in sections through the occipital lobe (Holmes 1931, Figs. 3–6, in the original paper), the intermediate foveal-macular segment appeared completely destroyed, although, in reality, it may rather have been split and its bundles dislocated upward and downward, which may account for the small central area eliminated. The posterior extremity of the lesion undermining the striate cortex in the very pole of the occipital lobe may, perhaps, have been the very cause of the sharp salient of the scotomatous wedge resting at the fixation point (Fig. 3, in the original). The wide extent of the blind area along the periphery, on the contrary, may be squarely charged to an interference with the monocular crescentic fibers on anterior levels at their entry into the striate cortex along the middle stretch of the calcarine fissure (Fig. 6, in the original). (For additional pathophysiological analysis of cases *see* chap. XII.)

The homonymous field defects of an irregular, complex shape are, in general, attributable to cortical lesions, with or without partial involvement of the visual radiation (Fig. 393). This interpretation, with some reservations, is also applicable to the homonymous field disturbances, where small rests, e.g., in the central portions of the fields, are left intact ("central" rests, Figs. 392, 397), although a case may be imagined where a single lesion destroyed both lips of the calcarine fissure along its anterior portion ("medial calcarine") and, in addition, both horizontal branches of the radiation, without involving the intermediate "foveal-macular" segment of the radiation and the "foveal-macular" portion of the striate area at the tip of the occipital lobe (*cf.* cases STRAUSS and HOLT, in chap. XII). In such a case all but a small centrally located island of one or both sets of the homonymous fields may be included in the blind area (Fig. 383, *16;* Figs. 406, 413, 428, 432, 433). In a similar way homonymous rests in the periphery of the fields of view may be explained by the destruction of the entire striate area, including the polar segment, and of most of the radiation as well, but sparing a portion of the striate cortex along the medial calcarine fissure and a segment or segments of the radiation.

The narrow, wedge-shaped, beltlike, or irregularly shaped preserved rests of the fields of view located close to the normal field centers,

often observed in a superior or inferior horizontal hemianopia, are also essentially of cortical origin. (Fig. 393; *see also* case HOFFMANN in chap. XII.) One factor responsible for the sparing of such narrow belts or islands in trauma is most probably the sheltered location of parts of the striate cortex in the sulci next to the tips of the occipital lobes (e.g., "lateral calcarine" pocket). While the more exposed portions suffer damage, by a bullet or a bone splinter, for example, other bands of cortex tucked into sulcal pockets may remain intact, producing belts or islands of bizarre shapes and location (Fig. 389). In vascular cases the different conditions of individual vessels supplying the striate area may account for the variety of sparings and defects (Fig. 392).

In an attempt to interpret segmental and zonal hemianopic field defects in terms of anatomical arrangements, it is necessary to consider not only the nervous structures but equally the blood supply of the parietal, temporal, and occipital lobes (*cf.* chap. X). Many irregular field disturbances may well be caused by compression, thrombotic clogging, or an arteriosclerotic obliteration of one or another of the arteries supplying the striate area, while not necessarily affecting in a marked degree, or affecting only slightly, the fibers of the visual radiation, even though these are in the immediate vicinity (good examples of this are cases HOFFMANN and MALLORY, in chap. XII). In this way a segmental or insular field defect close to the fixation point may be produced if one of

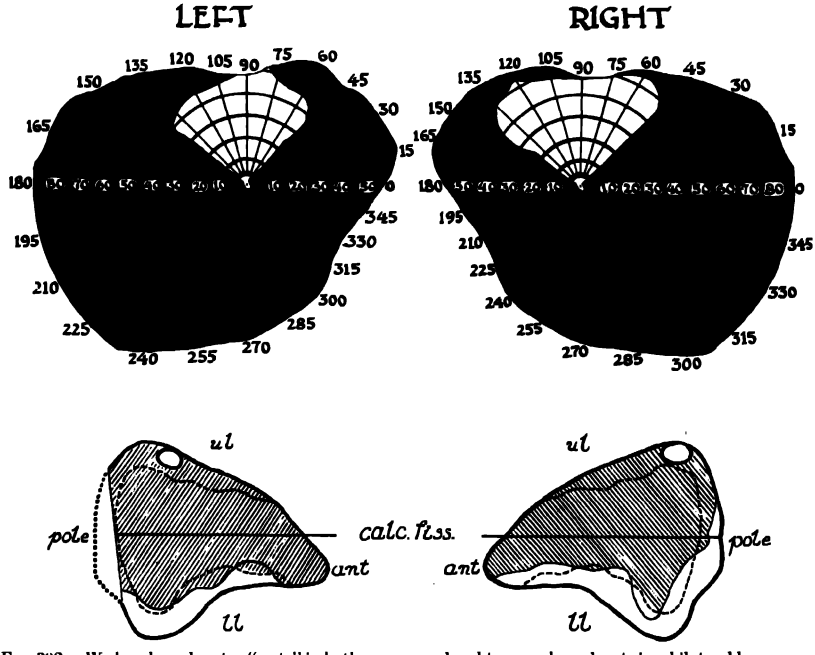

FIG. 392.—Wedge-shaped sector "rests" in both upper nasal and temporal quadrants in a bilateral homonymous hemianopia, caused by a superficial cortical softening. Preserved sectors along upper vertical meridians extend to the fixation points. Lower sketches show, by shading, the destroyed larger portions of both striate areae, with spared zones extending in an almost symmetrical way along the lower calcarine lips (*ll*) as far as the occipital poles (left pole largely missing). Floors of the fissures indicated by horizontal lines. This case demonstrates, first, a representation of sectors of homonymous hemiretinae along the vertical meridians in the fringes of calcarine fissures and, second, of the hemifoveae at the occipital poles. Age of the patient forty-seven, journalist, abuse of alcohol and tobacco. From G. Holmes, Jahrb. f. Psychiat. u. Neurol., v. 51, p. 39, 1934.

the smaller branches of the posterior or middle cerebral arteries is interfered with and the supply of a segment of the foveal-macular cortex in the occipital pole is shut off. Conversely, only a segment of the peripheral portions of the fields may be affected, if one of several branches of the posterior cerebral artery is obstructed (*cf.* Figs. 369, 370, 372, 373, 374).

of the visual radiation in the temporal lobe. It was frequently observed that in tumors and other expanding processes in and next to the temporal lobe, the upper homonymous quadrants of the contralateral side are affected much earlier than would be expected from the site of the lesion. Since, according to Flechsig, the ventral bundles of the radiation do not take a

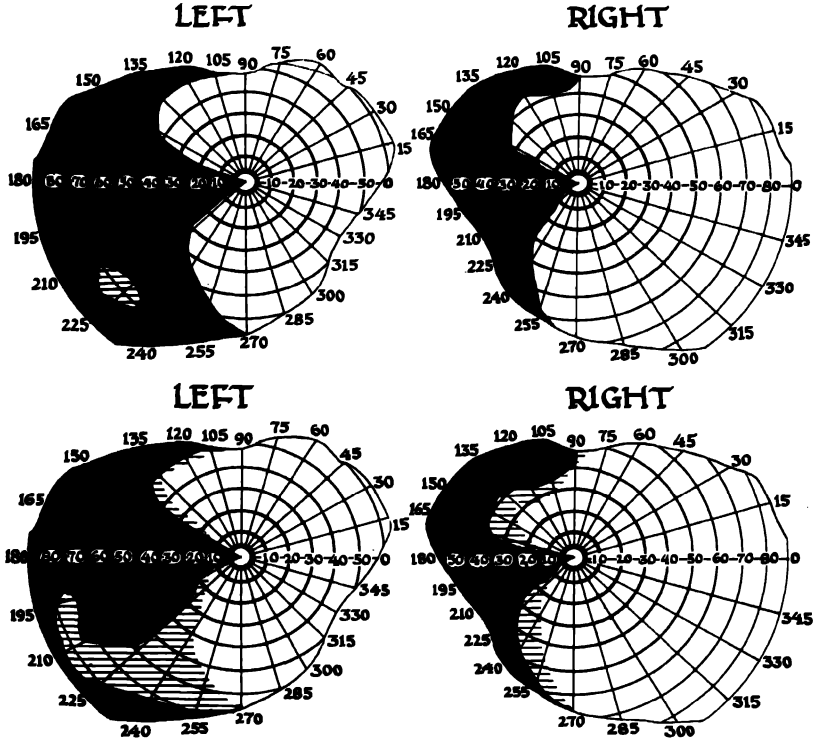

FIG. 393.—An irregular partial left-sided homonymous hemianopia extending in the shape of a wedge along the horizontal meridians as far as the points of fixation. Cause, a hemangioma with hemorrhage in the posterior portion of the right cerebral hemisphere, spreading almost to the tip of the occipital lobe, undermining the floor of the calcarine fissure, most extensively anteriorly, and gradually tapering toward the pole. Age of the patient thirty-two. Onset of illness 14 months before death, with influenza, headaches, vomiting, and photisms. Slight motor and somesthetic impairment. Onset of visual field disturbance 44 days before death. First field plotting 21 days, and second plotting 2 days preceding death. From G. Holmes, in Brain, v. 54, p. 470, 1931.

8. "TEMPORAL KNEE OR LOOP" OF THE VISUAL RADIATION AND SUPERIOR QUADRANTIC HOMONYMOUS HEMIANOPIA.—The anatomical interpretation of quadrantic hemianopia requires special consideration of the topography

straight course to the occipital lobe, as do the remaining and more dorsally situated bundles, but first turn down and forward, describing a "detour" or "loop" through the temporal lobe before turning sharply back and joining the rest

of the radiation, it was claimed that this inferiormost portion of the radiation is necessarily the first to be interfered with by an expanding lesion of the temporal region (A.Meyer, 1912; H. Cushing 1922). On the other hand, the presence of a wide detour of a portion of the visual radiation was questioned (Traquair 1922).

In order to clarify this problem, the position of the lateral geniculate nucleus must, first, be correctly determined. This nucleus, as Figures 235, 236, and 269 show, even though not so far back or so dorsally situated as indicated in Meyer and Cushing's diagram, is approximately an inch behind the anterior point to of the visual radiation and hence cause an upper contralateral quadrantic hemianopia.

One factor responsible for this is a mechanical compression of fibers. The other, and possibly primary, factor is an interference with the blood supply of the same radiation fibers by pressure upon the arteries and veins buried in the sulci of this region, particularly the posterior temporo-occipital (*poteocca*) and superior and inferior temporo-occipital Sylvian arteries (*Syteoccsua*, *Syteoccinfa*, in Figs. 369, 372, 373, 374). Such interference, by producing local ischemia, stasis, edematous infiltration, and the like, may interrupt the lower bundles of the

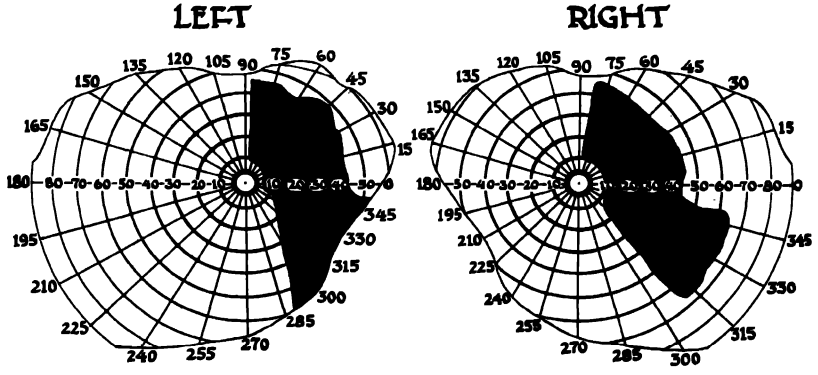

FIG. 394.—Irregular homonymous hemianopic scotomas of the right fields, probably of cortical origin. From Wilbrand & Saenger, *Die homonyme Hemianopsie*, etc. (v. 7 of *Die Neurologie des Auges*), Fig. 94, 1917.

which the detouring ventral fibers of the radiation extend. Furthermore, an examination of the serial sections through the temporal lobe shows the ventral margin of the radiation, formerly known as the "inferior longitudinal bundle" of Burdach, to be normally quite close to the cortex which lines deeper parts of the sulci on the ventral face of the temporal and occipital lobes—the inferior temporal and collateral sulci (*cf.* Figs. 228–33, 272, 273).

Projected upon the lateral surface of the brain, the lower margin of the radiation runs parallel to and only a few millimeters above the ventral outline of the temporo-occipital lobe (Figs. 235, 269). From this anatomical evidence it is safe to deduce that any process pressing upon the lateral and inferior face of the temporal lobe may first affect the lowermost bundles radiation, as suggested by the study of pathological cases. (*Cf.* Cushing & Heuer 1911; Johnson 1935; Sanford & Bair 1939.)

In the Monkey the arrangement and the course of the ventral fibers of the visual radiation, as the experiments show, is similar (Fig. 93). Here the ventralmost fibers arise from the anterolateral segment of the lateral geniculate nucleus. Without describing much of a "temporal detour," however, these fibers turn outward and backward and, from underneath, join the other and more dorsal fiber bundles of the radiation that follow one another serially as they emerge from the successive medial segments of the nucleus. Here, too, the ventral fibers are first interrupted when, in an experiment, the temporal lobe is removed. (*Cf.* chap. VII, 4; Fig. 244.)

9. HORIZONTAL OR ALTITUDINAL HEMIANOPIA.—This visual field defect is met with in cases where either the superior or the inferior homonymous quadrants of both sides are affected (Fig. 383, *10, 11;* Fig. 395; *also* case HOFFMANN in chap. XII). The effect of such bilateral quadrantic loss is blindness either in the upper or in the lower halves of both visual fields, hence a superior or inferior horizontal or altitudinal hemianopia.

While an inferior type is not infrequent, a superior horizontal hemianopia, especially in traumatic war injuries, is rarely found. The reason is obvious. The anatomical prerequisite for it would be either interruption of the ventral bundles of both visual radiations or destruction of the inferior lips of both calcarine fissures. Such an injury, as is clear from the study of Figures 228, 269, 369, and 370, would unavoidably involve other near-by structures of the brain and skull, which would be likely to cause a swift death. Such more or less vital parts of the brain or those whose damage is likely to interfere with the vital parts are the near-by arteries and veins, the venous sinuses, the cerebellum with the fourth ventricle, but, above all, the respiratory center in the medulla oblongata, and the pons of the brain stem.

In peacetime practice such cases are also rare, although it seems they had already been observed in the early period of clinical perimetry (Schweigger 1876). It is significant, however, that no case of a superior altitudinal hemianopia was observed by the principal reporters during World War I. This is to be expected, since the course of the channel that a bullet would have to take in order to interrupt both visual radiations at their lower margins or both inferior calcarine lips would have to be close to the base of the skull. In this case direct or indirect interference, by impact, pressure, laceration, or hemorrhage, with the vital structures around the fourth ventricle could hardly be avoided. (*See* chap. VII, 8 [6, 7]; and Fig. 269, for topographical relationships.)

As in other field disturbances, in altitudinal or horizontal hemianopia also, either a functional defect may be complete, with blindness extending to the fixation points (Fig. 383, *10*); or the central or paracentral vision may be more or less spared in one or both quadrants (Fig. 383, *11;* Figs. 390, 395; *cf.* also case HOFFMANN in chap. XII, and Fig. 417). Or the central portions of the normal halves of the fields above or below the horizontal meridians may also be included in the blind areas. Moreover, the superior or inferior horizontal hemianopia may be associated in the remaining halves of the fields with absolute or relative scotomas differing in size, shape, and location. Or the horizontal hemianopic defects may not extend over the entire upper or lower field halves but may leave smaller or larger portions more or less intact (thus in case HOFFMANN, in chap. XII;

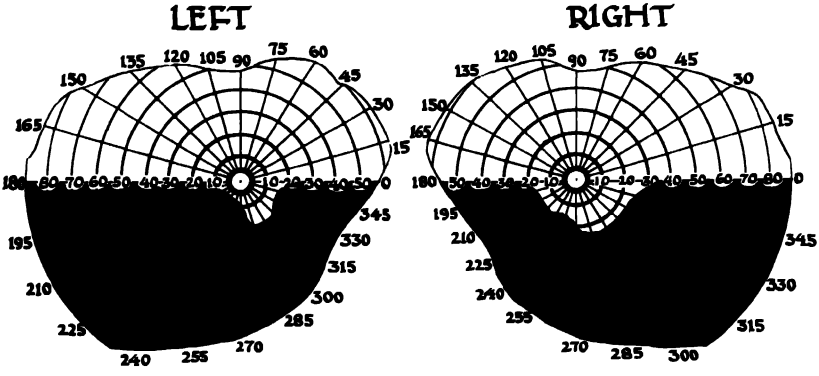

FIG. 395.—Inferior horizontal or altitudinal hemianopia with large, incongruous central sparings below the horizontal meridians. Bjerrum screen plotting. From A. von Szily, *Atlas der Kriegsaugenheilkunde*, case 39, 1918.

also Figs. 389, 390, 391). Again, if small enough and restricted to either the upper or the lower halves of both fields, such defects may appear as superior or inferior horizontal hemianopic scotomas: absolute or relative, central or peripheral, single or multiple, variously combined, and of various sizes, shapes, and location. (*Cf. also* case MALLORY, in chap. XII.)

The causative factors producing one or another form of horizontal hemianopia are as varied as those causing homonymous hemianopia in general. One of the frequent causes is the vascular and allied pathology of advanced age.

SEC. 6. HEMIACHROMATOPIA AND HEMIAMBLYOPIA

1. HOMONYMOUS IMPAIRMENT OF COLOR VISION AND OF VISUAL PERCEPTION OF FORMS AND OF LIGHT. —When the suprachiasmal portion of the visual pathways and centers is only moderately or indirectly interfered with, the functional disturbance is not necessarily a hemiamaurosis or homonymous blindness for all modes of vision, an absolute hemianopia, but an abolishment, a reduction, or a partial loss of some components or qualities which make up the function of vision. An example of such "relative" impairment is a reduction or loss of color vision of various kinds and degrees, with the perception of light and usually also of forms remaining more or less normal. This is hemianopic color dullness or blindness, or hemiachromatopia. A similar, but more intensive, disturbance, in which the colors and forms of objects are seen indistinctly or not at all and in which only a trace of light or "gray" is distinguished, is hemiamblyopia of various degrees, or "dullness of vision."

The manifestations of achromatopia or a selective impairment of color vision are as numerous as absolute forms of blindness. In a typical case of hemiachromatopia, colored objects appear to be different shades of gray. Perception of forms and visual acuity may be preserved (*see* Uhthoff 1899), or more often they also are reduced or are abolished altogether. In other cases colors are all distinctly perceived but appear subjectively duller. Or perception of some colors only may be lost, while others are perceived normally. First to suffer is the perception of green and red, followed later by the loss of blue and yellow. Complete destruction of chromatic vision is, however, usually associated with a measurable, or even considerable, impairment of the perception of light. In more severe cases the affected parts of the fields appear subjectively gray or dark, light assuming the quality of twilight. In such cases acuity and form perception are likewise, as a rule, reduced, although normal or almost normal acuity was described in cases with a total loss of chromatic vision in the respective portions of the hemiachromatopic fields. A peculiar subjective experience is dimness of vision in subdued illumination in the perception of light, form, and color resulting from certain cerebral lesions. It resembles the conditions in hemeralopia or night blindness, which makes finding one's way about in dim light extremely difficult, indicating a greater fragility of the scotopic component of

the central mechanisms in comparison with the photopic.

Amblyopic or achromatopic disturbance either may be a temporary phenomenon gradually decreasing in intensity or even disappearing completely or may result in permanent loss. Often it is an initial or prodromal symptom, subsequently transforming into absolute blindness. The portions of the affected fields of view may be exactly the same as in absolute hemianopia and in the scotomas. The division lines may pass through the fixation points, or there may be "central sparing." The relative field defect may be confined either to the upper or to the lower homonymous quadrants, or there may be homonymous amblyopic or achromatopic scotomas of different shapes and sizes, located in different parts of the fields of view. Also, a relative field defect may accompany others where blindness is complete; for example, an inferior quadrantic achromatopia may accompany an absolute superior quadrantic hemianopia on the same side (thus in case HOLT, in chap. XII, and Fig 413).

Color vision may be affected bilaterally and in varying degree and extent. In cases of an injury to both sides of the visual pathways and centers, color vision may be impaired bilaterally and is then usually associated with absolute field defects of various kinds (*see* par. 4, this section).

2. PATHOANATOMICAL BASIS OF HEMIACHROMATOPIA AND HEMIAMBLYOPIA.—A possible pathological cause of a partial qualitative impairment of visual function manifested in a hemianopic loss of color perception may be a unilateral trauma, a hemorrhage, a tumor, an abscess, a syphilitic process, or any other of the numerous pathological agents and processes already mentioned, which may interfere with, but may not completely destroy, normal conditions in the visual pathways and centers.

A hemorrhage or a thrombotic encephalomalacia which does not damage the visual pathway directly but exerts an effect from a distance seems to be the most frequent cause of impaired color vision of central origin. Both causative processes, in turn, may have their origin in an atheromatous change in the blood vessels, or a hemorrhage may complicate a trauma, as in gunshot injuries, and the like.

Such vascular etiology is suggested as a pathophysiological agent in hemiachromatopia characterized by a sudden onset. Gradual development and aggravation of symptoms that may eventually terminate in complete blindness point rather toward a slowly expanding process, such as a tumor. A scar, either in the cortex or in the subcortical fiber mass of the parietotemporo-occipital lobes, situated in the neighborhood of the visual pathway or visual cortical center, may have a similar effect because of its pulling action and the strangulation of blood vessels or of the fiber systems.

That an encephalomalacic ischemic focus may produce a disturbance of color vision is well illustrated by case HOLT described in the following chapter. At the time of plotting, this case also showed a combination of achromatopic disturbance in one quadrant with absolute blindness in the other quadrant of the same homonymous fields, both caused by a similar pathology present in a different degree in different localities (Figs. 413–16).

A temporary or transient hemiachromatopia may indicate a vascular functional origin—in any case, a reversible process—and hence may gradually give way to normal function. Or it may indicate the beginning of serious trouble which may eventually terminate in complete blindness.

To conclude, the prevalent opinion is that hemiachromatopia and hemiamblyopia and similar relative impairments of vision are distance phenomena caused by indirect action of the various pathogenetical factors and agents. Whereas in the field disturbances of an absolute and permanent character the underlying pathology is an interruption of fiber systems or destruction of the cortical substance, the interference responsible for the relative field disturbances is of a milder nature and lesser degree.

3. COMPLICATIONS IN HEMIACHROMATOPIA AND HEMIAMBLYOPIA.—A homonymous hemiachromatopia caused by damage to the occipital lobe and the adjoining portions of the cerebral hemisphere may be accompanied by disturbances of a higher order, localized on the same side as the field defect.

Of great theoretical interest is the visual hemiagnosia or inability to recognize or to identify by sight objects in the affected halves of the

fields, although acuity and form and color perception may themselves be more or less preserved. On the other hand, visual hemiagnosia without hemiachromatopia, with or without absolute hemianopic scotomas, does not seem to occur (Schiff-Wertheimer 1926). This points to the presence in both hemispheres of a substratum in the cerebral cortex that is instrumental in higher visual functions, organized upon the same topographical principle as that by which the retinal surface is represented. (*Cf.* association connections of the striate area with the adjoining para-peristriate area, in chap. VII, 7, and Figs. 274, 275.)

Not infrequently a relative visual field disturbance is associated with other somatic motor and sensory symptoms of central origin, such as hemianesthesia, hemiparesis, or hemiplegia, and with symptoms indicating involvement of the cranial nerves. Other disturbances, such as the various forms of aphasia, agraphia, alexia, amnesia, and so forth, usually indicate a widespread organic cerebral pathology. Sometimes a homonymous achromatopia is preceded or accompanied by visual hallucinations of objects or colors that are localized on the side of the field defects.

4. BILATERAL HOMONYMOUS HEMIACHROMATOPIA (CEREBRAL ACHROMATOPIA) AND BILATERAL HEMIAMBLYOPIA (CEREBRAL AMBLYOPIA).—A bilateral impairment of color perception in both homonymous sets of fields of view was observed in a few cases where a cerebral seat of injury was either probable or practically certain. It is remarkable that in some cases there was a reduction neither of central or foveal acuity nor of the extent of the fields of view. Such a condition may last for several years without change, or a slight degree of color perception may be recovered. In other cases acuity is also impaired. A rather pronounced cerebral amblyopia, with achromatopia resulting from a brain injury incurred during the war, was described by Uhthoff (1915, 1916).

An achromatopia may be preceded or accompanied by hallucinations either of formed objects, scenes, and the like or by colored photisms. The hallucinated color may be the same in all attacks.

5. PATHOPHYSIOLOGICAL DEDUCTIONS FROM HEMIACHROMATOPIA.—The fact of separate impairment of color perception and in many cases of individual colors or of combinations of colors led to the assumption of the presence in the visual system of a specific material substratum underlying the perception of color. Incomplete dissociation of the chromatic from the achromatic visual functions, however, indicates a close anatomical and functional relationship between the several basic components of vision: those serving the perception of colorless light (achromatic vision), of color (chromatic vision), and of dimensions (acuity, perception of form and space).

Whereas, phenomenologically, these manifestations are separate, anatomically and in terms of underlying physical, chemical, and electrophysiological factors they have to be considered as closely related. In fact, the several functional components may be merely manifestations of basically the same material substratum reacting differently under different conditions. In other words, part of the structures serving all the functions of the visual apparatus are common to all, as discussed in the preceding chapters.

Nor is there unimpeachable anatomical evidence of a special region in the cerebral cortex concerned with the perception of color. Color vision appears, accordingly, to be a partial function of the same visual mechanism which otherwise serves the perception of white-light sensations and is a repository of the "local signatures" manifested in the perception of form, movement, acuity, and so forth.

How the higher susceptibility of the chromatic mechanisms to various noxious agents, in comparison with the more robust mechanisms instrumental in perception of colorless light, is to be interpreted in terms of anatomical structures and of physical and chemical processes cannot even now be answered except hypothetically. Possibly the chromatic mechanism of the visual afferent system all the way from the retina to and including the striate cortex is composed of more delicate neurons, as is indicated by the retinal structures that most likely serve color vision (chap. V, 3, 4, 5, 11).

In this connection one could point to the reduced synaptical contacts, their smaller numbers, and other subtle histological details as factors which possibly make the delicate "epi-

critic" cone mechanism less resistant to the noxious agents in conditions where the more crudely organized "protopathic" rod system, composed of much more robust neurons, thicker nerve fibers, and more numerous synaptical contacts, still functions satisfactorily, or does so in an exaggerated fashion, as the intensive photophobia in acute pathology of the striate cortex and visual radiation definitely suggests. Still other factors of an even subtler nature, such as a particular chemical composition of the cytoplasm, possibly make the cone mechanism susceptible to very slight noxious influences which remain inconsequential for the rod mechanism. How this can be made to harmonize with the greater fragility of the central scotopic apparatus in brain injuries, previously mentioned, remains to be explained.

Hemiamblyopic disturbances, where no detailed forms are perceived, but only simple light in contrast to darkness, are somewhat easier to interpret in terms of anatomy, physics, and other basic factors. It is possible to visualize a profound interference with the visual pathway where the more delicate and hence less resistant neurons—the majority—are gone, leaving an irregular array of scattered and more robust neurons and fibers through which it is still possible for impulses to pass from the retina to the cortex, and disseminate there. In such a defective central visual mechanism, most or all of the more delicate neurons, which are instrumental in refined spatial functions and in color vision, may have been destroyed, with all finer "local signatures" and hue perception abolished. The few surviving more robust elements, themselves vitally impaired, may nevertheless be sufficient to mediate crude, summary light perception. When the vitality of these *ultima morientia*, or "last-dying elements," is also undermined, all visual perception becomes impossible.

SEC. 7. SCOTOMAS, FIELD RESTS, CRESCENTIC AND OTHER FIELD DEFECTS AND THEIR INTERPRETATION

1. Classification.—The term *scotoma* designates any relatively small defect in the field of view caused by a restricted injury to the visual system. The seat of the lesion may be anywhere in the visual system, from the retina to the striate area of the cerebral cortex.

The character of a scotoma varies considerably, depending upon the location of the lesion in the visual pathways and centers. In accordance with the general plan of the visual system, a single lesion in the retina or in the optic nerve produces a single scotomatous defect in the corresponding monocular field of view, whereas a single lesion in and above the chiasma results in a hemianopic defect in both fields of view (parts of the suprachiasmal pathways and centers related to the monocular temporal crescent are an exception).

According to the degree of the disturbance and the functions disturbed, three varieties of scotomas are distinguished. An *absolute scotoma* indicates a defect where all vision in the scotomatous area is abolished. Contrasting with this is a *relative scotoma*, where only color perception is impaired. Finally, in an *amblyopic scotoma* only dim vision remains.

Depending on the location in the field of view, two groups of scotomas are further distinguished. The *central* and *paracentral* scotomas are defects located in and around the fixation points, with or without involving these points. Defects located at some distance from the fixation points are the extrafoveal, extramacular or *extracentral* or *peripheral scotomas.*

2. Neuroanatomical mechanics underlying the scotomas.—A scotoma caused by a lesion below the optic chiasma residing in the retina or in the optic nerve differs in character from one caused by a suprachiasmal lesion. The

first is often unilateral (Fig. 382, *2, 4, 5, 6, 10*); or, if there are two bilaterally situated scotomas, they usually are not congruous in form, size, and location (sketches *3*, *15*). Circular, oval, arcuate, and annular scotomas are almost always caused by foci in the retina or in the optic nerve, on one or on both sides (Traquair 1946). The homonymous hemianopic scotomas are characterized by congruous shape, size, and location of defects in both fields (Fig. 383, *8, 9, 15, 17, 18*); they are most usually caused by a limited unilateral damage to the suprachiasmal portion of the visual pathway, including the striate area (Wilbrand & Saenger 1917).

Scotomas void of a hemianopic character, especially those restricted to central portions of the fields, are usually caused by either an infection or trauma or some other pathology of the eye. Such is glaucoma, or a degeneration of the "papillomacular" or, more properly, the "foveal-areal" bundle in the retina and in the optic nerve, caused by a toxic agent, usually tobacco or alcohol. Such scotomas, when present in both fields, are usually not congruous (Fig. 382, *3*).

Homonymous hemianopic scotomas are ordinarily caused by a vascular disturbance, such as hemorrhage, embolism, arteriosclerotic or spastic ischemia, or thrombosis, and less frequently by certain infectious diseases of the central nervous system, e.g., disseminate sclerosis, encephalitis, and syphilis. Tumors are, on the whole, of lesser account as an etiological factor because of their large size and usually expanding, progressive character. Trauma, on the contrary, is an important cause of scotomas, especially in war injuries, where bullets, shell fragments, and bone splinters may damage a portion of the visual pathway. Many such war-caused scotomas, especially if small in size, are liable to be overlooked, since they frequently do not cause subjective deficiency in function.

When, for one of these reasons, a small portion of one optic tract or a fraction of the lateral geniculate nucleus, a segment of the visual radiation or of the visual cortex—the striate area—is interrupted, destroyed, or otherwise affected, this manifests itself in a functional defect in the homonymous halves of both fields of view. For mechanical and anatomical reasons it is to be expected that, all other factors being equal, a small lesion may more readily produce a restricted functional field defect, if it applies to those parts of the visual system where its constituent fiber bundles and cells, or anatomical-functional units, are large and therefore widely spaced, than in those parts where they are crowded into compact tracts or nuclei. Damage to the optic tract or lateral geniculate nucleus is, therefore, less likely to produce a small scotoma.

More favorable in this respect are the visual radiation and, above all, the striate area. The latter offers a large surface which represents a mosaic made up of a great number of relatively large functional-anatomical units distributed over a wide area, as illustrated by our experiments (chap. VII, 5 [2]). A restricted mechanical injury such as that caused by a small instrument in an experiment, by Graefe's cataract knife, for example; or in trauma by a nail, a screw, a fragment of a shell, or a bone splinter; or in vascular pathology by a minute hemorrhage or an ischemic focus is likely to interfere with only a small group of functional units, producing a minute congruous hemianopic scotoma in both homonymous fields (Fig. 383, *15;* Figs. 388, 396; *see also* cases HOFFMANN, KRAFT, and MALLORY, in chap. XII).

Of special importance in understanding the intrinsic organization of the visual centers are small central, paracentral, and extracentral or peripheral homonymous hemianopic scotomas caused by an arteriosclerotic pathology or an arterial spasm restricted to the striate cortex, without any damage or with only insignificant damage to the subcortical fibrous substance, as illustrated by case MALLORY (*see* chap. XII, and Figs. 424–27). They may be satisfactorily explained by the size, shape, and location of the lesion limited to one of several arteries supplying the striate cortex or even to a single small arterial branch that may be shut off by a pathological process or agent.

When an ischemic or malacic focus is close to the anterior extremity of the striate area, the defects are located in the periphery (e.g., in the temporal crescent); when the lesion is at the occipital pole or close to it, the functional defects are central or paracentral scotomas; when either the upper or the lower calcarine lip is affected, the scotomas are located in the lower or upper field quadrants, etc. (*cf.* chap. X). When, as in

some war cases, both occipital lobes are damaged, a complex injury is produced, manifested in variously combined defects, with or without impairment of the centers, of the periphery alone, or of the centers around the fixation points of both fields of view alone, in the latter case with acuity reduced to 1/100 or less.

§ 3. PATHOPHYSIOLOGY OF THE SCOTOMAS.—The onset of a scotoma, as of other field disturbances, is often associated with symptoms indicating an irritation of the cerebral substance, usually of a vascular nature: arterial spasm, sudden thrombosis, or venous stasis. Such symptoms are photisms of various kinds and frequently also visual hallucinations.

During the actual origin of even a small scotoma, if it occurs during full consciousness, the initial phase may be a violent one: an overwhelming display of brightly illuminated objects, blocks of buildings and mountains crumbling into a brilliant nothingness! This terrifying subjective experience only gradually subsides, within minutes or hours, as the underlying pathological process quiets down to the phase of repair setting in as soon as the destructive phase is over (a classical example of this is case MALLORY, in chap. XII).

Various subjective phenomena may follow the origins of a scotoma. Such is a brilliant display of fantastic photisms, stars, and whirligigs of different hues, still or in motion, localized along the edges of the final scotoma. This display sometimes lasts for several hours, and it may subsequently be replaced by outbursts of scintillation of gradually decreasing frequency and intensity during the following weeks and months (author's personal experience).

Obviously, the underlying pathological process responsible for this subjective experience is an irritation of the marginal zone of the remaining surviving striate cortex after the shutting-off of one of the arterial branches supplying that cortex. As a parallel, in a physiological experiment with an isolated portion of the cerebral cortex, such spontaneous "outbursts" of activity have been described as occurring at short intervals of 10–30 seconds, each lasting from 2 to 4 seconds, resembling the scintillation in the zone surrounding the scotomatous defect (Burns 1951).

Scotomas, especially central hemianopic, after an initial period of expansion lasting from a few seconds to at most a few minutes, followed by a period of recession, may become absolute and, after a relatively short time, may remain stationary until the end. More rarely, in scotomas of central origin, color perception alone is affected (thus in a case described by Wilbrand 1926). If small enough, especially if eccentric, a scotoma may not necessarily produce a subjective sensation of a defect, except in situations requiring greater use of vision, e.g., in reading fine print (*cf.* cases KRAFT and MALLORY, in chap. XII). Even more elusive subjectively are small scotomas located in the periphery of the fields of view (Wilbrand's and the writer's personal experience). This may especially be the case with scotomas caused by war injuries, requiring careful testing by the examiner.

The characteristic persistence of scotomas during long periods is a manifestation and evidence of their organic origin, that is, of their being caused by a definite and irreparable damage to the visual pathway (*cf.* case MALLORY, in chap. XII, where a central scotoma lasted more than three decades). Scotomas are sometimes the only disturbance, as is often the case with traumatic war injuries in young and otherwise healthy individuals. In other cases they are associated with other symptoms, such as a contraction of fields of various shapes, sizes, and locations (thus in case KRAFT, in chap. XII). They can, furthermore, be accompanied by other disturbances, such as somesthetic or motor disturbances, hemianesthesia, hemiplegia, aphasia, agnosia, agraphia, alexia, and other psychic manifestations indicating a more general cerebral pathology.

4. TRANSIENT SCOTOMAS.—The reaction of living structures, nervous and vascular, serving vision under pathological conditions is fortunately more pliable than it would appear from presentation in the literature. Especially is this true of the scotomatous phenomena in and close to the fixation points. A rigid, static concept of a scotoma as an absolutely or relatively blind area in the fields of view is true only for a residuum of a process corresponding to an irreparably damaged portion of the nervous struc-

tures. There are reasons to believe that during life, particularly in advanced age, or during an intercurrent illness, local impairments of tissue occur that are temporary and reversible, with a full or almost full return to normal function within a few hours or days after the onset.

In toxic conditions such as occur during treatment with dicumarol or in conditions of general disturbance of the cerebrovascular apparatus, as in hypertension, or after a cerebral vascular insult, as well as under the influence of caffeine, theobromine, or tobacco, and after prolonged administration of nitroglycerin or theocalcium, small scotomas may appear, which within a few minutes, hours, or days disappear without leaving a trace of a defect that can be determined with the usual methods. (In other cases the same drug poisons, widely used in vascular cardiac disease and as food, may have fatal consequences.) This is of extreme importance, both practically and in the theory of function of the central visual mechanism. A minute hemianopic scotoma a few degrees to the right or left of the common binocular fixation point is highly bothersome, as it interferes with reading, even though it may not be a serious impediment to distance vision or orientation in space. Such a scotoma, when caused by a passing disturbance, e.g., an arterial spasm, possibly also by a reversible thrombosis, may be almost entirely erased by relaxation of the spasm, resolution of the causative clot, or establishment of collateral circulation. A multiple blood supply found in the occipital pole of the cerebral hemisphere, as described in chapter X, 6, 7, 8, is a powerful factor in the process of repair. (*See also* Wilbrand 1907.)

There are indications that in large scotomas caused by massive destruction of the brain substance a certain amount of repair also takes place along the fringes of the defect, as a slow, gradual reduction of the scotomatous territory is noticeable, even after a lapse of many months. (*Cf. also* following sections in this chapter.)

5. THEORETICAL SIGNIFICANCE OF SCOTOMAS. —From the beginning of modern clinical research much attention has been paid to the minute defects of the fields of view, especially to central scotomas. The theoretical importance of such defects is evident (*see* Wilbrand 1926). Such minute defects are possible only if the conducting fiber bundles and nerve cells making up the visual system are arranged so that the original topographical relationships present in the retina are preserved all the way along that system and as far as the visual cortex, the striate area (as presented in chaps. VI, VII). Only in systems thus organized is it conceivable that a small injury could destroy a small cell nest or interrupt a small, individual fiber bundle, which would produce a single small functional defect in one monocular field, if the injury was below the chiasma, and in each homonymous half of both fields one of an almost absolute congruity, if the location of injury was above the chiasma. (For the historical background *see* Part I in this book, especially chap. III, 8, 9, and chap. IV, 4, 5.)

Several inferences, each of basic importance to knowledge of the organization and function of the visual system, may be drawn from the foregoing proposition. The first is anatomical. The presence of scotomas measuring 1 degree of arc or less in diameter postulates a parallel course of fibers in the optic nerves, tracts, and visual radiations. Minute bundles arising from the adjoining minute territories of the retina remain close together in the optic nerve and also preserve in a high degree the same position relative to one another. If it were otherwise, if the bundles were in any considerable degree to deviate from one another and were to intermingle with the bundles originating from more or less distant points of the retinal surface, the outlines of a scotoma would not be sharp, but fuzzy and indefinite, with more or less wide transition zones of decreased function between completely blind and entirely normal territories of the fields of view. Or, if the mixing or overlapping of individual bundles of nerve fibers were to go beyond a certain degree, a small injury could never produce an absolute scotoma but only one where vision was reduced or in some way altered, as is the case in relative scotomas.

Furthermore, the fact that small injuries to the visual apparatus above the optic chiasma produce minute scotomas of an almost mathematically congruous shape, size, and location (except in the monocular temporal crescents) shows that the ipsilateral and contralateral

fibers and cells related to the "corresponding" or "syndynamical" points of two homonymous retinal halves in most of the visual pathway are very accurately aligned or apposited. This deduction is in complete accord with the results obtained by experiment (*cf.* chap. VI, 7, 9; chap. VII, 4, 5, 6).

Moreover, an absolute loss of all components of visual function in the scotomatous area (perception of light, color, and shape and acuity) indicates that if some or all of these particular functions are using special nerve fibers as conductors of their own, these different fiber categories must be uniformly distributed on a cross-section through the visual pathway. This view alone is consistent with the fact that, in absolute central scotomas, boundaries for white and those for several colors, even though not absolutely identical, differ only a little.

Finally, the persistence of minute scotomas in any part of the fields of view, especially in the very centers, indicates a high degree of anatomical and perceptive functional independence of each of the countless receptor-conductor units making up the visual system. This independence, in turn, is a prerequisite for the detailed function of the visual system. This same independence, unfortunately, prevents any substantial "vicarious" functional substitution for a loss by the adjoining units. Hence functional recovery in cerebral injury is entirely the result of rehabilitation of the structures that do not suffer irreparable or irreversible damage.

The indicated organization is to be accepted in the entire visual system from the retina to the occipital cortex. Anywhere along its course a small injury may produce a small scotoma of a particular type, subject to certain local variations. A small defect in one optic nerve or retina results in a scotoma in one monocular field only. A lesion above the optic chiasma, in the tract, lateral geniculate nucleus, visual radiation, and the striate cortex, produces defects of a hemianopic character in the corresponding territories of both fields. There are two localities which are exceptions. First is the chiasma, where a single monocular field defect may be produced, depending on the seat of the lesion, if, for example, one of the nondecussating fiber bundles is interrupted. The other localities above the chiasma are those segments of the visual pathways and centers where the monocular temporal crescents are represented; here a unilateral lesion produces a single, monocular scotoma in the contralateral field of view (Fig. 383, *13*).

While the basic principle upon which the visual system is organized remains essentially preserved in its entire extent, the relatively gross anatomical features vary much, as described in chapters VI and VII. Hence limited damage necessarily produces a different result, depending on the injured part or segment. In the optic nerve and tract and in the chiasma, because of their small size and compact structure, only lesions of very restricted size may produce defects smaller than one-fourth of a field that may be classified as scotomas.

Scotomas caused by a mechanical or toxic agent acting selectively are an exception (Fig. 382, *2, 3, 5, 6*). Almost the same is true, because of its small size, of agents damaging the lateral geniculate nucleus.

The visual radiation provides more favorable conditions for the production of a small scotoma by a restricted lesion. Here the fibers are distributed in a relatively thin lamina of considerable spread, requiring a much larger lesion to produce the same effect. Since the intermediate segment containing foveal or "macular" fibers is a relatively large portion of the radiation, even a sizable injury localized here may cause only a small hemianopic defect in the central portions of the fields of view. The responsible factors are the small size of the central fovea, the compact arrangement of its receptor-conductor units, and the minute dimensions of these units.

Conversely, a lesion in the upper or lower horizontal segments of the radiation, even though it may be restricted, produces a large scotoma, which may easily expand over one whole quadrant. Here, in contrast to the foveal segment, each receptor-conductor unit controls a relatively large territory in the extra-areal retinal periphery.

The same reasoning applies also to the lesions confined to the striate cortex. Damage to that cortex in the anterior or medial portion of the calcarine fissure may more readily result in a large field defect, whereas the same lesion in the posterior or lateral calcarine fissure around the

occipital pole would produce a minute homonymous hemianopic defect close to the fixation points.

The fact that minute central scotomas, especially of an absolute variety, are found in many shapes, sizes, and locations shows further that the retina, especially the fovea, has a very detailed representation in the entire visual pathway, including the striate cortex. This representation or "projection" is carried out according to the principle of a cable composed of numerous individual, insulated, parallel conductors. In this way the original topographical relationships, present in the retina and indispensable to the normal functioning of the visual mechanism, are maintained throughout that entire mechanism. This accounts for the great similarity in pattern on a cross-section at the beginning of the pathway, in the retina, and at its termination in the striate area. There is no confusion or any considerable mixing of the heterodynamical conductor units, the preservation of the original pattern being carried out with the greatest fidelity and most detail precisely where one would expect it: in the part conducting impulses from the central fovea-area ("macula"). The small size and sharp outlines of the central and paracentral scotomas are evidence of this. This interpretation of clinical observations fully agrees with the results obtained from experiments with monkeys (chap. VII, 4, 5, 6).

The detailed organization of the visual system discussed in the preceding paragraphs needs to be qualified in one point only. This concerns the important changes in the course of the fibers in the chiasma, in the optic tracts, and in the lateral geniculate nuclei. In the first the two nasal sets of fibers temporarily intermingle with each other, without coming into any functional relationship, however. In the tracts and geniculate nuclei the homonymous ipsilateral and contralateral fibers undergo an intimate relationship, which is fully achieved in the striate cortex. But all these changes are carried out without detriment to the fundamental requirement for the preservation of original topographical relationships, as found in the photoreceptor retina, throughout the whole system.

The preceding views on the intrinsic organization of the visual system may appear rather dogmatic. They will, however, appear less so if one realizes the uncompromisingly severe functional demands on the sense of sight exacted by biological and physiological conditions, as discussed in chapter XV. Slight individual departures from the prescribed principle of organization, e.g., a genuine hemianopic asymmetry, are, of course, possible but need to be documented by further observation (*see* par. 8, this section).

6. SCOTOMAS AND THE CORTICAL REPRESENTATION OF THE CENTRAL FOVEA.—Small hemianopic scotomas close to the fixation points are, in general, of value in the problem of cortical representation or localization of the central fovea or "macula." A sufficient number of cases has been reported to serve as evidence that the posterior portion of the striate area is related to the centers of the homonymous fields, the anterior portion closer to the splenium of the corpus callosum, to the periphery and to the monocular crescent. This agrees with the results derived from experiments.

The number of cases with small central or peripheral scotomas or with equally significant small field rests which have been carefully examined anatomically is still extremely small. Even so, sufficient clues have been collected to aid in devising a map of the topographic organization of the "cortical retina." Such is case EGGERZ (Fig. 396) reported by Henschen (1911), which indicates the position of the horizontal meridians in the floor of the calcarine fissure. Other valuable modern cases which help solve the question of precise topographical representation of the retina in the striate area are those published by Pötzl (1918, 1919, 1928), G. Holmes (1918, 1919, 1931, 1934), Brouwer (1930), R. A. Pfeifer (1930), Polyak & Hayashi (1936), and also case MALLORY, described in chapter XII.

The study of scotomas proves to be of great value in the controversy about the representation of each complete "macula" in both cerebral hemispheres (the term *macula*, unfortunately, was accepted in the clinical jargon as synonymous with *central fovea*). This hypothesis was devised in order to explain the sparing of central vision frequently found in homonymous hemianopia of central origin. Because some of

the most notable investigators have adhered to it, as, for example, Wilbrand, Henschen, and Brouwer, and because of the many discussions connected with it, this problem is dealt with in detail in the following sections of this chapter.

7. HEMIANOPIC "RESTS" OR "REMNANTS" OF THE FIELDS OF VIEW.—This term designates small remaining portions or "leftovers" in otherwise amaurotic homonymous fields of view. Such normally functioning field rests are "positive" counterparts of the "negative" hemianopic scotomas which represent blind defects that is left of the two fields of view are two minute central territories extending in various directions from one degree or less to several degrees from the fixation points (Fig. 397). Their shape usually is strictly congruous. Acuity, form, and color perception within such minute central field rests may be more or less impaired, or, on the contrary, some or all of these functions may remain normal. Other visual functions, such as orientation in space, judgment of size, position, and direction of stationary or moving objects, direction of the gaze, and similar complex functions, may in some, although

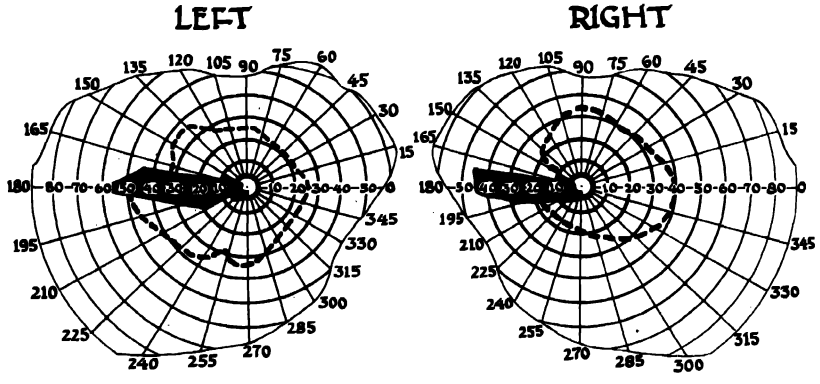

FIG. 396.—Homonymous hemianopic scotomas of left side oriented along the horizontal meridians, with minute central sparings around the points of fixation on that side. The case, perimetrically examined by Wilbrand, represents an injury in the floor of the right calcarine fissure. It indicates the position of the horizontal meridians in the striate area. From S. E. Henschen, *Pathologie des Gehirns*, Part 4, p. 94, case Eggerz, 1911. (*See also* Wilbrand 1907.)

in the normal visual fields (*see* preceding paragraphs in this section).

Depending on their location, two types—*central* and *peripheral field rests*—are distinguished. The first are located in or around the fixation points and are usually restricted in size (Fig. 383, *16;* Fig. 397). These may be interpreted as bilateral homonymous hemianopia with central sparing (*see* sec. 4 [2], this chapter). The peripheral rests often are of considerable size and may extend as far as the normal field limits. Occasionally a homonymous hemianopia may be present, with a monocular crescent in the extreme temporal periphery of one field alone spared (Fig. 383, *14; cf.* par. 7, this section).

Central rests of a restricted size are of special theoretical interest. In the extreme cases, all not in all, cases be considerably disturbed because of the extreme contraction or absence of the peripheral portions of the fields of view instrumental in these functions. The responsible factor is the presence and extent or the absence of an injury to the parts of the cortex surrounding the striate area and to the various fiber systems of the occipital lobes.

Frequently the past history of a "rest" case records an initial complete blindness which was subsequently modified by the reappearance of smaller or larger islands in the central or peripheral portions of the fields where function returned more or less to normal. Such field disturbances with partially restored rests may remain as a permanent condition. Conversely, an initial homonymous hemianopia of one side

may be completed on the contralateral side, with a central or paracentral rest as a final, permanent condition. The affected portions of the fields surrounding a rest may be absolutely blind for all qualities of vision, or a trace of function may still be preserved in the form of amblyopia. Sometimes signs of irritation, such as photisms or photopsias and visual hallucinations, may be an aggravating complication.

The pathology underlying the visual field rests is as varied as in other field disturbances of central origin. Among frequent causes are brain tumors and trauma, including war injuries, plete destruction of the central visual apparatus and, second, the characteristic intrinsic organization of that system, described in chapters VI and VII, which makes possible the elimination of most of that mechanism while leaving the remainder more or less intact. The bilateral field rests caused by a pathology applying to the visual system below the chiasmal junction are rarely congruous, since they are necessarily caused by a double or a single asymmetric process. The minute field rests of a homonymous hemianopic character are caused by extensive destruction of the visual pathway above the

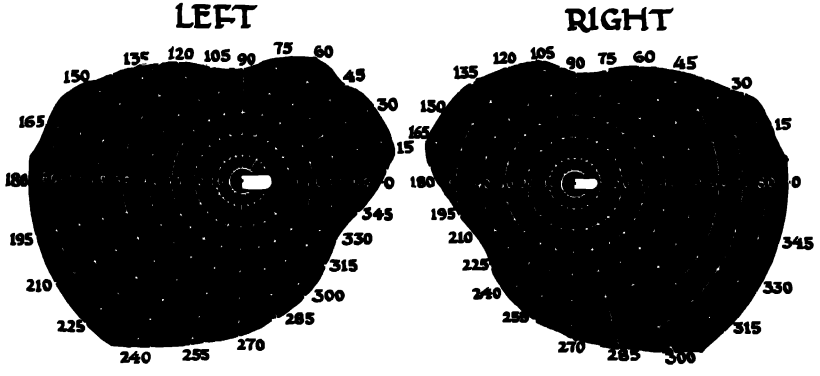

FIG. 397.—Minute hemianopic central rests (*white*) extending for a few degrees along the horizontal meridians into the right halves, surrounded by blindness enveloping by far the greatest parts of fields of view (*solid black*). Otherwise defined, this case represents a bilateral homonymous hemianopia made up of a left complete hemianopia, combined with a right incomplete hemianopia with central sparing. A war injury, fields carefully plotted with a 2-square-mm. target. Boundaries for red color same as for white (*see*, however, chap. XII, 7|4|). From Wilbrand & Saenger, *Die homonyme Hemianopsie*, etc. (v. 7 of *Die Neurologie des Auges*), Fig. 172, 1917.

vascular disturbances, such as hemorrhage, but especially the encephalomalacia following vascular changes in connection with kidney and heart troubles, a post partum embolism, and other similar etiology.

Like the other field disturbances, the central rests may also be accompanied by other cerebral symptoms, such as hemiplegia, hemianesthesia, speech disturbances, disorientation in space, impairment of memory, and the like, indicating an involvement of other parts of the cerebrum by the same pathology, besides the visual mechanisms proper.

The underlying anatomical factors responsible for the appearance of visual field rests of restricted size are, first, a widespread but incomchiasma. Small central field rests extending approximately equally on both sides of the fixation points indicate symmetrical damage to the right and left halves of the suprachiasmal central visual mechanism.

In case of softening in the territories of both posterior cerebral arteries or of the calcarine arteries, the two polar segments of the striate areae related to the foveae or "maculae" and perhaps also their immediate vicinity, supplied by the middle cerebral artery, may remain intact. There is little likelihood that such selective destruction with central sparing, because of the compact arrangement of the cells and fibers, could take place in either the optic tracts, lateral geniculate nuclei, or visual radiations close

to their origin. This is more likely to occur in massive lesions caused by a hemorrhage or encephalomalacia along the calcarine fissure.

It is possible to visualize a case with a rather symmetrical destruction of most of the striate cortex in both calcarine fissures, leaving, however, both occipital poles intact (e.g., case reported by R. Förster 1890, and by H. Sachs 1895). Since the poles may preserve sufficient collateral blood supply via the middle cerebral arteries, as discussed in chapter X, and since the intermediate foveal-macular branches of the visual radiations, separated as they are from the calcarine fissure by the posterior horn of the lateral ventricle, would not be affected by a process confined to the medial sides of the occipital lobes, central vision, mediated by the spared parts, would remain more or less preserved. (*Cf.* chap. X, 8 [2]; and case HOLT, in chap. XII.)

An interference with the visual radiations and the striate areae which produces small field rests may vary in a great many ways. Such destruction may, e.g., be complete on one side and incomplete on the other side, leaving the foveal or "macular" segment of the opposite radiation and the polar portion of the striate area intact. In such a case small hemianopic rests, one side of which is formed by the vertical meridians, would remain in the centers of the hemianopic fields (thus in Fig. 397).

The observation that in many "rest" cases the appreciation of color, form, and acuity either remains normal or is restored after an initial decrease and that these particular functions extend close to the boundary of the spared field rest indicates an intimate and uniform intermingling of structures instrumental in the transmission of color impulses with those structures which mediate the perception of "white," of form, and of acuity; or that the identical structures may perform, in part at least, all these functions. (*See also* Wilbrand & Saenger 1917, p. 132.)

The theoretical significance of the minute central rests of the visual fields for the understanding of the organization of the visual system is as great as that of the minute central scotomas (*cf.* par. 4, this section). Both indicate a collective organization of that system made up of a great number of minute anatomical-physiological units capable of independent existence and action, besides being able to influence, and being influenced by, one another.

8. CRESCENTIC HEMIANOPIA.—This term is applied to an absolute or relative blindness in the unpaired sickle- or crescent-shaped temporal monocular portion of the field of view (Fig. 383, *12;* Figs. 398, 399; *cf. also* Figs. 225, 259, 260). In the horizontal meridian this area extends from 60 to 95, 100, or even more degrees (depending on the extent of the field). A crescentic defect may be the only symptom, or it may accompany an impairment of other, binocular portions of the fields of view (Fig. 383, *17;* Fig. 399; cases STRAUSS, DYKSTRA, MUNSON, and HOFFMANN, in chap. XII; also Fig. 417).

A crescentic hemianopia may be present on both sides in bilateral lesions. It may be partial or incomplete, affecting either the upper or the lower quadrant, either completely or partially, in the latter case producing monocular crescentic scotomas of various sizes, shapes, and locations (Fig. 383, *13*). Often a crescentic hemianopia in one quadrant is merely an extension of more or less complete blindness in the adjoining upper or lower binocular quadrants of the same side. It may be either an initial symptom which gradually disappears (Fig. 383, *17;* case MUNSON, in chap. XII); or it may indicate the beginning of a process culminating in a typical homonymous hemianopia (case DYKSTRA, in chap. XII).

In general uniform depression of function in the entire homonymous halves of the fields, called *homonymous hemiamblyopia*, the blindness in the monocular crescent is usually more complete and may appear first (Fig. 399). This lesser resistance of the anterior monocular crescentic portion of the striate area to pathological agents, especially vascular, is probably caused by its blood supply, which, unlike that of the posterior foveal-areal portion, is more dependent on a single vascular source; if this one breaks down, because of local damage to the particular artery, for example, the entire crescentic area is eliminated, since vicarious substitution is insufficient here (*see* Figs. 369, 372, 374; *see also* the end of this subsection).

The cause of an impairment of function in

the monocular field crescent is a destruction of the crescentic portion of the visual pathway or center (*cf.* Figs. 225, 259, 260). It is self-evident that such selective damage is less likely in the infranuclear portion, on account of the compact arrangement of its fibers and cells, than above the chiasma, where the fibers and cells are farther apart.

In the optic nerves the crescentic fibers occupy a narrow zone along the inner or nasal margin. In the chiasma the crescentic fibers form its ventrolateral margin and may be affected alone, or first, by a pathological process

man 1926; Henschen 1926; Wilbrand 1926; Kronfeld 1932; Polyak 1932; *see also* chap. VI, 6, 7.)

Selective damage to the crescentic fibers may more easily occur in the visual radiation and in the striate area, where they are better segregated from the rest of the visual apparatus (*see* chap. VII, 3, 4, 5, 6). The belief that the most ventral bundles of this portion of the radiation are related to the entire monocular crescent disagrees with the absence of an isolated crescentic blindness in the temporal lobe tumor (Kronfeld). Another possibility, viz., that these fibers

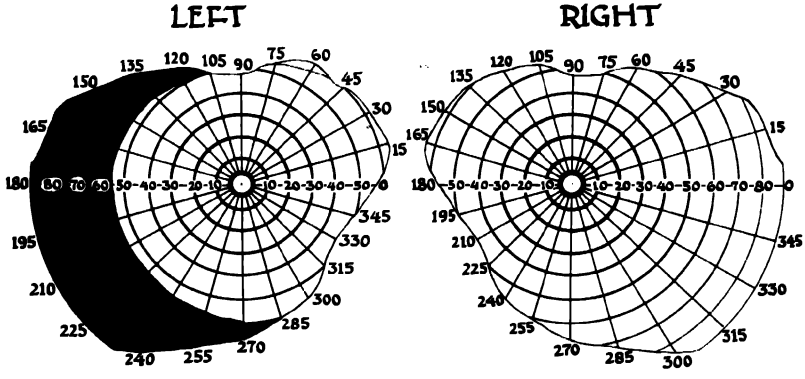

FIG. 398.—Left temporal crescentic hemianopia limited to monocular portion of the left field, caused by an artillery splinter (mine shell), lodged about 1 inch in front of the occipital protuberance, verified by X-rays. There were no other cerebral symptoms. Repeated checking during four months gave same results. Removal of the splinter, because of persistent headaches, resulted in complete permanent left homonymous hemianopia. From B. Fleischer, Klin. Monatsbl. f. Augenh., v. 57, case No. 1, 1916.

spreading from underneath—for example, by an aneurysm of the internal carotid artery and its branches or by an atypical tumor, an inflammatory process, or the like.

In the optic tract the crescentic fibers are assembled in and along its ventromedial margin, preserving this position as far as the lateral geniculate nucleus. In the latter the crescent fibers spread over the ventromedial and ventrolateral segments on both sides of the hilum in approximately the anterior half of the nucleus.

Any pathological process of limited extent at the base of the brain may, under favorable circumstances, affect these fibers in a more or less selective way. However, the pertinent clinical observations need to be further verified by careful post mortem studies. (*See* Brouwer & Zee-

may be the most lateral in the radiation, is likewise ill founded.

The crescentic fibers, as they emerge from the ventrolateral and ventromedial segments of the lateral geniculate nucleus, sweep partly downward and partly upward, closely attached to the rest of the radiation, and soon turn medially to the calcarine fissure (*cf.* Figs. 235, 236, 259, 260). In the radiation close to the lateral geniculate nucleus the crescentic fibers are probably only imperfectly segregated from the remainder. The segregation is more complete farther back, until, on the level of the oral extremity of the striate area, they sweep above and below the posterior horn of the lateral ventricle and in this way enter the calcarine fissure.

In this respect the bundles of the radiation

related to the upper and the lower halves of the temporal crescent behave in exactly the same way as do those related to the upper and lower binocular quadrants of the visual fields. Since the most anterior portion of the striate cortex is usually confined to the lower calcarine lip, the dorsal crescentic fibers have to describe a longer detour in order to reach this cortex than do the ventral fibers. Hence there is no evidence in support of the opinion advocating a lateral position of the crescentic fibers in the radiation. Numerous cases of quadrantic homonymous hemianopias, where the crescentic portion was included in the affected quadrant, are opposed to such an assumption (*cf.* case MUNSON, in chap. XII).

The representation of the monocular crescent of the retina in the most anterior portion of the contralateral striate area was confirmed by Foerster (1929) in a human experiment. In a patient suffering from an inferior crescentic defect he found a focus of softening in the upper calcarine lip close to its juncture with the parieto-occipital sulcus. Electrical stimulation of this locality produced a subjective sensation of a scintillating scotoma, corresponding to the affected portion of the field of view. (*See* chap. X, 8 [3], on scintillating scotoma.)

From the course and location of the crescentic fibers in the upper and lower segments of the visual radiation and in the visual cortex, it is possible to calculate the position that a lesion must have in order to produce a selective crescentic defect. This may take place most easily and completely in approximately the middle third of the calcarine fissure, corresponding to the anterior point of the cuneus and just in front of it (Figs. 182, 235, 269, 271, 273, 274, 278). The prerequisite is a limited and nonexpanding pathology, such as, for example, an embolic infarction, an ischemic or encephalomalacic focus, or a local hemorrhage or trauma. Such a lesion may, in a single "episode," eliminate the entire anterior extremity of the striate area, with or without simultaneous damage to the upper and lower crescentic fibers of the visual radiation.

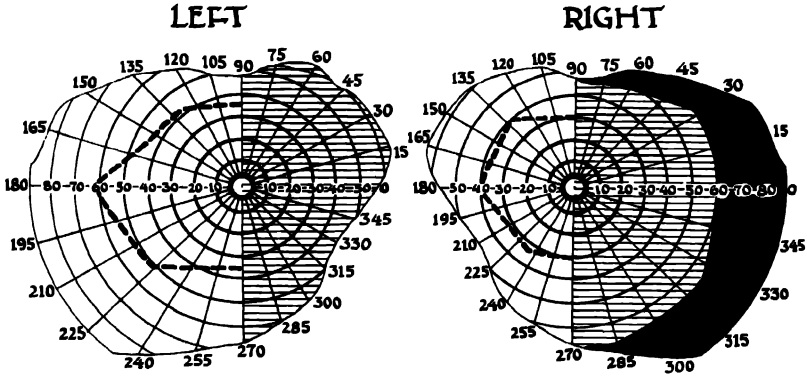

FIG. 399.—Right homonymous hemiamblyopia for colors (*shaded*), combined with an absolute scotoma in the monocular temporal crescent of the same side (*solid black*). From C. Behr, Klin. Monatsbl. f. Augenh., v. 56, p. 161, 1916 (*see* Wilbrand & Saenger, *Die homonyme Hemianopsie*, Fig. 193, 1917).

In other cases either the upper or the lower crescentic fiber bundles of the radiation may alone be interrupted, producing an inferior or a superior quadrantic crescentic hemianopia on the contralateral side. In still other cases the retrocrescentic binocular portion of the striate area, with or without its afferent fibers, may be damaged, producing a homonymous hemianopia with crescentic sparing.

If such a lesion is bilateral and symmetrical, the result is complete blindness, including the field centers, with a sparing of both temporal crescents flanking the blind central parts of the binocular field of view. Other complex cases of field defects involving the unilateral or bilateral

crescentic scotomas or sparings may be caused by irregular damage to the central visual mechanism. (*See* Fleischer 1916, 1920; Wilbrand & Saenger 1918; Balado, Adrogue & Franke 1928; Foerster 1929; Kronfeld 1932.)

The cases where unilateral crescentic blindness is caused by unilateral damage to the outward or lateral face of the parietal region of the cerebral hemisphere require special consideration. This, in the first place, may simply mean a general reduction of function in the entire extent of the homonymous fields, most pronounced in the temporal crescent. Possibly, a crescentic impairment is an expression of a lesser resistance or a greater vulnerability of the crescentic fibers of the visual radiation, perhaps caused by their unfavorable or exposed location or, more likely, by their less favorable blood supply (*see* above).

It may well be that the most anterior bundles of the radiation or the rostral segment of the striate area, both related to the monocular crescent, first become compressed or have their blood supply interfered with in case of pressure arising in one cerebral hemisphere. This may easily occur in parietal or temporal hemorrhages and tumors with chiefly a local effect. The responsible mechanism may be a compression of the hemisphere against the juncture of the falx cerebri and tentorium, in which way the crescentic fibers or the blood vessels supplying them first become compressed or strangulated. More light may be brought to this particular problem by an additional careful post mortem study of suitable cases. (*Cf.* case DYKSTRA in chap. XII.)

9. GENUINE ASYMMETRY AND INCONGRUITY IN HEMIANOPIC DEFECTS.—Unequal shape, size, and location of hemianopic defects in the right and left fields of view indicate a localization of a lesion in a section of the visual pathways where the right and left syndynamical or "corresponding" elemental units are not accurately aligned.

In the retinae and optic nerves, where the units are anatomically separated, it is only on rare occasions that two discrete bilateral lesions are sufficiently alike in their size, shape, and location to result in congruous defects in the two homonymous halves of the fields of view. This, owing to a partial decussation in the chiasma, becomes basically different in the suprachiasmal portion of the visual system. Here the crossed and uncrossed fibrous and cellular elements, working together in the binocular visual act, approach very closely. Hence a unilateral injury, small or large, produces field defects in the two homonymous halves that in appearance, extent, and location are practically alike.

This statement, however, requires some qualification. The first concerns the monocular temporal crescent which does not have a "corresponding" counterpart in the contralateral field (Figs. 225, 259, 260, 398, 399). The other cases are those of incongruous defects in strictly binocular parts of the two monocular fields. Such smaller or larger discrepancies may be simply the result of inaccurate plotting, found in almost every routine chart (Figs. 388, 389, etc.). However, a number of investigators have described in carefully plotted cases what is termed a "genuine incongruity."

It appears that certain levels of the suprachiasmal pathway more readily cause such a discrepancy of the two sides than others. One such locality, according to Wilbrand (1926, 1929, 1930), is the initial portion of the optic tract, where the two sets of fibers, the crossed and the uncrossed, are supposed to be still somewhat separated. Another locality, according to Harrington (1939), is the initial portion of the visual radiation, next to the lateral geniculate nucleus. Here the two sets of fibers are believed to be not accurately juxtaposed, permitting a certain degree of isolated injury to only one set. (*See also* Sanford & Bair 1939.)

Closer to the occipital pole, the adjustment of the ipsilateral and contralateral fibers becomes more accurate, and the lesions of this portion of the radiation result in almost mathematically congruous field defects: Wilbrand's "absolute congruity." The most perfect union of the crossed and uncrossed sets of conductor elements, it appears, is achieved in the striate cortex itself. Therefore, the unilateral lesions, although they may be very limited in size, if confined to the striate cortex are bound to produce hemianopic disturbances which appear practically alike in every respect.

Whether this indicates the mathematical accuracy of the union of the crossed and uncrossed conductors or whether, nevertheless, there is a

certain minute latitude, an overlapping, or the like, of the terminal ramifications is as yet uncertain. The alleged independent termination of the two fiber sets in the two sublayers of the inner granular layer of the striate cortex, improbable in itself and unproved, remains irrelevant to this problem (*cf.* chap. VIII, 7).

SEC. 8. CENTRAL SPARING IN HOMONYMOUS HEMIANOPIA: THE HYPOTHESES AND SPECULATIONS

1. THE ORIGIN OF THE CONCEPT OF "CENTRAL SPARING" IN HEMIANOPIA.—Even before the introduction of perimetry or plotting of the fields of view in clinical neuro-ophthalmology by R. Förster (1867), A. Graefe (1865) noticed a frequent "sparing" of the central portions of the fields of view around the fixation points in some cases of homonymous hemianopia, while in other cases the lines separating the blind from the normal halves of the fields were straight (*cf.* chap. IV, 1 [2]). This remarkable phenomenon, the frequent preservation of central, foveal, or "macular" vision, precisely that which makes sight the most important sensory instrument of Man's mind, could not fail to challenge many investigators to find an anatomical explanation for it, although Keen & Thomson (1871) assumed that central sparing was merely a product of an eccentric fixation (*see* Goldstein).

It was only natural that, since the exact organization of the visual mechanisms was not yet known, the early suggestions made were hypothetical. On general grounds it was assumed that the basis of "central sparing" was some particular pre-existing anatomical arrangement that makes central or "macular" vision less vulnerable in comparison with the less important "peripheral" or "extramacular" portions of the fields of view. Upon this speculative ground arose the "hypothesis of bilateral representation of the macula" (Wilbrand 1881, 1895; Marchand 1882; and others).

According to this, each complete or total "macula" or, more correctly, central fovea was represented in each occipital lobe. Thus defined, the hypothesis had been adhered to and propagated by numerous investigators until the present time, some of them most prominent in the investigation of the central visual mechanisms (Wilbrand; Henschen; P. Marie; Monbrun; O. Foerster; Penfield, Evans & McMillan; Halstead, Walker & Bucy; Penfield & Rasmussen 1950; and others). The emergence from time to time of other and quite different explanations, however, is the best evidence of the unsatisfactory nature of Wilbrand's concept.

2. THE HYPOTHESIS OF INTRARETINAL DECUSSATION OF FOVEAL-MACULAR FIBERS.—The earliest explanations of "central sparing" put stress on the peripheral portion of the visual system. Unlike the extrafoveal regions of the retina that are represented according to the principle of division along the vertical meridian, the foveal-macular fibers were supposed to pass to both halves of the brain.

The earliest suggestion, that of partial intercrossing of fibers in the retina, made, according to Seguin (1886), by Hannover (Fig. 400, upper sketch), was easily refuted on the evidence of

frequent complete homonymous hemianopias caused by an interruption of one optic tract: in these there was neither a contralateral central sparing nor a reduction of acuity in the ipsilateral halves of the centers, both necessary postulates of the hypothesis.

The same argument was also applicable to a bitemporal hemianopia, e.g., caused by an interruption of decussating fibers in the chiasma. Also, minute injuries either to the nasal or to the temporal half of the central fovea cause scotomas restricted to only half of the field of view, an observation in full accord with the author's experiments with monkeys (Figs. 202–5; *also* chap. VI, 1 [2], 6 [4], 7).

Finally, the hypothesis of an intraretinal crossing of the foveal-macular fibers suffers from an inherent weakness, in that it would force the assumption of two sets of fibers, one passing from the right half of the fovea to the

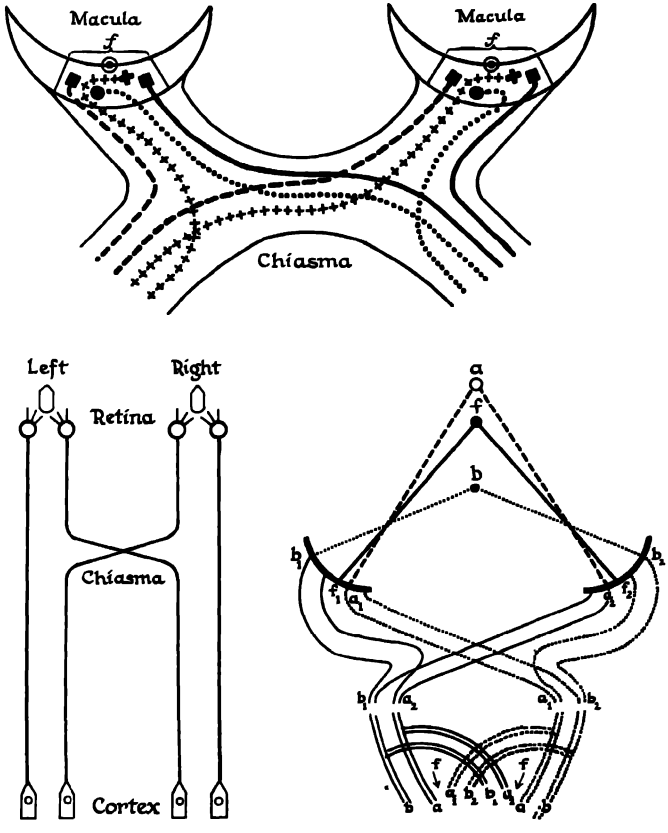

FIG. 400.—Diagrams illustrating various attempts to explain central foveal, or "macular," sparing often found in cases of homonymous hemianopia. *Upper diagram:* hypothetical partial crossing of fibers in the retina, resulting in a connection of both "macular" halves with each cerebral hemisphere. *Left lower diagram:* connection of each foveal cone with two ganglion cells in the retina, the axon of one of them passing over to the opposite cerebral hemisphere (Wilbrand & Saenger 1917). *Right lower diagram:* partial decussation of "macular" fibers in the corpus callosum (Heine 1900).

left half, and the other set passing in the opposite direction. This is required, since central sparing is found in unilateral lesions whether of the right or of the left side. A two-way crossing has not been observed in experiments referred to, nor is the visual acuity necessarily reduced in the functioning half of the field of view where there is a central scotoma in the other half. The same reasoning applies to a suggestion made by Morax (1919), according to which only the very center of the fovea, corresponding to the fixation point, is supplied with mixed crossed and uncrossed fibers (*cf.* chap. VI, 7).

3. THE HYPOTHESIS OF BILATERAL CONNECTIONS OF THE FOVEAL PHOTORECEPTORS WITH THE BRAIN.—This hypothesis assumes a connection of each foveal-macular cone with both hemispheres of the brain. Each cone, according to this, would be related to only one ganglion cell, but the axons or fibers of the ganglion cells would divide dichotomically into two branches, one proceeding to the ipsilateral hemisphere, the other passing over to the contralateral by way of the chiasma, as found by S. Ramón y Cajal and by Koelliker (*see* below).

Another variant of this idea suggested by Wilbrand could be that there would be two sets of the foveal cones, one set connected with the ipsilateral half of the brain, the other with the contralateral. Still a third possibility was suggested by Wilbrand (1930): that each foveal cone might be connected with two different ganglion cells, the axon of one of them proceeding to the opposite hemisphere (Fig. 400, left lower sketch).

The effect of any of the suggested hypothetical arrangements would be the preservation of function in the entire fovea or "macula," since the impulses, in unilateral suprachiasmal injuries, would still be able to pass over from the affected halves of the foveae to the cerebral hemisphere contralateral to the seat of injury (Wilbrand & Saenger 1917, v. 7, p. 19; Wilbrand 1930). The bilateral central connections of each complete fovea-macula, it was further assumed by some proponents of this hypothesis, would vary individually in extent and in some cases would be entirely absent (Wilbrand 1930).

All these speculations break down on close scrutiny because of a lack of concrete evidence. It is true that S. Ramón y Cajal (1899, 1899–1904, 1909–11) and Koelliker (1899) demonstrated the presence of bifurcating fibers in the chiasma of the Rat, Rabbit, Cat, Dog, and Ox. However, such bifurcations have never been discovered in Man and in other Primates. In fact, the experimental evidence shows fibers, originating from the nasal and temporal halves of the fovea, separating in the chiasma along a cleavage line coinciding with the vertical meridian passing through the foveal centers (chap. VI, 6 [4], 7).

The pathophysiological evidence is also against the bilateral concept. The cases of complete homonymous hemianopia or of a central hemianopic scotoma with a "splitting" of the centers of the fields of view are not necessarily associated with a reduction of visual acuity, as it would be legitimate to expect if, according to the hypothesis, half of the foveal photoreceptors and conductors were eliminated in the entire territory of the two foveae by a unilateral lesion. (*See* cases KRAFT and MALLORY, in chap. XII; *also* experiments by Le Gros Clark & Penman 1934 on detailed retinal representation in the lateral geniculate nucleus; and the experiments described in chap. VI, 6 [4], 7, and chap. VII, 3 [4], 4, 5, 6.)

The experimental evidence of a separation of the right from the left retinal fibers strictly along the vertical meridian referred to agrees with the clinical cases of a complete homonymous hemianopia caused by a complete interruption of one optic tract (Heine 1900; Rønne or Roenne 1911, 1914; Lenz 1914). In other similar cases the preserved central vision could be explained satisfactorily through a sparing of the foveal-macular bundle by the responsible pathological process.

The histoanalytical evidence is also opposed to the preceding hypothesis. The actual conditions of the structures found in the primate fovea show only individual synapses between the cones and midget bipolars (*b* & *h*) and between the midget bipolars and midget ganglion cells (*h* & *s*). These synaptical relations, obviously, are instrumental in the highest degree of visual acuity (*cf.* chap. V, 4 [10–14], 11).

4. THE HYPOTHESIS OF A MIDBRAIN DECUSSATION OF THE "MACULAR" FIBERS.—Since, according to the preceding review, there was no good reason to put the burden for central sparing upon the retina and the chiasma, Landolt (1875), Charcot (1876–80), and Ferrier (1886) suggested that the foveal-macular fibers that do not decussate in the chiasma may do so in the tectum or "roof" of the midbrain and, in particular, in the quadrigeminal commissure (*cf.* chap. III, 7 [4], 9 [6]). This hypothesis, without any concrete foundation to support it, also had no success. It is likewise clearly contradicted by the experiments of Barris, Ingram & Ranson (1935) and by those described in chapter VI, 4 [5], 5, esp. [7]. (*See* Figs. 186, 187, 191, 192.)

5. THE HYPOTHESIS OF BILATERAL REPRESENTATION OF THE COMPLETE FOVEA IN THE CORTEX.—In the course of the further evolution of Landolt and Charcot's idea of a partial crossing of the foveal-macular fibers in the midbrain arose the concept of bilateral representation of each complete fovea-macula in the cerebral cortex, which has been much discussed in modern controversies concerning the organization of the central visual apparatus. Ferrier (1886) devised a scheme of the visual pathways where only fibers belonging to the centers of the fields of view would cross in the supranuclear division and would terminate in the angular gyrus, which, in his opinion, was a center of "clear vision," that is, of the foveae (chap. III, 7). Elaborating upon this speculation, Heine (1900) and Lenz (1909, 1914) believed that the locality where the decussation took place was in the posterior segment or splenium of the corpus callosum (Fig. 400, lower right-hand sketch).

In Heine's view a portion of the fibers (a_1, b_2) of the visual radiation originating from the lateral geniculate nucleus, instead of proceeding to the striate area of the same side, crosses in the corpus callosum to the contralateral hemisphere, where it joins the opposite radiation (*a*, *b*). In this way the two foveal-macular halves of the retinae, separated by partial decussation in the chiasma, rejoin in the visual radiations and in the striate areae. (*Cf. also* O. Foerster 1929, Fig. 1.) When one of the occipital lobes is interfered with, impulses from both complete foveae would still be able to pass over to the other normal lobe, partly via the chiasma and partly by way of the corpus callosum.

For a number of years Heine's hypothesis was a convenient way of explaining "central sparing" in homonymous hemianopia, a phenomenon frequently observed in clinical practice. It remained a hypothesis, even though Niessl von Mayendorf (1914, 1926) made an effort to furnish anatomical evidence for it in a *fasciculus corporis callosi cruciatus*, or "crossed callosal macular bundle." The presence of this "bundle" seemed to become more certain when R. A. Pfeifer (1925) believed that he had demonstrated it with the help of Flechsig's myelogenetical method. This appeared to be so, even though the evidence produced was not convincing and the correctness of Pfeifer's interpretation was questioned by no less an authority than Flechsig (1927; *see also* Polyak 1932, 1933). A similar fiber connection, an "intertractal commissure," supposed to relate both lateral geniculate nuclei, was suggested by Klossowski (1930), without any substantial evidence.

More impressive evidence against the hypothetical callosal fibers is the preservation of centers in operations where the callosum was sectioned (Hyndman 1934). Maison, Settlage & Grether (1938) and again German & Brody (1940) also disproved the presence of a decussating tract.

However, in spite of the lack of positive evidence, Wilbrand's and Heine's concept of a "bilateral representation of a complete macula" in the cerebral cortex enjoyed and still does enjoy wide popularity among the clinicians (O. Foerster, 1929; Juba 1934; Penfield, Evans & McMillan 1935; Halstead, Walker & Bucy 1940; Penfield & Rasmussen 1950; and others).

Wilbrand & Saenger (1917, p. 9) went even further in expressing their opinion that central sparing must be present in every case of a homonymous hemianopia, correctly thinking that a mechanism of such importance would hardly permit any latitude in individual variation, i.e., the presence of a bilateral arrangement in some and the absence of it in others, as was lightheartedly assumed by many ophthalmologists and neurologists. In those cases where a divid-

ing line was seemingly passing through the fixation points, central sparing, according to Wilbrand & Saenger, would remain undisclosed because of the difficulties of exact plotting.

Since in a number of cases of central sparing a biopsy or a post mortem examination showed complete unilateral destruction of the visual radiation, either alone or with that of the striate area, the opinion was expressed that a "splitting" of the centers took place only in those cases where the lesion was close to the lateral geniculate nucleus whence the "decussating callosal macular bundle" was supposed to branch off. In foci farther back in the occipital lobe, since these would spare the decussating macular fibers, the central vision would remain preserved (Lenz 1914; *also* Penfield & Rasmussen 1950).

In support of this thesis, reference was made to statistical studies. In a collection published by Wilbrand (1930) there were, in pathology involving the cerebral hemispheres, 37 cases of hemianopia with central sparing and only 5 cases where there was no such sparing, a proportion of almost 8 to 1, whereas in tractus hemianopia there were 13 cases with, and 7 without, sparing, or a proportion of 2 to 1. Also, in 200 cases collected by Sanford & Bair (1939) where vision was involved, central sparing was present in approximately one-third of the temporal lobe cases (30.5 per cent), whereas the centers were spared in more than half of the occipital lobe cases (57.1 per cent). Such statistical studies are impressive and are undoubtedly in many respects valuable. However, the evidence which they furnish, in spite of its apparently objective character, may prove to be quite misleading unless carefully checked by other criteria, primarily by anatomical study.

The final verdict on Wilbrand's hypothesis of central sparing, in spite of all efforts, including modern ones, to sustain it, is negative: its anatomical, experimental, pathological, and theoretical foundations are all unsound. It certainly does not have any theoretical basis (*see* 9 [2], this chapter). In this connection, as a curiosity, may be quoted the opinion of no other than Monakow, a principal opponent of the concept of a detailed representation of the retina in the cerebral cortex advocated by Wilbrand and by Henschen. On logical grounds, and very correctly so, Monakow (1914, p. 408) considered Wilbrand's hypothesis "rather dangerous than useful" to his and Henschen's idea of a point-to-point representation of the retina in the cortex, since such organization would, in unilateral injuries, altogether preclude the appearance of hemianopic macular scotomas. (*Cf.* chap. IV, 5, 6.)

6. THE HYPOTHESIS OF ASYMMETRIC DIVISION OF DECUSSATING AND NONDECUSSATING FIBERS IN THE CHIASMA.—As a further possible cause of central sparing in hemianopia, a suggestion was made of an irregular or asymmetrical cleavage of the nasal and temporal fibers in the fovea-macula. In some individuals the line of separation would not coincide with the vertical meridians but would deviate to a greater or lesser extent toward one or the other side, hence making an asymmetric division of the foveal-macular fibers in the chiasma (Wilbrand 1881; Lenz 1915). In such individuals one occipital lobe would, accordingly, represent more, the other less, than half the foveae-maculae, or retinae. The amount and direction of deviation would vary individually.

This speculation is invalidated by the following considerations. First, if an unequal division of the foveal fibers were the anatomical basis of central sparing, one would expect, on the basis of statistical probability, the number of cases with and those without central sparing to be approximately equal, both in the infranuclear (chiasma, tract, lateral geniculate nucleus), and in the supranuclear or temporo-occipital lesions. This, however, is not borne out by Wilbrand's statistics, already quoted.

Furthermore, on the basis of the same law of probability, approximately as many cases of homonymous hemianopia with a central scotoma in the functioning halves of the fields should be expected as those with a central sparing in the blind halves. In any event, in some cases, instead of a central sparing, there would be at least a central amblyopia in addition to the usual hemianopia of the contralateral side. This is, however, not supported by the available evidence.

Finally, the experiments on the cerebral representation of the simian fovea made by Le Gros Clark & Penman (1934) and those de-

scribed in chapter VI, 6 (4) and 7, demonstrate the identity of the vertical meridian and the line in the fovea by which the uncrossed temporal fibers remaining on the same side are separated from the nasal fibers that decussate to the contralateral side by way of the chiasma.

7. CENTRAL SPARING CAUSED BY A MULTIPLE ARTERIAL SUPPLY OF THE OCCIPITAL POLE.—A hypothesis less spectacular than Wilbrand's but closer to reality was the explanation of central sparing by a multiple arterial supply of the occipital pole suggested by R. Förster, inventor of the perimeter (chap. IV, 1 [2]).

Describing a case of incomplete bilateral homonymous hemianopia or "central field rests," the first of its type on record, in considering the multiple vascular supply of the retinal "macula," he interpreted the minimal central rests as sparings of the macular cortex made possible by the anastomotical connections of two or more arterial territories in the occipital lobes. He wrote: "In case the principal vessel of the occipital lobe is obstructed, and an extensive area of the cortex is shut off, precisely that portion of the cortex which corresponds to the most acute vision may be spared" (Förster, 1890, p. 106).

Förster's view was shared by a number of reliable authorities, some with a firsthand knowledge of the cerebral blood supply (G. Holmes & Lister 1916; Igersheimer 1918; G. Holmes 1919; Monbrun 1919; Traquair 1925; Beauvieux & Ristich-Goelmino 1926; *cf. also* Beevor 1909; a very different and, according to our opinion, erroneous interpretation of Förster's case was given by Wilbrand [1895] in the sense of a bilateral representation of each complete fovea-macula).

Holmes & Lister, for example, found the pole of the occipital lobe to be at the "watershed" area of the posterior and middle cerebral arteries, and hence "it may under normal conditions draw blood from both, and if one is blocked, the other may suffice to maintain its nutrition"; and again "the presence or absence of macular escape in hemianopia due to vascular lesion may be explained by the varying degree of anastomosis between, and the relative extent in the distribution of, the posterior and the middle cerebral arteries at the occipital pole of the hemisphere. The frequent persistence of central vision in bilateral hemianopia due to bilateral cortical lesions may be possibly explained by this same fact."

Igersheimer and others, based partly on their own study of the vascular supply of the occipital lobe, also considered multiple blood supply as the true cause of central sparing. (*Cf. also* cases MARTIN P. and ANONYMUS, Figs. 428, 432, 433.)

In spite of the above-quoted opinion, however, the "magic" of the hypothesis of a bilateral representation of the complete fovea-macula in the cerebral cortex, supported by weighty authorities, even now prevails, as against Förster's concept, which requires a substantial knowledge of the cerebral vascular anatomy. (*Cf.* chap. X, 6 [3], 8 [4], and sec. 9, this chapter.)

8. CENTRAL SPARING: A SPECIAL FORM OF HEMIAMBLYOPIA.—An interpretation of central sparing as a variety of hemiamblyopia was advanced by Rønne (Roenne 1911). In many cases which appear as an incomplete homonymous hemianopia there was, in reality, only extensive reduction of function in the larger peripheral portions of the affected fields. This peripheral hemiamblyopia, when tested with ordinary perimetric methods, would escape notice, leaving only the central parts of the fields intact on account of their "functional superiority" (a concept itself in need of explanation).

Briefly, in Rønne's opinion an incomplete homonymous hemianopia was only a special form of homonymous hemiamblyopia. A similar view, assuming greater sensitiveness for the "macular region" and therefore greater resistance in comparison with the periphery of the fields of view, was also advocated by Sanford & Bair (1939).

9. PROTECTED LOCATION OF THE FOVEAL-MACULAR FIBERS IN THE VISUAL RADIATION THE CAUSE OF CENTRAL SPARING IN HEMIANOPIA.—In his further attempts to find a plausible explanation of the frequent sparing of the visual field centers in homonymous hemianopia, Rønne (1919) called attention to the protected location of the foveal-macular fibers in the visual radiation. The exact location of these fibers

was not known at that time (*see* chap. IV, 7 [6]). However, Rønne compared them with the arrangement in the retina, where the so-called papillomacular bundle is flanked above and below by the arching extrafoveal fibers from the upper and lower temporal quadrants (*cf.* Figs. 162, 207, 208). He believed that in some cases the "peripheral" fibers of the radiation would suffer more easily, while the centrally located "macular bundle" would remain intact more readily, with the resulting sparing of central vision.

This ingenious hypothesis of Rønne, like a similar concept of an "anatomical interval" filled by the foveal-macular fibers - a suggestion made by G. Holmes at about the same time—both closely approaching the truth, had no chance of being accepted by contemporary writers and was dismissed as "artificial" and "far-fetched." One reason for this was a lack of suitable pathological or experimental evidence to document it. But the most weighty deterrent was the confusion in the anatomical concepts of the organization of the visual radiation. (*Cf.* chap. IV, 7 [6]; chap. VII, esp. 4, 5, and 6; *see also* Figs. 235, 236, 259, 260, 269.)

10. Recent attempts to interpret central sparing in hemianopia.—The various attempts of many investigators of the past hundred years to explain the remarkable and teleologically extremely useful phenomenon of the sparing of central portions of the fields of view in homonymous hemianopia were obviously not satisfactory. Even the most popular hypothesis, that of a bilateral cortical representation of each complete fovea-macula in both cerebral hemispheres, suggested by Wilbrand, was accepted as a mere stopgap expedient until a better theory could be formed.

The unsatisfactory character of all explanations so far suggested is proved by further attempts made from time to time to devise a better solution. Unfortunately, none of the recent suggestions is any more convincing, some possessing even less ingenuity and logical appeal than the old ones. The obvious reason is their purely speculative character. None of the modern suggestions is based on an earnest effort to turn to the only reliable source of information: detailed study of the anatomical organization of the visual system and of its blood supply. The unavoidable result is "turning in circles" and perpetuation, one might almost say "in desperation," of fantastic concepts which should have been put to rest long ago.

Brouwer (1917), for example, discussing the cases where there was central sparing, even though the occipital pole was destroyed, believed that the "macular" cortex might stretch along the floor of the calcarine fissure as far as the anterior extremity of the striate area, reverting in this respect to Monakow's idea of a multiple or "diffuse" cortical representation of the retina (*see* chap. IV, 5). In the case of damage to the pole there would still remain enough of the "macular" cortex to account for the preserved central vision. Brower's speculation, while a priori possible, loses ground against contrary evidence represented by a case reported by R. A. Pfeifer (1930), in which there was central sparing and where careful histological examination revealed that more than the rostral half of the striate area was destroyed.

In a similar case with central sparing, published by Brouwer (1930) himself, the anterior portion of the striate area, corresponding to the wedge of the cuneus, was destroyed, while the occipital pole was preserved, a counterpart to a case of Holmes & Lister (1916), in which a central scotoma was caused by the destruction of the occipital pole.

To complete this account, reference may also be made to case Mallory described in chapter XII. Here a central scotoma was caused by a lesion localized in the posterior extremity of the striate area, with the anterior extremity of the same area, including the floor of the calcarine fissure, practically normal (Fig. 426). The various experiments upon monkeys, described in chapter VII, 4, 5, 6, also decidedly disprove a localization of the fovea in the anterior segment of the striate area. The same evidence likewise invalidates other similar attempts to localize the fovea-macula anywhere in the cortex except in the posterior, polar extremity of the striate cortex (Halstead, Walker & Bucy 1940; and others).

Another suggestion, equally without foundation, was of a second, additional representation of the fovea-macula outside the striate area or occipital lobe, to substitute in case of the destruction of the "regular" foveal representation in the occipital pole. This suggestion was made

by Balado, Adrogue & Franke (1928), Brouwer (1930), German & Fox (1934), and Hyndman (1939). Such a concept of double or multiple foveal representation would be tantamount to a reversion to Monakow's ill-founded idea of diffuse retinal projection in an extensive area of the cerebral cortex, which has been refuted with all desired clarity by modern experimental evidence, including that presented in this book (*see* chap. VII, 3, 4, 6).

In the same category of unsubstantiated hypotheses belongs the suggestion made by Monbrun (1919), according to which each complete fovea-macula would be represented not only in each striate area, as Wilbrand and his supporters insist, but also in the upper and lower half of each striate area. This, in his opinion, would account for the surplus areae above or below the horizontal meridians, or an altitudinal sparing, occasionally observed in homonymous central scotomas (*see also* Wilbrand 1930).

But the questionable honors for what appears to be a classical example of undisciplined pseudo-scientific speculation of modern times belong unqualifiedly to the noted neurologist and neurosurgeon, Otfried Foerster, late professor at Breslau (now Wroclaw). According to his opinion, not only the fovea-macula but also the remainder of the retina are represented in full in each cerebral hemisphere. His evidence was a case (case 3) of a large dural meningioma of the parietal region in a young man manifesting itself in an incomplete hemianopia. Bioptically, "the entire left occipital lobe, except for the insignificant rests, was compressed in an anterior direction as far as the *cella media* of the lateral ventricle." After successful elimination of the tumor, the function in the entire hemianopic field was restored, which, in Foerster's interpretation, was caused by a substitution by the contralateral striate area. No autopsy control, unfortunately, was possible.

Foerster's conclusion, we may say, is contradicted by all evidence at our command. It is not in any way borne out by the facts laboriously collected during a continuous study of three decades, now presented in this volume. It is also unwelcome, since it is supported by the great authority of a respected scientific worker, hence the more liable to bring confusion into a delicate problem requiring, above all, sober facts and clear thinking. (*Cf. also* Horrax & Putnam 1932.)

The preceding review may suffice to show the difficulties and the existing confusion in the problem of central sparing in hemianopia, a subject that had a great deal to do with the understanding of the anatomical and functional organization of the cerebral visual mechanism. In the following section an attempt is made to marshal all available information to clarify this problem.

SEC. 9. CENTRAL SPARING IN HEMIANOPIA: THE UNDERLYING FUNCTIONAL AND ANATOMICAL FACTORS

1. Testing of the fields of view and their interpretation.—Plotting of the fields of view is essentially a subjective reaction of the person examined. If not done with great care and repeatedly, small defects, such as minute scotomas, may easily be missed (Wilbrand &

Saenger 1917, p. 22; Traquair 1925, 1946; Wilbrand 1926, 1930; Putnam & Liebman 1942; *see also* G. Holmes 1946).

Conversely, it is possible that minute central rests may be found where there are none. Improperly tested cases, therefore, are not evidence for or against the hypothesis of bilateral representation of a complete fovea-macula in the brain. The flicker-campimeter method in a case where there may be, for example, sizable initial central sparing, after the condition becomes stabilized, may show the same sparing gradually receding to a vanishing point. Such striking reduction of an initially extensive central sparing cannot be attributed to the spreading of the underlying pathological process long after all pertinent symptoms have disappeared. It rather demonstrates the presence of a "functional factor" that simulates sparing where there is none (*see*, e.g., case KRAFT, in chap. XII).

Such a decrease or elimination of artificial central sparing in the course of prolonged testing shows the working of some innate tendency of the sensory-motor mechanism to make the contralateral functioning halves of the hemiretinae oscillate beyond the mid-line to the other side, precisely when the centers are tested, in this way producing a "pseudo-sparing."

This factor may in some cases be responsible also for the narrow surplus zones of the fields extending along the vertical meridians in the blind fields. Here, too, the oculomotor balance may have been "reorganized," but actually "disorganized," in a way to dislocate the points of fixation away from the centers of the anatomical foveae in the direction of the periphery of the normal halves of the fields.

The central "pseudo-sparing" appears to fall in the same category of phenomena as the "pseudo-fovea" of W. Fuchs (1920, 1922). This brings closer to our understanding those intriguing cases where, in spite of a complete removal or destruction of one striate area, an irreducible "central sparing" was found (Foerster 1929, case *2;* German & Fox 1934; Penfield & Evans 1934; Halstead, Walker & Bucy 1940; Penfield & Rasmussen 1950).

The factor responsible for the tendency to produce a "central pseudo-sparing" in an anatomically complete homonymous hemianopia may be designated as a disturbed dynamical oculomotor balance of the two cerebral hemispheres in the case of damage to the posterior extremity of one hemisphere. Probably it is essentially the same sensory-motor oculogyric mechanism, the slight physiological imbalance of which manifests itself in the oscillation of the points of fixation under normal conditions recorded by Marx & Trendelenburg (1911) and others. In pathological conditions such imbalance may be expected to be considerable.

From the preceding considerations it appears that many "macular sparings" recorded in clinical practice will be eliminated when refined testing methods are developed and regularly used (as applied, e.g., by Austin, Lewey & Grant 1949). For there is no doubt that much which is designated "central sparing" in present clinical routine is nothing more than "pseudo-sparing." However, even with this qualification, the fact of true central sparing is too well founded to need further discussion. Hence the problem posed is: What anatomical arrangements are responsible for the frequent sparing of the central parts of the fields of view in homonymous hemianopia?

Before trying to examine various factors, however, it will be useful—for the sake of clearing the atmosphere—to analyze the theoretical aspect, which has been the core of the problem: Is a bilateral representation of each complete central fovea or "macula" possible, without interfering with the very principle by which the visual system works?

2. VISUAL SYSTEM: HOW IT CAN FUNCTION AND HOW IT CANNOT.—In the modern way of thinking there are certain ideas and concepts gained from numerous observations, experiments, and tests which must be considered basic. These concepts must fully agree with the innumerable manifestations of nature, or else they must be modified accordingly.

One such basic revelation that has gradually emerged is a strict parallel between the functional organization of the eye as a reacting sense organ and the inherent properties of physical light as its adequate physiological stimulus (*cf.* chap. XIII, 2). A similar parallel between the intrinsic organization of the visual pathways and centers of the brain, on the one hand, and

the structure of the eye and physical properties of light, on the other, is only now beginning to be comprehended (*see* chaps. V and VII).

Even so, sufficient knowledge is at hand to indicate just what functional organization may be expected in the vertebrate visual system and what can safely be ruled out as improbable. This will give a general answer to the problem of "central sparing" in hemianopia, particularly to the controversial hypothesis of cortical representation of each complete fovea-macula in both cerebral hemispheres.

For this purpose several anatomical and physiological possibilities may be examined with the help of a diagram (Fig. 401). This diagram shows the essentials of the organization of the human and simian visual system. Uppermost in the figure is the object to be viewed, symbolized by an arrow (A–B), whose images are depicted in a reversed order on the retinae of both eyes focused on the center of the object ($f\phi$). The two sets of the impulses generated in the two retinae are propagated along the preformed pathways, represented by the optic nerves, chiasma, tracts, lateral geniculate nuclei, and visual radiations, to the two visual cortical centers or striate areae of the occipital lobes of the brain. The intrinsic organization of the visual pathways is assumed to be known from the description in chapters VI and VII and from Figures 225, 259, 260.

The two images (a-b and α-β) are transmitted to the two lateral geniculate nuclei in such a way that their right halves (a-f and α-ϕ, black) coincide in the right nucleus, and their left halves (b-f and β-ϕ, white) coincide in the left nucleus. This is a necessary deduction, first, from the partial crossing of fibers in the chiasma and, second, from the fact of a joint representation of the right and the left syndynamical or "corresponding" points of both retinae in the same minute segments of the optic nerves, chiasma, tracts, and geniculates (thus a and α; f and ϕ; b and β). The points f and ϕ on the retinae are the two points of fixation, or centers of two foveae, through which the two dividing vertical meridians pass, separating each retinal image into two halves—a black, pointed one and a white one with a blunt end.

From each lateral geniculate nucleus a double half-image is further transmitted along the visual radiations to the visual cortical centers, the striate areae of their own sides (for the sake of simplicity, only a single image is drawn: solid black on the right side, and in outline on the left side). Since each geniculate nucleus is represented in its own striate area strictly according to a one-to-one plan (as documented in chap. VII, 5, 6), the transmission of the double retinal half-images to the areae is also strictly preserved with all topographical relations. The two cortical half-images—the solid black one with the pointed end on the right side and the white one with the blunt end on the left side—together produce a complete cortical image. (*Cf. also* Figs. 361, 439; *see also* S. Ramón y Cajal 1898, 1899, and 1909–11, v. 2, p. 376; Jacobsohn-Lask 1924, 1928; Best 1930; *cf. also* chap. XIII, 3.)

The hypothesis of a bilateral cortical representation of each complete fovea-macula in both cerebral hemispheres, in addition to the homonymous mechanism just described, forces one to presuppose the coexistence of another heteronymous connection maintained by way of the hypothetical macular bundles decussating in the corpus callosum—crossed "macular" bundles. This also necessarily implies a connection of each "corresponding point" of both homonymous hemiretinae, for example, of a and α, not only in the homonymous cortical visual center (at $a\alpha$) but also with another symmetrical point in the contralateral heteronymous cortical visual center (at $b\beta$), a point in turn related to the "corresponding points" of its own contralateral retinal halves (b and β).

In order to analyze the consequences which must logically follow from the preceding exposition, certain facts evidenced by modern experience, both anatomical and clinical, have to be kept in mind. The first such fact is the separation of the central representation of each retina along a vertical meridian into two halves, a nasal and a temporal. Hence each cortical visual center or striate area represents homonymous halves of both retinae. The periphery of both halves along the ora serrata (a and α, b and β) is represented at the anterior extremity, the points of fixation (f and ϕ) are represented at the posterior polar extremity of the cortical center. All the other numerous "corresponding points" of the two homonymous retinal halves

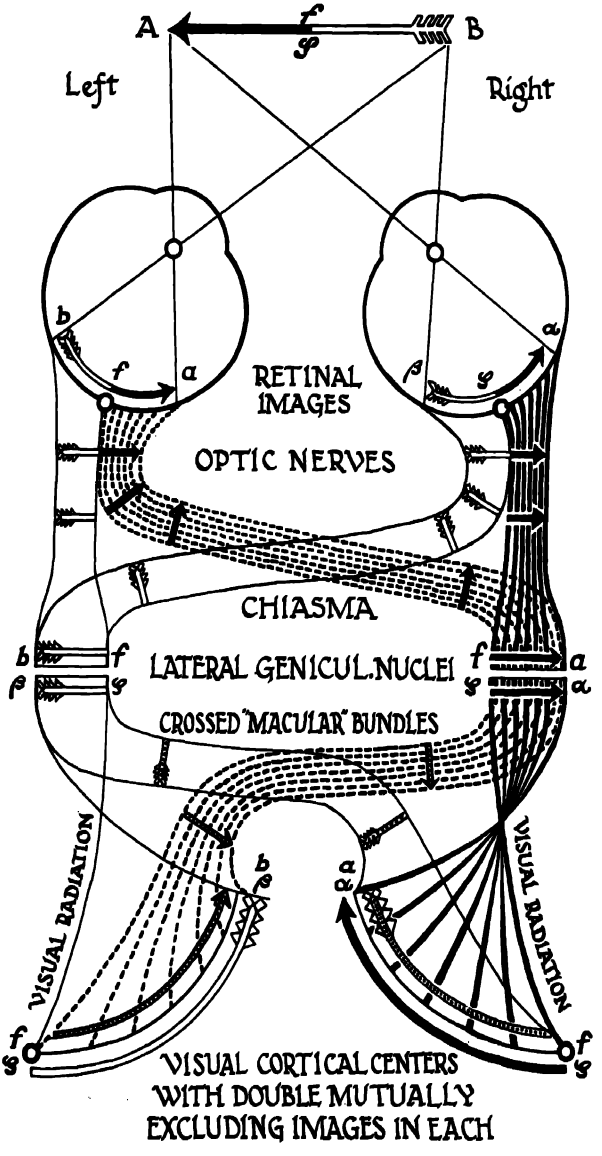

FIG. 401.—A diagram to illustrate the physiological impossibility of the conventional concept of the projection of each complete fovea, or "macula," upon both halves of the brain, as advocated by Wilbrand and by Heine. Such an arrangement, in particular the decussation of a portion of "macular" fibers in the corpus callosum, would reverse the retinal image in the cortex and hence would annul the physiological sense and aim of the topographical representation of retinal surfaces in the cortical visual centers of the brain. (For details *see* text and Figs. 361, 439.)

between the serrated margins and the dividing vertical meridians are evenly represented according to the same topographical principle between the points of fixation ($f\phi$) and the far peripheries ($a\alpha$ and $b\beta$). The cortical representation of, for example, point a of the nasal half of the left retina is the same as its "corresponding point" α, of the temporal half of the right retina (if, for the sake of simplicity, we disregard the surplus monocular crescent). In this way each two "corresponding points" of both retinae, which work in unison in the binocular visual act, merge in the cortical center into a single point.

If there were heteronymous connections in the foveal-macular portions of the visual system, as implied by the hypothetical "crossed macular bundles," both the point-to-point principle and that of a symmetrical representation must also be postulated for the retinal points that are at an equal distance from the fixation points. The "corresponding points" a and α, for example, would be represented not only in $a\alpha$ of the right cortical center but also in $b\beta$ of the left center, where the two heteronymous symmetrical "corresponding points" b and β of the contralateral retinal halves are already represented. In no case could a and α be represented asymmetrically, for example, at $f\phi$ of the contralateral center, precisely as they could not be represented at $f\phi$ of the ipsilateral cortical center; likewise a simultaneous representation of several "corresponding points," for example, of a and α and of f and ϕ, in a single cortical point, e.g., in $f\phi$, is unthinkable, since such a chaotic arrangement would obliterate all topographical retinocortical relationships whose presence has been demonstrated by experiment.

From the preceding analysis it is plain that in a quadruple projection of the retinal images upon the cerebral cortex—a necessary effect of a hypothetical "decussating callosal macular bundle"—the antagonistic or disparate retinal points would be represented in the same cortical points. For example, the "corresponding retinal points" a and α would be represented at $a\alpha$ of the right cortical center, but also at $b\beta$ of the left center, where the "corresponding retinal points" b and β are already represented. In other words, the same cortical locality would receive messages from more than a single object point, for example, the right cortical point $a\alpha$ from the object points A and B, the same from which the left cortical point $b\beta$ would receive its messages. The cortical fixation points of both sides, $f\phi$, alone would remain simple.

In the visual system thus organized, the action of the "dark-chamber effect" and of the dioptrical apparatus of both eyes would be annulled. The two cerebral images created in each visual cortical center would be superimposed in reversed positions, with nonmatching ends together. In the right center, for example, at $a\alpha$, the pointed end of the black arrow and the blunt end of the white arrow would be simultaneously depicted in one image.

The effect of this arrangement would be the same as taking a picture with a photographic camera of the same object on the same film twice—the second time with the film inverted. It is difficult, indeed, to imagine a more absurd, and biologically less purposeful, result of the creative forces of nature. (*Cf.* chap. XIII, 2, 3.)

From the preceding analysis of the known organization of the vertebrate visual apparatus and its mechanics, the concept of the representation of each complete fovea-macula in the cortical visual centers of both cerebral hemispheres is unthinkable on theoretical grounds alone. The explanation of central sparing in homonymous hemianopia is not to be found from nebulous concepts but is to be sought in a realistic way.

3. Anatomical factors responsible for the sparing of central vision in hemianopia.—The anatomical factors responsible for the phenomenon of sparing of central vision in homonymous hemianopia are several. The first and most important is the intrinsic organization of the visual system which makes possible an isolated injury to the parts of that system related to extrafoveal portions of the retinae, while leaving foveal-macular parts intact. The other, and in cerebral pathology equally important, factor is the multiple blood supply of the posterior portion of the cerebral hemisphere, especially of the occipital pole where the fovea is represented. This makes possible the preservation of a normal or nearly normal blood supply to the pole, even though other parts of the striate cortex serving the extrafoveal vision may be

suppressed or destroyed. The third and apparently less weighty factor is the nature of the underlying pathological process or injury, which becomes important only in connection with the first two factors.

In the preceding subsection certain anatomical and physiological reasons were advanced to show why, on these grounds alone, the hypothesis of bilateral representation of each complete fovea in both cerebral hemispheres is not defensible and hence cannot be accepted as a valid explanation of central sparing in homonymous hemianopia. In the following, other anatomical factors are discussed that make such sparing possible.

The fiber bundles that make up the visual radiation, at the point of their emergence from the lateral geniculate nucleus, form a compact system (Figs. 235, 236, 269). Here they may easily be interrupted by a single lesion, for example, in the posterior portion of the internal capsule or immediately behind it in the fiber mass of the parietotemporal lobes. Such a lesion, if of any considerable size, is likely to interrupt the entire radiation, including the foveal or "macular" fibers. The resulting functional defect is a complete homonymous hemianopia of the contralateral halves of the fields of view without central sparing.

Such an outcome is further facilitated by the fact that in this locality the bulk of the radiation is supplied by the middle cerebral artery (*mcea*) and the inferior branches of the posterior cerebral artery (*poteocca*, in Figs. 370, 371, 374; *cf. also* Figs. 226, 227, 230, 233). Any interference with the radiation in this locality must necessarily have a global effect. This, together with the other pertinent experimental and clinical facts (complete degeneration of the ipsilateral geniculate nucleus when one striate area is completely removed, and preponderantly a complete homonymous hemianopia in processes localized in the temporal lobe), effectively disposes of the hypothetical "crossed callosal macular bundle."

Farther back in the hemisphere the fibers of the visual radiation spread apart, forming the outer sagittal fiber lamina, curved on cross-section to resemble a horseshoe (Figs. 228–32). The inner curve of this horseshoe envelops from above, from below, and laterally the posterior horn of the lateral ventricle, which, in turn, separates it from the calcarine fissure. A limited lesion, such as may, for example, be caused by a thrombosis of one branch of the middle or posterior cerebral arteries, may interfere with only one segment or branch of the radiation (Fig. 377).

In one case, for example, a branch of the middle cerebral artery may be clogged, causing an encephalomalacic destruction of the upper segment of the radiation, manifested by an inferior quadrantic hemianopia (case MUNSON, Fig. 412). In another case lower branches of the posterior cerebral artery may be put out of commission, causing smaller or larger defects in the lower segment of the radiation and producing a superior quadrantic hemianopia (initial stage in case HOLT, Fig. 415).

The centers of the fields of view may or may not be spared, depending on whether the intermediate segment of the radiation and the posterior segment of the striate area were or were not spared. In case MALLORY, for example, the extreme polar segment of the right striate area was damaged, resulting in central hemianopic scotomas extending to the vertical meridians (Figs. 424–27).

Since in many individuals, possibly in the majority, most of the anterior portion of the striate area serving the periphery of the fields of view is supplied by the posterior cerebral artery, while the posterior segment of this area is, in part at least, supplied by the middle cerebral artery, an obstruction to the posterior cerebral eliminates only the extrafoveal-macular parts of the fields and spares the centers. The exact mechanism responsible for such "dissociation" is described in detail in chapter X, 8 [2, 4].

The medial or anterior portion of the calcarine fissure, accordingly, behaves in regard to its blood supply and its vascular pathology as a unit, largely separated from the lateral or posterior portion of the fissure at the pole, which depends largely or entirely on the middle cerebral artery for its vascular supply (as described in chap. X, 6). This fact is well illustrated by the later stage of case HOLT (Fig. 415). In this case a limited encephalomalacia destroyed most of the cortex along the medial calcarine fissure, leaving the pole of the occipital lobe intact (Fig. 414). Owing to this, most of the fibers of

the radiation degenerated in the retrograde sense except the axial segment passing to the spared occipital pole (*vr*), and in the lateral geniculate nucleus the posterior foveal extremity alone remained normal (Fig. 416), both parts being related to the spared central vision (Fig. 260). In two other cases examined, the situation was even more drastic, since here much or almost all cortex on the medial and inferior faces of the occipital and temporal lobes, supplied by the posterior cerebral, was wasted away, except the polar segment of the striate area (Figs. 428, 432, 433). This was the more remarkable, since in one case the axial segment of the radiation supplied by the middle cerebral artery was also interrupted. Here, unlike case HOLT, the posterior horn of the lateral ventricle broke down in its role as a vascular barrier, owing to the extensiveness of the lesion.

Simultaneous destruction of both lips of the calcarine fissure along its medial or anterior stretch, with or without damage to the incoming upper and lower radiation fibers, may easily follow a thrombotic occlusion of the principal calcarine artery (*pca* in Figs. 372, 374). The striate cortex lining the medial calcarine fissure, especially along its floor, is eliminated in this way. The fringes of this cortex in both lips of the fissure may be spared if they are supplied by the branches arising from the main stem of the calcarine artery (*ca*) below the obstructed locality—for example, by the paracalcarine or inferior calcarine artery (*paca, ica, ical*) and by other arteries (*cuaa, cuma, cupa, poteocca*).

In the fields of view this results in variously formed sparings along the vertical dividing meridians (Fig. 392; a typical example is the case published by G. Holmes 1934). An involvement of the field centers takes place only if the lesion spreads into the polar segment of the striate area (as it did in the same figure).

In traumatic cases, e.g., war injuries, a fairly isolated damage to the medial "peripheral" striate cortex may be made, depending on the course or direction of the missile. Another factor is the presence or absence of concomitant hemorrhage, which, in turn, depends on whether or not one of the larger arterial vessels was injured.

Infiltrating and even expanding tumors arising from the medial calcarine fissure may, in their bizarre spread, on occasion selectively eliminate the portion of the striate area related to the extrafoveal periphery of the fields and leave their centers spared (cases AMES and STRAUSS; *see* Figs. 403, 406). In these, the protecting mechanism is the lateral ventricle and the circuitous blood supply of the polar striate cortex from the middle cerebral artery.

A good example of this is a case published by Lenz (1914, FRAU M. G.), which is, however, reinterpreted here in our sense. Clinically a visual disturbance began as a relative impairment of the peripheral, extrafoveal vision, eventually terminating in complete hemianopia. The cause was a tumor originating from the ventricular endothelium at the meeting of the calcarine and parieto-occipital sulci. During the initial period, moderate pressure interfered with the extramacular cortex. In the further course, with expansion of the tumor and compression not only of the calcarine blood vessels but also of those belonging to the middle cerebral artery and strangulation of the foveal segment of the visual radiation laterad to the posterior horn of the ventricle, the centers of the fields of view also were eliminated. (*Cf. also* Morax 1919.)

In many gunshot injuries during the war, where a hemianopia with central sparing was observed, hemorrhage into the medial calcarine fissure as a complicating factor is a plausible interpretation. Here there was frequently an initial complete and absolute homonymous hemianopia, or amaurosis, caused partly by direct destruction and partly by an expanding hematoma or a calcarine hematocele exerting pressure and causing a collateral edema in the entire striate area, including its polar segment. The visual radiation, especially the segment situated laterad to the ventricle, may or may not have been substantially affected, but this was of no great account during the initial phase. As the hematoma gradually became resorbed and the edema receded, central vision became restored to a greater or lesser extent, leaving, as a temporary or permanent residue, a hemianopia with spared central vision.

In such cases it is necessary to assume that terminal recovery of central vision was made possible through rehabilitation of the foveal-macular cortex at the occipital pole and of the intermediate foveal-macular segment of the vis-

ual radiation sheltered behind the lateral ventricle. In other cases where an initial central sparing disappeared in the course of the illness, it must be assumed that this was caused by a further spread of the pathological process, engulfing the polar cortex and the foveal fibers in the intermediate segment of the radiation.

In some unfortunate cases, such a fatal outcome was caused by inexpert surgical interference to remove a foreign body, e.g., a bullet lodged in the calcarine region; with the removal of the bullet, the foveal-macular cortex and its afferent fibers were also destroyed, and central vision irrecoverably lost (thus in Fig. 388).

For the reasons hinted at, even though as yet little understood, the above-described vascular process in the territory of the posterior cerebral artery may take place in both occipital lobes, occasionally simultaneously and symmetrically (*see* case HOFFMANN, Figs. 417, 418, 419). In the resulting impairment, both fields of view may be eliminated with the exception of both centers around the fixation points (resembling Fig. 397). Such are the notable cases described by R. Förster (1890), H. Sachs (1895), Laqueur & Schmidt (1899), Laqueur (1904), and R. A. Pfeifer (1930). Other similar cases have been reported off and on in the literature, even though usually they have been poorly utilized and their underlying mechanism misunderstood.

From the older cases collected by Monakow (1914), such may be those of Anton (1886), Schmidt-Rimpler (1893), Peters (1896), Vossius (1896), O. Meyer (1900), Raymond, Lejonne & Galezowski (1906), and Poulard & Sainton (1910); among the newer cases are those of Rønne (Roenne 1914), Bolton, Bramwell & Robinson (1915), Bramwell (1915), Monbrun & Gautrand (1920), Segi (1923), Foix & Schiff-Wertheimer (1925), Manolesco (1928), Weekers (1928), and Pallarès (1931). (*Cf. also* Oulmont 1889; Neukirchen 1900; Toulouse & Marchand 1907.)

In conclusion, the several positive factors—neuroanatomical, physiological, vascular, pathoanatomical, and mechanical—discussed in the preceding paragraphs entirely suffice, in all their individual variety, to account for the preservation, or the absence of preservation, of the field centers in homonymous hemianopia.

Chapter XII

Clinical and Pathoanatomical Observations of Cases with Disturbances of the Visual Fields

SEC. 1. MATERIALS AND METHODS

1. General remarks.—An investigation of the visual mechanisms and their functioning in normal and pathological conditions would remain incomplete if it were limited to animal material and to normal human specimens. No matter how convincing the deductions obtained from a normal anatomical study and from experiments on animals, the true sense of the reality is obtained only by a study of patients suffering from disturbed vision.

Two reasons are obvious. The first is the general interest in human welfare and the factors which endanger it. The other is the ease with which visual disturbances in Man may be accurately tested and their particular features correlated with the underlying pathoanatomic changes. Well-analyzed human cases, therefore, not only are interesting in themselves but are necessary to complete the information gained from the study of animal and normal human material and from experiments.

2. Clinical observations and pathological specimens.—The clinical observations and the pathoanatomical material presented in this chapter were collected during twenty years from various sources, mostly from friendly ophthalmologists interested in the problem of vision. In some the clinical observations are very sketchy, almost nonexistent; in others they are rather complete. Fortunately, in almost all cases the brain specimens were in a satisfactory state of preservation.

The plan followed in each case was, first, to give as exact a description as possible of the functional disturbance, followed by a gross and microscopic analysis of the specimens and stained sections, upon which a plausible interpretation of visual disturbances observed during life was made. In this way, by further comparing the results with the observations recorded in chapters VI, VII, and VIII, the concept of the anatomical and functional organization of the visual mechanisms, gained largely from the study of normal human and animal material, was amplified and completed.

In the functional manifestations of the pathoanatomical causation, special attention was paid to the course of illness or the temporal sequence of clinical symptoms and the histopathological findings. In this way it was possible to interpret correctly the sequence of pathological processes underlying the visual disturbance and to correlate these processes with clinical manifestations as they occurred in the course of each case.

SEC. 2. CASE OF THE CHIASMA DISPLACED BY A PITUITARY TUMOR WITHOUT INTERRUPTION OF CHIASMA

1. HISTORY.—POPJOY, Rose, forty-two years of age, Billings Hospital, University of Chicago, UNo. 2654.

Diagnosis: Adenoma of the hypophysis without interruption of the chiasma of the optic nerves; cancer of the breast with metastases in various internal organs; no clinical diagnosis of disturbed vision.

Six years previous to admittance, patient hurt her left foot in a fall. Five years previously she was knocked unconscious in an auto accident. Four years and five months previously she suffered from a severe "cold," accompanied by a general involvement of the joints. After several months of medication, was cured but was left with a firm fibrous ankylosis of the left ankle joint.

Approximately five and one-half months prior to death she noticed a lump in the left cheek, accompanied by intermittent lancinating pains in the same region, and had a severe vomiting spell. At about the same time another lump appeared in her right breast. Six weeks and five days before death this was diagnosed as a cancer with a metastasis in the right axilla, and probably also in the left parotid gland. A radical mastectomy was performed the following day.

Thereafter the general condition gradually worsened, the patient at times becoming irrational, maniacal, suffering from continuous severe pains and vomiting, with metastases and complications of various internal organs, terminating in death. No ophthalmological or neurological examination was made.

2. PATHOANATOMICAL EXAMINATION.—The brain, in fresh condition, appeared grossly normal except for a 1.5 × 2-cm. incapsulated carcinomatous nodule on the convex face of the left frontal lobe at a distance of about 2 cm. from its pole.

In the sella turcica a large incapsulated tumor was found, protruding upward. Microscopically, the tumor was diagnosed as a chromophobe hypophyseal adenoma. The tumor compressed from underneath the tuber cinereum of the betweenbrain, which was found pushed up, the excavation formed in this way being at least ½ cm. deep. The chiasma of the optic nerves appeared to be completely interrupted in the middle, the lateral vestiges of it adhering to the respective nerves. The two optic nerves and tracts, if reduced in size, seemed to be so to only a small degree.

A careful inspection of the specimen, however, disclosed that the middle, bridgelike portion of the chiasma was not actually severed, but only flattened and expanded, appearing much wider and longer than normal, with ipsilateral nondecussating bundles spaced far apart. Hence the middle portion of the chiasma was pushed up, forming, with the betweenbrain, the dome or roof of a smooth cavity in which the enlarged hypophysis was lodged.

The examination of the continuous serial sections through the chiasma in a horizontal plane confirmed the gross inspection. On the lowermost levels the gap separating the two lateral parts of the chiasma was no less than 9 mm. wide (Fig. 402, upper sketch). On intermediate levels the gap gradually narrowed (middle sketch) until on the highest level, next to the betweenbrain, the middle portion or "bridge" of the chiasma alone remained as an island (lower sketch). This portion was made up entirely of crossed or decussating fibers. All portions of the chiasma appeared to contain normal fibers. A further comparison of the sections revealed certain features indicative of an interplay of several mechanical factors responsible for the conditions found.

3. COMMENT.—The initial condition in this case was necessarily that found in a normal chiasma (*cf.* Figs. 196, 197). How long prior to

death the hypophysis began to increase beyond its normal size, there is no way of telling. A severe vomiting spell suffered by the patient five and a half months preceding death probably indicates a tumorous increase of the gland at that time. Hence we may conclude that the pituitary tumor grew slowly for a considerable period of time. This would be in fair agreement with the absence of obvious ocular symptoms. Dislodgment of the chiasma in this case was an accidental anatomical finding, made during the autopsy.

The course of the chiasmal changes, as reconstructed from the anatomical findings, may have been as follows (Fig. 402): In the early period, during the initial slow increase in the size of the gland, the middle bridgelike portion of the chiasma was gradually pushed upward. With further growth of the pituitary tumor, this portion was pushed deeper into the betweenbrain, which was the direction of least resistance. Under continuous pressure from below, this portion became deformed into a broad but thin band, which formed the concave ceiling of the cavity in which the hypophyseal tumor was lodged. Simultaneously, the right and the left portions of the chiasma, made up principally of nondecussating fibers, as well as the adjoining portions of both tracts, became displaced laterally. This lateral displacement was also accompanied by some rotation along the longitudinal axes of the tracts and lateral parts of the chiasma, owing to a pull on the optic nerves fixed in their bony channels, the rotation being clockwise on the right side and counterclockwise on the left side when viewed from the back.

The result of these changes was that the two nondecussating systems of chiasmal fibers remained on a lower horizontal level (upper sketch), while the intermediate portion, made up of decussating fibers, was pressed high up into the vaultlike ceiling of the cavity formed in the betweenbrain (lower sketch). The central portions of the supraoptic commissures, it may be noted, were also pushed into the ceiling of the cavity, closely following the decussating chiasmal optic nerve fibers (*cf.* Fig. 402).

The appearance of the nerve fibers in the chiasma did not show any gross pathological changes beyond a beadlike arrangement of myelin usually found in routine specimens. From this it is probable that there was no gross interference with vision, albeit no fields were taken to make this certain. The good condition of the lateral geniculate nuclei agrees with this assumption. This indicates considerable adapt-

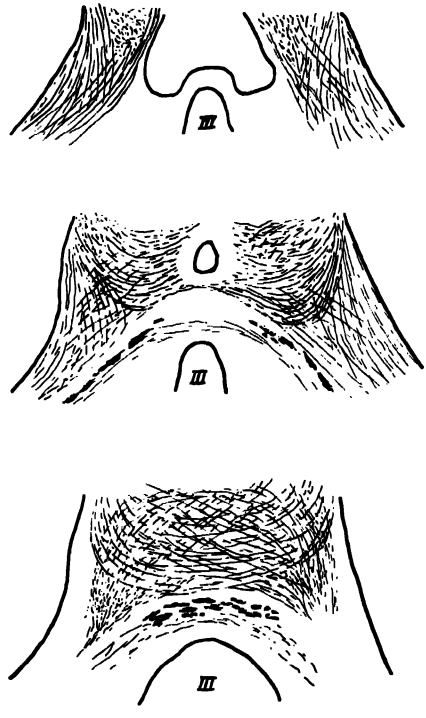

FIG. 402.—Case Popjoy: dislodgement of the chiasma of optic nerves caused by a tumor of hypophyseal gland. Upper sketch shows a complete separation of optic nerves and tracts, corresponding to the lower levels, while on the higher levels the intermediate bridgelike portion of the chiasma, shown in lower sketch, is still continuous. (For further details *see* textual description.)

ability in the chiasmal structures to deformation, pull, and pressure. Had the illness continued until the middle portion of the chiasma was severed, the eventual outcome would have been a bitemporal hemianopia (Fig. 382, *12*).

SEC. 3. CASE OF COMPLETE HOMONYMOUS HEMIANOPIA

1. HISTORY.—AMES, Walter, age forty-four years, Billings Hospital, University of Chicago, UNo. 18231.

Diagnosis: Right homonymous hemianopia without sparing of central vision, caused by a brain tumor (multiform glioblastoma) of the left temporal lobe (Fig. 403).

History indicates six months of "eye strain," one and one-half months of intermittent headaches with inability to concentrate, one month difficulty with vision, three weeks inability to read, one month increasing irritability, three weeks loss of memory and disorientation, two weeks crying spells, apparent blindness to objects on the right side, one week nausea and vomiting, ten days steady frontal headaches, one week bad taste in the mouth, intermittent periods of complete disorientation, incoherent talk, inability to recognize friends, inability to remember words or to grasp their meaning.

In summary, the clinical picture, composed of numerous symptoms, comprising sensory defects, such as blindness of a hemianopic character, and disturbances of a psychic character, falling into the category of visual agnosia, sensory aphasia, etc., and a steady, relentless, progressive course, all pointed toward an organic, malignant brain disease.

2. NEUROLOGICAL EXAMINATION.—Ophthalmoscopic examination revealed choked disks of from 2 to 3 diopters on both sides, slight facial weakness on the right side, no obvious paresis, although the muscular tonus was increased on the right side, increased deep reflexes, ankle and patellar clonus, and also probably the presence of the sign of Babinski on the right side, no sensory disturbance of the head, both pupils dilated and fixed, aphasia, disorientation, and confusion. Blood pressure 140/80.

Operation, craniotomy-decompression, revealed a subcortical glioma in the left parietal region. After the operation and X-ray therapy the psychic disturbances improved very rapidly, the disks receded to normal, but the reaction of the pupils remained poor.

3. OPHTHALMOLOGICAL EXAMINATION.—A week after the cranial decompression, examination revealed the blurred margin of the right disk, which, however, was of normal size and red in color, being surrounded by a grayish-white zone half as wide as the diameter of the disk. There was a group of hemorrhages in the disk and in its margin at approximately four o'clock. The veins were not dilated, but most arteries were contracted, with an exudative patch in the disk at three o'clock. The margin of the left disk was also blurred, but its size was apparently normal. The disk was surrounded by an areola of half its diameter, grayish-white in color. The excavation was visible. There was a linear exudation area along the superior nasal artery for a short distance. The veins were not dilated. The majority of the arteries were slightly contracted, and there were no hemorrhages. *Diagnosis:* a completely receded papilledema.

Eight months after the onset of the illness, a right homonymous hemianopia, with central vision involved (no "macular sparing"), was determined by stereo-campimetry, with a white target of 1°. The fields plotted with a routine perimeter, however, showed a small central sparing in the right upper quadrants (Fig. 403).

4. PATHOANATOMICAL EXAMINATION.—The gross macroscopic examination of the brain showed a glioma in the splenium of the corpus callosum spreading along the medial sides of the posterior horns of the lateral ventricles into both occipital lobes. The microscopic examination of sections through the brain, stained according to the Weigert-Kultschitzky method, revealed the following changes from the norm.

In the *left parieto-occipital* lobe the tumorous mass occupied a portion of the corpus callosum and penetrated far into the temporal lobe. The sagittal fiber layers were displaced down and outward. They showed a great loss of fibers, those still remaining being in an advanced state of degeneration. In the left occipital lobe the tumor gradually decreased to an irregular, round mass, 1½ cm. in diameter, inward to the posterior horn of the lateral ventricle, not quite reaching the subcortical fiber layer of the lower lip of the calcarine fissure.

The caudal end of the tumor was approxi-

mately at the middle of the longitudinal extent of the occipital lobe. At this level and in the tip of the occipital lobe the ring of the sagittal strata still retained its usual, normal appearance, surrounding the posterior ventricular horn, which was somewhat dilated, even though its fibers were mostly gone. The fibers of the tapetum (callosal) and of the internal sagittal stratum (efferent) were also greatly reduced in number, the rest being in a process of degeneration.

The external sagittal stratum, containing the visual radiation, was still well preserved in shape and position, but its constituent fibers were mostly gone. Its remaining fibers all exhibited unmistakable signs of an advanced degeneration, such as beadlike varicosities and disintegration, and these disintegrated fibers could

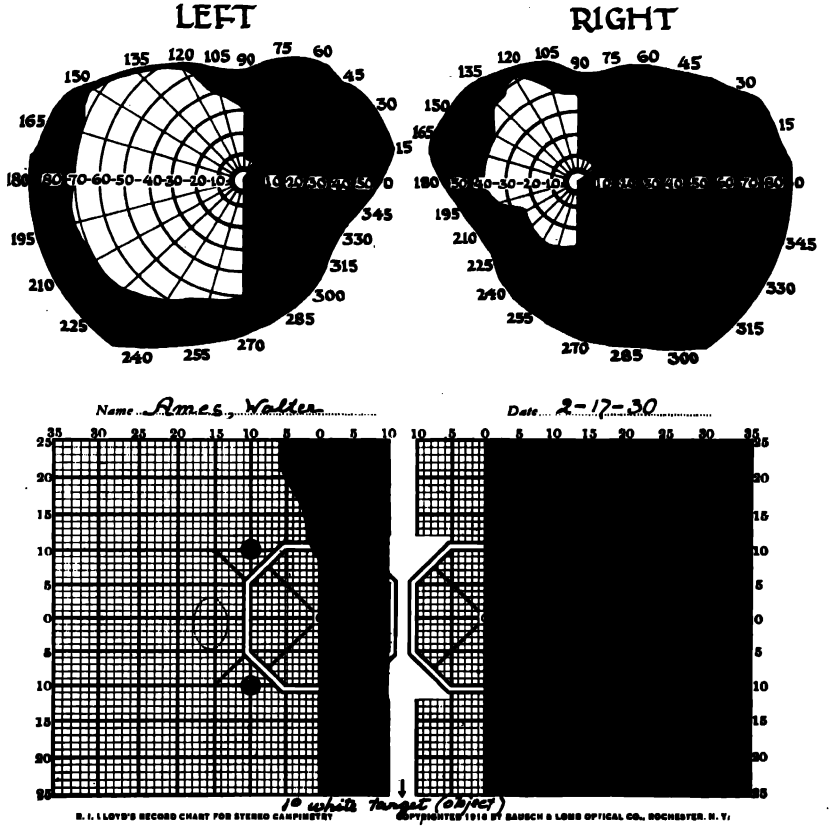

FIG. 403.—Case W. Ames: a complete homonymous hemianopia of the right halves of the fields of view, caused by a glioblastomatous tumor of the left temporal lobe of the brain (*see* following figure). Upper fields, plotted with an arc perimeter, show small central sparings in upper quadrants of the blind halves, while lower fields, taken with a stereocampimeter, show a splitting along the vertical meridians, with a slight encroachment of blindness upon the left upper temporal quadrants outside the central area. A slight sparing in the upper fields was possibly caused by an incomplete interruption of the intermediate foveal fibers of the radiation, while a surplus scotoma in the left lower field may be explained by the general condition of the patient.

be followed into the striate cortex. Practically all other fibers of the left occipital lobe—the callosal, associational, and efferent—were also degenerated.

A noteworthy observation concerns the intracortical stripe of Gennari or Vicq-d'Azyr. This stripe, in contrast with the much depleted supra- and infra-Gennarian layers of the striate cortex, was found to be practically normal. This observation, like the other similar observations, indicates a preponderantly intracortical origin and termination of this fiber layer (*cf.* chap. VIII, 6, 7).

clusters of which appeared more or less normal. Other cells had disappeared or showed signs of the intermediate stages of degeneration. On the anterior levels, represented in sketches *4* and *5*, cells of a more normal appearance were more frequent among the degenerated ones also found along the upper margin of the nucleus. In summary, the upper or dorsal layers of the nucleus suffered more. The lateral segment related to the upper field quadrants was most completely degenerated.

In the *right parieto-occipital lobe* (Fig. 404) the tumor mass in an almost identical way en-

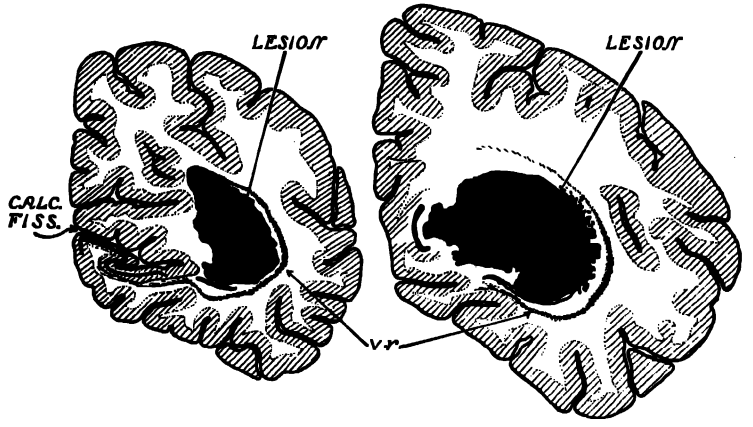

FIG. 404.—Case W. Ames: coronal sections through the right parieto-occipital lobe at two levels, the right one closer to, the left one farther away from, the callosal splenium. The lesion, a glioblastomatous tumor (*solid black*), originated from the splenium of the corpus callosum, spreading backward in both hemispheres in an almost symmetrical way. The growth in the left hemisphere was of an earlier date, destroying the visual radiation on that side completely, causing at the time of the plotting of the fields a practically complete hemianopia with split centers (Fig. 403). In the right hemisphere the tumorous growth at that time had not yet advanced enough to destroy the radiation *vr*, but merely pushed it aside and down, hence making vision still possible in the left halves of the fields. *Labeling: CALC.FISS.*, calcarine fissure; *vr*, visual radiation. Note in left-hand diagram fibers of the lower segment of radiation streaming into lower calcarine lip, which alone at this level contained striate cortex, as indicated by a stippled intracortical line of Gennari.

The *left lateral geniculate nucleus* (Fig. 405), examined in sections stained by the Nissl method, likewise showed profound degenerative changes. The caudal tip (sketches *1* and *2*), related to the fovea-macula and normally composed of small nerve cells, was completely depleted. In it only a few "shadows" of nerve cells remained. These and the increased number of glial cells showed the approximate outlines of the layers, which were blurred. The ventral layers still contained numerous nerve cells,

tered from the splenium of the corpus callosum into the subcortical fiber substance and penetrated far back into the occipital lobe. At the anterior limit of that lobe the tumor was the size of a pigeon's egg (left sketch). It was located inward and above the posterior horn of the lateral ventricle, which was dislocated down and outward (narrow slit below the tumor given in solid black, *lesion*). The sagittal fiber layers were also displaced down and outward. The upper horizontal segment of the visual

radiation (*vr*), normally related to the upper calcarine lip, was interrupted by a tumor mass pushing toward that lip. In the same way the fibers coating the calcar avis were destroyed, and the lateral ventricle obliterated. The tumor also infiltrated the tapetum and the internal sagittal layer and pushed through the destroyed dorsal horizontal branch of the visual radiation absent, while others showed signs of degeneration. The lower horizontal segment of the radiation was still well preserved and compact, and the fiber plexus in the striate cortex lining the lower calcarine lip was still almost intact. In particular, the thick, obliquely coursing terminals of the afferent visual fibers were abundant here and well stained. What the condition

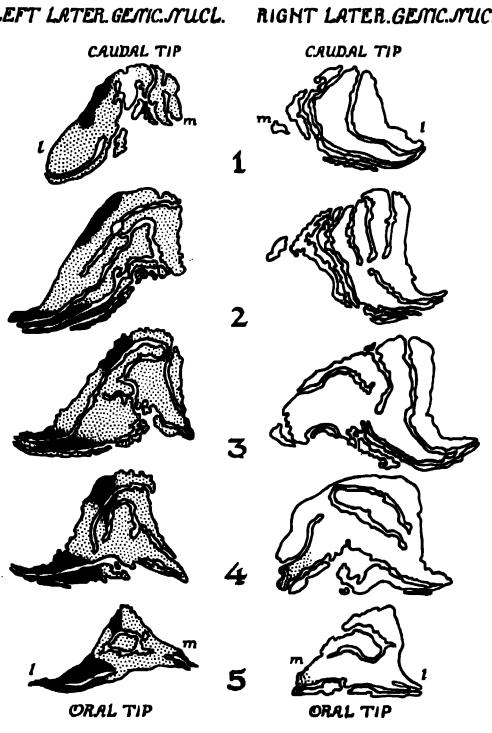

FIG. 405.—Case W. Ames: lateral geniculate nuclei, *left*, in an advanced state of degeneration, *right*, almost normal. Areae of complete cell degeneration in solid black; areae where only partial degeneration was present given in stippling; areae where cells still appeared fairly normal given in white. Medial sides of nuclei facing thalamus at *m*, lateral sides at *l*.

into the upper portion of the subcortical fiber mass of the occipital lobe.

The external sagittal fiber layer, or the visual radiation proper, showed no fibers in its upper horizontal segment and no intracortical fiber plexus in the upper calcarine lip (*CALC. FISS.*, Fig. 404). In the intermediate or vertical segment, displaced outward, numerous fibers were of the cortex and of the afferent fibers was in the occipital pole it was not possible to determine.

The *right lateral geniculate nucleus*, in contrast with the nucleus of the left side, proved to be almost normal (Fig. 405). It was of normal size, with layers well filled with apparently normal nerve cells. Here and there the cells seemed, however, somewhat decreased in numbers or

slightly changed in appearance, but nowhere could there be found a clearly degenerated zone. The only exception was the inner or medial tip in the oral fourth of the nucleus, which was somewhat degenerated (stippled in sketches *4*, *5*). The contrast between the right and the left nucleus was especially apparent in the posterior extremities concerned with foveal-macular or "central vision" (sketches *1* and *2*). Whereas in the left nucleus this portion was found almost completely degenerated, in the right nucleus the appearance and number of nerve cells were found to be almost normal.

5. CORRELATION OF FUNCTIONAL DISTURBANCE AND PATHOANATOMICAL FINDINGS.—In analyzing this case, the following points appear to be of interest. The tumor, causing an extensive cerebral destruction and eventually death, had its origin in the corpus callosum or close to it. In its expansive growth it spread in an almost symmetrical way into both hemispheres, sooner or more rapidly into the left one. Here it had completely interrupted the visual radiation, causing a complete right homonymous hemianopia (Fig. 403). In agreement with this, the left lateral geniculate nucleus degenerated almost completely. The only exception was a small cluster of cells in the foveal-macular tip of the nucleus, where the nerve cells were fairly normal (sketch *1*, in left column, in Fig. 405). This cluster may have been responsible for a small central sparing in the right upper blind quadrants. With this questionable exception, the completeness of degeneration both in the left radiation and in the left geniculate nucleus and also in the visual cortex of the left hemisphere agrees well with a complete hemianopia of the opposite, left side.

The symmetrical spreading of the tumor in both hemispheres is another remarkable feature. The anatomical factor responsible for it is the arrangement of the callosal fiber bundles, possibly also the vascular distribution, both similar in the two hemispheres, which may have served as a preformed pathway.

Another noteworthy feature, observed also in the preceding case, was the "plasticity" or resistance of the brain structures, especially of the nerve fibers. This is especially evident in the visual radiation of the right hemisphere (Fig. 404). Although displaced from its normal position, this system of fibers caused no marked disturbance in the function of the left homonymous fields as long as these could be tested, in view of the patient's mental state toward the end. This interpretation agrees well with the fairly normal condition of the right lateral geniculate nucleus (Fig. 405). It further indicates that the absence of a gross left hemianopic disturbance manifested itself in spite of the bad preterminal condition of the patient. However, there may have been a slight contraction of the left lower quadrants, indicated in the right perimetric field, in Figure 403, caused by partial damage to the upper horizontal segment of the right radiation and also evidenced by a limited retrograde degeneration in the medial tip of the right lateral geniculate nucleus (sketches *4* and *5*). The good condition of most of the right geniculate nucleus, including its posterior foveal-macular extremity, on the other hand, speaks against the hypothesis of "macular fibers" decussating in the corpus callosum to the left hemisphere, since on that side all sagittal fiber layers were completely interrupted. This again fully agrees with the experiment, described in chapter VII, 4, in which one occipital lobe was removed completely without causing any degeneration in the contralateral geniculate nucleus. (*Cf.* chap. XI, 8, 9.)

Finally, the extensive destruction of the association and callosal fiber systems in the left parieto-occipital lobes and similar, even though less extensive, degeneration of the same systems in the upper right lobes are sufficient to account for the disturbance of visual memory, disorientation, and other psychotic symptoms.

References: *See* chapter XI, especially 3 and 4.

SEC. 4. CASE OF AN INCOMPLETE HOMONYMOUS HEMIANOPIA

1. HISTORY.—STRAUSS, Louis, forty-eight years of age, Billings Hospital, University of Chicago, UNo. 19828.

Diagnosis: Left homonymous hemianopia with central sparing, caused by a brain tumor (multiform glioblastoma) of the right occipito-temporal lobes.

The illness began five months prior to admis-

sion, with weakness, convulsions, headaches, vomiting, paresthesiae, and difficulty in walking. Visual symptoms had appeared two months earlier, with a blurring of vision.

2. NEUROLOGICAL EXAMINATION.—The inspection of the eyes showed the left pupil to be somewhat larger, with both pupils reacting poorly to light. Ophthalmoscopically, there were choked disks with some hemorrhage. The conjugate eye movements were synchronous, but not full, and were jerky; notably incomplete was the movement to the right, which also had a tendency to relapse to the mid-line. The ventricle was punctured in the right hemisphere, and a decompression was made on the right side, with much discharge of fluid and pus. A slight hemiplegia and hemianesthesia on the right side were noticed.

3. OPHTHALMOLOGICAL EXAMINATION.—Both disks showed moderate choking, with some hemorrhage, with the physiological excavations still present, while the remaining portions of the retinae were normal. Two months later the choking disappeared. Perimetrically, an incomplete left homonymous hemianopia was found, with perhaps a slight contraction of the right halves (Fig. 406). This condition persisted for one month, which was approximately three months preceding death. Owing to the patient's bad general condition, especially mental, further plotting was not done, but the impression was that the left hemianopia persisted to the end.

4. PATHOANATOMICAL EXAMINATION.—Gross macroscopic examination of the brain showed the tumor to occupy the lateral face of the entire right temporal lobe. The tumor also invaded the lower portion of the right parietal lobe and extended backward to the preoccipital incisure. On coronal sections grossly examined, a vascular tumorous mass was revealed, diffusely infiltrating the entire right temporal lobe and the lower portion of the right parietal lobe. Medially, the tumor also involved the internal capsule and entered the thalamus. Posteriorly, it extended to 4 cm. from the tip of the right occipital lobe.

The *right cerebral hemisphere*, examined on sections stained according to the method of Weigert-Kultschitzky, revealed a tumorous mass at the level of the pulvinar, occupying approximately the lateral two-thirds of the hemisphere and penetrating through the subcortical fiber substance as far as the lateral ventricle (Fig. 407, *E*). The three sagittal fiber layers—the external, internal, and tapetum—were all partly interrupted and degenerated. Of the external stratum or the visual radiation proper, the lower horizontal segment alone appeared fairly well preserved (*vr*). On subsequent caudal sections this branch could be followed to the lower lip of the calcarine fissure (*D*, *C*, *B*).

Of the intermediate or vertical segment, only its lower portion was preserved, with its fibers considerably depleted. The remainder of the visual radiation, that is, the upper half of the intermediate segment and the entire upper horizontal segment, had degenerated completely.

On anterior sections the preserved portions of the radiation were seen slipping just underneath the tumorous mass and entering the posterior portion of the internal capsule (*F*). On sections through the anterior portion of the occipital lobe, the tumorous mass extended as far as the floor, or the deepest portion, of the calcarine fissure, but its two lips remained intact (*B*, *C*). So also remained the posterior portion of the calcarine fissure close to the pole of the occipital lobe (*A*).

The course of the preserved lower segment of the radiation and its entering into the cortex of the lower calcarine lip were clearly visible as far as the tip of the occipital lobe. In this portion of the striate cortex the oblique, irregular fibers in the lower half beneath the stripe of Gennari or Vicq-d'Azyr, identified in experiments as the exogenous afferent visual fibers, were present, although in reduced numbers (*cf.* Figs. 315, 316, 327, 328, 334). In the upper calcarine lip and in the upper half of the striate cortex which lined the tip of the occipital lobe, these characteristic slanting fibers were almost gone.

The *right lateral geniculate nucleus*, stained with thionin blue, was found partially degenerated (Fig. 408, right sketches). The loss of the nerve cells was more pronounced in its anterior or oral part (*3*, *4*) than in its posterior or caudal portion (*1*, *2*). The lateral segment was, on the whole, better preserved. On anterior levels all

nerve cells showed more or less pronounced signs of degeneration. On caudal levels most of the cells of the lateral segment were in a fair shape. Most completely degenerated was the inner or medial segment through the greater anterior portion of the nucleus (solid black in varying degrees, least advanced in its posterior extremity serving the foveal-macular or central vision and in the outward segment related to the upper homonymous quadrants. The *left lateral geniculate nucleus* was found to be normal (left column in the same figure).

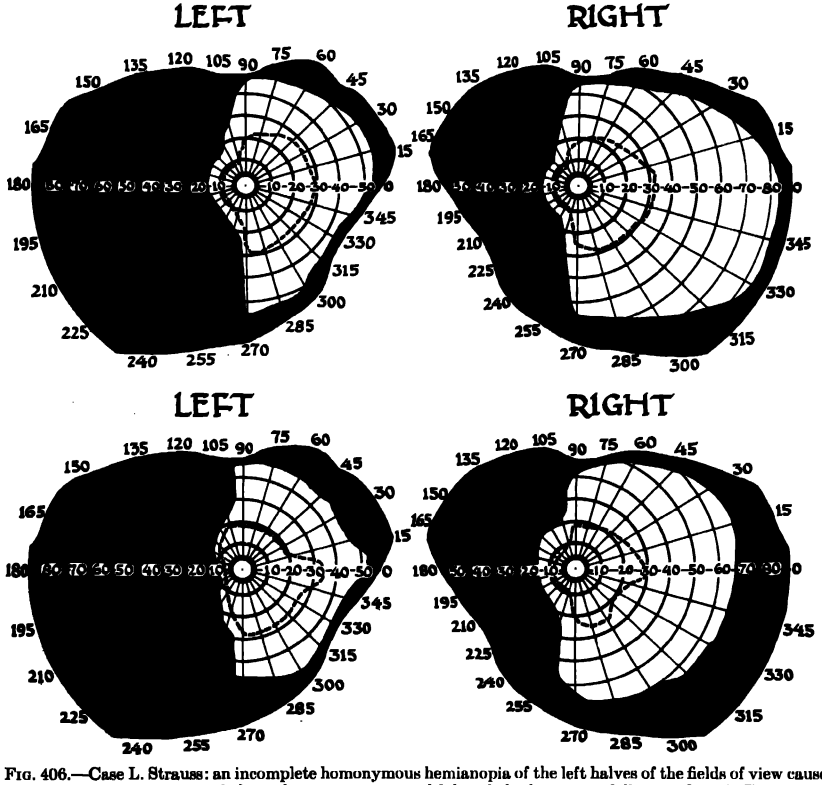

FIG. 406.—Case L. Strauss: an incomplete homonymous hemianopia of the left halves of the fields of view caused by a glioblastomatous tumor of the right occipitotemporal lobe of the brain (*see* following figure). Upper fields plotted approximately four months, lower fields three months, before death. In both fields, in the affected left halves, there are large central sparings tapering along the vertical dividing meridians toward the field limits. The only substantial change between the two plottings was a marked temporal restriction in the right halves, in the second plotting, amounting to a right monocular temporal crescentic hemianopia.

sketches *2*, *3*, *4*). The same was also true of the intermediate segment, except farther back, where many nerve cells were still present, although these, too, were considerably affected (white and stippled portions in sketches *1*, *2*). In fact, the entire lateral geniculate nucleus of the right side showed signs of degeneration in

5. CORRELATION OF FUNCTIONAL DISTURBANCE AND PATHOANATOMICAL FINDINGS.—In analyzing this case, the clinical course must be considered, especially the development of the visual field disturbance.

First, on two occasions a left homonymous hemianopia was found, both times with central

sparing. The last plotting was made three months prior to death. Whether the same condition remained until the end or whether subsequently a complete hemianopia without central sparing, or almost so, developed, the history does not tell. Judging from the pathoanatomical findings, it is likely that some sparing may have persisted until the end, particularly in the upper half of the central vision.

The probable terminal stage, as it can be reconstructed from the anatomical facts, seems to have been as follows: The tumorous mass, approaching from the region of the parietal lobe, at first pushed toward the dorsal or upper portion of the sagittal fiber layers. By breaking through these, it entered into the posterior horn of the lateral ventricle not far from the splenium of the corpus callosum. Finally, spreading backward and at the same time medially, the farthest portion of the tumor entered the anterior portion of the calcarine fissure. The interruption of the dorsal segment of the sagittal

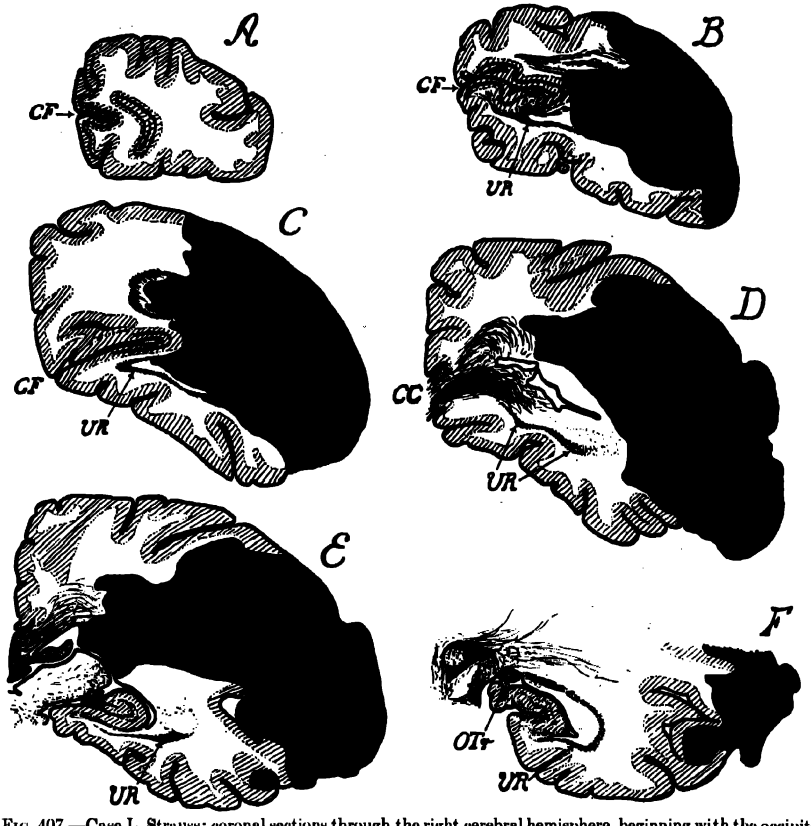

FIG. 407.—Case L. Strauss: coronal sections through the right cerebral hemisphere, beginning with the occipital pole (*A*) and extending as far as the posterior level of the thalamus (*F*), showing the tumorous mass in solid black which had destroyed and replaced the brain substance. In spite of the extensive destruction, the visual radiation (*vr*) in part remained preserved, which together with the preserved striate area, marked by an intracortical stippled stripe of Gennari in the polar calcarine fissure, may account for the large central sparings in the fields of view. This anatomical fact agrees well with the preserved posterior foveal-macular tip of the lateral geniculate nucleus of the same side (*see* Fig. 408).

strata and damage to the anterior calcarine fissure must have caused, first, a peripheral contraction of the homonymous fields of the left side, principally in the lower quadrants. The foveal-macular or central vision remained at first unimpaired, since the intermediate segment of the visual radiation was at first not interrupted but merely displaced downward and medially and also since the foveal-macular portion of the

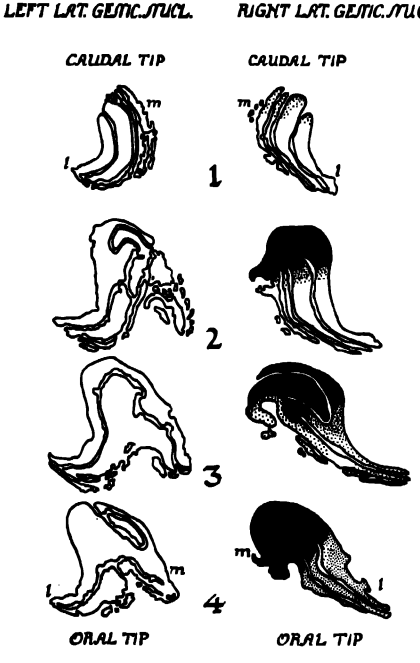

FIG. 408.—Case L. Strauss: lateral geniculate nuclei, left normal (*white*), right largely degenerated (*solid black and stippled*), except in the posterior foveal-macular extremity (sketches *1* and *2*). Most advanced degeneration was found in the medial half of the nucleus, corresponding with a complete interruption of the upper segment of the visual radiation shown in Fig. 407.

striate area around the tip of the occipital lobe remained out of reach of the tumor.

The subsequent course can only be surmised from the study of the lateral geniculate nucleus of the right side. Here practically all the nerve cells were more or less degenerated. However, there were important differences concerning the degree, that is, the advancement, of the degenerative process in different portions of the nucleus. Obviously, most completely degenerated and hence probably first affected were the inner and the intermediate segments of the nucleus on its more anterior levels. This agrees well with the fact that the tumor had apparently first interrupted the dorsal bundles of the radiation. The lateral or outward tip of the nucleus showed degenerative changes somewhat less advanced, again agreeing with the later involvement of the anterior portion of the calcarine fissure and its afferent fibers (which include both horizontal branches) and the sparing of the intermediate foveal branch.

Since both lips were involved, the extramacular portions of the upper homonymous field quadrants must have been affected during the preterminal phase of the illness, in addition to the lower extramacular quadrants, which were eliminated previously by reason of the interruption of dorsal bundles of the radiation.

The last to go was evidently the intermediate foveal-macular segment of the radiation, since the signs of the retrograde degeneration were least advanced in the posterior tip of the lateral geniculate nucleus concerned with central vision (Fig. 408, right-hand sketch *1*). This indicates that the foveal-macular fibers, at first only displaced downward, became interrupted, compressed, or infiltrated in their further course by the advancing tumor, eventually possibly producing a complete homonymous hemianopia on the left side without any central sparing. This, however, since the general condition of the patient did not permit further testing, remained unrecognized.

Several points in this analysis need to be emphasized. First is the fact that the opposite lateral geniculate nucleus, corresponding with the intact left cerebral hemisphere, remained completely unaffected (Fig. 408, left-hand sketches). This is interesting in connection with the hypothesis of bilateral representation of each total "macula" discussed previously (chap. XI, 8 and 9). It is fair to assume that if a part of the visual radiation were to decussate in the corpus callosum (splenium), as assumed by some, the left geniculate nucleus would have shown some degeneration, at any rate in its posterior foveal-macular extremity. It is necessary

to postulate this, not so much because of the probable ultimate complete impairment of the sagittal strata in the right occipital lobe, as chiefly because the tumor interrupted the callosal fibers of the splenium, exactly where, according to R. A. Pfeifer (1925), the decussating fibers are supposed to be located.

Another noteworthy fact to consider is the presence of an incomplete initial hemianopia, although it has been claimed that, in the pathology of the temporal lobe localized close to the lateral geniculate nucleus, the most usual type of field disturbance is a complete hemianopia. This, it was alleged, is caused by the interruption of the hypothetical decussating "macular" fibers as they arise from the lateral geniculate nucleus. Our case furnishes contrary evidence and disproves this hypothesis.

Of further interest is the course of the ventral segment of the visual radiation, easily followed all the way from its origin in the incompletely affected lateral segment of the lateral geniculate nucleus (*VR* in sketch *E*) to its termination in the lower calcarine lip (sketches *D*, *C*, *B*, in Fig. 407). The case shows that in Man this branch has an origin, course, and termination similar to that found experimentally in the Monkey, except that in the human brain it is longer and has a long detour, which it does not have in the Monkey (*cf.* chap. VII, 3, esp. [6], and Figs. 93, 235, 236).

Finally, this and the preceding case, AMES, both alike with respect to the pathophysiological process and clinical symptoms, well illustrate the limitations that human pathological material, especially the neoplasms, has for the finer analysis of the visual pathways. Such material may be utilized only with circumspection and by taking into account the knowledge obtained from other pathological cases caused by the nonexpansive and noninfiltrating processes and from experiments with monkeys and apes.

SEC. 5. CASE OF A QUADRANTIC HOMONYMOUS HEMIANOPIA TRANSFORMED INTO A BILATERAL INCOMPLETE HEMIANOPIA

1. HISTORY. DYKSTRA, Mike, Billings Hospital, University of Chicago, UNo. 10950.

Diagnosis: Right upper quadrantic homonymous hemianopia, expanding into a bilateral incomplete hemianopia with large central sparings, caused by a cystic multiform glioblastoma.

The illness began a year previous to admission, with spells of dizziness and "noise" associated with vertigo, uncinate attacks ("peculiar odors"), headaches, and weakness of memory. Six weeks before admission there had been a spell of complete blindness, lasting four hours, with subsequent improvement. Vision at the time of admission was below par. The fields of view, examined grossly, suggested a notching of the upper quadrants in the right homonymous halves. Both disks were well defined but were choked, on the right side for 3.5 diopters, on the left side for 5 diopters. There were also minute hemorrhages in the disks. A few months later a subtemporal decompression craniotomy was made on the left side in order to relieve the intracranial pressure. The tumor, on inspection during the operation, was found to occupy the anterior three-fourths of the left temporal lobe.

2. OPHTHALMOLOGICAL EXAMINATION.—Nine months after the onset of the illness the plotting of the fields revealed an incomplete right homonymous hemianopia in the upper quadrants (Fig. 409, upper fields). Ten days after the operation both disks were found to have subsided to a normal level. The visual fields, plotted on several occasions later, approximately eight weeks and again ten weeks after the operation, showed a progressive increase of the blindness from a right upper quadrantic to an incomplete homonymous hemianopia in the entire right halves of the fields, with a sparing of the central regions. There was also a concentric loss in the periphery of the left halves of the fields and, in general, a marked reduction of visual acuity (Fig. 409, lower fields). A few days later a recurrent papilledema was found, the right disk being swollen up to 3 diopters, the left one up to 2.5 diopters.

3. PATHOANATOMICAL EXAMINATION.—The anatomical inspection of the brain showed hemorrhages around the base and in the ventricular cavities, including the fourth ventricle. The

ventral half of the left temporal lobe was replaced by a tumorous cavity spreading almost as far as the thalamus. The left lateral ventricle was found compressed. The tumor also invaded the left frontal lobe.

Since much of the *left hemisphere* was destroyed by the pathological process and by a surgical intervention that followed, this hemi-

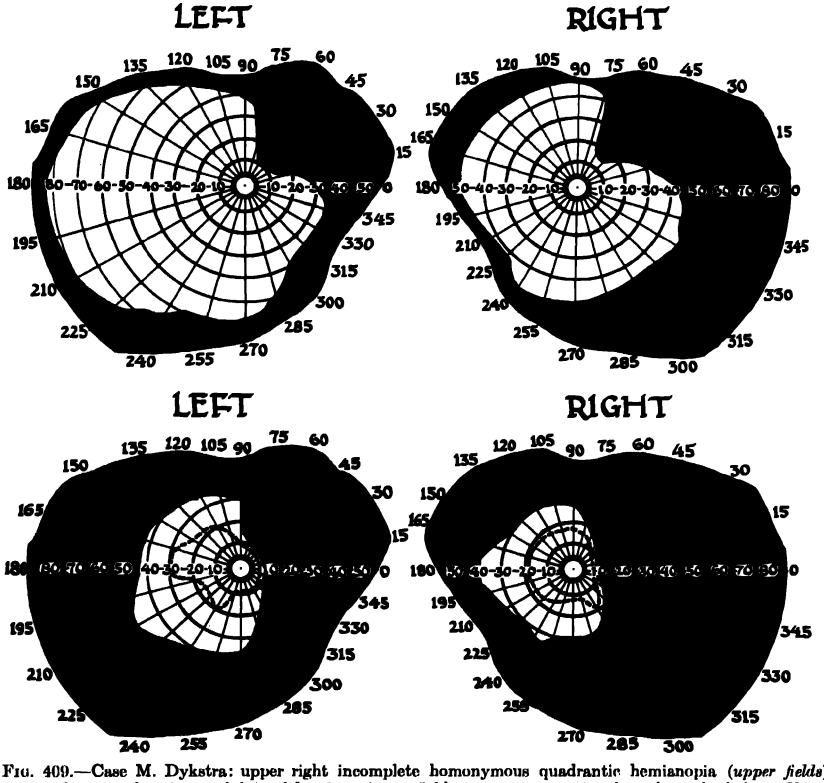

FIG. 409.—Case M. Dykstra: upper right incomplete homonymous quadrantic hemianopia (*upper fields*), subsequently expanding into a bilateral hemianopia, or field rests, more restricted in the right halves. Upper fields taken seven months and three weeks, lower fields taken twenty-seven days, preceding death. Cause: brain tumor in the ventral half of the left temporal lobe.

sphere was not examined histologically. The *right hemisphere*, on the contrary, was found to be free from tumorous growth. It was by no means free from pathology, however. This was manifested by an engorgement of all venous passages belonging to the system of the great vein of Galen, indicating a high degree of venous stasis. The spaces around the base of the brain were completely filled with extravasated blood and distended veins, which further filled the hippocampal fissure, extending backward in a decreasing amount into the medial or anterior calcarine fissure and into the collateral sulcus. These fissures, especially the calcarine, were filled with clotted blood as far posteriorly as the anterior segment of the striate area in the lower calcarine lip.

Almost the entire extent of the *left lateral geniculate nucleus* contained rarefied nerve cells, mostly showing an advanced stage of retrograde irritation and degeneration (Fig. 410, sketches *1–7*). Most advanced and most completely de-

generated was the outward or lateral segment, comprising approximately one-fourth to one-third of the nucleus (marked by letter *l*). Here all nerve cells were either greatly decreased in numbers and size or had disappeared. The medial segment was less affected (marked with letter *m*). The intermediate segment was also less changed, especially in the posterior foveal-matolysis, with a swelling of the bodies and with peripherally dislocated nuclei.

The posterior extremities (sketches *1*, *2*, and *8*) related to the foveal-areal or central parts of the fields were somewhat better preserved in both nuclei than the oral portions related to the extrafoveal-areal portions of the fields (*3–7*, *9*, *10*).

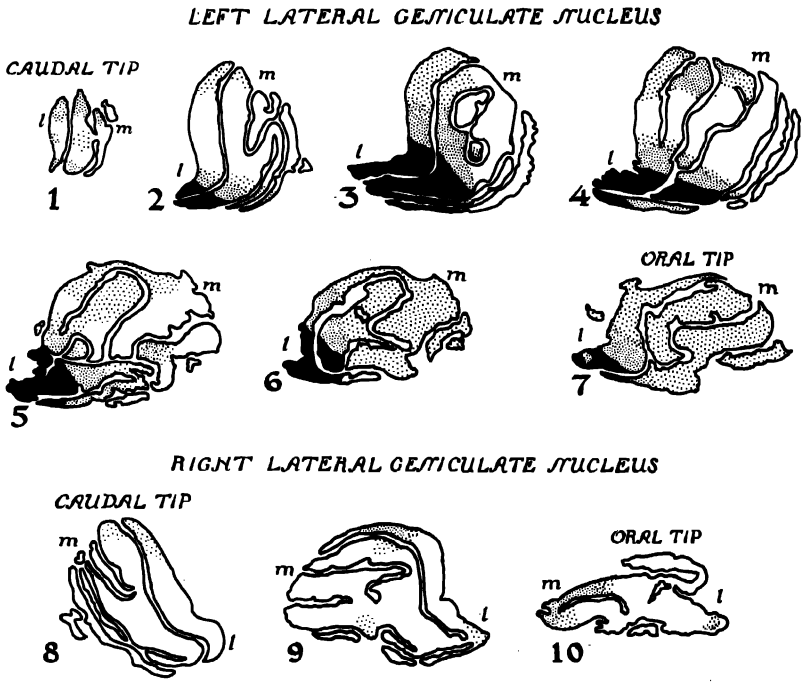

FIG. 410.—Case M. Dykstra: left and right lateral geniculate nuclei, showing variously advanced retrograde cell degeneration. The most intensive loss was found in the lateral segment of the left nucleus (*solid black*). This agrees with the most complete destruction of the lower segment of the visual radiation which had first abolished the right upper quadrants of the fields of view.

macular extremity of the nucleus (sketches *1*, *2*).

The *right lateral geniculate nucleus* was found to be, on the whole, in a much better condition (sketches *8–10*). But even here many scattered nerve cells showed signs of slight irritation. In the medial segment (*m*) and in the very tip of the lateral segment (*l*) the loss of nerve cells was most pronounced. In these localities some of the cells also showed unmistakable signs of chro-

4. CORRELATION OF FUNCTIONAL DISTURBANCE AND PATHOANATOMICAL FINDINGS.—On the basis of the clinical symptoms, especially the notching of the upper right homonymous quadrants of the fields of view and "uncinate attacks," it is apparent that the tumor originated in the left temporal lobe. The focus of the tumor, as determined by pathoanatomical examination, also proved to be in that lobe.

As the tumor expanded in the occipital direc-

tion, first the lower calcarine lip was separated from the visual radiation, whose lower segment was interrupted. This must have increased further the scotomatous area in the right upper quadrants.

The next step was an interference with all afferent fibers of the anterior portion of the striate area, resulting in an elimination of the entire right monocular temporal crescent, illustrated by the upper fields in Figure 409.

In the course of further expansion of the tumor, the upper calcarine lip was also undermined, which caused the blindness to extend into most of the right lower quadrants. This phase is illustrated in the lower fields in the same figure. The centers of the right homonymous halves and the adjoining zones in the same halves about 10° wide, extending along the vertical meridians as far as 30° in the lower quadrants, were spared. The quality of vision in the spared parts, owing to the general intracranial conditions, deteriorated also. To this is also to be attributed a reduction of the left halves of the fields, there being a compression of the anterior segment of the right calcarine fissure and of its afferent fibers, for which hemorrhage and thrombosis along the base of the brain, including the right hippocampal and calcarine fissures, must be blamed.

The principal feature of this case is central sparing during an advanced phase of the illness. This can be entirely explained by the elimination of the anterior portion of the striate area and its afferent fibers because of the location of a tumor medial from the lateral ventricle. The lateral salient of the visual radiation containing foveal-macular fibers, located on the lateral side of the ventricular barrier, escaped. This is of special interest, as it shows that the same protective mechanism responsible for central sparing in vascular cases may also function as a protective barrier in some cases of brain tumor. The remarkable fact is the long duration of this protection.

SEC. 6. CASE OF A PURE INCOMPLETE QUADRANTIC HOMONYMOUS HEMIANOPIA

1. HISTORY.—MUNSON, Le Roy, age twenty-two years, student.

Diagnosis: Left incomplete inferior quadrantic homonymous hemianopia, caused by an endocarditic embolic infarct in the right occipital lobe. Specimen kindly given by Dr. C. W. Rucker, then of the Department of Ophthalmology of the University of Minnesota Medical School at Minneapolis (now of the Mayo Clinic, Rochester, Minn.), through the initiative of Dr. F. Burch, of the same institution.

Since childhood the patient had suffered from "rheumatism" and an indefinite heart trouble. The terminal illness began fifty-eight days preceding death, with a sudden headache in the right frontoparietal region, associated with "double vision in the right eye, and blindness in the temporal half of the left eye." Fifteen minutes after the onset the patient felt nauseated and vomited. A tentative diagnosis was that of a subacute bacterial endocarditis with bacteremia. This was confirmed by cultures made from blood, which showed the presence of *Streptococcus viridans.*

2. OPHTHALMOLOGICAL EXAMINATION.—The plotting of the fields revealed the presence of a left-sided incomplete inferior quadrantic homonymous hemianopia (Fig. 411, upper fields). The visual fields were plotted for the first time thirteen days after the onset, which was forty-five days before death. The blindness extended also into the periphery of the left upper quadrants, eliminating the upper half of the left monocular crescent, together with the adjoining segment of the binocular portions of the same quadrants. The central portions of the affected quadrants were spared, up to 3° or 4° from the fixation points. In addition, there was a cotton-wool exudate in the right retina at the first branching of the superior temporal vein about 1.5 × 3 times the diameter of the vein.

A second plotting was made eleven days after the first, or thirty-four days before death (Fig. 411, lower fields). This time the left upper crescentic field was found to be restored, and the blindness limited to the left inferior homonymous quadrants. As before, central vision was

spared. This situation remained substantially the same until death. The target used in the plotting was 3 mm., white, at 33 cm. distance, by daylight. On both occasions the patient was ill because of the high fever which persisted until the last, but he was co-operative.

3. PATHOANATOMICAL EXAMINATION.—A post mortem examination corroborated and amplified the clinical diagnosis by the presence of a chronic endocarditis. Infarcts were found in the spleen, kidneys, and brain. The brain had a cyst in the right occipital lobe but appeared otherwise normal. There were no signs of meningitis.

The *right occipital lobe*, grossly examined, showed on the lateral face, near its dorsal margin, a small focus of softening, whose extent could not be determined macroscopically. The serial sections stained by the methods of Weigert-Kultschitzky, Van Gieson, and hematoxylin and eosin revealed the presence of a single cystically degenerated, crescent-shaped, vertically placed cavity (Fig. 412, solid black marked with * in sketches *A*–*F*). This focus ex-

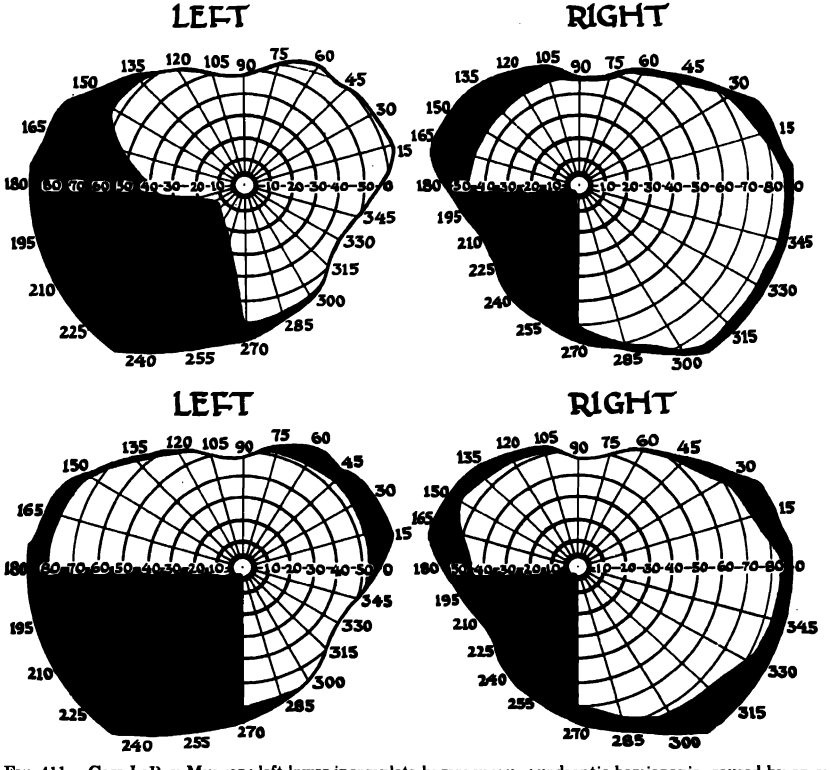

FIG. 411.—Case LeRoy Munson: left lower incomplete homonymous quadrantic hemianopia, caused by an endocarditic embolism of a branch of the middle cerebral artery in the right occipital lobe. Upper fields taken thirteen days after the cerebral insult, or forty-five days before death; lower fields taken twenty-four days after the cerebral insult, or thirty-four days before death. Cause of the visual defect a purely subcortical interruption of the upper segment of the right visual radiation (*see* following Fig. 412). Note the extension of blindness into the upper half of the left monocular temporal crescent, becoming entirely restored at the second plotting; the central sparings of about 4° in the affected quadrants, except in the left field at the first plotting, where the sparing was more extensive, extending also as a wedge along the vertical meridian, very likely caused by the poor condition of the patient during the plotting (headache, fever, fatigue).

tended from the surface of the brain through the white subcortical fiber mass, down to the ependyma of the posterior horn of the lateral ventricle (*lv*), through almost the entire longitudinal extent of the lobe. The cavity was lined by a reactive membrane that was even and smooth, without diffuse zones of transition or inflammatory infiltration. Obviously, the cavity was caused by an embolic obstruction of a branch of the middle cerebral artery, most likely the parieto-occipital Sylvian or superior temporo-occipital Sylvian artery (*Sypaocca, Syteoccsua*, in Figs. 370, 374). The ultimate etiology of the lesion was an infectious chronic endocarditis which produced the embolism.

An examination of the serial sections through the brain showed approximately the upper half of the sagittal fiber layers of the right occipital lobe to be absent and replaced by the cystic cavity. In particular, the upper segment or horizontal branch of the *visual radiation*, indicated by shading in the solid black lesion in sketches *B–F* in Figure 412, was found to be missing, with the exception of its innermost portion, made up of fibers entering the upper lip of the calcarine fissure (*fc*). The adjoining dorsal portion of the intermediate segment or vertical branch of the radiation was also interrupted (thus in *C*, *D*, and *F*).

On levels closer to the tip of the occipital lobe, the lesion destroyed almost the entire upper or dorsal half of the radiation, just sparing its "lateral salient," where the upper and lower segments join (*B*, *C*). In the occipital pole the posteriormost bundles of the radiation that supply it were just barely missed (*vr* in sketch *A*).

In the striate cortex lining the calcarine fissure, the following situation was found. In the anterior third of the longitudinal extent of the fissure the intracortical afferent visual fibers, distinguished by their slanting course, appeared normal in both lips (*cf.* Figs. 315, 316, 327, 328, 334). The immediately subjacent subcortical fibers, including those that line the calcar avis in the lateral ventricle, were likewise normal in this locality. In the middle third of the calcarine fissure, in its upper lip, beginning with the deepest point of this fissure, the subcortical fibers were considerably depleted In the same locality the slanting infra-Gennarian intracortical afferent visual fibers were also almost entirely absent. In the occipital or posterior third of the calcarine fissure and in the pole of the lobe, the subcortical and intracortical infra-Gennarian afferent visual fibers in the entire striate area again appeared normal.

In the *right lateral geniculate nucleus*, stained with the modified Nissl-Lenhossék's toluidine blue method, a single well-defined zone was found, where the nerve cells were in various stages of retrograde degeneration, beginning with "primary irritation," but mostly far advanced, including complete disappearance (Fig. 412, solid black marked with * in sketches *2–4*). The zone was wedge-shaped, with its broad base at the upper convex extremity and its sharp end turned toward the hilum of the nucleus, exactly as in the experiments with monkeys described in chapter VII, 4 [5], 5 [2]. (*See* Figs. 247, 250, 251, photo *2; cf.* a different type of degeneration in Fig. 200, but similar in Figs. 202–8.)

The second fourth was completely degenerated, if the nucleus be divided on a cross-section in the coronal plane into four segments. In the innermost segment, coinciding with the inner tip of the nucleus, a number of nerve cells appeared less affected. The degeneration passed through all six cellular layers, including the ventral layers with large elements. In the outward or lateral half of the nucleus the nerve cells appeared normal, filling the compact cellular layers in great numbers, except in the immediate vicinity of the degenerated zone.

The cell depletion was most complete in the center of the zone, where almost all cells were altered to a point where they were difficult to recognize. The neuroglia, as usual in such retrograde foci, was greatly increased in numbers in the entire degenerated territory, in comparison with the normal parts of the nucleus.

The position of the degenerated wedge, limited to the medial half of the nucleus, changed along its longitudinal extent. Closer to the anterior or oral extremity, the wedge extended to the mid-line or slightly beyond it (sketch *4*). On the middle levels the zone, together with the most medial and less affected portion, occupied almost exactly the inner half of the nucleus (sketch *3*). In the posterior or caudal third of the nucleus the zone of degeneration was gradually reduced to the inner third of the nucleus or

less (sketch *2*). In the posterior sixth (sketch *1*), where the nucleus is composed of four cell layers only—two dorsal ones made up of small cells and two ventral ones composed of larger cells—almost all cells preserved a normal appearance (lower photo in Fig. 213). The few scattered cells that were discolored or shrunken were an exception, probably in consequence of general factors such as toxic agents and fever.

In addition to a single large zone of retrograde degeneration caused by a single distant lesion that interrupted a compact portion of the visual radiation, there were a few small, scattered, primary infectious foci represented by an agglomeration of nonnervous cells, either in or outside the degenerated zone described. These minute, fresh, inflammatory nests, similar to those found here and there in other parts of the

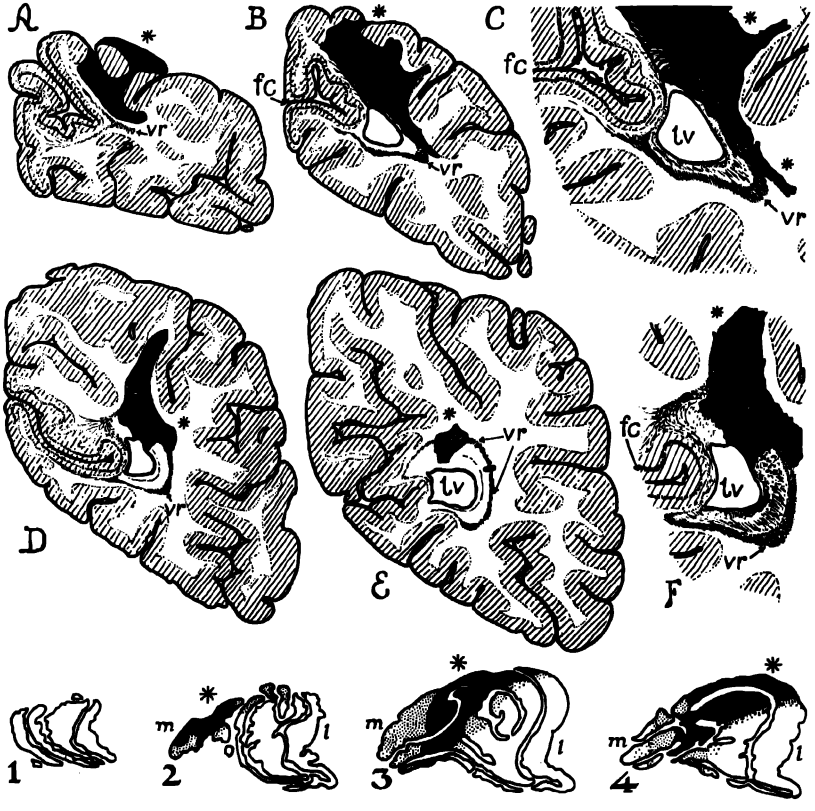

FIG. 412.—Case LeRoy Munson: right occipital lobe (*upper sketches*) and right lateral geniculate nucleus (*lower sketches*), showing the anatomical cause of the left lower homonymous quadrantic hemianopia (*see* Fig. 411). Sketches *A–F* represent coronal sections through the lobe at approximately equal intervals, beginning with the occipital pole; sketches *C* and *F* are slightly magnified details of *B* and *D*. Sketches *1–4* represent coronal sections through the right geniculate nucleus at approximately equal intervals, beginning with its posterior extremity (*1*) and terminating at its anterior extremity (*4*). Solid black in upper sketches indicates the brain lesion, in lower sketches the zone of advanced retrograde cell degeneration, surrounded by partial degeneration, indicated by stippling. Striate area shown by a stippled intracortical line of Gennari or Vicq-d'Azyr. *Labeling: fc*, calcarine fissure; *l*, lateral side of lateral geniculate nucleus; *lv*, lateral ventricle; *m*, medial side of lateral geniculate nucleus; *vr*, visual radiation; *, lesion (*upper sketches*) or core of degenerated zone in lateral geniculate nucleus.

brain, were obviously caused by a recent slight widespread encephalitic process, in turn caused by bacteremia of endocarditic origin. Such foci could easily be dissociated from the large, solid retrograde degeneration, the more so since the nerve cells located in the immediate vicinity of, or even imbedded in, these foci showed only slight degenerative changes or none at all.

The left lateral geniculate nucleus, in contrast with the right nucleus, was found to be normal. Here no noticeable zone of retrograde degeneration or scattered degenerated cells were found which could in any way be brought into connection with a partially interrupted visual radiation in the right occipital lobe.

4. CORRELATION OF FUNCTIONAL DISTURBANCE AND PATHOANATOMICAL FINDINGS.—Owing to a remarkably clear pathoanatomical situation in this unique case, equal to the best experiment, its analysis and correlation of functional disturbance with the changes in the central visual mechanism were easily made.

First, since the cortical lesion was slight and was located outside the striate area, it was to be ruled out as a possible cause of the homonymous quadrantic visual field defect (Fig. 412, *A* and *B*, marked with an asterisk [*]). The striate cortex itself was also entirely undamaged. Hence the functional field defect must be entirely attributed to the lesion in the subcortical fiber substance. Here again the destruction of the fibers outside the sagittal layers, since these are not instrumental in the conduction of impulses from the retinae to the striate area, was irrelevant. Thus, by exclusion, a partial interruption of the external sagittal layer, which, as indicated by the previous evidence, contains the afferent fibers of the visual radiation (*vr*, in corresponding figures), must be considered the cause of the visual field defect.

The next fact of consequence is an almost complete interruption of the upper horizontal segment of the radiation on the anterior levels through the occipital lobe (Fig. 412, *D*, *E*, *F*). This segment terminates in the upper calcarine lip, as clearly evidenced by the experiments with monkeys and other anatomical procedures described in chapter VII. This agrees well with the functional defect, which was limited to the contralateral inferior homonymous quadrants of the fields of view (Fig. 411, lower fields). A single lesion had in this case interrupted fibers that carry impulses from the right upper homonymous halves of both retinae, with the exception of the foveae-maculae.

This is evidenced, first, by the clinically observed defect, an incomplete left-sided inferior quadrantic hemianopia, contralateral to the side of the lesion. In the first plotting, this defect extended into the upper crescentic territory also (upper fields). This initial extension was likely caused by an indirect, probably edematous, interference with the normal blood supply of the lower lip in the anterior extremity of the calcarine fissure, caused by the same focus (exemplified by sketches *D* and *F*). The left upper crescentic blindness, as was made fairly certain by the second plotting, was merely an initial symptom, disappearing afterward and leaving as a permanent residue a defect strictly limited to the inferior left quadrants.

The second evidence is the position of the degenerated zone in approximately the inner third to half of the lateral geniculate nucleus, the same locality where, according to experimental evidence, optic fibers from the upper extramacular homonymous retinal quadrants terminate (*see* chap. VI, 7, 11, and corresponding figures).

The final evidence is the absence of afferent nerve fibers in the striate cortex in the upper calcarine lip, in the middle third of this fissure, a locality related to the upper retinal, or lower opposite, field quadrants (*see* chap. VII, 4, 6, and corresponding figures).

The analysis of this case points decidedly toward a vertical division of the visual radiation, with the upper and lower extrafoveal or "peripheral" retinal quadrants represented in the upper and lower segments, respectively, and the foveal-macular or "central" vision represented in the intermediate or axial segment of the radiation placed between the first two. This possibility was suggested by G. Holmes (1918) and advocated by Rønne (Roenne 1919) and in a somewhat different way by Monbrun (1919), and was experimentally demonstrated in the Monkey by Heuven (1929) and by the author (1932, 1933). (*See* chap. IV, 7 [6].)

The case MUNSON further shows that the assumption that the "foveal-macular bundle"

is located either in the dorsal segment (Pfeifer, Niessl von Mayendorf) or in the ventral segment of the visual radiation (Niessl von Mayendorf) or that the "foveal-macular fibers" may be scattered all over the visual radiation (Monakow) is not borne out by the evidence. For, in spite of the almost complete destruction of the dorsal segment of the radiation, in our case the central fields of the affected inferior left homonymous quadrants remained spared to the extent of from 3° to 4° around the points of fixation. It is therefore apparent that the fibers which carried impulses from the preserved central portions of these quadrants must have been in the segment of the radiation that escaped destruction.

Since the origin of the interrupted upper segment of the radiation in the lateral geniculate nucleus is contiguous with the intermediate foveal-macular segment and is separated by the latter from the lateral "peripheral" segment of the nucleus and since the inferior segment of the radiation, remaining intact in this case, terminates in the inferior calcarine lip, the chain of evidence is complete in favor of the intermediate location of the foveal or "macular" bundle in the visual radiation, that is, in its intermediate or axial segment.

In sections through the anterior part of the occipital lobe, the radiation somewhat resembles a horseshoe, with an upper and a lower segment, both linked by an intermediate segment, as described (Fig. 412, *D, E, F;* compare with Figs. 228, 229, and 231–33). The upper segment, together with the adjoining portion of the intermediate segment with which it is continuous, was destroyed in this case. Accordingly, it is this vertical segment which, if one looks upon the radiation as a fan composed of rather parallel bundles of fibers, forms its axial or central rib (*cf.* Figs. 259, 260). Here are located fibers that represent both homonymous halves of the central areae of the two retinae, including the foveae-maculae, measuring up to 3° or 4° on both sides of the horizontal meridians.

On levels closer to the pole of the occipital lobe the radiation changes its shape somewhat, the vertical branch becoming transformed into an obtuse angle pointing down and outward, with its concavity facing the calcarine fissure (Fig. 412, *B, C;* also Fig. 231, *B*). Here it is more proper to speak of an upper and a lower segment and of a lateral angle or salient of the radiation. In our case the fibers of this salient just escaped the injury (at *vr* in sketches *B, C*).

Farther back, in the tip of the lobe, these fibers slip behind the posterior horn of the lateral ventricle and turn inward, to reach the most posterior portion of the striate cortex at the occipital pole (*A*, in Fig. 412). In this way the "central," "axial," or foveal segment of the radiation (at *vr*) remained preserved all the way from its origin in the caudal tip of the lateral geniculate nucleus of the same side (*l*) to its terminal station in the tip of the occipital lobe (*A*, in same figure).

The preservation of the axial foveal or "macular" fibers, in turn, explains the sparing of the central portions of the affected quadrants of the visual fields. The position of the foveal or "macular" bundle in the radiation thus determined agrees well with the one found in case HOLT (Fig. 415) and is essentially the same as that found in the experiments with monkeys (Figs. 259, 260).

Case MUNSON also illustrates the position of the horizontal meridians in the visual radiation. It shows that if the upper segment, on anterior levels through the occipital lobe, is completely interrupted or almost so, the extrafoveal portions of the blind homonymous quadrants are separated from the seeing ones of the same side by straight horizontal lines, which are the horizontal meridians (Fig. 381; *also* Fig. 383, *5*).

The exceptions are the small areae, corresponding to the central portions of the respective quadrants, around the fixation points, which remain normal when the foveal or "macular" fibers are spared. The only possible explanation of this remarkable feature—a straight linear delimitation of the quadrantic hemianopia—is the assumption of a sizable "gap" between those fibers of the radiation that represent the extrafoveal periphery of the upper homonymous quadrants and fibers representing the extrafoveal periphery of the lower, as suggested long ago on the basis of analysis of clinical cases by Gordon Holmes (1918), Monbrun (1919), and Rønne (Roenne 1919). Hence it is this mechanism whose partial destruction is responsible for the strictly quadrantic hemianopic defects in purely subcortical lesions. The "gap" of

G. Holmes, however, is not void but is filled with the foveal or "macular" fibers, which, as pointed out, lie between the two "peripheral" or "extrafoveal" branches of the radiation. The foveal or "macular" fibers form, accordingly, a central or axial rib of the fiber fan that is the visual radiation. (*Cf.* chap. XI, 5; and Figs. 235, 236, 259, 260, 269.)

In accepting this arrangement, one has to assume further that, beginning with the most peripheral bundles at the upper and lower margins of the radiation, those closest to the upper and the lower calcarine lip, respectively, each narrow subsequent segment of the outer sagittal fiber layer closer to the axial bundle represents a narrow concentric quadricircular belt or zone of the corresponding homonymous quadrants. These belts are necessarily longer in the extreme field periphery, becoming gradually shorter, the closer they are to the points of fixation.

Each fiber segment is to be imagined as made up of minute bundles of homonymous fibers representing individual functional visual units, each capable of functioning independently. Such a series of the respective functional units makes up each of the quadricircular belts in the corresponding homonymous visual quadrants. In the far periphery of the fields the functional units are relatively large and few, and hence few fibers in the visual radiation represent a relatively large territory. Closer to the fixation points, the units gradually decrease in size and increase in number. This again requires an increasing number of fibers, although the respective belts in the fields of view rapidly decrease in territory.

The uppermost and lowermost and, at the same time, the most medial bundles in both upper and lower segments of the radiation, passing, on anterior levels of the occipital lobe, to the upper and lower calcarine lips, respectively, are related to the extreme nasal segment, or monocular crescent, of the contralateral retina. In case MUNSON these crescentic fibers in the upper segment of radiation were interrupted with the binocular fibers of the same quadrant, showing that both are arranged on the same principle, the upper crescentic fibers adjoining the upper binocular quadrantic fibers, the lower crescentic fibers adjoining the

A logical corollary to the expounded concept of visual radiation is that, in purely subcortical lesions, caused by a single focus, interrupting a smaller or larger portion of the radiation, the field defect should always comprise a belt-shaped quadricircular zone (Fig. 383, sketch *9*). Such a scotomatous zone will be either narrow, if a small segment of the radiation is damaged, or wide, if a broad segment is interrupted. The blindness may eventually spread over the entire upper or lower homonymous quadrants, if exactly half the radiation is interrupted. The central vision may or may not be preserved, depending on whether or not the adjoining intermediate foveal-macular segment of the radiation was preserved or destroyed (*see* chap. X, 8).

In other words, any small, purely subcortical, damage to the radiation may produce a visual field defect in the shape of a more or less narrow belt extending concentrically around the fixation point from the horizontal to the vertical meridian. The same should be expected in the case of a field "rest" caused by extensive subcortical damage that spares a segment of the radiation. The width of a scotomatous belt or a single spared rest may vary, depending upon whether a smaller or larger portion of the radiation is interrupted or preserved.

The wedge-shaped defects, or field "rests," of a more or less triangular shape, with a broad base at the periphery of the fields and a pointed end at the fixation points, are present only in purely cortical cases, where the striate cortex alone is involved, if the lesion is of suitable shape and location.

Irregular homonymous field defects likewise cannot be explained by means of purely subcortical lesions. They must be referred to the lesions where the striate cortex is damaged alone or is damaged in addition to the radiation. Nor can small lesions in the "axial" segment of the radiation produce narrow, homonymous, wedge-shaped or stripelike field defects extending more or less along the horizontal meridians, since each such lesion is bound to produce central or paracentral scotomas in any case, extending from the vertical to the horizontal meridians, with or without sparing the area around the fixation points.

No mention is made in the history of case MUNSON of visual disturbances of a complex or

disorientation in space. The absence of these symptoms is best explained by the location of the lesion in the right occipital lobe and by the sparing of the right parietal lobe, although the examiners may have failed to test for such disturbances.

Attention should also be called to the accurate lateral subjective localization of the sudden headache as an initial symptom by the patient in the right frontoparietal region of the head and the absence of such subjective sensation in the right occipital region. This is of interest because of the modern interpretation of the causes underlying headaches (Moench 1951; Pickering 1951). This again may have been merely an omission on the part of the attending physician, since in vascular pathology, especially acute, involving the calcarine region, an intensive, dull, prolonged headache accurately localized in the affected lobe is a very marked subjective symptom. Finally, the absence of a subjective experience of symptoms of irritation (photopsia, photophobia, etc.) may be merely the result of the confusion which is not surprising in a severe cerebral insult.

SEC. 7. CASE OF A SUPERIOR QUADRANTIC HOMONYMOUS HEMIANOPIA ASSOCIATED WITH QUADRANTIC HEMIACHROMATOPIA

1. HISTORY.—HOLT, George H., age fifty-eight years, vocal teacher.

Diagnosis: Left incomplete homonymous hemianopia, absolute in the upper quadrants and relative in the lower, caused by a thrombotic encephalomalacia of the right occipital lobe, of approximately six months' duration, situated along the medial calcarine sulcus, developed on the basis of general arteriosclerosis and hypertension. Specimen received from Dr. E. F. Hirsch, of St. Luke's Hospital, Chicago; clinical information and field chart received from Dr. T. Allen, Chicago.

The patient had suffered from hyperthyroidism (goiter), for which he had been operated on seven years earlier. Five years previous to admission some mental irregularity and forgetfulness had been noticed. The present examination revealed general symptoms of senility, right hemiplegia, aphasia, and irrationality. On two occasions the patient showed signs of a cerebral "stroke," the last, one month before death, caused by a thrombotic softening in the left internal capsule. A few days preceding the last stroke he was lifting timbers. After the second stroke his vision became disturbed ("blindness"). He also had difficulty with hearing, more on the left side, and became paralyzed on the right side of the face, in the right arm and the right leg. He was able to speak, however.

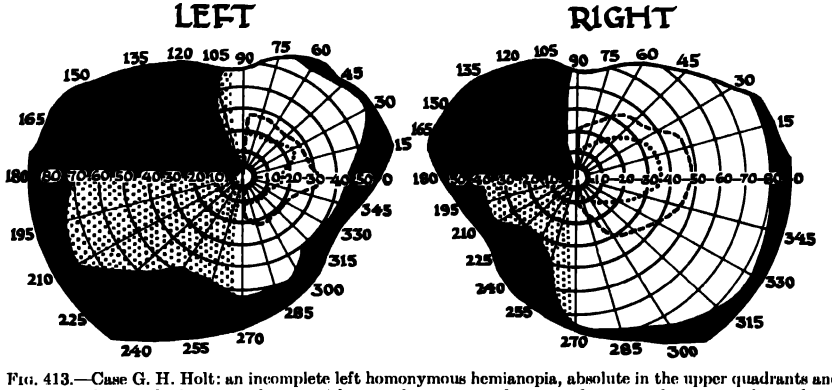

FIG. 413.—Case G. H. Holt: an incomplete left homonymous hemianopia, absolute in the upper quadrants and relative for colors in the lower quadrants, with central sparings and an overshot zone along vertical meridians. Cause: a thrombotic encephalomalacia of the calcarine sulcus of the right occipital lobe, developed on an arteriosclerotic basis (*see* Fig. 414).

2. OPHTHALMOLOGICAL EXAMINATION.—The fundi of the eyes, examined approximately six months before death, revealed a marked arteriosclerosis of the retinal blood vessels. At the time when the fields were tested first with the hand, and when again two days later perimetrically, which was forty-eight days before death, a left homonymous hemianopia was discovered (Fig. 413). The upper quadrants were found to be absolutely blind, with the exception of a narrow zone along the vertical meridians, where ried from the blind to the seeing portions of the fields. The target not only was brought from the periphery to the center but was likewise held at a certain meridian on the arc, which itself was rotated. The patient was fairly co-operative, although perhaps not so much as would have been desirable.

General arteriosclerosis with arterial hypertension, followed by cerebral hemorrhage from the lenticulostriate artery of the right side, was diagnosed.

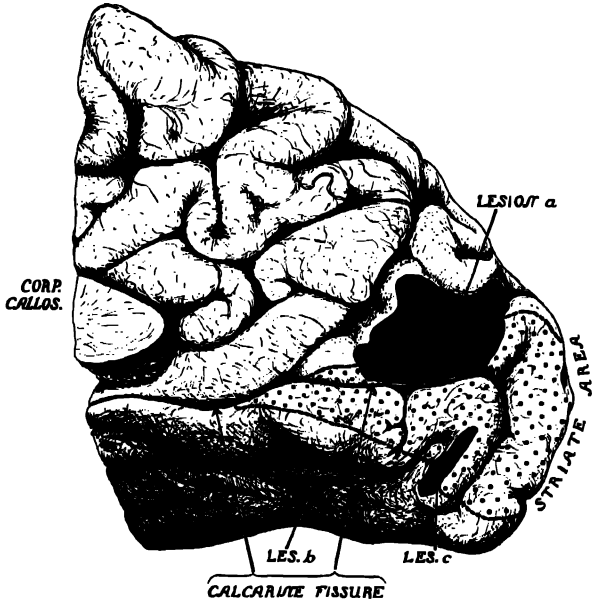

FIG. 414.—Case G. H. Holt: medial aspect of the right occipital lobe, showing the three foci of softening visible at a gross examination, a large one (*Lesion a*) spreading over much of the cuneus, and the two smaller ones (*Les. b* and *Les. c*) below the calcarine fissure (*cf.* Fig. 415). Striate area stippled. *CORP. CALLOS.*, corpus callosum.

only a relative scotoma for colors was found. The left lower quadrants were relatively blind for red and blue and were contracted in the periphery. The central vision was spared between 2° and 3°.

The light during the examination was good, although the day was overcast (December). A simple arc perimeter, with a radius of 33 cm., and a target of 1 cm. were used. To determine the edge of the blind areas, the target was car-

3. PATHOANATOMICAL EXAMINATION.—Examined grossly, three encephalomalacic foci were found *in the right occipital lobe* (Fig. 414, lesions *a*, *b*, *c*). The larger lesion (*a*) was on the inner face of the hemisphere, where it spread over the greater part of the cuneus. It extended to the calcarine fissure, destroying its upper lip. The other two malacic foci, located ventral to the calcarine fissure, appeared much smaller on the surface The anterior focus (*b*) was at the

level of the anterior tip of the cuneus; the posterior focus (*c*) was closer to the posterior curved end of the calcarine fissure next to the occipital pole.

Microscopic examination of the serial sections, stained according to Weigert-Kultschitzky technique, showed that all three superficially visible foci were, in reality, but one single large focus, located between the posterior horn of the lateral ventricle (*lv*) laterally and the inner face of the hemisphere medially (Fig. 415). This focus, essentially of a thrombotic ischemic nature arising on the basis of arteriosclerosis of the brain, had destroyed a substantial portion of the cortex of the calcarine fissure and parts of the cortex and of the subcortical fiber mass immediately adjoining this fissure.

In particular, on the most anterior levels through the occipital lobe, the lower calcarine lip was either destroyed or undermined to such an extent as to become separated from its afferent fibers streaming to it from the lower horizontal segment of the visual radiation (sketches *D*, *F*). Here the lesion corresponded with the anterior small superficial focus (*b*). The fibers arriving from the upper horizontal segment of the radiation just missed the damage. Farther posteriorly, where the malacic focus approached the upper calcarine lip, these also must have been affected (sketch *C*).

In sections through the middle of the occipital lobe the destruction expanded to the upper lip of the calcarine fissure (sketch *B*). Here a portion of the striate and extrastriate cortex, with all subjacent fibrous substance, was destroyed (at *). In all sections through the occipital lobe the lesion was strictly confined to the medial half of the hemisphere inward to the lateral ventricle (*lv*), hence limited to the territory of the posterior cerebral artery.

Farther back toward the occipital pole, the lesion decreased (sketch *A*) and finally disappeared, leaving the pole of the occipital lobe and its fiber mass intact. Lateral to the ventricle, only two small lesions were present in sections passing through the parietal and temporal lobes (small, black, triangular area and a gap in *vr*, in sketch *E*). These lesions interrupted portions of the intermediate segment of the visual radiation.

In summary, in this case, in spite of its superficial appearance, a single malacic focus directly destroyed or undermined the lower, lingual lip along the entire main body of the calcarine fissure; the upper, cuneal lip, however, was destroyed only along the posterior third of the fissure. A considerable segment of the upper lip, with its afferent radiation fibers, was fairly well preserved (sketch *D*), as was also the tip of the occipital lobe. In consequence, the lower segment of the visual radiation degenerated because of the complete destruction of the lower calcarine lip and its afferent fibers. The upper segment of the radiation degenerated only partially, owing to partial destruction of the upper lip and its fibers and also because of a small primary vascular focus in the medial half of the lateral geniculate nucleus of the right side (small coarsely shaded area in Fig. 416).

In the intermediate segment of the radiation, even though depleted, many fibers remained, being best preserved in a single solid bundle in the "lateral salient" (thus at *vr* in sketches *B* and *E*).

Most striking was the contrast between the upper and the lower calcarine lips at the level of the sketches *D* and *F:* whereas in the former a fair number of the afferent geniculostriate fibers was found in the infra-Gennarian half of the cortex, in the latter they were practically absent.

The *lateral geniculate nucleus* of the right side (Fig. 416), stained with Lenhossék's modified Nissl-toluidine method, was found reduced in all dimensions, its layers poorly defined, with its nerve cells in the anterior half mostly gone (*4–7*). In approximately the middle third (*3, 4*) the intermediate segment alone showed a considerable number of cells still somewhat preserved, although these, too, exhibited clear signs of degeneration. Farther back in the same intermediate segment, the number of normal nerve cells increased, until close to the caudal extremity of the nucleus the cells seemed to differ little from the normal (*1, 2*). On the anterior levels both the medial and the lateral tips of the nucleus also remained less affected.

In addition, there was a small, narrow, primary vascular focus located in the inner segment, extending slightly into the intermediate segment. This focus was present in the middle third of the longitudinal extent of the nucleus

(oblong, coarsely shaded area in *3*, *4*, *5*). The glial cells, as usual in a retrograde process, were considerably increased in those parts of the nucleus where the nerve cells degenerated.

The lateral geniculate nucleus of the opposite, left, side proved normal in all respects, except for such changes as were compatible with the general pathophysiological makeup of the case (*8–14*).

4. Correlation of functional disturbance with the pathoanatomical findings.—The analysis of this rare case must, first, take into consideration the fields of view (Fig. 413). Concerning these, it is probable that, in spite of only one plotting, the observation of absolute blindness in the left upper homonymous quadrants and of relative blindness for colors in the left lower quadrants was roughly correct. The questionable points concern spared zones along the vertical meridians above and below the fixation points and the central sparings. In an attempt to correlate the functional loss with the lesion, the time factor must also be considered.

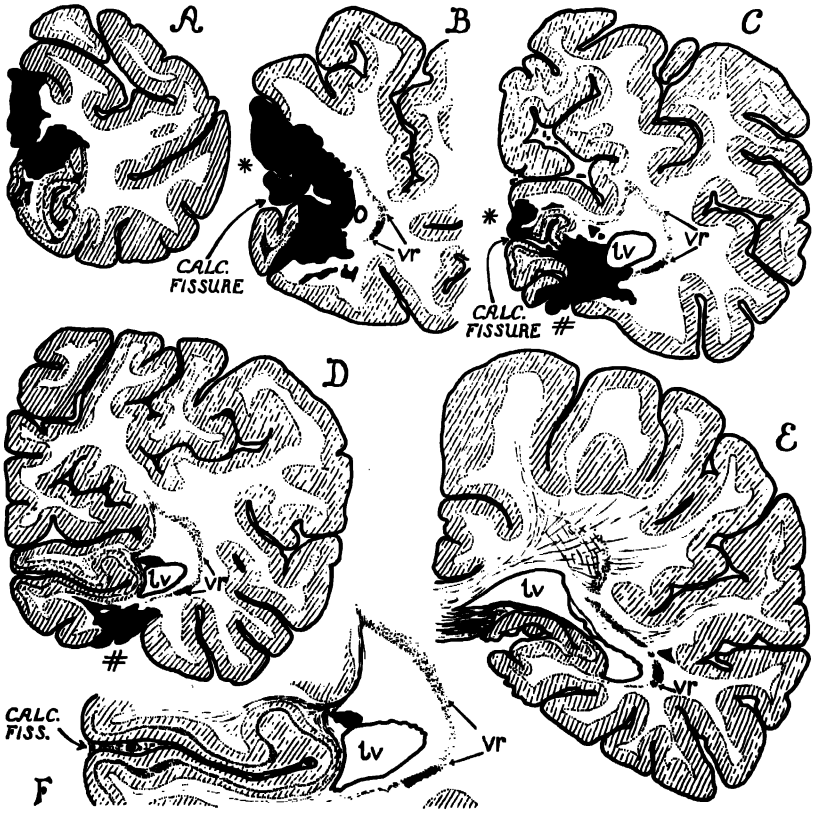

Fig. 415.—Case G. H. Holt: coronal sections through the right occipital lobe, beginning with the most posterior, closest to the occipital pole (*A*), and terminating with the section passing through the posterior extremity of the corpus callosum (*E*). Sketch *F* is an enlargement of a portion of sketch *D*. Foci of softening given in solid black. *Labeling: lv*, lateral ventricle; *vr*, visual radiation; asterisk (*) indicates focus *a* in the cuneus; double cross (#) indicates foci *b* and *c* in the lingual gyrus.

To begin with, the partial escape of the upper calcarine lip and its afferent fibers streaming from the upper horizontal segment of the radiation may indicate that the lesion started at the lower face of the occipitotemporal lobes (focus marked with # in Fig. 415, corresponding to *Les. b* and *Les. c* in Fig. 414). The most likely responsible factor was thrombosis of a branch of the

The elimination of the lower lip must have taken place at a time prior to the field plotting, forty-eight days before death, at which occasion absolute blindness in the upper quadrants and relative blindness for colors in the lower quadrants were found. At the time of the plotting of the fields, the upper calcarine lip was still functioning as a "protopathic" visual organ capable

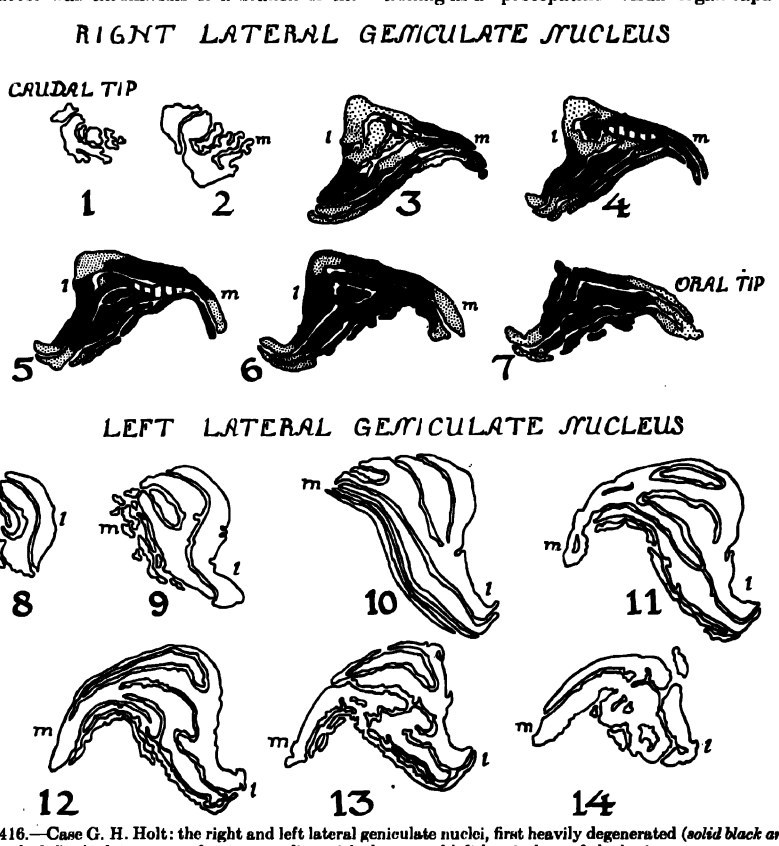

FIG. 416.—Case G. H. Holt: the right and left lateral geniculate nuclei, first heavily degenerated (*solid black and variously shaded*), the latter normal, corresponding with the normal left hemisphere of the brain.

posterior temporo-occipital artery (*poteocca*, Fig. 369) or of some other subsidiary artery supplying, in this individual case, the root and the core of the lower calcarine lip, e.g., the inferior calcarine artery (*ica, ical*, Figs. 369, 372) or the inferior accessory calcarine artery (*accica*, Fig. 374).

of appreciating crude photic stimuli, but no hues and no finer spatial details. This agrees very well with the fair preservation of finer structures in the upper lip, especially of the terminals of the geniculostriate fibers, which were practically absent in the lower lip.

During the terminal phase of the illness, the

thrombotic occlusion spread farther, probably by way of anastomotic connections with the principal calcarine artery (*pca*, Fig. 372), over the upper calcarine lip along its middle, cuneal stretch, transforming it into lesion *a* of Figure 414, identical with the focus marked by * in Figure 415.

A pathophysiological factor responsible for the spreading of the thrombosis may have been a hemodynamical imbalance in the common anastomotical territory. This, in turn, by eliminating the accessory or collateral arteries, placed a greater burden on the principal calcarine artery than this artery, itself diseased, could carry. Thrombotic softening of the upper calcarine lip, again, transformed a relative inferior quadrantic scotoma into absolute or near-absolute blindness, which, owing to the absence of further field testing during the six preterminal weeks, remained unrecorded.

Whether the centers of the fields of view remained spared until the end or were also affected remains uncertain also. However, considering that the "axial" lateral salient of the radiation (*vr*, in Fig. 415), the posterior extremity of the geniculate nucleus (*1*, *2*, in Fig. 416), and the polar segment of the striate area (Fig. 414) all remained fairly well preserved, it is probable that the field centers were somewhat preserved to the end, the total result being an incomplete left homonymous hemianopia with central sparing.

From the preceding evaluation of the pathoanatomical facts and the probable course of the terminal phase of the illness, several valuable conclusions may be drawn about the anatomical organization of the supranuclear division of the visual system.

The first and least questionable inference is the relationship of the lower calcarine lip to the lower segment of the radiation and hence to the upper contralateral field quadrants, including the upper half of the temporal monocular crescent, but excluding the foveal or central vision.

The second point concerns the qualitative impairment of vision manifested in relative blindness for colors in the lower homonymous quadrants. Without hesitation, this can be accounted for by incomplete impairment of the upper calcarine lip and of the afferent fibers from the upper segment of the radiation by which it is supplied; judging from sketches *C*, *D*, and *F* in Figure 415, this lip was preserved on anterior, cuneal levels until death, even though a small malacic focus in the upper wall of the ventricle was dangerously close to the fibers streaming into it. A considerable number of oblique afferent fibers, experimentally identified as terminals of the visual radiation, found in the upper lip and missing in the lower calcarine lip, is direct evidence of this. (*Cf.* chap. VIII, 6, 7.)

The third point to be considered is the single preserved compact bundle in the "lateral salient" of the visual radiation (*vr*, in Fig. 415). This bundle could be followed along the lateral side of the lateral ventricle to the pole of the occipital lobe, which also remained in good condition. Since in our experiments described in chapter VII, 4, 5, 6, the intermediate segment of the radiation was found to be related to the polar portion of the striate area and to the intermediate segment of the lateral geniculate nucleus, where the foveal-areal fibers of the retinae terminate, the preservation of the central vision in case HOLT is made understandable in this way. The lesion here largely eliminated those parts which are related to the extrafoveal or extramacular vision, while it spared the segments of the radiation and of the striate cortex related to the centers or to the "macula" of the fields of view (*cf.* chap. X, 8 [4]; chap. XI, 9). The preceding evidence shows the preserved "lateral salient" of the radiation to be the much-debated foveal or "macular" bundle.

The upper and lower segments of the radiation, flanking the foveal-macular bundle, are related to the extrafoveal or peripheral parts of the upper and lower homonymous retinal quadrants, as found in experiments and pathological cases described previously. The location of the foveal-macular bundle thus revealed is not exactly "axial" but a little below the center of symmetry on a cross-section, more radiation belonging to the upper peripheral segment than to the lower one. This, in turn, indicates that there is more striate cortex above than below the horizontal meridians, which agrees with the somewhat larger inferior quadrants in the field of view.

In the lateral geniculate nucleus the horizontal meridians are also a little off-center, being more lateral, that is, closer to the lower retinal,

or upper field periphery, as might be expected from the smaller size of the upper quadrants in comparison with the lower quadrants of the fields of view (Fig. 381). All this agrees well with the information gained from other cases, especially from case MUNSON (Figs. 411, 412), and from experiments (Figs. 259, 260).

The fourth point deserving attention is the fact that practically the entire pathological process involving the central visual apparatus in case HOLT was confined to the inner portion of the occipital lobe, inward to the posterior horn of the lateral ventricle. The pathophysiological factor which determined this is the peculiar vascular supply, or distribution of blood vessels, described in chapter X, 6, 7, 8, 9. This case demonstrates in the manner of a pathological experiment the relative vascular independence of the greater medial portion of the striate area and of its subjacent fiber systems from the cortical and subcortical regions on the lateral side of the occipital lobe supplied by the middle cerebral artery. When either one of the principal arterial territories is obstructed, the other, if in fair condition, may preserve the polar region by way of anastomotical connections and hence save the central vision, provided that the foveal-macular fibers in the radiation are also spared.

In case HOLT, in spite of extensive destruction of the calcarine cortex, the nutrition of the polar striate cortex was upheld via the middle cerebral artery. The posterior horn of the lateral ventricle, in this mechanism, played the role of a barrier preventing a pathological process from spreading to the other arterial territory. The region of the calcarine fissure, except for its caudal portion around the pole, acts as a pathophysiological unit largely independent of the region of the lobe lateral to the "watershed" represented by the lateral ventricle. (*See* chap. X, 8, and Fig. 377 for further details.)

The fifth point of interest is how far in the polar striate area the representation of the central fovea or "macula" extends. Since in our case the portion of the area behind the curved posterior end of the calcarine fissure was found intact, it would seem that this rather large segment of striate cortex was related to the central vision measuring no more than 2° or 3° from the fixation points. It might be easier to accept this if one considers the tremendous demand on the central vision as the principal instrument of the "epicritic" or "gnostic" visual functions. The central fovea of the retina—the main "gateway" of the human intellect—requires and is also well provided with a great number of individual anatomical-functional units, as the great number of the foveal cones and the large area in the lateral geniculate nucleus indicate. An extensive foveal cortex in the occipital pole would seem plausible.

At any rate, it is fair to assume that the polar cortex behind the curved calcarine fissure does represent homonymous halves of both central areae, corresponding to from 8° to 10° from the fixation point in the field of view, and that a substantial portion of the polar cortex belongs to the central hemifoveae (2°30′), much of it belonging to the homonymous halves of the outer foveae (from 40′ to 1° of arc) best supplied with the cones. (*Cf.* chap. V, 10 [4, 5], and case MALLORY, sec. 10, this chapter; *see*, for phylogenesis of foveal cortex, chap. VIII, 3 [6].)

The last point requiring consideration is a separation of the upper amaurotic quadrants from the lower amblyopic quadrants along the horizontal meridians. This is of special interest, since, unlike case MUNSON, where the responsible lesion was subcortical, in case HOLT it was a combination of cortical and subcortical softening. The most logical interpretation is the preservation of the foveal-macular bundle and of the polar cortex, the central vision acting as a barrier between the upper and the lower extrafoveal quadrants, as discussed in chapter XI, 9.

It may be noted that a boundary separating the striate cortex in the upper lip containing afferent fibers from the cortex in the lower lip devoid of such fibers was exactly in the floor of the calcarine fissure, indicating the position of the horizontal meridians.

SEC. 8. CASE OF HORIZONTAL OR ALTITUDINAL HEMIANOPIA AND MENTAL BLINDNESS

1. HISTORY.—HOFFMANN, Mary, sixty-six years old, schoolteacher.

Diagnosis: Inferior horizontal or altitudinal hemianopia caused by a cerebral softening or encephalomalacia on an arteriosclerotic basis. Specimen received from Dr. D. T. Vail, of Cincinnati, Ohio, through the courtesy of Dr. P. Bailey, of the University of Illinois Medical School, Chicago.

Four years previous to admittance the patient had fallen, probably collapsed, and had had to be led to a chair. During this incident she did not become unconsious, however. After this the left side of her face had been drawn up for several hours. Since that time the patient had become easily exhausted. She did not notice weakness of her left leg or arm, however. For six months prior to hospitalization the patient had suffered from blurred vision while reading, which gradually became worse. Changing glasses one month previously had not improved vision.

Four months earlier she had suffered from bronchitis, after which she had periodic severe headaches, reaching their peaks at noon each day. Lately the headaches had lessened. For a number of years she had had high blood pressure.

During the preceding two weeks the patient had felt that if she were away from home, she would be unable to find her way back. Even in her house she could not locate familiar articles from memory. Thus, for example, in trying to recall the furnishings of her dining-room, she could not remember where the radio was placed. She felt certain that she would have a great deal of difficulty in finding her home, even if she were only a few blocks away. Her memory was good for present and recent events, and she was well oriented as to time and place. There was no complaint of a motor or sensory disturbance other than the blurring of vision, which was gradually getting worse. In the past there had been no major illness, injury, or operation.

2. CIRCULATION AND NEUROLOGICAL EXAMINATION.—The examination revealed blood pressure of 184/160, on two other occasions 185/90 and 170/90. There were a few casts in the urine, later no casts but only albumen. Neurologically, there was a paresis of the left side involving the face, arm, and leg. Abdominal reflexes were absent, left knee-jerk was increased, and there was a tendency toward falling to the left when walking. The somatic sensation was normal. There was no ataxia, adiadochokinesis, or astereognosis.

3. OPHTHALMOLOGICAL EXAMINATION.—With the right eye the patient saw fingers at 15 feet, corrected to 20/40 with a 4.50 + 2.75 cyl. ax. 130, add +2.75 read J. #2 slowly. With the left eye the patient saw fingers at 15 feet, corrected to 20/25 with +4.25 + 1.0 cyl. ax. 65, add +2.75 read J. #2 nicely. She could not read the finest print (J #1) with the left eye with any correction at any distance.

A congenital muscle defect had persisted through her whole life in the form of a bizarre alternating divergent strabismus, so that, in fixing with the right eye, the left eye deviated outward and down, and, in fixing with the left eye, the right eye deviated up and out.

The optic papillae were entirely normal and remained so throughout her illness. At no time did they show any sign of increased intracranial pressure. The retinal blood vessels in each eye showed a moderate degree of vascular sclerosis, and there were no hemorrhages or exudates. The pupils were equal and responded promptly.

4. FIELDS OF VIEW. A perimetric plotting of the fields of vision showed a lower horizontal or altitudinal hemianopia (Fig. 417). Twenty-one days later, the patient complained about her vision dropping considerably. Ophthalmological examination showed the right vision 20/50, the left 20/50, with a correction. She was unable to read any print. The fields of vision showed the same horizontal inferior hemianopia, with the beginning of a right homonymous hemianopia as well. This remained so until approximately six days before death. A provisional diagnosis was a vascular lesion, changed later into that of a small tumor situated in the cunei of both occipital lobes, more on the left

side. The inferior hemianopia also involved the macular region (?).

The preceding information obtained from the treating physician is to be amplified by the following considerations. Both mappings of the fields, the first made approximately four weeks before death and the second made one week before death, showed somewhat incongruous defects in all blind parts. Only taken together do they permit a judgment as to the probable course of the underlying pathological process.

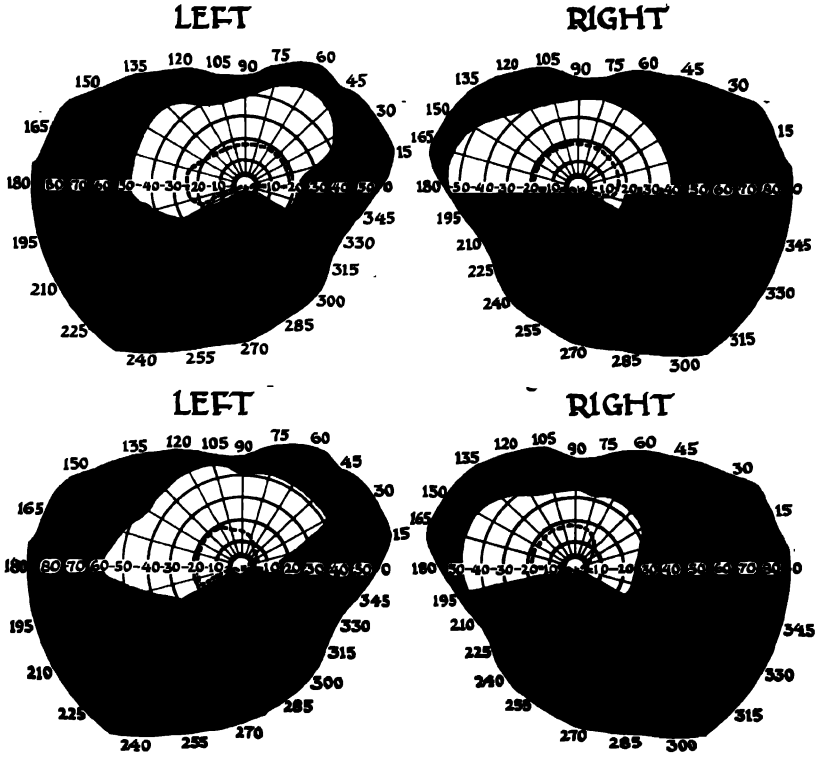

FIG. 417.—Case M. Hoffmann: inferior horizontal or altitudinal hemianopia expanding into a bilateral homonymous hemianopia and mental blindness. Cause: encephalomalacia developing on an arteriosclerotic basis (*cf.* Figs. 418–22). Upper fields taken four weeks, lower fields taken one week, before death.

First, it appears fairly certain that the temporal monocular crescents of both fields of view were put out of function prior to the first plotting. In addition, the blindness extended into binocular portions of the upper quadrants, along the horizontal meridians up to 40 or less degrees in the right homonymous halves, and up to 50 degrees or more in the left halves. In the upper periphery, along the vertical meridians, the fields were contracted only a little. The lower quadrants of both sides were blind, with the exception of wedge-shaped sectors along the horizontal meridians. These triangular rests were turned with their wide bases toward the periphery, their sharp ends toward the fixation points. At the second plotting, substantially the same situation was found, except that the scotomatous areas expanded in the right upper temporal quadrant to approximately 25° and in the left upper nasal quadrant along the horizontal meridian as much as 15°. The incon-

gruity found in both fields can be most easily explained by reduced central acuity, which made fixation difficult, and by the generally poor condition of the patient.

Concerning the central vision, the accompanying note expressly states that the lower parts of the "macular" areas were also included in blind portions enveloping the lower field halves. However, both field charts show sparings of about 3° below the horizontal meridians

calcarine fissure close to the occipital pole (lesion *b*). Other similar foci were found outside the territory of the striate area (stippled).

Serial sections through the left occipital lobe, stained for myelin sheaths, revealed numerous small and large softenings throughout its substance, some quite irregular and spreading through both the subcortical core and the cortex, others again being principally or entirely confined to the cortex (Fig. 420, solid black).

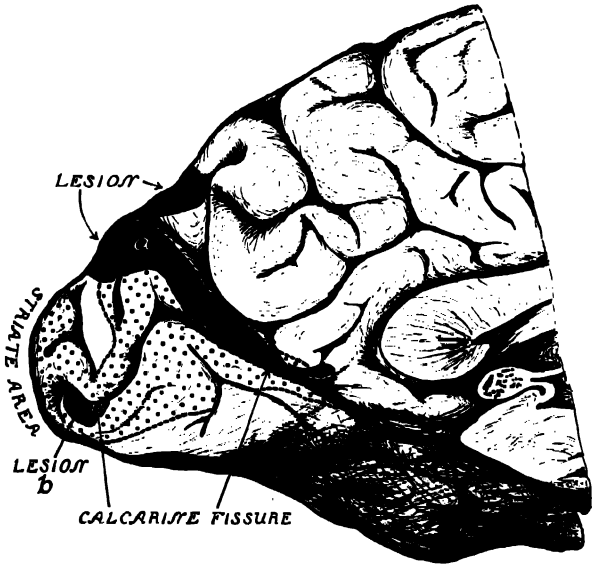

FIG. 418.—Case M. Hoffmann: medial aspect of the left occipital lobe, showing a large, principal focus of softening in the cuneus (*a*) and a smaller focus (*b*), just below the curved end of the calcarine fissure at the occipital pole. Striate area stippled. (For cross-sections *see* Fig. 420.)

and possibly more, equal for a white target and for hues.

5. LEFT OCCIPITAL LOBE.—Grossly examined, this lobe showed a narrow encephalomalacic focus in the anterior portion of the cuneus, located between the parieto-occipital sulcus and the calcarine fissure (Fig. 418, lesion *a*). The lesion destroyed the anterior extremity of the upper lip of the fissure and extended to the dorsal margin of the lobe along the parieto-occipital sulcus. Another and superficially smaller focus was found in the lower lip of the

The larger stripelike lesion, visible on the inner face of the lobe (*a*, in Fig. 418), directly destroyed a portion of the upper calcarine lip, including the peripheral fringe of the striate area in that lip (*a*, in Fig. 420). On the intermediate levels (*4*, *5*, *6*) this lesion penetrated but little into the subcortical substance, except on level 4, and hence damaged only a small number of fibers streaming from the upper segment of the visual radiation (*vr*) into the striate cortex. On the anterior levels (*7*) this lesion enveloped the entire upper calcarine lip and interrupted all fibers streaming into that lip from the

upper segment of the radiation. Now entirely concealed from the surface and becoming quite irregular, lesion *a* extended anteriorly in several directions, undermining and partly destroying much of the striate cortex at its anterior extremity and finally reaching the splenium of the corpus callosum (*8*). The conspicuous feature of this focus was its symmetrical extent and location with a similar lesion in the contralateral hemisphere (*cf.* 7 and *8* in Fig. 420 with *6*, *7*, *8* in Fig. 421).

entirely or almost entirely confined to the cortex. A nest (*c* in sketch *8*) arising from the tentorial surface of the lobe, a replica of a similar focus in the contralateral hemisphere, interrupted with its two prongs two small fiber segments in the "lateral salient" of the visual radiation (*x*, *y* in sketches *6*, *7*, *8*).

The occipital pole, as in the opposite hemisphere, was almost entirely spared (sketch *1*). Considerable segments of the striate area in the posterior portion of the calcarine fissure (*C.F.*)

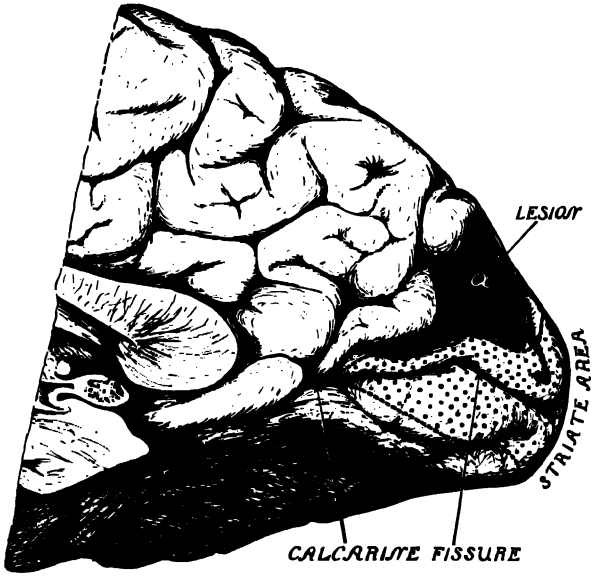

FIG. 419.—Case M. Hoffmann: medial aspect of the right occipital lobe, showing a single, large focus of softening taking up much of the cuneus. Striate area stippled. (For cross-sections *see* Fig. 421.)

The posterior and superficially quite insignificant focus in the lower calcarine lip close to the occipital pole (lesion *b* in Fig. 418) extended in serial sections through the entire length of the striate area as far as its anterior limit (*b* in sketches *1–7*, in Fig. 420). In most sections this lesion remained strictly limited to the cortex, or almost so. Its effect, because of extensive destruction of the cortex itself, was equally devastating.

Besides these two principal lesions, other independent and much smaller foci were scattered throughout the left occipital lobe, many of them and close to it were also spared (sketches *2*, *3*, *4*, *5*).

6. RIGHT OCCIPITAL LOBE.—The gross examination of the right occipital lobe revealed a single encephalomalacic focus with an irregular, depressed surface on the medial face (lesion *a*, solid black in Fig. 419). Its shape was roughly that of a triangle, fairly congruous with the shape of the cuneus. Its horizontal side extended for a short distance along the calcarine fissure, its anterior side running along the parieto-occipital sulcus. The upper extremity

of the focus just touched the dorsal margin of the occipital lobe. The inferior calcarine lip and the pole of the occipital lobe appeared superficially normal.

The examination of sections stained with Weigert-Kultschitzky technique revealed two large and several smaller malacic foci (Fig. 421). Other numerous larger and smaller foci, not directly affecting the visual system, were scattered throughout the brain substance. Of all foci, the most conspicuous was the cuneal focus visible on the surface (*a* in sketches *2*, *3*, *4*, *5*). It was wedge-shaped, with the base at the surface and an irregular, lacerated point penetrating deep into the subcortical core of the cuneus. In part, this focus directly affected the upper lip of the calcarine fissure (*Calc. Fiss.* or *C.F.*) and destroyed the marginal zone of the striate cortex in it, and in part it may have interrupted fibers of the upper segment of the visual radia-

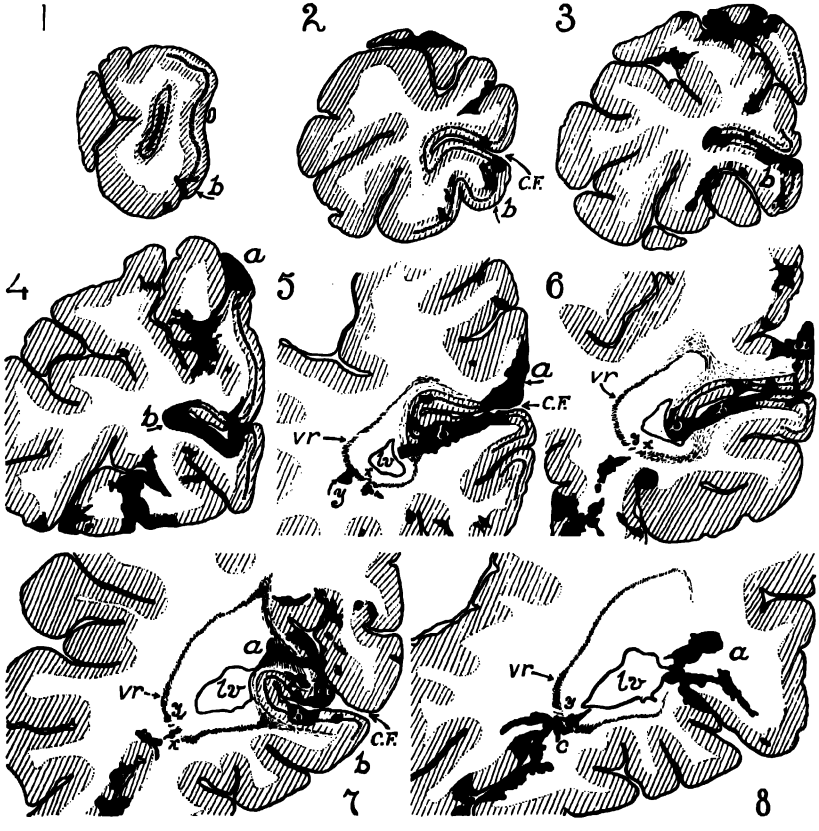

FIG. 420.—Case M. Hoffmann: coronal sections through the left occipital lobe, beginning with occipital pole (*1*) and ending with a level not far from the callosal splenium (*8*). (For description *see* text.) *Labeling: a*, large cuneal focus which destroyed a portion of the upper calcarine lip; *b*, focus, little seen from the surface, which destroyed much of the lower calcarine lip; *c*, focus in the tentorial surface of the temporal lobe which interrupted a bundle in the lateral salient of the visual radiation at *x*; *C.F.*, calcarine fissure; *lv*, lateral ventricle (posterior horn); *vr*, visual radiation; *y*, gap in the visual radiation caused by a small focus of softening. Striate area marked by a stippled intra-

tion streaming into the upper lip (*vr*). Several small foci in the cortex of the upper lip further added to the injury of this lip. The floor of the calcarine fissure and the adjoining parts of the striate cortex, as well as the lower lip on the levels described, did not show any damage.

On intermediate levels the small foci in the upper lip and in its subcortical substance increased in extent and interrupted fibers of the upper segment of radiation at the point of entry into that lip (sketch 5). One of these foci (*c*), placed at the deepest point in the floor of the calcarine fissure, interrupted fibers in the calcar avis next to the posterior horn of the ventricle (*lv*). A noteworthy feature of some of the smaller foci was their restriction to the striate cortex itself, formerly a point of dispute between Henschen and Monakow; our evidence, supporting Henschen's viewpoint, shows the possibility of strictly cortical lesions besides

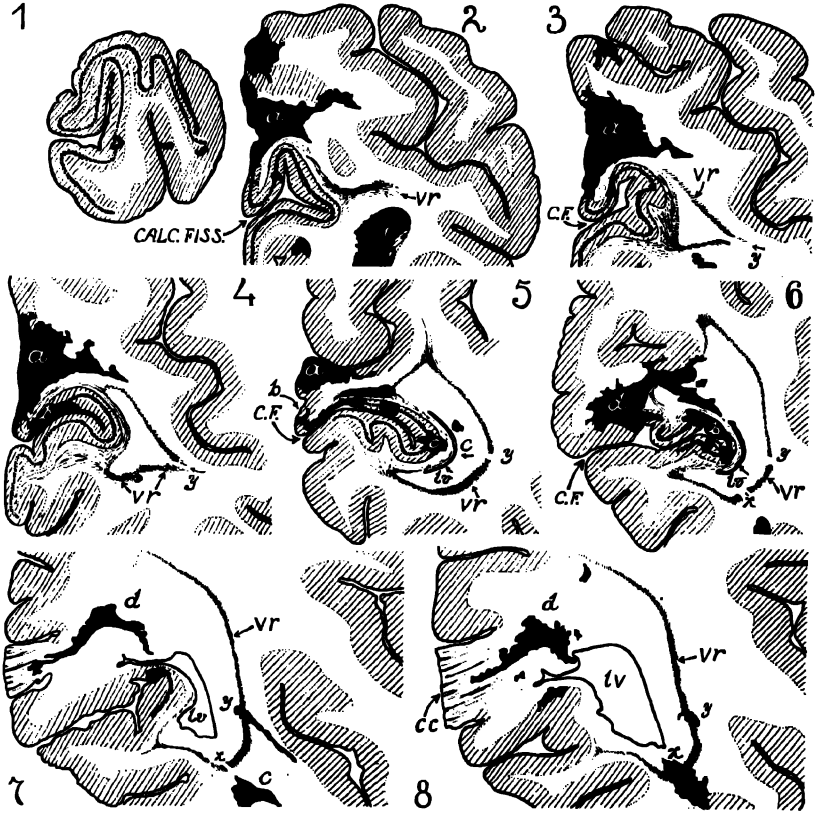

FIG. 421.—Case M. Hoffmann: coronal sections through the right occipital lobe, beginning with the occipital pole (*1*) and ending with a level in the splenium of the corpus callosum (*8*). (For description *see* text.) *Labeling: a*, large cuneal focus visible on the medial face of the occipital lobe in Fig. 419; *b*, series of small, mostly strictly cortical, foci in upper calcarine lip; *c*, small focus in *calcar avis* opposite the floor of the calcarine fissure; *C.F.* and *CALC. FISS.*, calcarine fissure; *lv*, posterior horn of lateral ventricle; *vr*, visual radiation; *y*, gap in the visual radiation caused by a small focus visible in sketches *7* and *8*; *x*, another similar gap in the lateral salient of the visual radiation. Striate area indicated by a stippled intracortical line of Gennari and Vicq-d'Azyr. (*Cf.* Fig. 420.)

other, larger ones that destroy both the cortex and the subcortical fiber substance.

The series of small foci just described, which on intermediate levels practically eliminated the upper calcarine lip, formed a bridge to a large and quite irregularly shaped focus (*d*), extending from the upper calcarine lip (sketch *6*) into the fibrous core and farther anteriorly into the splenium of the corpus callosum (*7, 8*). This focus interrupted the most anterior fibers in the upper segment of the visual radiation (*vr*) supplying the upper calcarine lip. Because of this and because of the several small foci located in the most anterior portion of the striate cortex, this cortex must have been put entirely out of function (*6, 7*).

The polar portion of the striate area in the right occipital lobe remained fairly well preserved except for the presence of a few minute malacic foci, strictly confined to the cortex (sketch *1*). The subcortical fibrous core of this lobe was also mostly spared. In spite of this, it is probable that many afferent fibers supplying the foveal-macular cortex of the pole must have been interrupted by smaller and medium-sized malacic foci in the core of the hemisphere. A fairly large focus, located in the ventrolateral "salient" of the radiation, made a breach at *x* (sketch *8*), while another similar but smaller focus made a breach at another point in the radiation (*y*). Such gaps made in the solid formation of the sagittal fiber strata, measuring approximately 1 mm., could be followed posteriorly on many sections through the hemisphere, retaining the same relative distance from one another; this agrees with the composition of the radiation of individual, parallel bundles as revealed by dissection (*see* Figs. 235, 236). Farther back toward the occipital pole, where the fibers of the radiation begin to deviate from a sagittal direction, these gaps became obliterated.

In summary, in the right occipital lobe a series of foci, beginning anteriorly with the splenium of the corpus callosum and extending backward through the upper calcarine lip close to, but not quite reaching, the occipital pole partially destroyed or separated this lip from its afferent fibers. On anterior levels the striate cortex was almost completely eliminated. The pole of the lobe was largely spared. A number of fiber bundles in the visual radiation, particularly in the "lateral salient," were interrupted. The lower calcarine lip was spared throughout its entire length except in its most anterior portion. The same was also the case with most of the fibers of the radiation supplying that lip.

7. Right lateral geniculate nucleus.—Along its entire length from its oral to its caudal extremity (*1–10*), this nucleus showed an irregular zone of retrograde cell degeneration in all sections (Fig. 422). The zone was almost entirely restricted to the inner half of the nucleus, closer to the thalamus (*cf.* Figs. 205, 206, 208).

On most posterior levels where there are only four cell layers, the degeneration was represented by two narrow stripes confined to the inner or medial third of the nucleus (sketch *1*). The stripes passed through all four layers, resembling similar stripes in experiments involving minute lesions in the foveal segment of the striate cortex (thus in Figs. 254, 258). These stripes were probably caused by an interruption of two separate fiber bundles in the intermediate foveal-macular segment of the visual radiation by two small softenings (*x* and *y*, in Fig. 421, sketches *7, 8*). Toward the middle levels these two small zones merged with the others (*2 7* in Fig. 422) until on the anterior levels the entire medial half of the nucleus was found degenerated (*8, 9*), the zone again decreasing in the rostral tip of the nucleus (*10*).

The left lateral geniculate nucleus, because of inexpert handling, was unfortunately lost.

8. Correlation of functional disturbance and pathoanatomical findings.—The analysis and correlation of clinical symptoms and of pathoanatomical findings in this case, in spite of the complex situation caused by bilateral lesions and by a great number of foci, did not offer insurmountable difficulties.

The striking feature was the presence of almost identical and symmetrically located foci, spreading from the callosal splenium along its forceps major into the anterior portions of both calcarine fissures. In a very similar way they partly destroyed and partly separated the most anterior segments of the striate areae from the upper segments of both visual radiations (Fig. 420, *7;* Fig. 421, *6*). This destruction, in accord-

ance with our functional scheme of the radiation, satisfactorily accounts for the complete elimination of the temporal monocular crescents of both fields of view (Fig. 259).

The long, but narrow and less penetrating, lesion, *a*, in the left cuneus (Fig. 418; sketches *4–6* in Fig. 420), spreading over the upper lip along its middle and anterior extent, with several small foci in this lip, may help explain the sizable loss in the right upper binocular quadrants, must have made more complete a functional loss in the right lower quadrants, caused by an incomplete damage to the left upper calcarine lip. The spared segments of the cortex in the upper lip (sketches *1* and *2* in Fig. 420), in turn, may account for the sparing of the central parts of the right lower quadrants.

The large wedge-shaped lesion *a* in the right

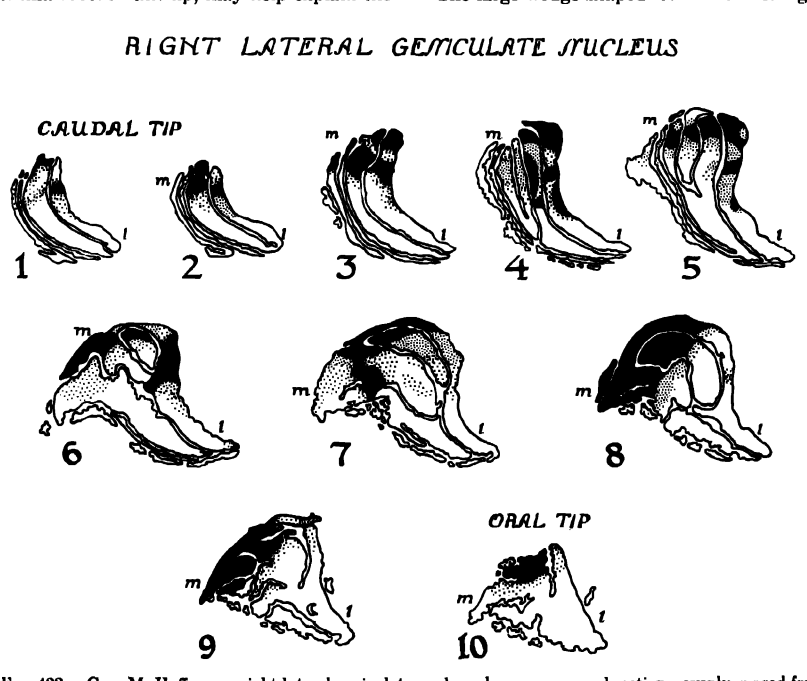

FIG. 422.—Case M. Hoffmann: right lateral geniculate nucleus shown on coronal sections, evenly spaced from the caudal extremity (*1*) to the anterior end of the nucleus (*10*). Zones of retrograde cell degeneration given in solid black and stippled; normal parts of the nucleus in white. Note that almost entire degeneration is found in the inner, or medial, half of the nucleus next to the thalamus (*m*), the lateral half (*l*) remaining normal. This degeneration was caused by a large wedge-shaped focus *a* and by smaller foci *b* in the cuneal lip of the right occipital lobe (Figs. 419, 421). It caused blindness in the left lower homonymous quadrants of both fields of view, including the lower half of the contralateral monocular temporal crescent (Fig. 417).

loss of the binocular portion of the right lower quadrants, even though fair-sized segments of the striate cortex and of the incoming fibers of the upper segment of the visual radiation were spared on the same levels. This aggravation was probably caused by the almost complete destruction of the lower lip by lesion *b* on the same levels. This destruction, besides causing a cuneus (Fig. 419; sketches *2–4* in Fig. 421), together with the several smaller foci (*b*) in the upper calcarine lip of the same right side (Fig. 421, sketches *4–6*), must be held responsible for a loss in the binocular portions of the left lower field quadrants. Moreover, the sparing of a wedge-shaped sector in the same left lower quadrants along the horizontal meridians is to

be explained by a sparing of the striate cortex in the upper lip of the right calcarine fissure on posterior levels, as far as the occipital pole (sketches *1*, *2*, *3* in same figure). The sparing of the lower lip of the right calcarine fissure along practically its entire length (sketches *1–5*), except on its most anterior levels (sketch *6*), agrees well with the preserved left upper binocular quadrants and a loss of the upper half of the left monocular crescent. A degeneration found in the right lateral geniculate nucleus is an accurate copy of the supranuclear lesions found in the right occipital lobe just described (Fig. 422).

The sparing of a small wedge-shaped sector in the left lower quadrants extending along the horizontal meridians to approximately 60° is to be interpreted by the integrity of the striate cortex in the deeper portion of the right upper calcarine lip on levels closer to the occipital pole (sketches *2–5* in Fig. 421). The position along the horizontal meridian and the varying width of the sector, especially its tapering in the peripheral direction, are understandable when the location of the spared cortex, close to the deepest point of the fissure, and its decreased extent from posterior to anterior levels are taken into consideration.

The poles of both occipital lobes were not grossly damaged (Fig. 420, *1;* Fig. 421, *1*). This merits special attention, since the perimetric notes expressly state that the blindness included the inferior halves of the field centers also, even though the charts show a small sparing below the horizontal meridians, both for white and for colors. A functional test with reading about three weeks before death revealed a marked decrease in visual acuity, making the patient unable to read any print. Obviously, the few minute malacic foci in the two polar cortices are insufficient to account for this rapid preterminal impairment of the fine spatial sense of the central foveal apparatus. For this the blame must be placed directly upon the malacic foci in the core of both hemispheres, especially the foci *c*, *c*, or *x* and *y*, arising from the inferior face of both temporal lobes (Fig. 420, *8;* Fig. 421, *8*). These foci, in a bilaterally remarkably symmetrical way, have damaged precisely those portions of both visual radiations which, according to our scheme of the visual pathways, are instrumental in the transmission of impulses from the central areae and foveae, or "maculae" of the clinicians, to the polar portions of the striate areae (*see* Figs. 225, 259, 260; *cf. also* cases MUNSON and HOLT, in this chapter).

The last-mentioned observation poses an important question that concerns the very foundations of cerebral vascular organization: Why, in a decaying brain, should precisely those parts of the transmitting visual fibers which are related to the centers of the fields of view most intensively used suffer a degenerative vascular insult in both hemispheres of the brain, at precisely the same moment, and in almost exactly the same manner, because of the degeneration of small vessels which do not seem to be directly interconnected anatomically? It is a further elaboration of the problem of the functional symmetry of both hemispheres, strikingly demonstrated in our case by symmetrical lesions in the anterior segments of the striate areae and of the visual radiations (Fig. 420, *7;* Fig. 421, *6; cf. also* chap. XI, 9[3, last paragraph]).

Another important topic on which case HOFFMANN sheds light is the controversial problem of bilateral representation of each complete fovea-macula in both cerebral hemispheres. This problem is dealt with in detail in chapter XI, 8, 9. Here only the most concrete arguments against this hypothesis, emanating from our case, may be pointed out.

As is clear from the history of this case and from the field charts, the monocular temporal crescents of both sides with a goodly portion of the adjoining binocular fields, as well as the inferior quadrants, were eliminated prior to the plotting of the first charts of the fields of view (Fig. 417). In spite of this extensive loss, our patient still had fair central acuity at that time, although it dropped abruptly a few weeks later (*see* pars. 3, 4, this section).

The loss of the peripheral portions of both fields during the early period was accordingly compatible with good central acuity. Since the loss of the peripheral portions of the two fields is fully accounted for by the destruction of the anterior portions of both striate areae, the hypothesis of a foveal-macular localization in the oral-rostral portion of the striate area becomes untenable. This, in turn, makes localization of central vision in the polar portion of the striate

areae mandatory. A preterminal reduction of central acuity in this case, explainable by an impairment of the foveal-macular fibers in both radiations, harmonizes well with this view.

9. Summary.—In case Hoffmann, far-reaching destruction of the anterior portions of both striate areae fully accounts for the loss of both monocular temporal crescents, while partial destruction and undermining of the upper calcarine lip of both sides account for the loss of the binocular portions of the inferior field quadrants of both sides. Preterminal reduction of the central acuity, in spite of the sparing of both occipital poles, was caused by symmetrical malacic damage to the foveal-macular fibers in both visual radiations. The psychotic symptoms, especially disorientation in space, are explainable by disseminate damage to the extrastriate parts of the parietotemporal-occipital lobes and their fiber systems.

SEC. 9. CASE OF CENTRAL HOMONYMOUS HEMIANOPIC SCOTOMA

1. History.—Kraft (Crofts), Harry, age fifty-four years, Billings Hospital, University of Chicago, UNo. 83289.

Diagnosis: Right central homonymous hemianopic scotomas caused by a local vascular spasm developed on the basis of primary vascular hypertension.

Until three or four months before admission the patient had been in rather good health. The trouble began with gradually increasing persistent headaches behind the eyes, radiating to the occiput, particularly on the left side. The headaches were more pronounced during the morning. Two months before admission, the blood pressure was 174/100. Two days before admission, there was a rather sudden development of a right central homonymous scotoma. The patient noticed that "things looked queer." While reading, he could see only the first half of a word (a symptom described by Wilbrand 1907 as a "hemianopic disturbance of reading"). Similarly, he could see only half of a person's face, while at the same time he was able to see the objects in the periphery of the affected side.

2. Ophthalmological examination.—An ophthalmoscopic examination showed a very slight arteriosclerosis in the retinal fundi, which were otherwise normal. The fields taken with an ordinary perimeter revealed right homonymous central scotomas of an approximate extent up to 6° along the horizontal meridians and up to 4° along the vertical (upper fields, in Fig. 423). According to a stereoscopic field plotting, the horizontal extent of the scotomas was up to 7 degrees, the vertical from 3 to 4 degrees below, and up to 5 degrees above, the horizontal meridians (lower fields in the same figure). In the stereoscopic charts, remarkably, there was also a minute sparing of less than 1 degree around the fixation point, but only in the right field. This slight incongruity may be of less significance than it appears, since the patient was fatigued from the preceding examination and had a severe headache. (*See* chap. XI, 9 [1].)

3. Somatic examination.—There were very few indications of general arteriosclerosis. Nor was there any enlargement of the heart, although numerous extrasystoles were present. The blood pressure was 185/110. Hyaline casts and traces of albumen were found in the urine. The neurological examination was negative.

4. Subsequent development.—As far as the available information goes, the above-described "episode" terminated in an incomplete recovery, which remained stationary for several years. Gross visual disturbance disappeared within three days or so after onset. Seven months later the patient still occasionally saw "black spots" in the right fields, but otherwise saw well. Four years after the beginning, there was no recurrence of the central scotoma. During this time he was treated for hypertension, and the blood pressure decreased to 146/86. Five years after the beginning of the trouble, however, the field examination showed a contraction up to 40°, although at intervals the patient seemed to be able to see in the periphery as well. The contraction was bilateral but was more marked in the right field. There was, besides, some reversal of the limits for the red and blue hues. A central scotoma at that time was not mentioned.

5. COMMENT.—In view of the absence of autopsy, only circumstantial evidence can be used to determine the probable seat and nature of the injury responsible for the scotomas. Since these scotomas had a hemianopic character and were fairly congruous in size and shape, it is practically certain that they were caused by a single lesion and that the seat of the lesion was above the chiasma.

In a further attempt to determine the locality of the injury, the optic tract and the lateral geniculate nucleus may safely be ruled out, for the reasons discussed in chapter XI, 3. This reduces the possible location of the injury either to the visual cortex or to the visual radiation.

A single, small transient thrombotic or spastic ischemic focus either at the left occipital pole next to the posterior boundary of the striate area or in the intermediate foveal-macular segment of the visual radiation at its "lateral salient" could have caused a comparable disturbance (latter alternative illustrated by lesions *x* and *y* in case HOFFMANN, in Figs. 420, 421). In both localities the anatomical-functional units are widely spaced, making it possible for a small focus to produce a restricted

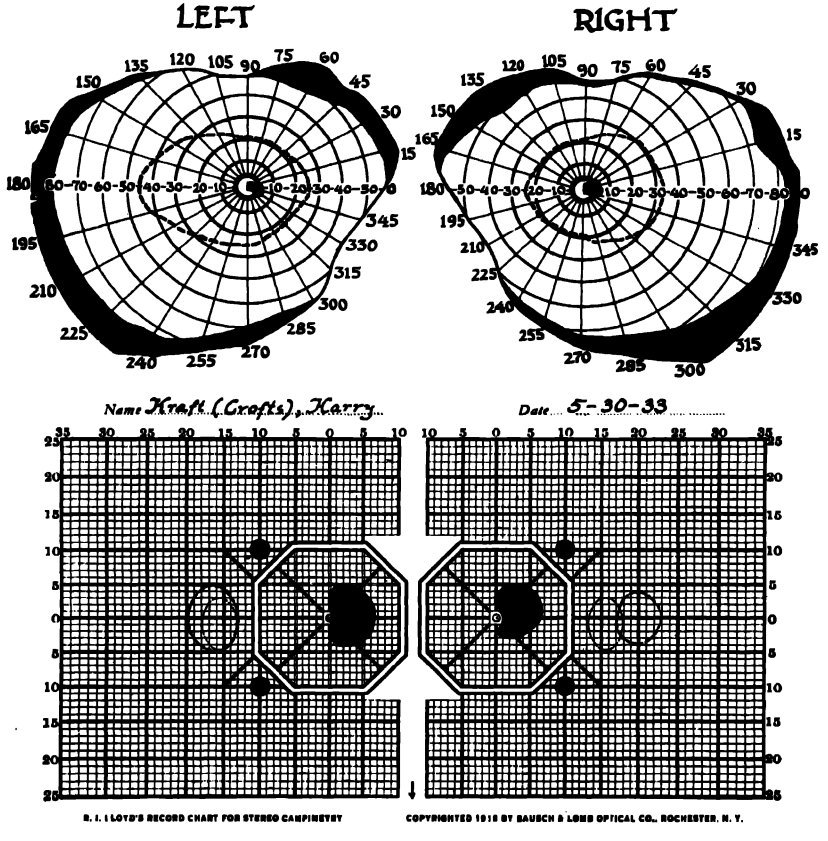

FIG. 423.—Case H. Kraft: right central homonymous hemianopic scotoma, presumably caused either by a local "vascular spasm" or rather hemorrhage, developing on the basis of a primary vascular hypertension.

injury, which, in the centers of the fields of view, manifests itself in a minute field defect. The most likely underlying pathoanatomical mechanism was vascular, probably spastic.

The noteworthy features in this case were the rapid initial improvement and the long duration of the residual symptoms. The first may be partly explained by the multiple blood supply of the occipital pole discussed in chapter X, 6, 7, 8. The long duration, as well as a gradual contraction of both fields, was most likely caused by a gradual spread of the basic deficiency of the cerebral blood vessels, by an essentially less efficient blood supply of the anterior calcarine fissure, and by the vascular interdependence of the occipital lobes discussed in case HOFFMANN.

SEC. 10. CASE OF CENTRAL HOMONYMOUS HEMIANOPIC SCOTOMA WITH POST MORTEM EXAMINATION

1. HISTORY.—MALLORY, Dr. Frank B., noted American pathologist, age seventy-eight years, of Boston, Massachusetts.

Diagnosis: Homonymous hemianopic scotomas in the upper quadrants of the left fields of view caused by an old brain softening of the inferior lip of the calcarine fissure in the right occipital lobe. The brain specimen received from Dr. G. A. Bennett, of the Department of Pathology, Harvard University Medical School, UNo. H-41-530, on November 27, 1941, thanks to Professor K. S. Lashley, of Harvard University and of Yerkes Laboratories of Primate Biology, at Orange Park, Florida.

At the age of eighteen the patient suffered from a streptococcal infection of the right side of the face and of the right eye. The cornea of that eye was affected by an ulcer which left a scar and impaired vision. Similar trouble apparently developed forty years later.

From his late twenties on, the patient began to suffer from recurrent attacks of an "ophthalmic migraine," regularly accompanied by a scintillating scotoma in the left fields of view, sometimes also by nausea.

At the approximate age of forty-seven, on a Sunday in the summer of 1910 while at dinner, immediately after the reflection from a white surface of bright sunlight into the patient's eyes, he began to complain of brilliant flashes recurring at very frequent intervals, leaving within a few hours—at any rate in less than a day—a visual field defect. The defect, according to the patient's estimate, was at first large, but subsequently it "cleared up." The duration of this attack was approximately from 20 to 40 minutes. Whether or not the subjectively experienced "light" was colored and whether or not the photism had a definite shape it was not possible to ascertain by questioning the patient's associates.

After this attack the patient remained for the rest of his life very sensitive to brilliant white light, and flashes of sun on a window in a neighboring building would often bring on a transitory attack of scintillating scotoma. The spontaneous attacks of scintillating scotoma, off and on during the subsequent years, were of short duration, none lasting more than a minute or two, and without further restricting the fields of view.

At the age of fifty-six the patient's right hand became infected at autopsy, followed by erysipelas and high fever. At the age of sixty-one the patient began to suffer from attacks of syncope, with a lapse of consciousness for periods up to 30 minutes. These attacks did not have the character of epilepsy and were diagnosed as cerebral ischemia caused by a spasm of the arteries. At the age of seventy-one bothersome pains appeared in the lower parts of the legs, developing into an intermittent claudication. At the age of seventy-two the patient's memory for recent events began to fail, and he occasionaly became disoriented. With advancing age the mental symptoms grew more pronounced..

In February, 1941, six or seven months prior to his death, the patient appears to have suffered a fall, thereafter experiencing difficulty in

moving his legs. After this accident he lost interest in his laboratory, where, until then, he had been doing a certain amount of work. He also ceased reading and listening to the radio. Whether this was because of his eye trouble or because he lost interest, his consulting physician could not determine but was inclined to attribute the condition to cerebral pathology. Pains in the lower parts of his legs, attributed by the patient to "rheumatism," induced him to seek relief in Florida. A blood examination at that time showed moderate anemia, with 85 per cent hemoglobin and 3 million red blood corpuscles.

His physical and mental condition gradually deteriorated. On September 17, 1941, he fell down a flight of stairs and was found unconscious. The right side of his face and skull were bruised, and five ribs on the right side were fractured. Subsequent to this accident the patient contracted pneumonia, from which he died on September 27, 1941 (for obituary *see Science*, v. 94, p. 430).

2. OPHTHALMOLOGICAL EXAMINATION.—In 1911, or one year after the dramatic attack of photisms resulting in a defect of the fields of view, the patient consulted an ophthalmologist (Dr. F. H. Verhoeff, of Boston, Mass.), in order to have a foreign body removed from his right cornea. On this occasion a superficial examination showed a large hemianopic scotoma in the left upper fields, "too far from the macula to cause him any disturbances in microscopic work." No accurate plotting of the fields was done on that occasion, however. The patient was conscious of the defects in the fields of view, although ordinarily this did not annoy him except when playing tennis. The central acuity was 20/15 in each eye.

In March, 1934, seven years and six months prior to his death, at the age of seventy-one, the patient was examined by an ophthalmologist for an undisclosed reason (Dr. J. H. Waite, of Boston, Mass.). On this occasion the only plotting of the fields of view was made. The testing with a Ferree & Rand 330-mm. arc perimeter showed normal peripheral limits of the fields of view (Fig. 424, upper fields). The examination with a tangent screen at 1,000 mm. disclosed absolute homonymous hemianopic defects in the upper left quadrants, extending from the fixation points along the vertical meridians for 10° and along the horizontal meridians for 20°, "predicting a lesion in the occipital cortex on the right side and below the calcarine fissure" (lower fields).

In the right eye an old posterior synechia, binding the iris to the lens, and a centrally located nebula of the cornea were found, sufficient to explain the maximum acuity of 20/40 with a correction. In the retina of this eye there was a moderate sclerosis of the blood vessels, but no retinopathy was found. The left eye was normal except for sclerosis of the retinal vessels and astigmatism of ½ diopter, its acuity with a correction being 20/10. The ocular muscles were well balanced by the Maddox test, but the stereopsis was faulty.

The additional information obtained from the patient's son, Dr. Tracy B. Mallory, revealed his father as a conscientious, hardworking scientist, always intent upon his work, never communicating his symptoms to his associates, and visiting physicians only rarely. In his microscopic work he always used a monocular microscope, using his left eye, and preferred daylight illumination. His detailed discrimination or visual acuity and his appreciation of minute shades of color were both extraordinary. His consulting ophthalmologist, who was also one of his staff, "never knew a man who could see more detail in a microscopic section of tissue within a short time than Dr. Mallory."

Until a year or two prior to his death his visual acuity and form vision were at a supernormal level. In a microscopic slide he was able to see more than other competent histopathologists. Despite a visual field defect and a scarring of the right cornea, he was able to play tennis until he was well into his seventies, and his judgment of the speed and distance of the ball was surprisingly good. When reading, the patient apparently experienced no difficulty in following the lines and in scanning the page from left to right, the field defect being on the left side of the points of fixation. The patient knew of his defect, although it is doubtful whether in the circumstances of daily life he was conscious of it. He never complained of visual hallucinations.

3. GENERAL PATHOANATOMICAL EXAMINATION.—The autopsy, made 12 hours post mortem, revealed the following changes: marked generalized arteriosclerosis; marked coronary arteriosclerosis; a large, old infarct of the left ventricle of the heart, likewise small irregular areas of fibrous replacement just visible to the unaided eye; aneurysm of the abdominal aorta, with an organized mural thrombus; arteriosclerosis of the cerebral arteries; an old infarct in the right occipital lobe of the brain; bronchopneumonia of the inferior lobes of both lungs; etc. A dominant feature was the extreme degree of arteriosclerosis. The cause of death was bronchial pneumonia in consequence of a recent fall and trauma associated with it.

4. GROSS EXAMINATION OF THE BRAIN.—Both cerebral hemispheres, grossly examined, appeared symmetrical and showed no discoloration from hemorrhage or other causes. No areas of softening could be detected by palpation. The total brain weight was 1,400 gm. The carotid arteries were extremely tortuous and mark-

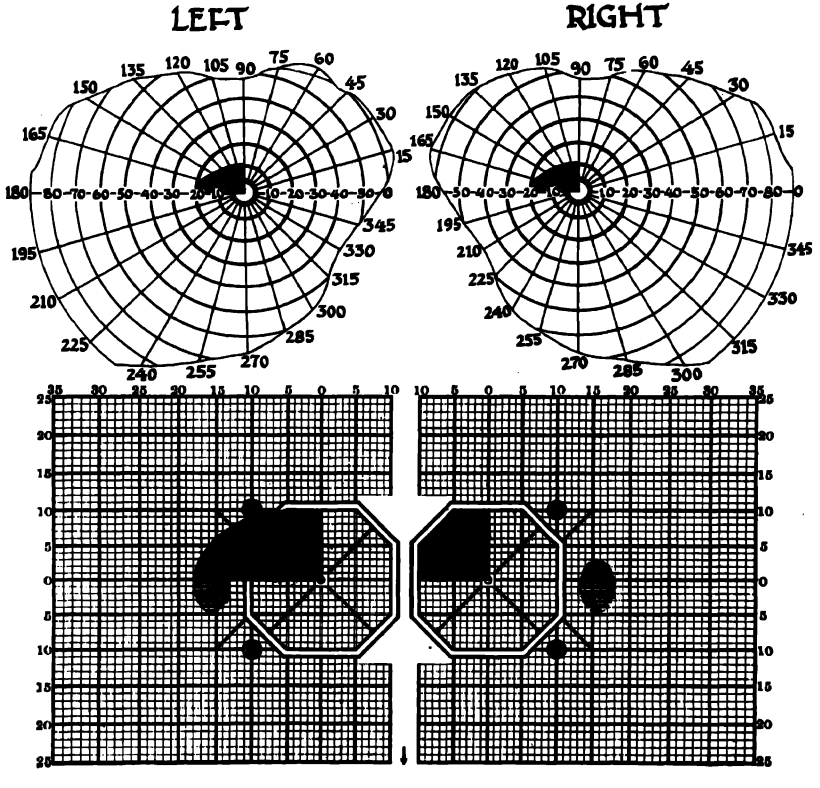

FIG. 424.—Case F. B. Mallory: centroparacentral homonymous hemianopic scotoma, strictly limited to the left upper quadrants, extending to the points of fixation, persisting without change for more than thirty years. Upper fields plotted with Ferree & Rand arc perimeter, lower fields taken with Bjerrum's tangent screen, then transferred to Lloyd's stereocampimetric chart of Bausch & Lomb. Cause: a limited softening of the lingual lip of the calcarine fissure of the right occipital lobe, caused by a transient arterial spasm. Note linear boundaries of the field defects accurately outlined by vertical and horizontal meridians as far as their intersection. Mariotte's blind spots in lower charts indicated by horizontal shading. Courtesy Dr. J. H. Waite, of Boston, Mass. (*Cf.* Figs. 425–27.)

edly thickened, with small calcified areas in their walls. Evidence of arteriosclerosis in isolated patches for a considerable distance was found in the larger vessels at the base of the brain.

The sectioning of the brain into thin parallel slabs revealed a single long and narrow scar on the inner face of the right occipital lobe, located in the lower lip of the calcarine fissure (solid black, including white shading, in Fig. 425).

The configuration of the right occipital lobe showed a calcarine fissure (*mc*, *lci*, *lcs*) entirely beyond which it proceeded in a fairly straight course in the direction of the occipital pole. This it did not reach but divided into an ascending and a descending prong running parallel to the contour of the pole (*lcs*, *lci*).

The striate area, projected onto the inner face of the occipital lobe, formed a narrow wedge asymmetrically divided by the calcarine fissure, with a shorter and wider stripe in the upper calcarine lip and a longer and more narrow stripe in the lower one (stippled area in Fig. 425). As in the majority of specimens, in the

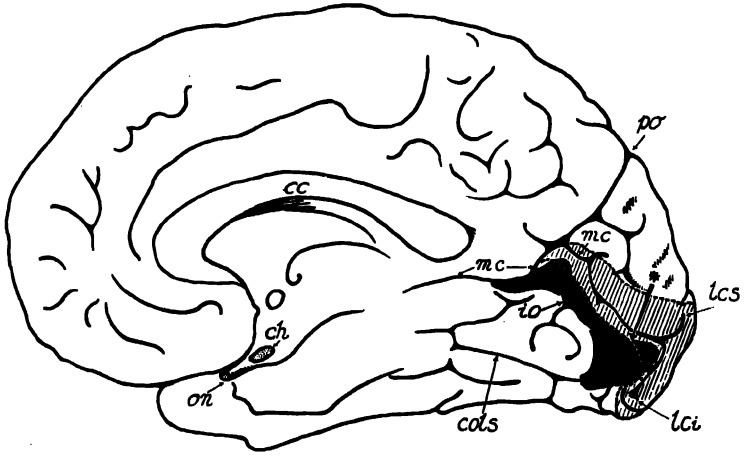

FIG. 425.—Case F. B. Mallory: right cerebral hemisphere, showing the size, shape, and location of the lesion, caused by a large ischemic softening. The lesion (*solid black*), largely outside the striate area, undermined or destroyed the striate cortex in the lower calcarine lip. The striate area is indicated by black or white shading, its boundaries indicated by black or white broken lines. The arrow, marked with an asterisk (*), indicates the level behind which, right to the arrow, a portion of the striate cortex was destroyed, whereas in front, to the left of the arrow, little or no direct damage to the striate cortex or its afferent fibers was done. Note a strict limitation of the lesion to the lower calcarine lip. *Labeling*: *cc*, corpus callosum; *ch*, chiasma of optic nerves; *cols*, collateral sulcus; *io*, inferior occipital sulcus; *lci*, lower prong of lateral or posterior calcarine sulcus; *lcs*, upper prong of the same sulcus; *mc*, medial or anterior calcarine sulcus; *on*, optic nerve; *po*, parieto-occipital sulcus.

located on the inner face of the lobe (*cf.* chap. VIII, 3 [5]). The lateral or posterior calcarine sulci (*lci*, *lcs*) at the occipital pole were superficially continuous with the medial or anterior calcarine sulcus (*mc*), but the basic sulcal arrangement probably resembled the type shown in Figure 293, middle sketch (no detailed macroscopic inspection was made for the sake of further microscopic study). Just anterior to the point of branching of the occipitoparietal sulcus (*po*), the calcarine fissure made a sharp bend, lower lip the striate area extended farther anteriorly than in the upper lip, where it was present only as far as the occipitoparietal sulcus (*cf.* Figs. 289, 290, etc.). Posteriorly the striate area enveloped the occipital pole (*cf.* Figs. 288, 293).

Upon superficial examination, the lesion—a smooth, narrow scar caused by an old malacic infarct thirty-one years earlier—was found to be situated in the lower or lingual lip of the calcarine fissure, corresponding to the narrow, black zone below *mc* and in front of *lci*, in Fig-

ure 425. Its anterior extremity was midway between the callosal splenium and the junction of the parieto-occipital and calcarine fissures. Posteriorly the superficial scar extended as far as the descending prong of the calcarine fissure. At its posterior extremity the lesion fanned out, extending over the posterior end of the fusiform gyrus and also a little beyond the collateral sulcus (*cols*). On cross-section the scar appeared in part as a narrow, shrunken lingual gyrus, yellowish in color, just ventral to the calcarine fissure. At the posterior end of the lesion the gray matter was largely destroyed, but the white matter appeared to be quite well preserved throughout the extent of the lesion.

The striate area, based on macroscopic examination, appeared to be affected only in its posterior segment along the calcarine fissure and in front of its descending prong (*lci*), while the polar striate area behind the prong did not appear to have been directly damaged.

5. MICROSCOPIC EXAMINATION OF THE BRAIN. —The preceding description of the extent of the lesion is to be somewhat qualified by the examination of sections through the right occipital lobe stained with the Weigert-Kultschitzky method for myelin fibers and with the Nissl-Lenhossék toluidine blue stain for nerve cells (Figs. 426, 427).

The microscopic examination showed the lesion to be somewhat more extensive than at an inspection of the intact specimen (solid black area, including parts shaded by white lines, in Fig. 425). Briefly, all along the inferior calcarine lip the extreme margin of the striate area was damaged by the malacic process. Just how much of the striate area was destroyed here could only be guessed, but it appears that it was merely a narrow zone along most of the inferior fringe of the striate area. One exception was the anterior extremity of the striate area at the cuneal lip, the other at the posterior extremity next to the inferior calcarine prong. In the first locality the extent of damage at best was small (marked by white dots at *l*, sketch *D*, Fig. 426). In the posterior locality, close to the occipital pole, the lesion definitely destroyed a portion of the lower calcarine lip (*l*, sketch *A*, same figure). This appeared to be the principal damage that must be blamed for the clinically found scotomas. Here most of the cortex lining the inferior calcarine prong (*lci*) stained poorly and contained but few of the obliquely coursing intracortical fibers, elsewhere identified as the terminals of the visual radiation. The anterior limit of the polar focus was at a point indicated by an arrow marked by an asterisk (*) in Figure 425.

Along most of the calcarine fissure (*mc*) between these two localities, the lesion partly un-

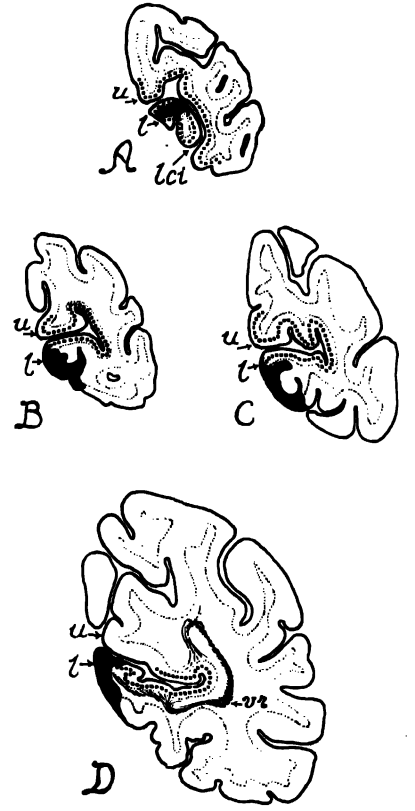

FIG. 426.—Case F. B. Mallory: coronal sections through successive levels of the right occipital lobe shown in Fig. 425, beginning with the occipital pole (*A*) and ending with a level through the anterior portion of the cuneus (*D*). The striate area indicated by dotted lines, the lesion by solid black. Visual radiation *vr*. Note that the lesion on all levels is strictly confined to the lower calcarine lip. (*Cf.* sketch *B* in Fig. 427.)

dermined the lower calcarine lip, as shown in sketches *B* and *C*, in Figure 426, with little direct damage done to the fringe of the striate cortex in that lip (marked by a few white dots). This was remarkable, since the lesion (solid black in same sketches) undermined that lip for at least half its extent. Another noteworthy observation was the preservation of the incoming afferent fibers streaming from the lower segment of the visual radiation into the lower calcarine lip (*vr*, in Fig. 427). These fibers hugged the inferior boundary of the cortex very closely and gradually passed into it, where they could

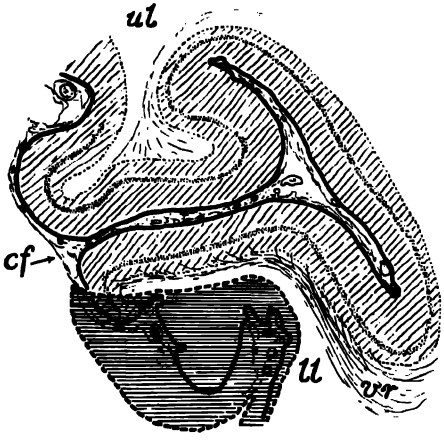

FIG. 427.—Case F. B. Mallory: slightly magnified detail of sketch *B* in Fig. 426. The horizontally shaded area indicates the probable size and shape of the normal lower calcarine lip, *ll*, shown here much reduced. The extent of the striate cortex indicated by an intracortical stippled stripe, the line of Gennari or Vicq-d'Azyr. Note fibers of the lower segment of the visual radiation, supplying the lower calcarine lip, well preserved, in spite of the proximity of the focus. *Labeling: cf*, calcarine fissure; *ll*, lower calcarine lip; *ul*, upper calcarine lip; *vr*, visual radiation.

be identified as terminals in the infra-Gennarian half of the cortex. In fiber stains the number of these slanting afferent fibers, as well as those of other categories such as radial, and the fine fuzz in and below the stripe of Gennari, belonging to the various association and callosal systems, were but little less abundant than those found in the upper calcarine lip on the same level, which remained at a considerable distance from the lesion.

In the sections stained for cells, other and even more marked changes from the norm than those in the sections stained for fibers were found in the undermined lower lip. Here all cells were a little paler, less numerous, and smaller in size than in the normal upper lip. In this process of general depletion and devitalization there were marked gradations in different layers. In general, the infra-Gennarian half of the cortex suffered most. Here the cells were markedly reduced in numbers, layer *6* being almost absent. In layer *5* the normally conspicuous Meynert's giant "solitary cells" were still recognizable but were much shrunken. In the inner granular layer the larger elements of sublayer *4-b* were quite atrophic, the process of atrophy having also affected sublayers *4-a* and *4-c*. In the supra-Gennarian layers the process of atrophy was less pronounced, even though noticeable, not excluding layer *1*. The atrophy had affected not only the cell bodies but also the intercellular substance, made up of the expansions of nerve cells and fibers.

The total reduction of the cortex in the lower calcarine lip may be guessed at one-tenth or more of its normal size. The intensity of the atrophic process decreased from the fringe of the lower lip, where it was most pronounced, toward the floor of the fissure, where it gradually faded away. The calcarine floor and the upper lip were entirely free from any recognizable pathological changes.

In summary, microscopic study of sections through the right occipital lobe confirmed and somewhat extended that obtained from gross macroscopic inspection. There was a single ancient malacic scar which undermined the lower calcarine lip along its entire length, encroaching upon the lower fringe of the striate area but little except at its anterior end, and more especially next to the lower calcarine prong. The afferent fibers of the visual radiation were found substantially spared, but the fiber connections with other cortical regions must have been largely severed. The cell and fiber content of the lower lip was found much depleted.

Whereas the principal pathological features of the right striate area were in good accord with the visual field defect, only a slight depletion of fibers was noticeable in the lower segment of the visual radiation—the external sagit-

tal fiber stratum of the occipital lobe. In the "lateral salient" of the radiation, especially, there was no gap to be found, as could be expected from the site of the principal lesion in the occipital pole. A possible explanation may be the closing of the gap during the three decades following the vascular "episode."

The lateral geniculate nucleus, however, produced more positive clues. In the lateral fourth or less, in the so-called lateral spur, the cells were clearly atrophic, which would agree with the location of the lesion in the lower calcarine lip. In the posterior extremity of the nucleus, precisely where, from our experiments with monkeys described in chapter VII, 4, 5, one would expect them to be, clear signs of localized degeneration were found in all four cell layers on this level. The process bore the signs of retrograde degeneration, including local proliferation of the neuroglia. The location of the retrograde zone of degeneration in the most posterior extremity of the nucleus and its intensity agreed well with the principal lesion next to the inferior prong of the calcarine fissure.

6. CORRELATION BETWEEN FUNCTIONAL DISTURBANCE AND THE PATHOANATOMICAL FINDINGS.—The task in this, as in other similar cases, was to furnish a plausible explanation of the visual defect, observed during life, by means of the abnormal changes found in the brain.

A rough correlation, in the light of information about the organization of the central visual apparatus presented in chapters VI, VII, VIII, and X, was relatively easily made. A much more difficult problem was to give an exhaustive account of a long process of decay of a living, working, central nervous organ stretching over a period of almost five decades, beginning with the initial manifestations in the late twenties, down to the concluding phase of a long, laborious, and fruitful life. Hence the insistent queries as to the why, how, and when of the particular underlying process can be answered only conditionally. The somewhat sketchy clinical information on the visual disturbance recorded during life is also a hindrance, precluding any adequate interpretation.

The principal facts, in spite of the difficulties mentioned, are plain. Clinically, approximately thirty years prior to death, during a single cerebral vascular event or "episode" lasting only a few minutes, a homonymous hemianopic central scotoma in the left upper quadrants developed, which, after a relatively short initial period, apparently remained unchanged for the rest of the patient's life. As anatomical evidence of the cause of this scotoma, a shrunken malacic scar in the lower calcarine lip in the right occipital lobe was found. The underlying anatomical cause of the scotoma was a malacic focus in the lower lip, just in front of the inferior prong of the calcarine fissure (*lci*, in Fig. 425; *l* in Fig. 426). The affected territory, its anterior limit indicated by an arrow in the first figure, was situated along the lateral or posterior calcarine fissure, which is the later phylogenetical addition to the original calcarine fissural complex of the Primates (*cf.* chap. VIII, 3, and *lc* in accompanying illustrations). The much less extensive portion of the lesion in front of the level, indicated by an arrow marked by *, stretching along most of the calcarine fissure, whose lower lip it undermined, must be absolved from direct responsibility for the central scotoma.

The probable course of the pathophysiological process may have been as follows. In his early thirties, possibly even before, a state of cerebral vascular irritability developed, manifesting itself in recurrent attacks of an "ophthalmic migraine," regularly accompanied by a scintillating scotoma, sometimes also by headache and nausea. The eliciting factor or factors remain unknown and may only be surmised as any one or a combination of infections or toxins, including coffee, tea, tobacco, medical drugs, and, perhaps the most important, overexertion in eyework to be expected in an assiduous and eager microscopist ("dynamic factor").

During the fourth and fifth decades of life the same recurrent attacks of scintillating scotoma may have continued with increasing frequency and intensity, even though no mention was made of this in the scanty report. At one time, at the age of forty-seven, at mealtime, a particularly violent attack, apparently elicited by bright light stimulation, occurred, which left in its wake a permanent defect in the fields of view. During the subsequent years, milder attacks of scintillation took place without, however, further impairing the vision. While this

indicated that the state of cerebrovascular irritability continued, the focal visual attacks ceased, ending in partial destruction of the central visual apparatus.

What the extent and quality of visual function was in the period just preceding the fateful attack remains unknown. It is possible that a careful testing would have disclosed some reduction of acuity or color vision in the territory later permanently affected, indicative of the wearing-out of the responsible artery. Equally beyond discovery is the actual condition of vision during the period immediately following the fateful attack. However, the fact that, according to the patient's own estimate, the defect was at first large and that it subsequently "cleared up" indicated a considerable reduction in the initial disturbance. Hence it is fairly certain that after the fateful attack not only the central but also the peripheral or extrafoveal-areal vision in the left upper quadrants was impaired.

This assumption is corroborated by the finding of a hemianopic scotoma "far up in the left corner of each eye," whereas a central scotoma on the same occasion was overlooked by the examining ophthalmologist. Slender as this evidence is, it nevertheless indicates that the peripheral or extrafoveal portions of the upper left quadrants may also have been initially impaired.

The peripheral fields subsequently improved to a degree subjectively appreciated as "normal." This restoration agrees well with the histological findings in the lower calcarine lip anterior to the point indicated by the arrow (*). Even though its structure was found below par when compared with the upper lip, it still preserved a majority, possibly most, of its cells and afferent fibers and some of the association fibers, permitting it to function in a fairly normal way. A slight retraction of the useful area along the periphery of the left upper quadrants—for example, up to 60° or 50° or less—which must be postulated from the actual destruction of the extreme margin of the lower lip, could also have been easily "absorbed" or disregarded in the patient's subjective experience.

As a final, residual state the only defect that mattered and the only one found during the plotting of the fields remained a central scotoma up to 20° in the horizontal meridian. But this, too, was so well psychophysiologically compensated for that the scotoma ordinarily did not inconvenience the patient except in certain difficult situations. Undoubtedly, the scotoma was no serious impediment to the patient's activity, including microscopy, during the thirty remaining years of his life. This is noteworthy, since his occupation certainly required a high degree of "epicritic vision" (one of the patient's coworkers "never knew a man who could see more detail in a microscopic section of tissue within a short time than Dr. Mallory").

In the evaluation of the patient's defect, the completeness of the pathoanatomical destruction in the affected portion of the striate cortex and the degree of functional impairment to be expected in the scotomatous territory are also to be considered. It is possible that while finer discrimination was here abolished, or at least made more difficult, not all vision was destroyed. A "hard" scotoma, difficult to crack, or a high-threshold condition may perhaps be a more adequate description. Hence, under the ordinary conditions of clinical testing, an impenetrable or "absolute" scotoma would be found, while under favorable conditions some stimuli would still be appreciated.

This interpretation would agree better with a sparing of segments of fairly well-preserved striate cortex and its afferent fibers adjoining the malacic focus along the lower calcarine, especially along the lower calcarine prong and probably behind it, in the occipital pole (thus in sketch *A*, Fig. 426). This would also fit the presence of some crisscrossing infra-Gennarian fibers experimentally identified as the terminals of the geniculo-calcarine visual radiation, entirely absent only in the localities where the striate cortex was completely undermined. A territorially discontinuous lesion in the polar cortex, varying in degree at different points, and its diffuse character and long duration reflected in a patchy appearance in the zone of retrograde degeneration in the posterior extremity of the lateral geniculate nucleus, with a few scattered nests of relatively preserved cells, would also harmonize with this view.

The preceding considerations logically lead to a question of the genesis of the entire pathological process. From the clinical symptoms,

consisting in the recurrent attacks of scintillating scotomas for many years preceding the fateful "episode," and from the sudden onset and short duration of the principal event that had left in its wake a scotomatous defect, it is beyond doubt that the anatomical basis of the responsible underlying process was vascular. Less certain is the identity of the vessel, owing to individual variations in blood supply of the occipital lobe, as pointed out in chapter X.

A careful study of the serial sections showed that the main stem of the calcarine artery (*ca*) and its continuation—termed in this book *principal calcarine artery* (*pca*)—were in no way to be blamed, since the vessels in the calcarine fissure were all of normal appearance and were patent. The only vessels that would come into consideration were those supplying the lingual gyrus on the inner face of the hemisphere. These, in our own specimens used for the study of blood supply in chapter X, have been termed *posterior temporo-occipital artery* (*poteocca*), *inferior calcarine* or *paracalcarine artery* (*ica* or *ical*, or *paca*), and *accessory inferior calcarine artery* (*accica*).

Since in case MALLORY the lesion did not extend laterally beyond the inferior occipital sulcus (*io*), as it did in case MANTENO (*see* Fig. 428), the stem of the posterior temporo-occipital artery must be ruled out. This leaves as an alternative either the *ica* (*paca*), the *accica*, or the posterior branch of *poteocca*. Closest to the required type would come *ica* (*paca*) or *ical*, depicted in Figures 369, 372. Its secondary branches, however, in case MALLORY did not enter the calcarine fissure, which appears to have depended entirely on the calcarine artery. (*Cf. also* Fig. 374.)

Microscopic examination of sections surprisingly revealed no obstructed, sclerosed vessels (as, e.g., in the MANTENO case). Most vessels, including those in the degenerated territory, were found patent, some filled with formed blood elements, the erythrocytes. The very artery responsible for the necrosis, deeply sunk in the pial fold of the inferior medial paracalcarine sulcus, surrounded by its bared walls caused by a necrotic colliquation and removal of the cortical tissue, was found wide open and of normal size.

This observation forces one to conclude that the essence of the fateful vascular event occurring thirty years earlier was not an occlusion of the blood vessel in the sense of a permanent thrombosis or embolism, as is usually implied by such a definition in clinical diagnosis. Rather, the pathophysiological cause may be visualized as a temporary occlusion owing to an arterial spasm or angiospasm, lasting long enough to cut off the necessary flow of blood, hence primarily an anoxemia or hypoxemia. An unavoidable consequence was the suffocation of the sensitive nervous parenchyma, varying in intensity or degree in different parts of the vascular tree, all the way from a slight impairment to complete death of the nerve cells. A further process was merely a sequence of the histopathological changes induced by suffocation of the neurons, resulting in the picture found in the post mortem conditions. (On the extreme sensitiveness of the nerve cells of deep cortical layers to anoxia *see* Adrian in *J. Physiol.*, v. 88, quoted by Burns 1951; *see also* R. W. Gerard 1937, 1938, 1941.)

In the final analysis, the same factors that had induced a transient scintillating scotoma on other numerous preceding occasions, from the patient's late twenties to his forty-seventh year, on that particular summer afternoon culminated in a complete temporary spasm in a branch of the right posterior cerebral artery. The spasm lasted long enough to cause an irreversible, and hence irreparable, injury to the delicate structures of the lingual gyrus, including parts of the right striate area.

From the state of the vessels thirty years later, it is certain that, after the termination of the attack a few minutes later, almost normal circulation was restored. This restored circulation, owing to the irreparable character of the injury in the core of the affected vascular territory, had but little effect. Only along the periphery of the affected territory, which included most of the lower calcarine lip and most of the afferent fibers of that lip, the circulation was not completely shut off. Here a normal flow of blood soon permitted true rehabilitation of the nervous parenchyma, manifesting itself subjectively in a "clearing-up" of much of the initially large functional defect. In this process of restoration the anastomotical connections of the affected vascular territory with other ad-

joining and less affected territories had certainly played an important role, as discussed elsewhere. (*See* chap X, 8; *cf. also* following MANTENO case.)

In the light of the views, expressed in the preceding paragraphs, it is plain that a purely static anatomical concept of a pathovascular process, termed "cerebral thrombosis," needs to be replaced, at least in many cases, by one in which all pertinent factors, such as anatomical-mechanical, physiological-dynamical, and pathological in the narrow sense, receive due consideration. Of these much remains obscure.

The foremost problem of what causes an arterial spasm that so completely shuts off the lifegiving blood from the delicate brain tissue as to kill it cannot be answered. Is it a lowering of the threshold in the sympathetic constrictor nerves and centers regulating the arteries of the brain, or in the smooth muscles themselves?

What agents—dynamic or functional, chemical, metabolic, toxic, nutritional, or others, including medical poisons—are instrumental in such a lowering of the sympathetic threshold or increased irritability?

Are there any physical factors to point at—for example, increased blood pressure, perhaps temporary and localized to a particular vascular territory? Could such a localized rise of blood pressure be caused or induced by a preceding localized stimulation of vasodilators, in turn stimulated by a greater demand upon parts of the nervous organs under greater functional stress ("overwork"; *cf.* Field *et al.* 1951)?

Could an unusual demand upon a part of the nervous system, in our case the visual cortex, bring on a state of greater irritability of the supplying vascular sympathetic apparatus, with all its dangerous potentialities, including an arterial spasm capable of killing off the nervous parenchyma?

Is not a scintillating scotoma, then, essentially a premonitory sign signaling a state of functional unrest or lability of the central visual apparatus, preceding its "breakdown," with an outcome of irreparable damage? Hence, could not such a signaling be interpreted as essentially a defense mechanism intended to prevent a condition of intolerance, and thus avoid an injury?

Is it not logical to look upon physical light, normally an "adequate physiological stimulus," in one way as an agent necessary for maintenance of normal physiological conditions in its "adequate nervous substance" that makes up the visual system, and in another way as a "destroyer" or "decomposer" of the same substance, which is the essence of the process of vision (by analogy with the synthesis and decomposition of the retinal visual purple)?

In this connection the organic or anatomical angle of the genesis of hemianopic scotomas must not be overlooked. It is probable that both factors, the "organic" and the "functional," may work hand-in-hand. The first, for example, as an incipient local atheromatosis of a particular blood vessel, may be the anatomical basis upon which the "functional," "dynamic," "toxic," etc., factor, in the form of a local spastic constriction elicited by any one of the above-mentioned agents, may be superimposed, the result manifesting itself in a narrowing or constriction of an artery varying in time and hence in intensity of the subsequent organic damage. (*Cf.* experiments by Echlin 1942.)

7. GENERAL DEDUCTIONS CONCERNING THE VISUAL SYSTEM.—As few of the cases in our collection, case MALLORY is eminently suitable to shed full light upon the basic facts of the intrinsic organization of the human visual system and some on its behavior in pathological conditions.

The first point concerns the cortical representation of the central fovea ("macula"). Here the focal question is: Is the central fovea represented according to the same plan as the remainder of the binocular portions of the retina, that is, by a projection of each two homonymous foveal halves upon one single striate area, or is each complete fovea represented in both striate areae?

The answer is unequivocally in favor of the first concept. Making a legitimate assumption that the field charts in Figure 424 are reasonably accurate, case MALLORY shows the homonymous halves of both hemifoveae to be exclusively and entirely represented in one particular striate area. Just as the lesion extended close to the posterior limit of the affected right striate area at the occipital pole, so the central scotomas extended to the very fixation points,

or dividing meridians, in the contralateral halves of the fields of view. The contralateral, or left, occipital pole, as the serial sections stained with toluidine blue showed, was normal, just as the central vision to the right sides of the dividing meridians was entirely normal. Hence the thesis, supported by other evidence presented in this book, notably the experiments upon monkeys and upon other human pathological cases, is corroborated in this human experiment: each retinal fovea or "macula," like the remainder of the binocular portions of the retina, is divided through its center by a vertical meridian, its temporal half being projected upon the ipsilateral hemisphere, its nasal half upon the contralateral. (*Cf.* chap. X, 8; and chap. XI, 8, 9.)

The other closely related question which received a clear-cut answer is: Where, precisely, are the homonymous halves of the two foveae represented in the striate area? Since the lesion responsible for a central scotoma in case MALLORY was found in the occipital pole, the polar segment of the striate area—and that alone—must be regarded as representing the fovea (sketch *A*, in Fig. 426). The remainder of the striate area, the portion situated in front of the arrow marked in Figure 425 with an asterisk (*), in particular its floor, is not related to central vision. Especially is this true also of the anterior segment of the striate area, which, as well as its afferent fibers, remained almost entirely outside the lesion (sketch *D*, in Fig. 426). A sparing of the central vision found in many cases of homonymous hemianopia cannot, therefore, be explained by an assumption of a sparing of the anterior segment of the striate area, as has been suggested by some, but is in all cases caused by a sparing of the polar, foveal segment of the striate area and of its afferent fibers (*see* chap. X, 8; and chap. XI, 8, 9).

How far anteriorly does the representation of the central vision in the striate area extend? The answer will depend on where the limit to the central vision is set in the field of view. If anatomical criteria are applied, and half the diameter of the human fovea is set at 750 microns, then, roughly, 3° in the field of view from the fixation point or 6° in diameter would correspond to it. Again, if half the central area is set at 2,750 microns, in the field of view this would correspond to 11° for one half or to 22° for its total diameter.

On this basis, in case MALLORY, where the scotoma extended along the horizontal meridians up to 20° and along the vertical meridians up to 10°, one may say that the destroyed segment of the striate cortex in the dorsovertical sense, parallel to the inferior calcarine prong, corresponded approximately to the central area, while in the longitudinal sense, from the polar extremity to the arrow marked with *, the destroyed cortex represented twice the extent of the central area.

The fovea in the strict sense or, more correctly, the two superimposed homonymous hemifoveae would have a correspondingly smaller representation, roughly corresponding to the area back of the two prongs of the calcarine fissure at the very occipital pole (Fig. 425). This approaches fairly closely the estimate made more than thirty years ago by Gordon Holmes, shown in Figure 124, and is in fair agreement with other cases of our own and those found in the literature (Holmes & Lister 1916; Brouwer 1930; R. A. Pfeifer 1930).

Another item clearly illuminated by our case is the one that has caused much debate between the localist viewpoint advocating a firm and stable representation of the retinal surface in the cerebral cortex and the opposing, more or less "omnivalent," concept of an ill-defined, diffuse, vague, unstable, or floating representation of the specific functions, with the possibility of a "vicarious" substitution or compensation, also expressed in such concepts as the "functional fovea" or "pseudo-fovea," and the like (*cf.* chap. IV, 4, 5). From the patient's own words it is obvious that after the onset of the visual "episode" the considerable initial disturbance subsided (the defect "cleared up"). In the further course the disturbance improved so much that, even though the patient was conscious of it, it did not interfere with his ordinary occupation except in conditions requiring perfect vision, as, for example, when playing tennis. In the words of his eye doctor and associate, it is doubtful whether he was conscious at all of his defect in the circumstances of daily life.

A marked improvement in the patient's vision indicated that the defect became largely eliminated from his consciousness, or was

"psychically compensated." What a "psychic compensation" means in concrete terms of anatomy and physiology remains unknown, the more so, since the entire question of a "psychophysical" correlation still remains in a nebulous state. The reality of the scotomas in the patient's fields of view, of their hemianopic character, of their definite shape, size, and location, however, cannot be disputed. Hence, even though in ordinary circumstances the visual defect in the patient's conscious awareness was nonexistent or practically so, the same defect could easily be measured by even so gross a procedure as routine perimetry. Undoubtedly, a defect was present all the time, even though subjectively it was not felt. This makes it resemble a physiological scotoma caused by an absence of retinal structures in the region of the optic papilla, the so-called Mariotte's blind spot. Hence, a "psychic compensation" was at work, even though we do not know what it is.

One factor contributing to the emergence of the defect to the level of conscious awareness of the visual defect was the suddenness of change. This was especially apparent during the onset of the disturbance and the period after it, when the patient was most keenly aware of his trouble. During the further course the awareness of a scotoma gradually "faded away" and sank to almost a vanishing point, at least temporarily or periodically.

Besides the "psychic factor," a purely histoanatomical process of repair was also at work in our case. This factor, in the final analysis, may have been entirely responsible for the improvement and for a "psychic compensation" of the functional defect. The traces of this palpable, material process of repair were very clearly distinguishable in the microscopic sections. They were histological signs of a restitution in much of the lower calcarine lip adjoining the lesion.

It is probable that during the initial period, immediately following the vascular insult, much and perhaps most of the lower calcarine lip, together with the entire striate cortex in and around the inferior calcarine prong at the occipital pole, was impaired, resulting in a scotoma enveloping practically the entire left upper quadrants. Soon, probably within the next few minutes following the relaxation of the spasm of the paracalcarine artery, the process of rehabilitation set in. In this, in so far as the striate area and visual radiation were concerned, the major share was contributed by the calcarine artery proper, buried in the calcarine fissure. This artery evidently was not subjected to the spastic occlusion that had temporarily knocked out its neighbor, the paracalcarine artery. The evidence of this is the good condition of the upper calcarine lip and of its incoming fibers. Since both calcarine lips were largely supplied by the calcarine artery, only the nutrition of the lower lip was partly affected by the subtraction of that share of blood contributed by the paracalcarine artery—just enough to put it temporarily out of commission but not enough for complete anoxemic suffocation and necrosis.

In the further course of the process of "repair" and "restitution," several factors worked hand-in-hand: anatomical, physiological, hemodynamical, and nutritional, besides direct histological processes of degeneration and regeneration. With cessation of the spasm in the affected vascular territory, the circulation was resumed, possibly in increased volume, into the partly suffocated tissue of the lower lip, thus speeding up the process of repair (as in the inflammatory processes). In this way most of the gross quadrantic hemianopia was erased in a matter of minutes or, at the most, hours or days. The rehabilitation of the finer structures and hence of the subtle qualities of vision in the left upper quadrants, however, required a longer time, extending probably over many weeks and possibly months, never to reach the normal level possessed before the insult. Of this we have no knowledge, owing to an absence of detailed testing. The depletion of the cells and fibers in the lower calcarine lip alone remained an unmistakable indication of permanent damage. Even so, since the majority of cells in the lower lip escaped destruction, enough of "function" was left in that lip for vision in the affected quadrants to be felt subjectively as "normal."

The foregoing set of anatomical and physiological factors in case MALLORY appears to represent the essence of the process of "rehabilitation" or "restitution," fully accounting for the observed functional disturbance: a central scotoma in the left upper quadrants, found in the perimetric testing of the fields of view. There is, therefore, no place here to invoke other unac-

countable factors, such as "psychic," "functional," "plastic," and what not, that have so largely confused and obscured the problem of rehabilitation in modern discussions of this item.

Together with the other evidence adduced in this book, case MALLORY puts a question mark upon some modern concepts of the normal working and rehabilitation of the impaired functions of the nervous system, for example, of the "pseudo-fovea" of Fuchs (1921) and of the "reorganization" of the cerebral mechanism in general, championed by Goldstein (1923, 1925, 1931). In fact, all factual evidence at our command, in opposition to these and similar modern attempts at resuscitation of the antistructuralist functional equipotentialism of the nervous system, points toward a strict parallel between the anatomical structures and functional performance: the first being the material basis, the second a working manifestation of the same thing. (*Cf.* chap. III, 3, 4; and chap. IV, 5.)

Briefly summarized, the following are the results that may safely be drawn from case MALLORY concerning the organization of the human visual system: the central foveae are represented in the posteriormost segments of the striate areae in exactly the same way as are the extrafoveal portions of the retinae, each two homonymous hemifoveae in the right or left halves of the brain, with the upper homonymous quadrants in the upper half and the lower homonymous hemifoveal quadrants represented in the lower half of the foveal portion of the respective striate area.

The topographic representation of the retinae in the cortex is permanent and immutable, putting a functional displacement of any retinal point outside the realm of concrete possibility. Hence the migrating "pseudo-fovea" of Fuchs, Goldstein, and others, appears to be a product of undisciplined, pseudo-scientific faddism.

In fact, the cortical representation of the fovea and, in general, of the retina is the very antithesis of the idea of "cerebral plasticity" championed by the modern opponents of cerebral functional localization. In the light of all available information, the foveal portions of the vertebrate visual apparatus appear as the very culmination of the most exquisitely organized sensory instrument, created during the incalculably long vertebrate evolution, and a basis upon which the ascendancy of the Primate Order was built and is maintained. (*Cf.* chap. XIII, 2 and 3; and chap. XV.)

SEC. 11. CASE OF INCOMPLETE HOMONYMOUS HEMIANOPIA WITH CENTRAL SPARINGS

1. HISTORY.—PAGLIERO, Martin (MANTENO case), age fifty-three, Manteno State Hospital, UNo. 1029 (1944), Manteno, Illinois.

Diagnosis: Left homonymous hemianopia with central sparings, caused either by cerebral thrombosis or embolism of cardiac origin.

From the scanty information one learns that the patient suffered from a coronary disease. Three years previously (1941) he had suffered a stroke. He died of an acute cardiac complication, presumably of coronary nature. During life the patient had no noticeable psychic symp-

toms, particularly none of the visual kind. However, the clinical examination was rather casual, and the fields of view were not tested except with the hand. In this way a left homonymous hemianopia was found, with a central sparing. The specimen and information were received from Dr. W. R. Kirschbaum, then affiliated with Manteno State Hospital, Manteno, Illinois.

2. PATHOANATOMICAL EXAMINATION.—A gross inspection of the brain revealed, as a prominent feature, general arteriosclerosis of the cerebral vessels, most noticeable in the large arteries at the base of the brain. The pathological change which makes this specimen of special interest was a single, large area of softening on the medial and inferior faces of the right cerebral hemisphere (Fig. 428, shaded). This area comprised the entire lower face of the occipital lobe and much of the temporal. Another area of softening, measuring 1 × 1½ inches, located in the center of the right parietal lobe, was presumably of less concern for the problem of vision and will not be considered here.

The temporo-occipital softening appears as a shallow depression lined with a smooth, glistening, opaque membrane continuous with the pial membrane covering the preserved parts of the brain which formed a frame of the depression. In places this membranous lining was in folds, oriented mostly longitudinally. Through this membrane and imbedded in it, the principal arterial stems were visible, pursuing their tortuous course. These were the various branches of the posterior cerebral artery. They could be followed across the defect as far as the normal cortex, which formed the rim of the defect.

The rim formed by the normal cortex surrounding the defect was represented in the temporal lobe by the inferior margin of the second temporal gyrus (*t2*). The rim passed over on the inferior face of the hemisphere into the uncus (*u*). Behind the uncus most of the hippocampal gyrus was missing as far as and including the isthmus of the hippocampal and cingular convolutions.

The upper boundary of the defect was represented by the precuneus and the cuneus, of which, however, the lowermost zone was either missing or atrophic. The lower calcarine lip (*lcl*) was mostly gone. Of the upper calcarine lip (*ucl*), only a vestige remained. The occipital pole (at *), upon superficial inspection, alone seemed to be in a fairly good state of preservation. This pole was formed by the posterior cuneolingual gyrus, which in this case remained on the surface.

Of the medial or anterior calcarine sulcus, as defined in chapter VIII, 2 [2], the most caudal portion remained as a forked end: the original primate termination exemplified by the Lower Monkeys (*mc* in Figs. 280, 284, 289). The lateral or posterior calcarine sulcus (*lc*) was found entirely separated from the medial calcarine by an interposed polar posterior cuneolingual gyrus; it ran obliquely across the posterolateral face of the occipital lobe. Its identity was ascertained by the presence of a whitish intracortical stripe of Gennari, visible on a smooth cut surface through the striate cortex. The lateral calcarine sulcus was approximately 1 inch long. Laterally, it was surrounded at a distance of ⅓–½ inch by a typical curved lunate sulcus (*l*) marking off a small occipital operculum (*cf.* Figs. 290, etc.).

In summary, in this case, almost the entire striate area of the right side, with much other cortex of the inferior and medial faces of the temporo-occipital lobes, was wasted away, except for a small segment in the upper lip and in the occipital pole, the latter, as evidenced by experiments and other pertinent pathological cases described in this book, being related to the foveae or centers of the homonymous fields of view.

Owing to a wasting of the nervous parenchyma, almost the entire inferior face of the occipitotemporal region was found to be nothing but a pial-arachnoid membrane, covered on the inside by a smooth ependyma of the lateral ventricle. The ventricle, in turn, was considerably enlarged *e vacuo*, and so also was the chorioid plexus, which otherwise did not show any gross abnormality.

3. ARTERIES IN AND AROUND THE AREA OF SOFTENING.—The blood vessel responsible for a single large focus in the right temporo-occipital lobe found in the MANTENO case was the posterior cerebral artery (Fig. 428, *pocea*), including all its subdivisions—the superior and inferior calcarine arteries (*scal, ical*), the posterior

temporo-occipital artery (*poteocca*), and the hippocampal artery (*hipa*). The upper branches —the anterior and posterior cuneal arteries (*cua, cup*) and the posterior parietal artery (*popaa*)—escaped (for comparison *see* figures in chap. X, esp. Fig. 372). The preservation of the occipital pole apparently was accomplished circuitously: reverse circulation via the preserved branches above the obstructed locality.

Careful dissection revealed the stem of the posterior cerebral artery (*pocea*), close to its origin at the basilar artery, to be completely clogged by an atheromatous process. The superior calcarine artery (*scal*) was free, even though it was found to be diseased. Just what were the connections of that artery that permitted a backward flow of the blood in this case it was not possible to make absolutely certain. Such circulation could have been established, e.g., through the posterior parietal artery (*popaa*) from the convexity of the hemisphere, since this artery was found in fairly good condition. The two branches of the inferior calcarine artery (*ical*) were also found in fair condition

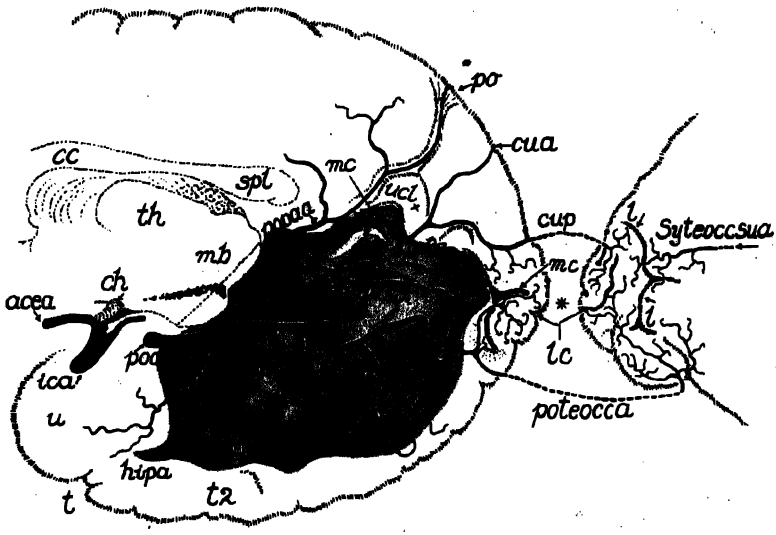

FIG. 428.—Case M. Pagliero (Manteno case): right cerebral hemisphere showing a large temporo-occipital area of softening (*shaded*), responsible for a left incomplete homonymous hemianopia with central sparings observed during life. Left diagram shows the inner face of the hemisphere; right diagram shows the posterolateral face of the occipital lobe of the same hemisphere. System of posterior cerebral artery (*pocea*) presented to show all principal branches involved in the pathology of this case. Note a sparing of the occipital pole, marked with an asterisk (*), and its circuitous vascular supply both from the posterior cerebral artery (*cup, poteocca*) and from the middle cerebral artery (*Syteoccsua*), responsible for that sparing. *Labeling: acea*, anterior cerebral artery; *ca*, calcarine artery; *cc*, corpus callosum; *ch*, chiasma of optic nerves; *cua*, anterior cuneal artery; *cup*, posterior cuneal artery; *hipa*, hippocampal artery; *ica*, internal carotid artery; *ical*, inferior calcarine artery; *l*, lunate sulcus; *lc*, lateral or posterior calcarine sulcus; *lcl*, lower calcarine lip; *mb*, midbrain with substantia nigra; *mc*, medial or anterior calcarine sulcus; *pca*, principal calcarine artery; *po*, parieto-occipital sulcus; *popaa*, posterior parietal artery; *poteocca*, posterior temporo-occipital artery; *scal*, superior calcarine artery; *spl*, splenium of corpus callosum; *Syteoccsua*, superior temporo-occipital Sylvian artery; *t*, temporal lobe; *t2*, second temporal gyrus; *th*, thalamus; *u*, uncus of hippocampal gyrus; *ucl*, upper calcarine lip.

and communicating with the patent calcarine artery (*ca*) above the point of its obstruction. The principal trunk of the posterior temporo-occipital artery (*poteocca*) was also found patent everywhere, even though its passage was reduced in diameter.

A tentative diagnosis of the state of the posterior cerebral arterial system as found at the time of death was an obstruction of its principal stem close to its origin, with the compensatory collateral circulation re-established above the point of obstruction by way of the anastomotic backflow from the surrounding preserved arteries.

4. CORRELATION OF FUNCTIONAL DISTURBANCE AND THE PATHOANATOMICAL FINDINGS.—The occipital lobe examined in a cut specimen showed an encephalomalacic defect penetrating deep into the hemisphere. In the occipital pole and close to it, only the cortex and the short subcortical association fibers of Meynert, connecting the adjoining gyri in the manner of the letter U, were found, the longer fibers having altogether disappeared. In the temporal lobe the sagittal fiber layers were present in their upper and intermediate segments as far as the "lateral salient"; their appearance, however, indicated an abnormal condition that could have been confirmed only by stained sections. Of the striate area a segment in the upper calcarine lip (*ucl*), directly continuous with the remaining mass of the subcortical fiber substance of the hemisphere, showing a line of Gennari, may have preserved a modicum of normal function. The occipital pole, in spite of its sparing, undoubtedly was functionally dead, since the afferent fibers from the visual radiation were gone. The central sparing recorded in the sketchy history must therefore be considered as a typical "pseudo-sparing" frequently found in carelessly plotted cases of homonymous hemianopia.

The question concerning the primary etiology of this case, whether thrombosis on an arteriosclerotic basis or embolism of cardiac origin, must remain unanswered. The numerous signs of advanced atheromatosis suggest the first; definite obstruction in the principal stem and heart trouble rather indicate the latter pathology.

In either case, the circuitous, multiple arterial blood supply of the occipital pole, the very locality where the foveal-macular or central region of the retina is represented, has been demonstrated in a practical way, and its importance as a mechanism by which central vision may be preserved in homonymous hemianopia shown. (*Cf.* chap. X, 8 [2, 4]; chap. XI, 8 and 9.)

Anatomical sparing of the occipital pole, in spite of a complete malacia of the afferent fibers, is of interest, since it shows that an extensive malacia caused by an occlusion of the posterior cerebral artery may destroy foveal-macular fibers, even though the foveal-macular cortex may be spared. In a less extensive injury both the foveal fibers and the foveal cortex may be saved and central vision preserved.

SEC. 12. CASE OF A LESION IN THE LOWER CALCARINE LIP AND OCCIPITAL POLE

1. HISTORY.—ST. LUKE'S case No. 101 (1940), unidentified patient of unknown age and sex.

Diagnosis: Limited encephalomalacic lesion of the lower lip of the calcarine fissure in the left occipital lobe; encephalomalacia of the lateral side in the right parieto-occipital lobes of the brain. Specimen received from St. Luke's Hospital, Chicago, 1940.

Eleven days before death, weakness of the face on left side, paralysis of the left arm, and a Babinski sign of the left foot were noticed, indicating a lesion of the pyramidal tract in the right half of the cerebrum. No neurological examination was made, or fields of view taken. *Streptococcus viridans* was cultured from the heart blood. Kahn test was negative. Pathoanatomical diagnosis was of a thrombo-ulcerative endocarditis of the mitral valve and of the left auricle. Other findings: multiple infarcts of the spleen and kidneys (as well as the brain); cholecystitis and cholelithiasis; general arteriosclerosis and hyperemia; multiple fibrous and fibroplastic scars and fatty degeneration of

myocardium; fatty degeneration of the liver; chronic fibrous interacinar pancreatitis; general hyperemia and edema of the brain; moderate arteriosclerosis of the cerebral blood vessels.

According to the preceding pathoanatomical report, it may be accepted that the specimen belonged to an individual in later middle life or in advanced age. It is also fairly obvious that the essential etiology was of cardiac origin, apparently of an infectious nature. Upon this basis, in the course of illness, a vascular degenerative process in various parts of the body gradually developed, including the brain. The involvement of the visual system was incidental.

Since no information was available concerning the visual disturbance, the only recourse was to venture a probable diagnosis from the facts found on gross and microscopic examination of the brain. Such *tentative diagnosis* would be: homonymous hemianopic scotoma in the right upper quadrants, extending as far as the fixation points, but probably affecting little, if at all, the periphery beyond 20° or 30°. In this respect, ST. LUKE'S case is almost a copy of case MALLORY, with the essential difference that, while in the latter the scotoma was "monosymptomatic," apparently caused by a vascular spasm during the fifth decade of life and continued for about thirty years, in ST. LUKE'S case the visual defect developed during the terminal phase of a general organic vascular decay originating from an infectious endocardial process.

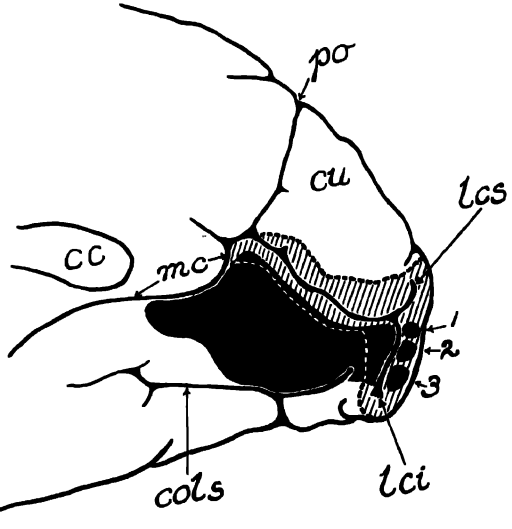

FIG. 429.—Case St. Luke's Hospital No. 101 (1940), drawn into the outlines of case Mallory, hence transposed from the left to the right occipital lobe. The diagram represents the inner face of the right occipital lobe, showing the location of the lesion below the calcarine fissure. Solid black indicates the destroyed portions of the extrastriate cortex lining the lingual and fusiform gyri. Black area shaded with white lines indicates the destroyed portions of the striate area. Undamaged striate area white, shaded with black lines. Boundaries of the striate area marked by black or white interrupted lines. In spite of the large size of the lesion and the undermining of the lower calcarine lip along its entire length, as shown in Fig. 430, only a narrow strip of the striate area was directly destroyed, the principal damage being in front and behind the lower calcarine prong (*lci*), making this case an enlarged copy of case Mallory (*cf.* Fig. 425). *Labeling: cc*, splenium of corpus callosum; *cols*, collateral sulcus; *cu*, cuneus; *lci*, *lcs*, lower and upper prongs of lateral calcarine sulcus; *mc*, medial calcarine sulcus; *po*, parieto-occipital sulcus; *1*, *2*, *3*, polar lesions. (*Cf.* Fig. 431.)

2. PATHOANATOMICAL EXAMINATION.—The gross examination of the brain showed an encephalomalacic lesion in the lower lip of the

calcarine fissure of the left occipital lobe (Fig. 429; in this figure, in order to facilitate comparison, the lesion was drawn into the outlines of the right occipital lobe of case MALLORY; *see* Fig. 425). Superficially, the lesion was strictly limited to the lingual and fusiform gyri below the calcarine fissure. A narrow zone along that fissure seemed to have been spared. Downward, the lesion at its widest extent just reached the collateral sulcus (*cols*). The anterior limit of the lesion was slightly in front of a point midway between the callosal splenium (*cc*) and the juncture of the calcarine (*mc*) and parieto-occipital sulci (*po*). The posterior extremity of the macroscopically visible lesion was 1 cm., or a little less than ½ inch, in front of the occipital pole. The surface of the lesion showed rather normal contours.

Microscopically the lesion extended anteroposteriorly beyond the indicated limits. This was especially apparent in the occipital pole, where a series of ischemic foci was present in the very tip of the lobe behind the lower prong of the calcarine fissure (*lci*). The exact extent of the lesion, given in solid black, is illustrated in sketches *A* and *B*, in Figure 430. These show that, in accord with the macroscopic examination, the lesion was limited throughout its longitudinal extent to the region below the lower lip of the calcarine fissure, the upper lip of that fissure being entirely free from any pathology determinable in the usual way.

The next fact of interest was the limited extent to which the central visual apparatus in the restricted sense - the visual radiation (*vr*) and the striate cortex (indicated by a dotted or stippled line)—was damaged, in spite of extensive total destruction of the occipital lobe. On most anterior levels in front of the striate area there were only a few diffuse ischemic foci, confined to the cortex of the lingual gyrus. Through the anterior segment of the striate area, corresponding to the widest extent of the lesion, only the fringe of the striate cortex was directly destroyed, while by far the greater portion of that cortex in the lower lip was only undermined (*cf.* sketches *B* and *C*, Fig. 430).

The most noteworthy observation was the escape of the bulk of the afferent fibers, which, closely skirting that lip, streamed from the lower segment of the visual radiation (*vr*) into the lower calcarine lip. These fibers could be followed underneath and into the striate cortex, where, according to our own previous experiments, they spread in the infra-Gennarian half, pursuing a slanting course (*see* Fig. 315). However, many of these fibers in the ST. LUKE'S case had undoubtedly perished. This was evidenced by their gradual numerical decrease from the floor of the calcarine fissure, where they appeared normal, toward the fringe of the lower lip, where they were practically bleached out. The same must be assumed also for the other categories such as the in- and outgoing callosal and associational fibers.

An instructive indication of the partial disappearance of fibers was found in the Gennari fiber layer itself; here the bleaching kept pace with that of the subcortical fibers of the lower calcarine lip. Thus, while Gennari's layer was approximately normal in and close to the calcarine floor, that layer almost vanished toward the margin of the lower lip. This partial loss of Gennari's autochthonous fibers may be attributable partly to an actual loss of those terminal ramifications that belong to the afferent geniculo-cortical and perhaps to other fibers, while in part it may be an expression of impaired vitality of the neurons and their expansions caused by their proximity to the ischemic focus. This latter factor was especially obvious in the margin of the lower lip.

In the occipital pole more definite changes appeared in the form of minute malacic foci, strictly limited to the cortex (Fig. 430, sketch *A;* and Fig. 431). These were located in the floor of the lower prong of the calcarine fissure (*lci*) and in the portion of the striate cortex in the very pole just behind that prong. The three larger foci (*1*, *2*, *3*) in the last-mentioned figure were from 2 to 3 mm. wide and were fairly evenly spaced, being separated by segments of less affected cortex, each 2 mm. wide. Focus *1* spread almost entirely in the infra-Gennarian half of the cortex. Focus *2* was principally located in the supra-Gennarian half, with its tentacles passing into the infra-Gennarian half. Focus *3*, in turn, spread through almost the entire thickness of the cortex. In all foci the innermost zone, closest to the subcortical fiber layer, roughly corresponding to layer *6*, was spared.

There were other features of interest from the viewpoint of the organization of the striate cortex. Such was especially the intracortical fiber layer of Gennari, from which the striate area received its name (*see* G. Elliot Smith in chap. VIII, 4). This layer remained visible almost everywhere in the foci, although it was reduced to roughly a fourth of its density outside the foci. Only in places where the causative process was most intense was the visibility of Gennari's layer reduced to almost the vanishing point. Hence the layer could be followed as a continuous formation throughout the cortex, irrespective of the gaps represented by the foci (stippled stripe in Fig. 431). Another noteworthy feature was a more intensive staining of that layer next to the margins of the foci, instead of a reduction in staining, as one would expect, when a focus crossed that layer. This, with the experimental evidence given in chapter

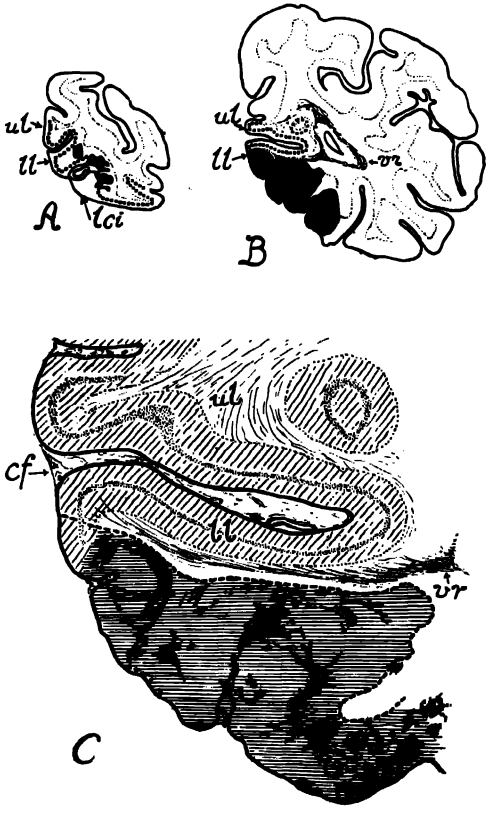

FIG. 430.—Case St. Luke's Hospital No. 101 (1940), showing the lesion in the lower calcarine lip, in sketch *A* through the occipital pole, in sketch *B* through the middle stretch of the calcarine fissure; *C*, slightly magnified detail of sketch *B*. In upper sketches lesions given in solid black, striate area marked by a dotted line. In lower sketch the lesion indicated by horizontal shading, the striate area by oblique shading and a stippled stripe (Gennari), the hemorrhages in the lesion by solid black. Note the sparing of the incoming fibers of the visual radiation (*vr*), in spite of the proximity of the lesion. *Labeling: cf*, calcarine fissure; *lci*, lower calcarine prong; *ll*, lower calcarine lip; *ul*, upper calcarine lip; *vr*, visual radiation. (*Cf.* Figs. 429, 431.)

VII, 7 [2], indicates Gennari's layer to be made up largely of short association fibers, this being in harmony with the observations on Marchi-stained material and with the study of Golgi-stained structures of the striate cortex (*see* chap. VII, 7; and chap. VIII, 7).

In the visual radiation, however, no clear gap interrupted its course. This observation, as in case MALLORY, may be interpreted as being caused by the diffuse character and incompleteness of the malacic process in the cortex, owing to which only those fibers degenerated in a retrograde sense whose terminal arborizations had been destroyed in the infra-Gennarian half of the striate cortex or in the Gennarian layer itself (*cf.* experiments in chap. VII, 5). Another possible factor may be the short lapse of time since the "episode" which caused the infarct in the left occipital lobe.

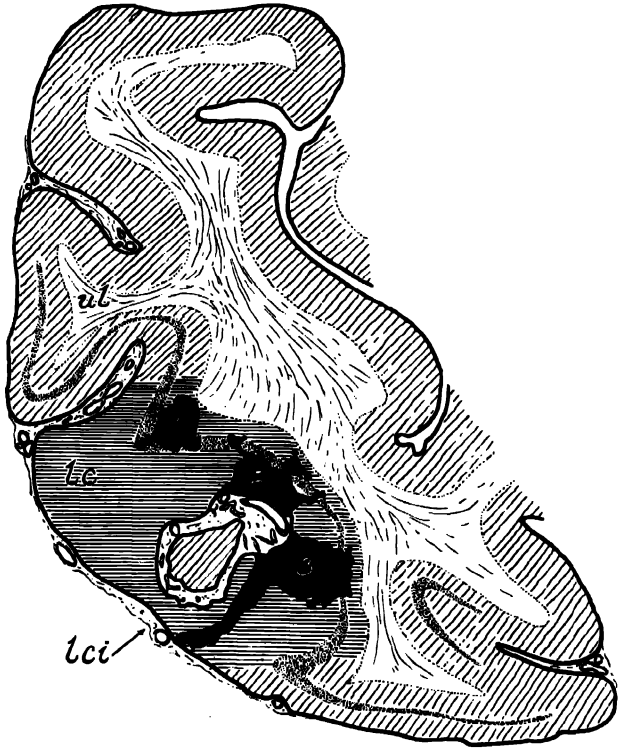

FIG. 431.—Case St. Luke's Hospital No. 101 (1940), figure representing medium magnification of sketch *A* of Fig. 430. The extent of the striate area indicated by a stippled intracortical stripe of Gennari. The horizontally shaded area shows the total extent of the damaged cortex, the solid black areas *1, 2, 3,* indicating the ischemic foci along the lower prong of the calcarine fissure *lci* in the occipital pole (*cf.* Fig. 429, foci *1, 2, 3;* and Fig. 430, sketch *A*), Gennari or Vicq-d'Azyr stripe in the normal or slightly affected striate cortex given in black stippling, in severely damaged foci by white stippling. The striate area along the upper calcarine lip (*ul*) and along the lower end of the inferior calcarine prong was found to be normal or only slightly affected.

Somewhat clearer were the signs of retrograde cell degeneration in the left lateral geniculate nucleus, where a scattered loss of cells was found in its posterior tip and in its lateral segment along much of its length.

3. COMMENT.—The distinguishing feature of ST. LUKE'S case was the limited damage to the striate cortex, even though the causative lesion destroyed a large portion of the cortex on the inferior, tentorial surface of the occipital lobe. In this respect ST. LUKE'S case resembles case MALLORY.

There are further similarities because of the underlying pathological factors acting in a like way in both cases. The artery responsible for the infarct was apparently the terminal branch of the posterior temporo-occipital artery (*poteocca*) or a similar vessel with a comparable spread. The lesion, even though it undermined the lower calcarine fissure, spared the bulk of its fibers, which, with its cortex, depended upon the calcarine artery. The lower half of the polar portion of the striate cortex was also affected, the same that was spared in the MANTENO case in spite of a much larger lesion there (Fig. 428). The responsible factors may have been either greater dependence of the polar cortex on the mentioned artery in ST. LUKE'S case or an underdevelopment or a shutting-off of the anastomotical connections with the adjoining arterial territories by the underlying pathological process in the responsible vessel.

SEC. 13. CASE WITH AN ENCEPHALOMALACIC FOCUS ALONG THE CALCARINE AND PARIETO-OCCIPITAL SULCI

1. HISTORY.—Case ANONYMOUS, of whom very little is known except that the patient was a male, of advanced age, probably a luetic and a drunkard, and had impaired vision, possibly caused by a cerebral stroke. Because of the mental symptoms which followed, the patient was confined to the State Hospital at Manteno, Illinois. No examination of vision was made.

2. PATHOANATOMICAL EXAMINATION.—Gross inspection of the brain revealed pronounced brachycephaly and general opacity of the entire soft covering of the cerebral hemispheres, indicative of chronic leptomeningitis (possibly specific luetic, or of some other infectious origin). The principal arteries, surprisingly, showed hardly any rigidity, and there were no macroscopically visible atheromatous changes in their walls. A single focus of softening found in the right occipital lobe was the reason for including this specimen in our collection.

The encephalomalacic area was roughly of a triangular shape (Fig. 432). Its upper and anterior boundaries were formed by the anterior lip of the parieto-occipital sulcus (*po*) and the upper lip of the medial calcarine fissure (*mc*). The lower boundary roughly followed the collateral sulcus (*cols*), which was posteriorly obliterated. The anterior fourth of the cuneus (*cu*) was destroyed. On the inferior face of the hemisphere the lingual gyrus was entirely erased. The occipital pole was formed by a superficially located cuneolingual gyrus (*cul gyr*). The lateral calcarine sulcs (*lc*) was 1⅓ inches long and followed a horizontal course, turning around the pole onto the exposed face of the hemisphere directly posteriorly (a position caused by extreme brachycephaly). A long and flat lunate sulcus (*l*) encircled the posterior extremity of the lateral calcarine sulcus.

The malacic focus, solid black in the figure, just reached the lower branch of the lunate sulcus (*see* right diagram). As a result of the malacic softening, a V-shaped defect was formed, roughly following the parieto-occipital and collateral sulci, its concavity facing backward. This concavity was filled in by the posterior spared portion of the cuneus (*cu*). The loss of substance, even though limited, was considerable, the depth of the defect where most pronounced being no less than 8–10 mm. below the level of the surrounding normal cortex.

Superficially, the entire lower lip (*ll*) of the medial calcarine fissure, with the exception of a narrow strip at its posterior end (shaded in the figure), and much of the upper lip (*ul*), which normally forms the anterior point of the cuneus, were gone. The cavity was covered by a smooth, but thickened and slightly opaque, arachnoidpial membrane, through which the principal blood vessels and some smaller ones were visible.

3. BLOOD VESSELS IN AND AROUND THE MALACIC FOCUS.—The posterior cerebral artery (*pocea*), in this particular hemisphere, divided

in the following order into several principal arteries (Fig. 433): a smaller and a larger medial temporal artery (*mta*), followed by a posterior temporo-occipital artery (*poteocca*), and a calcarine artery (*ca*). The latter, in turn, gave rise to a single long and rather thin principal calcarine artery (*pca*), as well as a posterior parietal artery (*popaa*). The *pca*, following the upper calcarine lip in its posterior course, dipped into the medial calcarine fissure; and, after giving off fine branches to both lips and again emerging upon the surface of the cuneolingual gyrus, it shriveled arachnoid-pial membrane, turned around the inferior posterior margin of the occipital lobe and, after emerging upon it, dipped into the lower section of the lunate sulcus (*l*); then, after crossing the lower lip of the lateral calcarine sulcus (*lc*), it spread in that sulcus. The lateral division of the *poteocca* spread in and around the more lateral portion of the lunate sulcus (*l*) in a similar fashion.

Hence the principal supplier of the foveal-macular cortex in this hemisphere was the posterior temporo-occipital artery. In addition, the

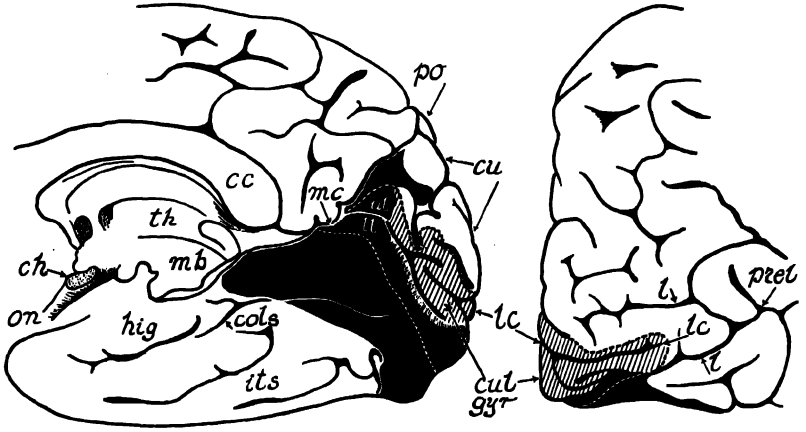

FIG. 432.—Case Anonymous, showing the inner (*left*) and posterolateral (*right*) views of the right occipital lobe, with a focus of softening, given in solid black, in relation to the sulci and to the striate area. Boundaries of the striate area marked by broken lines. White portions shaded with black lines indicate spared parts; black portions shaded with white lines indicate malacic parts of the striate area. Note spared posterior portion of the striate area around the occipital pole (*cul gyr*). For pathophysiological analysis *see* text and the following figure. *Labeling: cc*, corpus callosum; *ch*, optic chiasma; *cols*, collateral sulcus; *cu*, cuneus; *cul gyr*, cuneolingual gyrus; *hig*, hippocampal gyrus; *its*, inferior temporal sulcus; *l*, lunate sulcus; *lc*, lateral calcarine sulcus; *ll*, lower calcarine lip; *mb*, midbrain; *mc*, medial calcarine sulcus; *on*, optic nerve; *po*, parieto-occipital sulcus; *prel*, prelunate sulcus; *th*, thalamus; *ul*, upper calcarine lip.

ended in the polar portion of the lateral calcarine sulcus (*lc*).

The much thicker stem of the calcarine artery (*ca*) continued as a posterior parietal artery (*popaa*). The posterior temporo-occipital artery (*poteocca*) spread its several smaller and larger branches in the arachnoid-pial membrane in the area that was the lingual gyrus, its principal branch reaching the posterior inferior margin of the hemisphere, where it divided into two divisions of fair size (right diagram, Fig. 433).

The medial division, still enveloped in the edge of the foveal cortex along the upper section of the lunate sulcus and the surrounding area were supplied by the superior temporo-occipital Sylvian artery (*Syteoccsua*).

A small contributor to the visual cortex was also the cuneal artery (*cua*), which in this case was single. It originated from the common stem of the posterior parieto-occipital artery (*popaa*). It was easily followed in the floor of the malacic parieto-occipital sulcus (*po*) and over the surface of the spared posterior portion of the cuneus not far from the occipital pole.

4. Relation of the occipital arteries to the malacic focus and to the striate area.—The problem of why in this case a vascular insult damaged some parts of the occipital lobe, while sparing others, after a careful dissection of the specimen, appeared far more difficult to solve than it would seem at first sight. The questions arising concern the state of the particular artery in each of its divisions, as well as the arterial distribution, and the state of each particular territory of the brain substance, both spared and destroyed. Only after this could an attempt have been made to interpret the final post mortem condition in terms of pathological cause and effect.

Examined on coronal sections through the occipital lobe, in accordance with the examination of the uncut specimen, the focus on the anterior levels through the calcarine fissure destroyed both lips and the floor of that fissure medially to the posterior horn of the lateral ventricle. The territory eliminated from circulation belonged entirely to the posterior cerebral artery, while the territory lateral to the lateral ventricle, supplied by the middle cerebral artery, was spared.

Of the fibrous core of the occipital lobe, both the upper and the lower segments of the sagittal strata related to both calcarine lips were gone or appeared seriously affected. Closer to the oc-

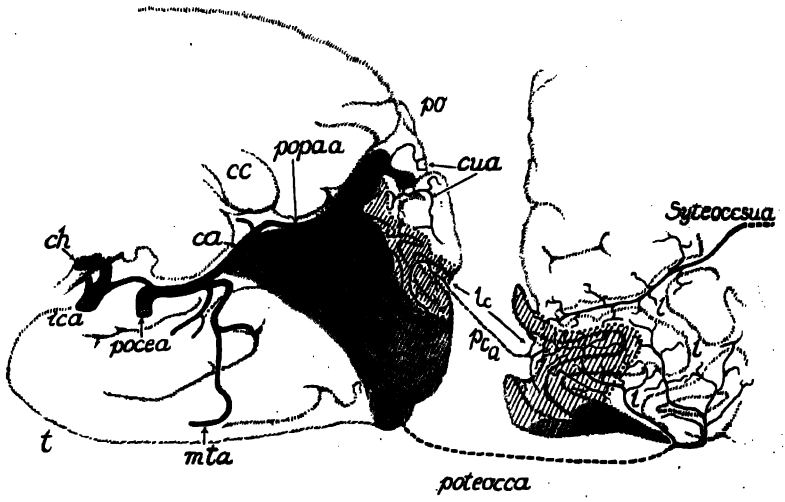

Fig. 433.—Case Anonymous, showing the distribution of arteries in and around the extensive focus of softening in the right occipital lobe. Left-hand diagram represents the inner face of the lobe, right-hand diagram represents the posterolateral face. Uniformly shaded area, including the white shading, represents the malacic territory. Striate area given in black or white shading, the latter indicating the destroyed parts of the same area. Boundaries of the striate area indicated by dotted lines. Arteries which continue from the inner to the posterolateral face of the hemisphere indicated by broken lines. Note a multiple blood supply of the occipital pole to which several arteries contribute, belonging partly to the middle cerebral and partly to the posterior cerebral artery, resulting in an almost complete sparing of the foveal-macular cortex. *Labeling: ca*, calcarine artery; *cc*, corpus callosum; *ch*, optic chiasma; *cua*, cuneal artery; *ica*, internal carotid artery; *l*, lunate sulcus (opened, to show arterial distribution); *lc*, lateral calcarine sulcus (opened, to show arterial distribution); *ll*, lower calcarine lip; *mta*, medial temporal artery; *pca*, principal calcarine artery; *po*, parieto-occipital sulcus; *pocea*, posterior cerebral artery; *popaa*, posterior parietal artery; *poteocca*, posterior temporo-occipital artery; *Syteoccsua*, superior temporo-occipital Sylvian artery; *ul*, upper calcarine lip. (*Cf.* Figs. 428, 432, and colored figures in chap. X.)

cipital pole, back of the posterior extremity of the lateral ventricle, the malacic process affected only the lower calcarine lip, both at the back end of the medial calcarine fissure and along the inferior limb of the lunate sulcus. The striate cortex in the upper calcarine lip, both along the back end of the medial calcarine sulcus (*mc*) and along the lateral calcarine sulcus (*lc*), and the underlying fibrous core of the lobe remained preserved.

Special mention is to be made of the sparing of the cortex in and around the lateral calcarine sulcus (*lc*) and in the lunate sulcus (*l*) surrounding the first and its subcortical fibrous core, except along the lower margin of the occipital pole, where the fiber substance underlying the lower lip of the lateral calcarine fissure was partly gone and was partly undermined.

Examination of the blood vessels, carried out with a dissecting magnifier, showed little that could explain the encephalomalacia. All principal arteries—the anterior, middle, and posterior cerebrals—were of normal size. Their walls were surprisingly elastic and translucent, with none of the atheromatous patches usually found in places of predilection in advanced age. This was also true of all medium and smaller branches visible at the magnification employed. All lumens of the arteries of all sizes were free, no clogging having been found in any vessel. The nearest approach to a narrowing was found in a deep medium branch of the principal calcarine artery (*pca*) imbedded in the most advanced locality of the malacic focus (in Fig. 433 terminating with a broken line next to *ll*). But even this vessel was not found obliterated and contained some blood.

5. Comment.—From the state of the arteries it is obvious that the etiological background of encephalomalacia in this case was not an atheroma. No signs were found which would justify a diagnosis of arteriosclerosis. The only questionable exception referred to in the preceding paragraph, that of a narrowed branch of the principal calcarine artery, could be explained by a secondary influence caused by encephalomalacia rather than vice versa.

Even if a doubtful admission were made that a primary thrombosis took place in that particular instance on an atheromatous basis, this would still in no way explain the huge loss of nervous parenchyma in most of the medial calcarine sulcus, in the parieto-occipital sulcus, and along the collateral sulcus on the cerebellar face of the occipital lobe. For this, no concrete anatomical cause was found. Unlike the Manteno case, where, in addition to widespread atheroma, complete plugging of the stem of the posterior cerebral artery was found, in case Anonymous all arteries, even those imbedded in the necrotic tissue or enveloped in the empty leptomeninges, were found without visible pathological changes. It is, however, possible that some such changes of a subtle character could be discovered by a careful microscopic examination.

With the exception of the doubtful qualification just mentioned, the absence of concrete pathoanatomical evidence in the arteries of the affected area forces one to assume that the cause of the defect of the nervous parenchyma was purely functional. As in case Mallory, discussed in detail, in the present case, too, the destruction must have been produced by a spasm of a sufficient intensity and duration to kill off the sensitive neurons by anoxemia.

The artery responsible for the suffocation of nervous parenchyma, according to the spread and location of the focus, was obviously the posterior cerebral from the point just in front of the separation of the posterior temporo-occipital artery (*poteocca*). This is indicated by the sharp demarcation line of the focus along the collateral and parieto-occipital sulci. The barrier that prevented further spread of the destruction to the temporal and parietal lobes was the normal circulation in those lobes, maintained by the medial temporal artery (*mta*) and the vessels supplying the precuneus. The spasm that had killed off nervous tissue in much of the occipital lobe was, accordingly, an entirely local affair, limited to the posterior territory of the posterior cerebral artery.

Not the entire territory of the posterior cerebral artery described was affected by the spasm, however; nor was it affected uniformly. The spared portion of the cuneus on the inner face of the occipital lobe was continuous with the preserved cortex on the posterior and lateral faces of the hemisphere. In the preservation of the cuneus the terminal branches of the middle

cerebral artery, in particular the superior temporo-occipital Sylvian artery (*Syteoccsua*), must have played an important part. This alone, however, does not seem to have been sufficient. The large size of the spared territory must be considered against the assumption of the middle cerebral as the only alleviating factor. But, above all, against this interpretation one may point to the distribution of the terminal branches of the cuneal (*cua*), the principal calcarine (*pca*), and the posterior temporo-occipital (*poteocca*) arteries. Even assuming an abundant anastomotical connection of all these arteries with the adjoining arterial territories, it is unlikely that a backflow from these alone would have sufficed.

One is, then, further forced to hypothesize that the shutting-off of circulation in the posterior cerebral territory was not complete but was merely partial. In the area of the focus, especially where the loss of substance was greatest, the circulation slowed down below the level of tolerance compatible with the survival of neuronal parenchyma. This was the case in the zone between the collateral (*cols*) and medial calcarine (*mc*) sulci and also along the parieto-occipital sulcus (*po*). These two belts, farthest away from the unaffected arterial territories, represented the core of the ischemic area that was most severely affected. A little less severely affected was the lower calcarine lip (*ll*), where the colliquation and the removal of the necrotic tissue was not complete. In the medial calcarine sulcus (*mc*) the zone of demarcation followed its floor, with a sparing of the upper lip (*ul*) along most of its length.

On the back face of the occipital lobe, shown in the right sketch in Figure 433, the merging of the terminals of the three contributing arteries: *pca*, *poteocca*, and *Syteoccsua*, was particularly evident. The sparing of the foveal-macular cortex in the lateral calcarine sulcus (*lc*) and next to it was probably accomplished by both of the following factors. One was the reduced flow in the spastically constricted posterior cerebral territory, which alone, being subliminal, did not prevent anoxemia in most of its territory; the other factor was the additional flow from the middle cerebral, that, taken with the first factor, was sufficient to keep conditions within the normal range and the tissue alive.

Concerning the basic cause—the factor or factors which had elicited the spastic condition—one may refer to the discussion of this topic in the section dealing with case MALLORY. Perhaps it will not be amiss here to emphasize again our present ignorance of the many functional factors by which the normal conditions of circulation are maintained, which factors are in many ways responsible for the reaction of the cerebral mechanisms in pathological conditions and in the processes of repair.

A tentative diagnosis of a functional defect in the fields of view, in this case, deduced from the anatomical findings, would be a left-sided incomplete homonymous hemianopia with a large central sparing, the spared parts of the fields being almost entirely in the lower parts of the fields below the horizontal meridians.

PART IV

Origin, Development, Comparative Anatomy, Physiology and Biology of the Vertebrate Organs of Sight

Chapter XIII

Origin and Development of the Vertebrate Eye and Visual System

SEC. 1. ONTOGENESIS OF THE VERTEBRATE EYE

1. Inception of the vertebrate eye in the ectodermal layer of the embryo.—Our knowledge of the development of the vertebrate eye during ontogenesis, or the early period of individual life, derives from embryological research. It is the product of investigations which began more than a century ago with the notable work of K. E. von Baer (1828) and his contemporaries. Through it the principal facts and innumerable details of the development of the eye, of the optic nerves, of the visual centers, and of the brain in general became known. Of these, the most important disclosure is the intimate genetical relationship of the eye and the brain.

The earliest differentiation of that part of the ectoderm of the human embryo which subsequently develops into retinal membranes around which the eyes are formed is represented by two thickened localities, the retinal primordia, at the rostral end of the neural or medullary plate, which in that early stage is still wide open (shaded parts in Fig. 434, *A*). At still earlier and as yet little known stages the retinal primordium is possibly a single patch (*see* Mangold 1931).

The remarkable fact shown in Figure 434 is that during its earliest known period of development most of the neural plate at its rostral and most differentiated end is taken by the retinal primordia. At the stage indicated by eight somites, approximately corresponding to 21 days of intrauterine life, the human embryo is essentially a tiny sac of ectoderm containing the primordia of the endodermal viscera, e.g., the pharynx (*ph*), and of the mesoderm. The incipient invagination along the mid-sagittal axis of the neural plate into a neural groove is indicated by a shallow, centrally located primitive groove or furrow (*pg*), flanked on cross-section by two thickened wings. Two barely noticeable dents, one in each wing, mark the beginnings of the optical grooves or sulci (*os*). In the center, in the primitive groove, and on both sides where the neural plate is continuous with the general integument (*int*), the ectodermal cover is much thinner.

2. Formation of a tubelike embryonic brain, with optical primordia dominant.—When the twelve-somite stage is reached, the primitive groove (*pg*) deepens further, and the optic sulci (*os*) become more marked (Fig. 434, *B*). The total transverse expanse of the neural plate is also somewhat increased. The thickened portions of the plate, still entirely optical at this stage, indicated by single and double shading, do not extend beyond the lateral corners, where the general integument begins. The optic sulci, further deepened into optic *foveolae* or pits, are the earliest indication of an incipient invagination of the two optic primordia, which are later to develop into primary optic vesicles.

The process of deepening the neural groove and the optic foveolae proceeds further until, at the stage of fourteen to sixteen somites, the lateral parts of the two wings of the neural plate are raised into folds (*f*, in sketch *C*), and their margins finally merge (sketch *D*). In this way the neural groove is transformed into a neural tube or, more correctly, into a primitive neural or cerebral vesicle (*cv*) at the rostral end of the tube.

By far the largest part of the wall of the neural vesicle is represented by the two thickened retinal primordia, together forming the

primitive eye-brain. Both primordia (shaded parts) almost meet at the anterior end, only a minute vestige remaining between, the raphé or seam, which is nonoptical (*r*, solid black). The caudal portion of the cerebral vesicle given in solid black, where the vesicle is continuous with the neural tube (*nt*), also does not contribute to the formation of the eyes. At this early stage the orimental or incipient brain, clearly, is still mostly an *ophthalmencephalon* or "visual brain."

3. Beginnings of the preponderance of the nonoptical over the optical parts of the embryonic brain.—During the subsequent stages of development, from sixteen to twenty-seven somites (up to 4 mm. in length), important changes take place (Fig. 435, *A*). These are brought about by rapid expansion of the nonoptical bridge (*C*, *C*, solid black) separating the two optic primordia (shaded segments). Within this period this intervening bridge increases to such an extent that the optic

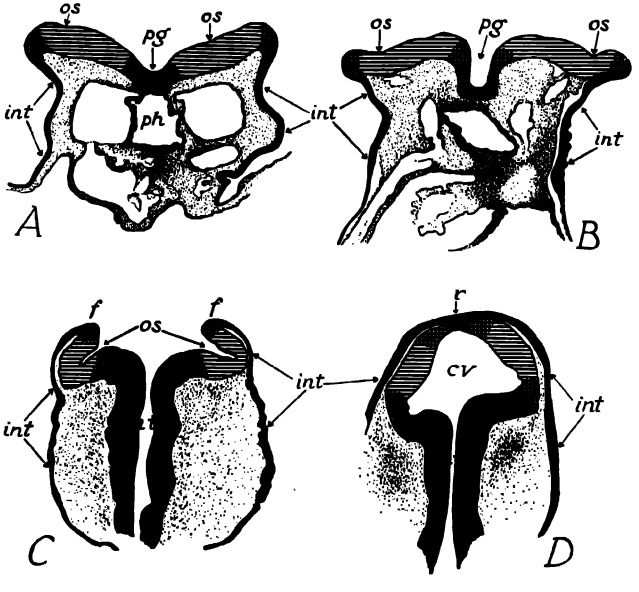

Fig. 434.—Early stages of human embryos showing successive steps in the development of the eye and brain. *A*, eight-somite stage with thickened neural plate wide open, with a shallow median sulcus, the primitive groove (*pg*), flanked by two optic primordia from which future retinae develop, each primordium dented by a slight nick, the optic sulcus (*os*) (from the University of Chicago collection, H87). *B*, twelve-somite stage with widely opened optic primordia, separated by a deepened primitive groove (*pg*), with optic sulci (*os*) more pronounced and optic primordia sharply marked off by lateral folds against general integument (*int*), rendered in solid black (University of Chicago collection, H197). *C*, fourteen-somite stage with advanced folding of optic primordia around greatly deepened optic sulci (*os*), forming open primary optic cups (Carnegie embryological collection, No. 4529; *see* Heuser 1930). *D*, seventeen-somite stage, showing fusion of two lateral folds (*f*, *f*, in sketch *C*) of primary optic cups in a median *raphé* or "seam" (*r*), by which the primitive cerebral vesicle (*cv*) is closed (University of Chicago collection, H951; *see* Wen 1929). Note that throughout their further development, shown in Fig. 435, the nervous optic vesicles remain close to the nonnervous general integumental layer (*int*) or its derivative, the lens primordium (*l*) and the lens (*lv*), in this way continuing the exposed location of peripheral photoreceptors characteristic of the Vertebrates from the earliest ontogenetical stage to full development. Optic primordia shaded, simple shading indicating the inner or nervous sheet, double or crossed shading indicating the outer sheet or pigment layer, of fully developed retina. *Other labeling: nt*, neural tube, into which cerebral vesicle continues; *ph*, primitive pharynx with surrounding entodermal and mesodermal tissue, out of which viscera, skeleton, muscles, and all other organs develop, except the nervous system and nervous constituents of the sense organs. Preparations used by courtesy of Professor G. W. Bartelmez, of the University of Chicago. (*Cf.* following figure.)

primordia come to lie far apart. These two primordia, in turn, also begin to expand and form vesicular protrusions. The entire anterior portion of the primitive brain now consists, on cross-section, of three vesicles, a bulky central one representing the brain proper (*cv*) and two lateral smaller ones—the primary optic vesicles (*ov*), as the future retinae are now called.

The intermediate cerebral vesicle already has much thicker walls (*c*) and is larger, suggesting a preponderance in bulk of the brain proper over the optic primordia. This eventual preponderance of a part of the original cerebral mechanism destined to serve the integration of the incoming impulses and their co-ordination into effector channels over the chiefly receptor ophthalmencephalon, or future retinae, becomes even more accentuated as the subsequent stages of thirty-three somites or 5.7 mm. (sketch *B*) and 11 mm. in length (sketch *C*) are attained. Finally, the two primitive optic vesicles, with their hollow stalks (*ost*), and the future optic nerves appear as mere appendages of a huge cerebrum (*c*), at least in the advanced Vertebrates such as Birds and Mammals.

4. Differentiation of the vertebrate retina.—Coincident with these changes goes a detailed histological differentiation of the optic primordia into retinae and, with the addition of other ectodermal and mesodermal tissues, their elaboration into eyeballs. First, the two primary optic vesicles (Fig. 435, *A*, *B*) become gradually invaginated in the center, forming at the end double-walled secondary optic vesicles or optic cups (*C*, same figure). The thicker inner leaf of the wall, by a complex process of differentiation, develops into nervous layers (*2–10*, Figs. 127, 128), the thinner outer wall becoming the pigment layer of the retina (*1*, same figures). The inner space or ventricle of the optic vesicle, toward the middle of the second fetal month in Man, communicating with the cerebral ventricles through the tubelike, hollow optic stalk —the future optic nerve—becomes reduced to an intraretinal slit or cleft (*ov*, in Fig. 435, *C*), which eventually also disappears in the finished organ.

On the ventricular face of that slit the thicker inner leaf of the retina at a later stage becomes coated with photoreceptors—the rods and cones—their "outward" or ventricular location being easily explained by the afore-mentioned facts of developmental mechanics. The ventricular position of the mature photoreceptors shows that, in the final, fully differentiated retina of modern Vertebrates, the photoreceptors preserve exactly the same "outward" position, facing outside space (which the cerebral ventricle and its derivatives in the optic cups, actually or potentially, are) which they had at the very inception of individual embryogenesis. This may be considered, in the light of Haeckel's concept, an ontogenetical recapitulation of the phylogenetical conditions present at the very inception of vertebrate evolution, with the neural plate wide open and the surface of the optic primordia bathed by the circumambient liquid medium in which the Vertebrate Ancestor, the primitive Prevertebrate, lived (Fig. 436, *A*, *B*; *cf.* following section).

In order to complete the description of the principal points of development of the vertebrate eye, it suffices to mention that from the thickened locality of the integument closest to the optic vesicle—the *lens placode* (*l*, in Fig. 435, *B*)—the crystalline lens develops by a process of invagination and separation and is eventually included in the "hollow" of the optic cup (*C*). Most other parts of the eye develop from the surrounding mesodermal tissue (*m*). This forms the two outer coats of the eyeball, the scleral and the chorioid membranes. By invading the interior of the cup either through the chorioid fissure (*chf*) of the secondary optic cup or through the primitive "pupil" of the cup, the mesodermal tissue provides the blood vessels for the retina.

The ciliary body and the iris, including the dilator and sphincter muscles of the pupil, are derivatives of the retina; and so the vitreous (*vi*, in *C*), which is chiefly a product of the supporting retinal structures, also appears to be. The nerves (*n*) which supply the ocular muscles, blood vessels, and other tissues have a peripheral character and reach their destination during the period of development.

5. The interdependence of the ontogeny and phylogeny of the eye.—The evaluation of the afore-mentioned facts established by embryology leads to the following important de-

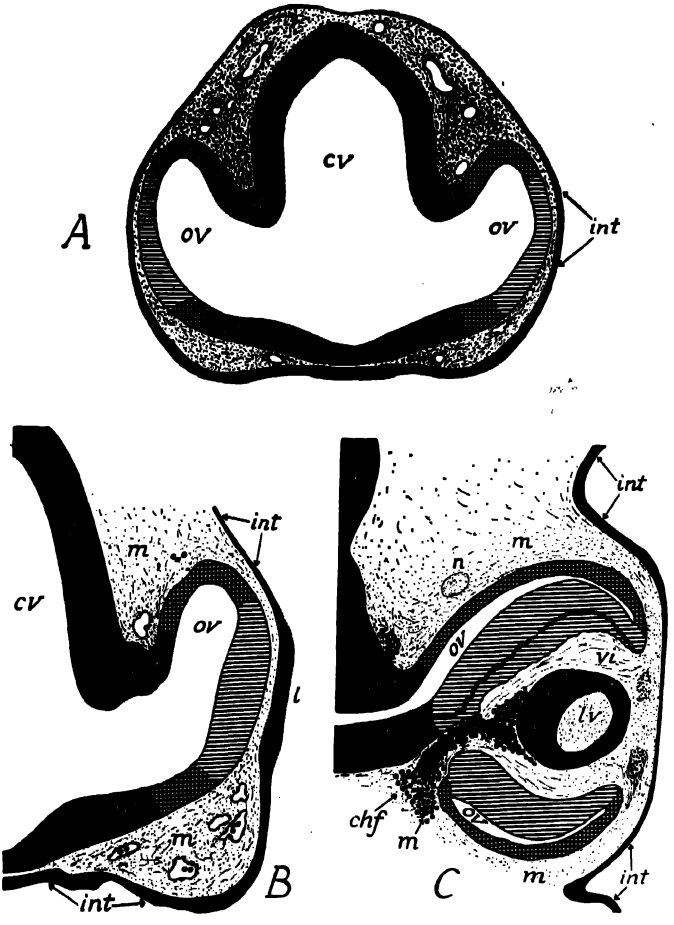

FIG. 435.—Further stages in the fetal development of the human eye. *A*, twenty-seven-somite stage, 4 mm. in length (University of Chicago collection, H1261), showing optic primordia transformed into primary optic vesicles, inclosing optic ventricles (*ov*), which freely communicate through hollow optic stalks (*ost*) with central cavity or cerebral ventricle (*cv*) of brain vesicle *c*. *B*, thirty-three-somite stage, or 5.7 mm. in length, approximate age four menstrual weeks (University of Chicago collection, H1426), showing a local thickening of the general integument or lens placode (*l*), opposite primary optic vesicle, from which the lens develops. *C*, 11 mm. in length, age six menstrual weeks (University of Chicago collection, H566), showing a double-walled secondary optic vesicle, or optic cup, with an outer leaf (crosshatched) containing granules of incipient retinal pigment epithelium (future layer *1* in Figs. 127, 128), and a much thicker inner leaf (*simply shaded*) which subsequently develops into the inner or vitreal portions of the retina containing photoreceptor rods and cones, bipolars, horizontals, amacrines, and ganglion cells (layers *2–10*, in same figures). Parts surrounding primitive pupillary opening gradually transform into pigment-containing nonnervous retina that lines the ciliary body and the interior of the iris. The lens vesicle (*lv*), formed by the invagination of the lens placode (*l*) and separated from the general integument (*int*) where it originates, becomes lodged in the optic cup, which is also invaded by mesenchymal tissue (*m*) by way of the chorioidal fissure (*chf*) and primitive pupil, to form a system of central artery and vein and in part the vitreous body (*vi*). Simple shading indicates the inner, nervous leaf of optic primordia, double shading the outer leaf. Preparations used by courtesy of Professor G. W. Bartelmez, of the University of Chicago. (*Cf.* preceding figure.)

ductions concerning the probable course of the evolution of the veretebrate eye and the factors by which it was brought about (for details see following sections).

The retina, ontogenetically the earliest, and in the developed state the most important, part around which, like a core, the eye is formed, was the start not only of the vertebrate organs of sight in the process of evolution but also of the brain itself.

Ordinarily, the origin of the vertebrate eye-retina, following the original description by von Baer, is presented as if it were an evagination, or outpocketing, of the primitive cerebral vesicle. In truth, however, as the course of ontogeny followed step by step clearly demonstrates, the retinal oriments, or optic primordia, are the principal and dominant parts of the neural plate, being the earliest and most advanced differentiations of the ectoderm or "outer skin" of a vertebrate embryo.

The brain develops from the nonoptical parts of the neural plate at a later stage. The eyes, therefore, do not appear as subordinate appendages "sprouting out of the cerebral vesicle," but rather the reverse is the embryological truth: the eyes, that is, the optic primordia, are the ontogenetical germ or "initial agent" from which the impulse for the development of the brain originates.

Ontogenetically and very probably also phylogenetically, the eyes are first to appear, the brain being a subsequent outgrowth. When in the further course of evolution the brain is largely taken over by other systems: the somesthetic and its derivative, the auditory, the motor, olfactory, and gustatory systems, the dominance of the eye is reduced, according to the species, to a varying degree, even though it is rarely eliminated.

Keeping the preceding in view, other facts of ontogenesis become understandable. The eyes-retinae never develop as outpocketings of the brain, sprouting from the central organ toward the integumental periphery in order to become accessible to the action of light (as the hypotheses of T. Boveri, Studnička, Walls, and others maintain). Vertebrate eyes, as embryology unequivocally shows, originate, from the very first, on the surface of the body and uninterruptedly, throughout ontogenesis, preserve their original peripheral location into the fully developed state (*see* following section).

Very likely vertebrate eyes originated during phylogenesis as superficial organs and have remained on the surface during all evolutionary stages, being always accessible to the maximum action of physical light and with minimum interference by intervening impediments, including parts of the body itself. Only in biological conditions where the stimulation of light is reduced in intensity or totally absent do the eyes recede from their favored position on the surface of the body and become immersed in the bodily tissues and reduced to insignificance, as exemplified by cave-dwelling, burrowing, nocturnal, and abyssal Vertebrates.

Migration of the eyes from a central location in the head or brain to the surface of the body, as the "ependymal hypothesis" insists, never took place, because it was unnecessary. Such a migration—if such it may be called—was carried out, instead, by the brain, which became central instead of retaining its originally superficial location as a medullary plate. As the brain was gradually freed from its original role of peripheral receptor and became an organ of integration, it was incapsulated by the other organs and tissues which formed the "head," leaving on the surface as its outposts the receptors, of which the foremost and most ancient are the eyes.

SEC. 2. THE PHYLOGENESIS OF THE VERTEBRATE EYE

1. GENERAL CONSIDERATION OF THE PROBABLE FACTORS RESPONSIBLE FOR THE EMERGENCE OF THE VERTEBRATE EYE.—The way in which the vertebrate eye came into being is unknown, in spite of some of the best efforts in biology to find the answer. Numerous more or less ingenious hypotheses have been made, without any of them being sufficiently convincing (for modern summary *see* W. K. Gregory 1951, p. 83). The reason for this failure is the complete absence of concrete information about the dawn of vertebrate evolution. Therefore, our speculations must be limited at present to an evaluation of the probable factors which may have been instrumental in the creation of the vertebrate eye and of Vertebrates in general.

The most remarkable feature of the eye of now living Vertebrates is its uniformly high state of structural and functional perfection. This is noteworthy, especially in view of an almost endless variation in detail. The vertebrate eye, as we know it, is a finished product, a perfect apparatus, even in the phylogenetically lowest representatives, the Cyclostomes and Fishes. This fact is further demonstrated by the well-developed orbits and channels for the optic nerves found in fossil Ostracoderms, the most ancient Fishes known, which lived during the early Paleozoic Era, approximately 400 million years ago.

In the case of the vertebrate eye, one gets the impression of an organ which, from the beginning, was well conceived and logically manufactured to serve its specific purpose. Truly, it is difficult to visualize an eye more perfectly devised than that found even among the most primitive of the modern Vertebrates, the Cyclostomes (Lamprey, Hagfish). A less perfect eye, it seems, would not have satisfied even a minimum of the biological needs of the Vertebrate Phylum.

The impression of the vertebrate eye as a perfect, finished organ appearing as if from nowhere, at an unknown time in the dim phylogenetical past, is well expressed in the words of Froriep (1906, p. 140): "A finished product, like Athena from the head of Zeus, the vertebrate eye appears on the scene, and both comparative anatomy and embryology are powerless to explain how it came about." A similar negative attitude, tracing the origin of the vertebrate eye back to the simpler photoreceptors of more primitive forms of life which preceded the Vertebrates, was recently announced by Walls, one of the best-informed of modern authorities on the eye: "The vertebrate eye owes nothing whatever to the visual organ of any invertebrate animal" (*Ciba Symp.*, v. 5, p. 1586, 1943).

And yet, difficult though the problem of the phylogenetical origin of the vertebrate eye may be, a roundabout way to its solution may be indicated. For this, it is necessary to reach far into the past of life on earth. For we are entitled to believe that just as the Vertebrates may have evolved from some more simple creatures, so the vertebrate eye must have been preceded by more primitive photoreceptors.

To trace the probable history of this remarkable organ, we may profitably begin with the well-established paleontological fact that the entire Phylum of Vertebrates or rather Chordates is a rather late newcomer among living beings. The vertebrate period does not represent more than a fraction of the estimated time since the beginning of life, roughly calculated at 3 billion years (Zeuner; Church, quoted by Schuchert 1931). By comparison, the "age of the earth" has been estimated at from 7 to 10 billion years (Bock & Watson, quoted by Zeuner), and the time since the formation of its crust at 6–7 billion years. It is probable that these estimates, as knowledge progresses, will have to be revised upward, as was done on several occasions during the last hundred years, and that the figure of 30 billion years for the duration of life and of 65 billion years for the age of the earth, given by V. Franz (1924), will appear less fantastic.

In any case, long ages must have passed before living creatures had sufficiently advanced to be considered as immediate precursors of the Vertebrates (the earliest Fishes appeared during the Paleozoic Era or about 360–400 million years ago, according to Zeuner). It is, therefore, permissible to speculate that the preliminary period during which the Vertebrate Ancestors were evolved must have been a long one, probably not less than the entire known span of the

Vertebrates and possibly several times that much.

What the Vertebrate Ancestors were and what their external appearance was we do not know. Most likely they were small, soft-bodied animals living in the water, somewhat resembling young embryos of the Ascidians and of *Amphioxus* (*see* Parker & Haswell, v. 2, 1940). Since they had no bony skeleton, they have left no known petrifacts which would indicate the intervening steps by which the vertebrate eye was evolved. There is little hope, therefore, of tracing the history of living forms from their inception through the Archeozoic (825–1,550 million years ago), Proterozoic (500–825 million years), and the early period of the Paleozoic Eras (450–500 million years), down to the time when the true Vertebrates appeared. Obviously, any attempt at present to explain the phylogenesis of the vertebrate eye factually is futile.

Again, the information one gains from the eyes found in many modern Invertebrates (Worms, Arthropods, Mollusks) is highly unreliable. Interesting as such study is, it helps little except as an illustration of the various possibilities of which animals availed themselves in developing the organs of sight (*cf.* R. Hesse 1896–1932; Taliaferro 1917, 1920; Plate 1924; Ovio 1927; Buddenbrock 1932; Hagedoorn 1936; Nowikoff 1944–45; Verrier 1945; Buchsbaum 1948; and others). The suspicion is justified that all living Invertebrates have in some way gone too far in specialization to be acceptable as samples of the original conditions.

This is equally true of the borderline forms between the Invertebrates and Vertebrates, the primitive Chordates (Hemichorda, Urochorda, Acrania). All these subphyla have undergone a greater or lesser degree of degeneration. The *Amphioxus* or *Branchiostoma*, for example, this most interesting of the living Higher Chordates and probably most akin to the actual Vertebrate Ancestor, is a disappointment (Fig. 445). In this Acranian there is nothing that could be considered an incipient eye or retina and little that could be looked upon as a primordium, or residue, of the "brain" or "head," as found in the true Vertebrates. The photosensory cells or optic cups discovered by R. Hesse and by Joseph, scattered through its spinal cord, in both shape and distribution are of a kind difficult to use in any hypothesis without undue stretching of the imagination (*see* Ariëns Kappers, Huber & Crosby, v. 1; *see also* Joseph, Parker, Franz, Crozier, Lönneberg).

Almost the same negative verdict must be given about other representatives of the Chordates: *Balanoglossus*, Ascidians, and *Salpa*. In fact, none of the living creatures more or less related to the early Vertebrates is particularly helpful in the attempt to find some clue to the preceding history or in determining the factors which ultimately fashioned the perfect photoreceptor organ, the vertebrate eye.

2. The probable photic environment of primitive animals.—It is by now generally accepted that life originated in water. Whether it was the fresh water of the swamps, rivers, and lakes or the salty water of the seas and oceans, even if at that remote period there were two such categories of water, is essentially immaterial. Also it is of only secondary importance whether the nursery of life was the shallow shore waters or the wide pelagic bodies of the seas.

The abundance of dissolved and formed potential nutritive substances seems to have been of greater importance. All other factors being equal, the shore waters may have offered more favorable conditions. In the first place, oxygen was more abundant near the shore and surface than in the deeper zones. (*Cf.* Sverdrup, Johnson & Fleming 1942.)

Besides water and its contents, the other and equally essential factor for the rise of life was the radiant energy emitted by the sun—light and heat. The complete dependence of all plants and indirectly of all animals upon solar radiant energy illustrates how fundamental this was.

Exactly how the process occurred of putting together the inorganic molecules into the first organic matter still remains to be explained (*cf.* Lichtig 1938; Alexander 1948; Bertalanffy 1949; Bernal 1951; Oparin 1953; Shapley 1953). The process of "photosynthesis," beyond doubt the most fundamental of all biochemical reactions, according to Rabinowitch (1945), is being repeated every day in the action of chlorophyll in the green, red, and yellow leaves of terrestrial plants and of seaweeds and takes place on an even more gigantic scale in the unicellular algae

that populate both fresh and salt waters in uncounted quantities. Light, then, which created life, has always been and still remains the essential factor in its maintenance.

Since light and heat are absorbed by water, the surface layers of this transparent fluid medium are most accessible to its penetration and contain most of it. Reflection of light and heat from the bottom, where it is possible because of the shallowness or great transparency of the water, is an added factor increasing the amount of radiant energy it stores up. Shallow waters are likely to be better illuminated and warmer and thus eventually contain more nutritive material, including oxygen. Shallow waters may well have been as advantageous to the creation of life as they are to its maintenance. Here both plants and animals found the most light and heat and food which the plants could assimilate with the help of light.

The sensitiveness to light or the ability of living protoplasm to respond to photic stimuli may not be a universal property of all modern living beings, particularly of animals. However, this may not always have been so. Especially during the initial period, all living substance must have been photosensitive. This must be positively assumed for the forms which gradually evolved into "plants," which otherwise would not have been brought into existence. The "animals" in due course of time could have become largely emancipated from direct dependence upon light, as they became converted into "parasites" living upon the plants. Photochemical and, above all, photosynthetic processes must be viewed as the source from which life on earth took its origin.

The "animals," even though proceeding along their own independent evolutionary course, have nevertheless retained a great deal of their original universal photoirritability, as certainly for a long time they were entirely dependent upon solar heat and still largely remain so. The fundamental similarity in the modes of reaction to light of all animals, from the most primitive to the most complex, as far as they have been investigated, is remarkable. It is evidence of the essential identity of the basic photochemical reactions of all living beings (*see* experiments by Hecht, Crozier, Hartline, Wald, *et al.*).

With the emancipation of the "animals" from direct dependence upon light as a food producer, one property of light—its ability to initiate organic photosynthesis—receded to a second place or was eliminated. For the initiation of protoplasmic reactions, a photolytic phase of light's action, dissimilation—that is, the breaking-up of chemical compounds and the release of stored-up energy—sufficed. This ability, in turn, could now have been further perfected, differentiated, and refined to render protoplasm specifically responsive to various aspects of light, in particular, to wave lengths or "colors," and to increase its sensitiveness to weak stimuli.

Still another fundamental quality of light—its rectilinear propagation—could now have been made use of. With the abandonment of photosynthesis and a sedentary mode of life and with the assumption of active hunting habits by the now mobile animals, this became of paramount importance. The form of energy which is universally present and potentially connects along straight lines every point with all other points in an illuminated habitat is of such superior biological significance that it could not have been left unused. Most animals, and certainly all higher forms, would be unthinkable without this medium of orientation. Higher animal life, in fact, is synonymous with photobiotic existence, or "life in the light."

3. The Vertebrate Ancestors and their utilization of light.—The question of how the ancestors of the Vertebrates looked, what their living habits were, and how they utilized light may be answered in the present state of our ignorance, if at all, only hypothetically. Their soft bodies have disappeared without leaving discoverable traces in the rocks formed during primeval times.

Again, the living representatives of the various Invertebrates or animals without backbones—for example, the Jellyfish; Worms (e.g., Planaria, Leech, Earthworm); Arthropods such as Crustaceans, Insects, and Spiders; Mollusks; Echinoderms; and to hardly a lesser extent the Lower Chordates (*Balanoglossus*, Ascidians), including the nearest relatives of Vertebrates, the Acranians or Cephalochordates (*Branchiostoma, Amphioxus*)—all seem to have gone far

along the road of specialization, or retrogression and degeneration, as the case may be. They may therefore be used only with discretion to illustrate in one way or another the past history of Vertebrates (Fishes, Amphibians, Reptiles, Birds, Mammals).

The problem of the probable origin of the vertebrate eye must, accordingly, be treated upon its own merits rather than upon analogy to modern Invertebrates. One may cautiously obtain glimpses from the early embryonic stages of Craniates or Vertebrates. In doing so, however, it must be borne in mind that there is no way of telling to what extent Haeckel's "first law of biogenesis"—which assumes ontogenesis to be an abridged recapitulation of phylogenesis—is correct. Some, if not all, features of an embryo may be merely adaptations to the necessity of a practical task—to grow a body of a new being from scant material, within a limited space, and in a restricted period of time.

General reflection suggests that there must be a firm causal relationship between the present form and function of the vertebrate eye and the photoreceptors of the ancient creatures from which the Vertebrates have evolved. The vertebrate eye, in all its present complexity and perfection, could not possibly have arisen from a phylogenetical vacuum. Like all other parts of a Vertebrate's body, the eye, too, must have evolved out of an original animal matrix, endowed with the properties characteristic of all early organic matter. Only those fundamental evolutionary potentialities present in the original living substance and possessed by the early animals could have developed fully into the complex structures of vertebrate organization and, in the long course of evolution, have produced the vertebrate eye.

At the beginning of animal life, sometime during the Archeozoic Era, variously estimated at from 825 to 1,550 million years ago or even earlier, it is possible to assume that there were creatures later to become Vertebrates that had not yet developed any organs that could justly be called "eyes." One may imagine them as minute, soft-bodied animals, almost without any differentiated parts. They were almost nothing more than clumps or aggregates of cells, as yet poorly integrated into a whole organism.

At a slightly advanced stage of evolution their bodily tissues had differentiated into three layers: an outer ectodermal, an inner endodermal, and a third, the mesodermal, between. At the outset, their body form probably more or less resembled a sphere. In advancing further, they became cylindrical, with a bilaterally symmetrical arrangement of parts somewhat resembling the embryo of a modern *Amphioxus* or an Ascidian.

Whatever were the unknown factors that initiated this particular evolutionary trend, they had a compelling urgency. The result was a body with a wide opening, the "mouth," at one end, leading into the "gut." Food, consisting of minute plants and animals floating in the water, was brought into the gut by means of cilia or flagella, the whiplike processes of cells coating the mouth and gut.

At some time after its inception, this early "Prevertebrate" or "Protovertebrate," as the creature may be called, developed limited locomotion, attained by means of lateral movements of its body carried out by the groups of contractile cells of the middle, mesodermal, layer. The integration of the action of these motor cell groups, it may be imagined, was extremely primitive. It probably was achieved by short expansions of cells of the outer, ectodermal layer arranged in a longitudinal chain with partial overlapping of the links.

The fact that the outer cell layer eventually became an integrator was logical. It came most frequently into contact with the environment. The ectoderm had to stand the impact of small bodies carried by the currents of the water in which the Prevertebrate lived. The other and almost synonymous role of the ectoderm was to protect the entire individual against the attacks of small, predaceous animals. By developing sensitiveness, an ability to react to any physical or chemical attempt to disrupt its integrity as an "individual," and to communicate this reaction to the locomotor mesoderm, the Prevertebrate became able to move itself from place to place and thus escape damage.

The fundamental properties of living substance as formulated by Albrecht von Haller in the second part of the eighteenth century, universally possessed by all living beings including the unicellular—irritability, or sensitiveness of

the outer skin to outside agents; conductivity, or ability to transmit impulses to the middle layer; and contractility of the middle layer, with the help of which the body was moved—all developed simultaneously in the Prevertebrate, for the development of any one alone would have had no effect and would have made no sense. Indeed, there is good reason to assume that all three properties were already present in the unicellular ancestors and were merely segregated and accentuated in the particular layers when this ancestor progressed to the point of becoming a multicellular Metazoön.

In the transformation of the ectoderm into a sensory receptor and integrator layer, small noxious agents, repeating their attacks innumerable times during untold ages, even though each agent represented but a slight potential injury, probably played by far the most important role. Larger, more powerful, and more perfectly organized predatory animals could have been only a negative factor in the evolutionary game at that early period. From attacks of such adversaries, the small and as yet poorly organized Prevertebrate had no chance of escape; and, with every individual perishing, there was no accumulation of phylogenetical experience and no resulting perfection. This became possible only when the Prevertebrate attained a higher level of organization.

Since the locomotion of the Prevertebrate was still limited, the creature is to be imagined as one of rather sluggish habits, spending its life mostly at the bottom of shallow waters. In several respects this was an advantage. Such a habitat offered shelter in the nooks and recesses between the grains of sand and gravel. Again, since all the minute microörganisms that died or were otherwise incapacitated tended to fall to the ground, there were good prospects for an abundant food supply.

Life on, or close to, the bottom had other consequences. For just as all food came from above, so also did most of the enemies. These, having necessarily a more advanced organization, not only possessing distinct sense organs with a fair range but also being able to move about at a fair speed, populated the watery habitat above the floor. In this world in which the primitive Prevertebrate lived, its principal interest, therefore, was "above." The part of the ectodermal layer facing up, the "back" of the Prevertebrate, received by far the greatest number of relevant, diversified stimuli, whereas the part facing down, the "underbelly," remained in a relatively sheltered, neutral position.

In due time the cells along the back of the Prevertebrate became more responsive, that is, more ready to react quickly to appropriate stimuli. Accordingly, they developed phylogenetically into the earliest "neurosensory cells" of the budding Vertebrate Phylum. When this stage of development was attained, the specialized receptor-conductor cells of this newly differentiated "neural or medullary plate" spread their processes farther up and down the longitudinal axis of the animal. Gradually they became more like the nerve cells or "neurons" of modern animals, capable of some limited integration of groups of the contractile mesodermal cells into a now faster-responding locomotor "muscular" system.

Briefly, at that stage of phylogenesis the Prevertebrate attained a level of organization above that of a mere "gastrula" and could be compared with the "neurula" of modern vertebrate embryology.

4. The inception of the vertebrate photoreceptors.—In the earliest period of prevertebrate evolution the outer ectodermal cell layer necessarily was barely sensitive. It responded but little at first and probably chiefly to directly applied physical and chemical stimuli. Light at this stage probably had only a small effect. However, a trace of the original, inherent responsiveness to light, as well as to heat, possessed by all living matter must also have been retained by the bodily tissues of the Prevertebrate, in particular by the ectoderm, the first tissue to be exposed to such stimuli. This photosensitiveness must have increased further in the neural plate—the streak of thickened ectoderm along the "back" of the animal.

At a certain slightly advanced phylogenetical stage, this stripe facing toward the ceiling of the water, whence light and enemies came, became in a sense an "eye" in its entire extent. It became more definitely so when the integrative ability of the neural plate and the locomotor ability of the mesodermal layer had progressed

further and were able to move the Prevertebrate from place to place more efficiently. For only now was the utilization of the advantage of an extended exteroceptive range possible.

Heretofore, with the responsiveness of the ectoderm, including the neural plate, restricted to immediate touch and chemical action, the protective role of this specialized locality was limited to stimuli caused by the attacks of small creatures and the action of various chemicals dissolved in water. When, in addition to being a "tangoceptor" and "chemoceptor," the neural plate also became a "photoceptor" or "eye," a real opportunity was given the Prevertebrate to survive against the attacks of bigger, better-organized, and faster predators. Now these could be detected at a distance which, no matter how small originally, was greater than immediate contact, which, when established, must usually have been identical with the lost battle for survival. The conversion of the neural plate into a photoreceptor meant an immeasurable achievement, an advantage upon which the entire future of the incipient vertebrate development was built.

5. PREVERTEBRATE OPTIC PRIMORDIA, THEIR UTILIZATION AND GRADUAL PERFECTION.—It is intriguing to speculate further upon what use the Prevertebrate, now in the possession of definite, even though as yet very primitive, photoreceptors, could have made of these wonderful new sense organs which widened its "world" from immediate surroundings to a radius of, perhaps, a few inches and later to a few feet.

The question is: Was the hypothetical creature positively or negatively phototactic or phototropic? To answer this, the only guide is the possible biological usefulness of either of the two properties. To an almost helpless creature, living on the floor of a world of water where most light came from above, any unusual change in illumination may have signaled the approach of a potential foe. Mostly it may have been a shadow, a dark patch moving on the bright ceiling, where the intensity of illumination was suddenly reduced in comparison with its "background." It was a sign of a prowling predator looking for a victim. Any shadow moving about, therefore, was likely to be avoided.

Practically the same would be true of any bright spot, such as might be caused by a reflection of light from the smooth, glistening surface of the body of an animal of prey suddenly appearing on the uniformly illuminated ceiling. Briefly, any unusual condition of light from the "viewpoint" of a Prevertebrate was a suspicious thing, to be avoided as rapidly as possible. The creature, accordingly, must have been attuned to an avoidance of all unusual positive and negative photic stimuli.

The next step in the development of prevertebrate photoreceptors was to concentrate and to increase sensitivity to photic stimulation, or to a sudden absence of it, at the cephalic, or front, end of the neural plate. As the Prevertebrate became more efficient in moving about, it was apt to develop a preferential use of either of the two ends of its elongated body. Moreover, it is probable that the entire process of elongation of the body consisted in a simultaneous and complex interaction of several factors—in the advantage of moving the body with one end ahead; in the elongation and bisymmetry of the body, facilitating locomotion by a reduction of resistance to water; and in an increase of sensitivity at the front end of the neural plate, which thus became a refined exploratory receptor organ. The increase of photosensitivity at the front end of the neural plate was, then, merely a continuation and intensification of the same tendency toward greater locomotive efficiency and thus toward greater safety, better food supply, and perhaps other advantages.

The various steps of a hypothetical evolutionary process of the incipient vertebrate photoreceptors may be understood if two things are constantly borne in mind. First, of a general character, is that each of the subsequent phylogenetical steps in the perfection of the photoreceptors was a goal in itself, serving particular biological needs of their possessors in particular circumstances. No matter how primitive the photoreceptors were at a particular evolutionary stage, they must have served their possessors fairly well and would have continued to do so, even if there had been no further "progress" (as countless primitive "eyes" of modern Invertebrates show).

That in the particular case of the Vertebrates the whole long-lasting evolutionary process eventually culminated in the creation of an

elaborate chamber eye is a consequence both of evolutionary mechanics and of the inherent properties of light and of physical environment rather than the result of some preordained supernatural wisdom. Or, to speak in harmony with modern times, the creation of the vertebrate eye, as of other parts of the body, cannot be looked upon as a result of purposeful planning by some omniscient "brain truster," "commissar," or "Führer" of the universe. That the vertebrate eye is what it is, instead of still being a simple patch of thickened ectoderm coating the "back" of a primitive creature crawling over the bottom of the ocean, is solely the result of its limitless original plastic potentialities and of the slight discrepancy between what the organ at a certain phylogenetical stage could do and what was required from it—just enough difference to push it toward further perfection.

A second consideration is the inseparable organic and functional dependence of the photoreceptor upon the remainder of the organism and, in particular, upon the neuromotor system (and to some extent vice versa). While it is possible to imagine a motor system of an animal without photoreceptors (since the former may be associated with other receptors, particularly those of touch), a reverse situation is unthinkable. An eye without nerves and centers and without a locomotor system would be an absurdity, without biological purpose.

The vertebrate eye, from its very inception and through all subsequent steps of its phylogenesis, must have had its appropriate nervous and motor counterparts to work with. For a simple photoreceptor, capable of utilizing light stimuli only a little, a poorly organized neuromotor apparatus sufficed, and vice versa. When the capabilities of photoreceptors expanded, more complex and more efficient nervous and locomotor systems developed, this in turn being a stimulus for the continuous perfection of photoreceptors. The separation of the stimulus-perceiving "photoderm" and its co-ordinated motor "mesoderm" is, in fact, an artificial procedure, at least in the early period of vertebrate phylogenesis, justified merely to facilitate an analytical understanding and interpretation of the factors and forces at work. The true process of the phylogenesis of the vertebrate eye may be likened to a continuous chain of actions and reactions, with mutual interdependence of various factors and with ultimate consequences for all. It is for this reason that the various attempts to explain the origin of the vertebrate eye by twisting and molding of parts of the embryonic ectoderm and neural tube alone, touching, as they do, merely upon a superficial phenomenon, must remain unsatisfactory (Balfour, Boveri, Froriep, Hesse, and others; *see* Walls 1939, 1942, 1943).

6. PROBABLE STAGES IN THE EVOLUTION OF THE VERTEBRATE EYE.—The various stages in the phylogenetical development of the vertebrate eye, one after another, and the external and internal factors responsible for them may be imagined in the following way (Fig. 436; *cf. also* Fig. 434, and sec. 1, this chapter).

The earliest stage (sketch *A*) would show, on a vertical section, the body of a Prevertebrate with a somewhat round or oval shape, with, perhaps, its dorsal extremity or "back" somewhat expanded. The ectoderm in this locality may have contained sensory cells not necessarily in a compact arrangement and not greatly differing in shape and properties from the other adjoining ectodermal cells. Such an only slightly differentiated patch, because of its general, nonspecific functional character, could be called a primitive sensory "omniceptor." It extended about equally down both sides of the body. It may be considered the phylogenetical inception of the "neural plate" of a modern vertebrate embryo from which the nervous system and the eyes develop.

As far as this ectodermal patch also responded to photic stimuli, it could be regarded as a primordial "cyclopean eye." Optically and therefore functionally, such an "eye," even though extremely primitive, was not in all points equivalent. The reason is obvious: with every change in position of the body or of the optic stimulus, a different group of photosensory cells of the curved surface was stimulated, and stimulated differently. If, for any considerable length of time, the creature was capable of maintaining an upright position, with its mid-sagittal plane of symmetry oriented vertically, a unilateral photic stimulus must have affected the side closer to the stimulus more than the opposite side. If, for example, of the two sources

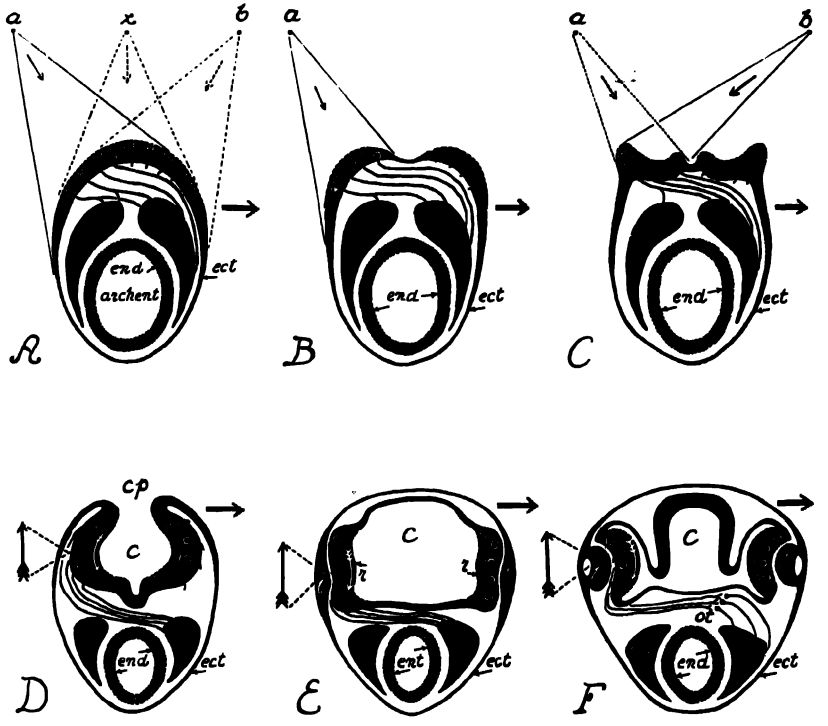

FIG. 436.—Probable stages in the phylogenetic origin of vertebrate eye and visual system, illustrated on cross-sections through the cephalic end of a hypothetical Prevertebrate or Vertebrate Ancestor. *A*, open neural-plate stage, with a single common everted integumental photoreceptor patch on "back," facing light stimuli (as in Earthworm), permitting crude local differentiation of intensity, and hence of direction, without image formation, with efferent fibers partly mixed but mostly decussated (a photophobic arrangement); *B*, neural-groove stage with photoepithelium concentrated in two lateral patches, with an incipient median invagination, with accentuated functional differentiation of "right" and "left," or of "direction," with efferent fibers largely decussated (a photophobic arrangement); *C*, incipient invagination of optic sulci of optic primordia into primitive optic cups, their incipient rotation under prevalence of contralateral stimuli (e.g., left primordium influenced from *b*), with each primordium facing opposite half of field of view, with a preponderant decussation of efferent fibers (a photophilic or photopositive arrangement subsequently compensated by a complete inversion of optoneural plate and restoration of original photophobic arrangement, as illustrated by next stage); *D*, complete invagination of optoneural plate, with inversion of photoepithelium and inception of tubular nervous system, approaching closure of neural groove or "cerebral pupil" (*cp*) into cerebral vesicle (*c*), rotation of primitive optic cups, and eversion of efferent connections, their convex face acting as a primitive collecting lens, with a lateral position of primordia and a complete decussation of efferent fibers, the effect of these changes being restoration of original photophobic arrangement ("turning of evolutionary corner"); *E*, closing of the cerebral pupil in a median *raphé* and completion of primitive cerebral vesicle (*c*), complete inversion of photoepithelium (*r*), lateral position of optic primordia, inception of nonnervous ectodermal dioptrical apparatus (*l*, lens placode) with early image formation, complete decussation of efferent fibers (a secondary photophobic arrangement); *F*, formation of essential parts of final vertebrate visual system, with "eyes" or secondary optic cups consisting of a nonnervous outer pigment layer (eliminating all light stimuli except those coming through pupil and lens) and an inner nervous or photosensitive layer or retina proper, with a cornea and lens at some distance from the retina, hence forming an image-producing dioptrical apparatus; nutrition of retina by a mesodermal chorioid, hence permitting the unobstructed passage of image-forming rays, and with completely decussated optic nerve fibers, resulting in the preservation of the original photophobic arrangement. (*Cf.* Figs. 434, 435.) *Labeling: a, x, b*, left, central, and right viewed points or source of stimulating rays of light; *archent*, archenteron or primitive gut; *c*, primitive cerebral vesicle; *cp*, cerebral pupil or passage before closure of cerebral vesicle; *ect*, ectoderm; *end, ent*, endoderm or entoderm; *l*, lens primordium, later lens vesicle; *md*, mesoderm; *r*, retina. Shaded arrows indicate direction of response or body movement (e.g., to right when left half or left optic primordium is stimulated by stimulus *a*).

of light, *a* and *b*, situated at two symmetrically opposite points, one—e.g., point *a*—sent a greater number of light rays, more rays would be arrested by the ipsilateral half of the body than by the contralateral half. This, for reasons of geometrical optics, must have taken place even if the transparency of the body was great, which was likely. In the modern *Amphioxus*, with its highly transparent body, such a lateralizing effect is absent because of the location of photosensitive cells in the center of its spinal cord and their particular orientation; hence the creature customarily lies on its side when at rest.

The effect of unilateral photic stimulation of the Prevertebrate must, necessarily, have been preponderantly unilateral: right, when the stimulus came from the right side, and vice versa. The total effect upon the creature, however, depended upon its internal organization—the efferent structures or organs of execution along which the excitation spread from the stimulated groups of photosensory cells to the locomotor or muscle cells of the mesoderm.

Initially, it is possible to imagine that each photosensory cell had a tendency to contact, by its short expansions, the nearest group of the mesodermal muscle cells. The connections and the effect of visual systems thus organized were essentially ipsilateral, the photic stimulation of the right half of the neural plate activating the muscles of the right side and vice versa.

Biologically, this would make sense only if the consequence was beneficial. Since at the earliest evolutionary stage a rather passive way of feeding or, at most, by means of cilia was probable, and considering an as yet poorly developed intrinsic organization of the Prevertebrate, which prevented it from embarking upon an active, hunting mode of life, it is most likely that a negative optokinetic response was far more advantageous—activation of the contralateral set of mesodermal muscle cells. When a threatening shadow or an ominous bright spot appeared on one side within its effective range, the activation of the contralateral musculature effected a contralateral deviation and a flight in the opposite direction from the approaching potential danger. The way to accomplish such contralateral response was by making the efferent connections of each half of the neural plate cross to the musculature of the contralateral half of the body.

Such partial or preponderant decussation, a "primordial chiasma," was advantageous in yet another respect: it offered a simple mechanism for an alternating activation of the right- and left-side myotomes, a prerequisite for rectilinear, unidirectional movement of the body. In order to achieve this, the other addition required was a "central integrator" to regulate the alternating activity and keep it up for some time. This, too, could easily have taken place by making some efferent fibers of one side establish contact with the sensory cells of the other half of the medullary plate, instead of directly with the contralateral muscle cells. Once this stage of differentiation was achieved, a foundation was laid for the development of the future complex central nervous system of Vertebrates.

The visuosensory and visuomotor mechanisms, in the light of the preceding speculation, seem like two sides or aspects of a basically identical apparatus. Both have contributed equally, or almost so, to the rise of the central nervous organ, the brain. The phylogenetical inception of both components must have been practically simultaneous. Photosensory cells without effectors would have had no influence upon the behavior and welfare of the Prevertebrate and would never have developed; the effector structures alone would likewise never have arisen, nor could they have existed independently (unless served by other receptors). This assumption is self-evident, even though it is plausible that both constituents of the incipient visual system—the receptive-sensory and the effector-motor—have evolved out of the same primitive tactile-motor or possibly chemoceptor system which preceded them.

The next stage in the evolution and perfection of the eye—or rather visual system—was attained with a segregation of photosensory cells into two patches, each facing up and somewhat laterally (sketch *B* in Fig. 436). That this should have been the case was logical and unavoidable. With a vast majority of visual impulses coming from the lateral direction, in a creature now capable of moving about, the lateral impulses prevailed in the long run (since in an aquatic habitat, limited by two horizontal levels, a ceiling above and a floor below, there is

vastly more "biological space" laterally than "above" or "below"). In consequence, the dorsolateral parts of the originally uniform photosensitive neural plate became thicker. In early human embryos these two localities appear as two "optic primordia" or "retinal oriments," from which and around which the two definitive eyes develop (Fig. 434, sketch *A*).

The third stage (sketch *C*, in Fig. 436) was characterized by dents or depressions in the two optic primordia (*cf.* sketch *B*, in Fig. 434). First to appear were shallow primitive optic sulci or grooves (*os*). These sulci gradually deepened until each primordium resembled a cup. The deepening of the two primordial optic cups was coincident with another remarkable change—rotation of the cups from the original position, in which their concavities faced up to one where they faced each other (Fig. 436, *D*).

The functional factors which have necessitated such profound changes are difficult to fathom. Heretofore the relation of cause and effect was rather clear: at first, a single photosensory area covering the more or less convex "back" of the body, with superficially located photosensory cells first to meet the light rays coming from above (sketch *A*); then, when the creature became more active, a concentration of the photoreceptors at its anterior end and their segregation into two somewhat laterally placed patches partly facing up, and preponderantly stimulated by the rays coming from either the right or the left side (sketches *B* and *C*). Such an arrangement appears advantageous, since the majority of photic stimuli arrived from the sides. Why, at this point in evolution, should this arrangement be abandoned, and a new one adopted that amounted to a veritable revolution (sketch *D*)?

The factors responsible for this reversal remain, for the time being, hidden. Whatever they were, the urge must have been compelling. The turning point may have been reached when, at stage *C*, the stimulation of the contralateral primordial optic cup gradually increased until it finally threatened to prevail—that is, stimulation of the left cup by rays coming from the right side (point *b*), and vice versa. With the efferent fibers largely or completely crossed, no biologically useful purpose would have been served by this, unless the Prevertebrate fundamentally changed its life habits at this stage and frankly became positively optotactic.

Since the creature still must have been a small and rather sluggish animal, with its sensory and motor apparatus precluding the great mobility necessary for a predator, this was unlikely. In this situation any unilateral stimulation would have brought it directly into the path of its foe rather than away from it, as heretofore. Here a complete inversion of the two optic cups may have restored the former advantageous situation, provided that the decussation of the efferent pathway also was complete, as indicated in sketch *D*. Now, by a relative shading-off of the contralateral optic cup, made more effective by inside pigmentation (*see* Eycleshymer), the normal negative optotactic situation was again restored, or, since the change was gradually accomplished, the original situation was preserved, and stimulation was again chiefly concentrated upon the optic cup ipsilateral to the stimulus. With the efferent fibers crossed, the beneficial photofugal reaction, leading away from the danger, could again be effectuated (indicated by horizontal arrows in our sketches *D*, *E*, *F*).

A complete inversion of the primitive optic pits had other important advantages. From now on, the stimulating rays of light, instead of reaching the primordial photosensory epithelium directly, had to penetrate through the whole thickness of the overlying ectoderm and the tissue between. While this may appear to be an impediment to effective penetration of light, in the subsequent evolutionary stages it became manifestly transformed into an advantage. In the phase represented by sketch *D*, the bulging convex face of the body, inclosing the optic primordia, may already have acted as a collecting lens, by which the intensity of stimuli focused upon photosensory cells behind was increased.

This situation remained basically unchanged in the entire further phylogenetical perfection of the vertebrate eye. When at the following stage (*E*) the two localities of the ectodermal integument contiguous to the retinal primordia thickened into the lens primordia (*l*), as illustrated by the ontogenetical phase *B* in Figure 435, and the formation of double-walled secondary optic cups was initiated (sketch *F*, in Fig. 436), the integumental ectodermal lens, increas-

ing in size and structural homogeneity and probably located at a distance from the photosensory layer equal to its focal length, was a much more efficient dioptrical apparatus than the outside curvature of the optic primordium and its integumental covering alone (as in sketch *D*).

There are a few more phylogenetical deductions of special interest, which, without any undue stretching of the imagination, one may read into the ontogenetical record registered in the early stages of vertebrate embryology. During the earliest phylogenetical period the photoreceptor organs were located dorsally, at the "back" of the Prevertebrate's body, facing upward (sketches *A*, *B*, and *C*), as exemplified by the ontogenetical stages *A*, *B*, and *C*, in Figure 434. In the subsequent stages the optic primordia, simultaneously with their inversion (*D*), moved downward, eventually to assume a frankly lateral or ventrolateral position (sketches *E*, *F*, in same figure).

At its inception the Chordate Phylum was probably represented by bottom dwellers, as already mentioned. From this lowly and restricted habitat the somewhat advanced forms gradually worked themselves into the upper reaches of their fluid world, eventually becoming frankly pelagic. This they achieved after developing more perfect eyes and more efficient motor and central regulating mechanisms. When they began to move freely through the upper regions of the water, the direction of their visual interest also changed. Whereas in the beginning the "visual world" of the Prevertebrate was "above," at a later period it became "lateral." For this, laterally situated eyes were appropriately placed sensory organs.

The road from the floor to the upper regions of the water and toward higher evolutionary possibilities was the road toward the source of light. The means which alone permitted this was the perfection of the visual organs. The alternative, without this improvement, was to remain on the ground or partly buried in it, a habit still practiced by the contemporary eyeless *Amphioxus*. The advantages and consequences of this "visualization," or increasing dependence upon visual organs of the chamber-eye type, are clear.

Once more casting a glance upon embryology as a clue to the phylogeny of the vertebrate visual system, one cannot help being impressed by the precociousness and relative size of the visual primordia. In the earliest embryo, more than at any other period of the subsequent development and maturity of the individual, the visual organs dominate. Here they represent a substantial part of the central nervous system (later to become brain and spinal cord), wherein most of what is to be the brain belongs to the visual primordia.

Does this indicate that in the Vertebrate Ancestor most of the "brain" consisted of the eyes? That the huge nervous organ called the brain, so characteristic of the advanced Vertebrates, received its first and most potent impetus from visual stimuli? That, accordingly, the Vertebrates from their inception were principally "visual animals," "creatures of light and sight"? That the "visualization" of Vertebrates or a biologically almost complete dependence upon sight adopted by them was the magic formula by which they climbed from the twilight of the ocean's floor into the upper reaches of the water and finally out of it into the unlimited photic freedom of the air?

SEC. 3. THE PHYLOGENETICAL ORIGIN AND FUNCTIONAL SIGNIFICANCE OF DECUSSATION OF THE VERTEBRATE VISUAL SYSTEM

1. Introduction.—One of the most remarkable and at the same time most baffling features of the vertebrate visual system is the decussation of the optic nerves. In the lower classes, the Fishes, Amphibians, Reptiles, and Birds, the decussation is considered to be complete (Figs.

188–90). In the Mammals a smaller or larger portion of the fibers remains on the same side, thus producing a partial decussation. The proportion of the nondecussating to decussating fibers increases from a small fraction found in the Rodents (Fig. 191) to approximately one-third or more in the Carnivores (Fig. 192) and the Primates (Figs. 186, 193–99; *see also* chap. VI, 5, and chap. XIV, and corresponding figures).

From its universal occurrence it is obvious that this anatomical feature must be of fundamental importance in the bodily organization and in the physiology and biology of the Vertebrate Phylum. Hence its phylogenetical inception must be sought in those factors and circumstances that gave rise to the Vertebrates.

In order to determine what factors, in what way and for what biological purpose, created the crossing of the optic nerves, various hypotheses have been proposed. Of these, the most plausible is the one by S. Ramón y Cajal (1899, 1909–11). Briefly, it is as follows. The total decussation of the optic nerves found in the Inframammalian Vertebrates represents a phylogenetical phase preceding a partial decussation. It is related to the centralization of the nervous system, culminating in the creation of the brain. The decussation appears first in the afferent or centripetal visual pathway and is followed by a decussation of the efferent or motor pathways correlated with the first.

In the Inframammalian Vertebrates, e.g., in a Fish, a Frog, a Lizard, or a Bird, each optic nerve terminates in the contralateral optic lobe or tectum of the midbrain (Fig. 437, right-hand sketch). The right eye, accordingly, sees to the right with the left optic lobe, and the left eye sees to the left with the right optic lobe. The two monocular fields of view are separate, with no overlapping in the center. Such an arrangement may be called "panoramic." In it, owing to an assumed absence of binocular convergence and of superimposable "corresponding retinal points," a third dimension or stereopsis would be absent in a subjective experience (this and other similar statements must be qualified in view of our own observations to the contrary, made on a Golden Eagle, Barn Swallow, Anole Lizard, and Pike; *see* chap. XIV).

Even without binocular overlapping, which S. Ramón y Cajal assumed was absent, in a panoramic system the two eyes always work together. Since the retinal images, because of the action of the chamber eyes, are inverted, they are necessarily projected in an inverted way upon the optic lobes (*C*). However, because of complete decussation, the natural or logical order of the central images is again restored.

Just as the two monocular fields of view are spread in one plane, alongside each other, and are natural extensions of each other, so the two visual centers, the optic lobes, are placed side by side, the details of the visual fields represented therein being arranged in a logical way, corresponding to the details of the panoramic view of the two eyes. The only difference is the reverse order, caused by the inversion of retinal images, the right end of the common panoramic field of view being represented at the left end of the left visual center, and the left end of the field at the right end of the right visual center. In this way a single "mental image" of the entire panoramic field of view is created.

This arrangement is possible because of complete decussation of the optic nerves. If there were no decussation and each nerve terminated in the optic lobe of its own side, the two halves of the "mental image" would be arranged illogically, that is, would be incongruous or incompatible with each other (as shown in the left-hand sketch, Fig. 437). As it is, the "mental image" is always complete, each half of it representing one half, the contralateral, of the external, visible reality. In a panoramic visual system thus organized, the "symmetrical points" in both optic lobes represent two different localities in visual space, and there is no "functional duplexity." Putting it into a single phrase, "the decussation of the optic nerves is motivated by a necessity to restore the lateral inversion of the two images caused by the action of the lenses" (that is, chamber eyes).

In the mammalian visual system, S. Ramón y Cajal assumed that there is a common binocular field of view caused by the "parallel" position of the two visual axes (Fig. 438). Here a portion of the optic nerve fibers does not decussate, and parts of both retinae, working together, send their fibers to the same cerebral hemisphere. Hence each cerebral hemisphere is related to the homonymous parts of both reti-

nae or to the contralateral parts of both monocular fields of view. Each point of a visual object, depicted at the "corresponding points" of both retinae, is projected on a single point in either the right or the left cortical center, depending on its position in the viewed object.

Partial decussation, accordingly, permits the formation of a single "mental image," *Rv*, comparable to that in the Inframammalian Vertebrates, made up of a right and a left half, representing the left and right halves of the viewed object. The important difference is that, whereas in a panoramic system each half of the viewed object is seen with only one eye monocularly, in a stereoscopic system each half of the object is viewed to a greater or lesser extent with both eyes, even though the impressions from both eyes come together in the same half of the brain, the contralateral relative to the viewed object. In this way the advantage of decussation is fully preserved, owing to which the two halves of a "mental image" remain congruous, each being a natural or logical extension of the other half (but for the lateral inversion, which is immaterial). The two visual centers in the brain of a Mammal may be looked upon as a

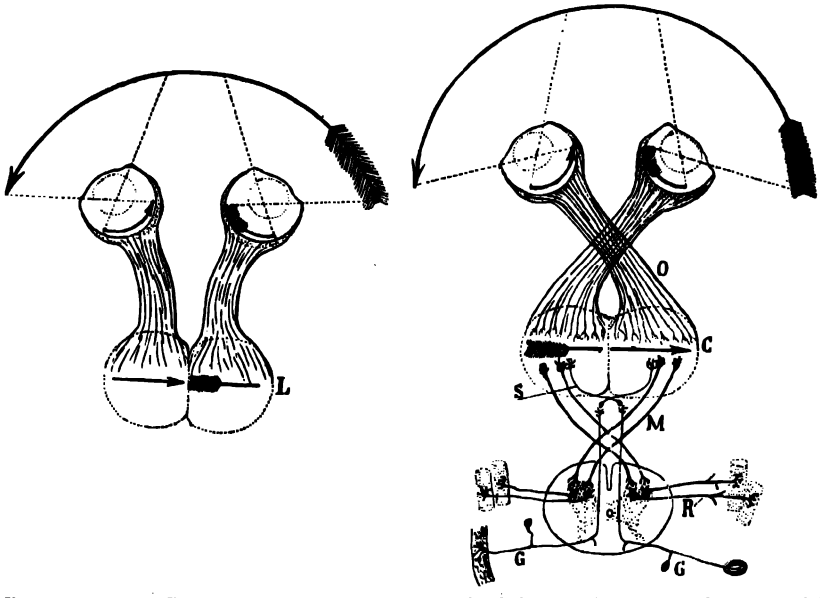

FIG. 437.—Ramón y Cajal's diagrams purporting to explain the phylogenetical origin of the decussation of the optic chiasma and of the functional organization of the vertebrate visual system. Left-hand sketch illustrates the misplacement of two central images formed in optic lobes (*L*) of the brain received by two retinae, in a hypothetical case where optic nerves remain uncrossed (no such case is on record among Vertebrates). Right-hand sketch shows the effect of total decussation found in all lower Vertebrates such as Fishes, Amphibians, Reptiles, and Birds and the almost total decussation in Lower Mammals possessing panoramic vision. In each case each retinal image represents half of the viewed object, each image being inverted in the same sense, as against the particular half of the object (owing to the dark-chamber action of the eye). In the first case, where there is no decussation, the two single central images are projected ipsilaterally, hence incongruously, not forming a single harmonious central representation of the total object. In the second case the ocular inversion of two retinal images is compensated by a chiasmal decussation, which makes the two central images (in *C*) assume a logical order, with the right retinal image projected upon the left center, and the left image upon the right center, both fitting together and forming a single harmonious central image. The optic decussation in turn has inforced a secondary decussation of the motor and somesthetic pathways, making possible co-operation of these systems with the visual system. From S. Ramón y Cajal, *Die Struktur des Chiasma opticum*, etc., 1899; also *Histologie du système nerveux*, v. 2, Figs. 242, 243, 244, 245, 1909–11. (*Cf.* following figure.)

single cerebral retina made up of two halves, one half in each cerebral hemisphere, each half representing one half of the common field of view.

Both types of visual system—the one with complete decussation, and the other with partial—require a crossing of motor fibers in the brain. This is necessary to preserve the original functional relationship between the sensory and the motor mechanisms of the body working together, e.g., between the right monocular field, or right halves of both monocular fields of view, and the limbs of the right side; and vice versa, as illustrated in the right sketch in Figure 437.

S. Ramón y Cajal's hypothesis of the visual decussation, brilliant and effective though it appears to be, did not become popular or was rejected outright. The blame for this was chiefly the general aversion to a new idea. Wundt and Spitzer objected to the assumption of the accurate projection of retinal images upon the cortex.

Wundt's objections to an accurate adaptation of the ipsilateral and contralateral fibers in the cortex along which the impulses from the "corresponding retinal points" arrive are invalid, since precisely this was proved by our experiments (*see* chap. VI, 7; chap. VII, 5, 6). Both Wundt's and Spitzer's opposition to an accurate, quasi-photographic reproduction of retinal images in the striate cortices, like other similar objections, was also nullified by modern research, including electrophysiological experiments (Talbot; Talbot & Marshall 1941; Marshall & Talbot 1942; Köhler). Wundt's demand for a vertical chiasma in order to compensate for the vertical inversion of the retinal images in the brain is positively naïve.

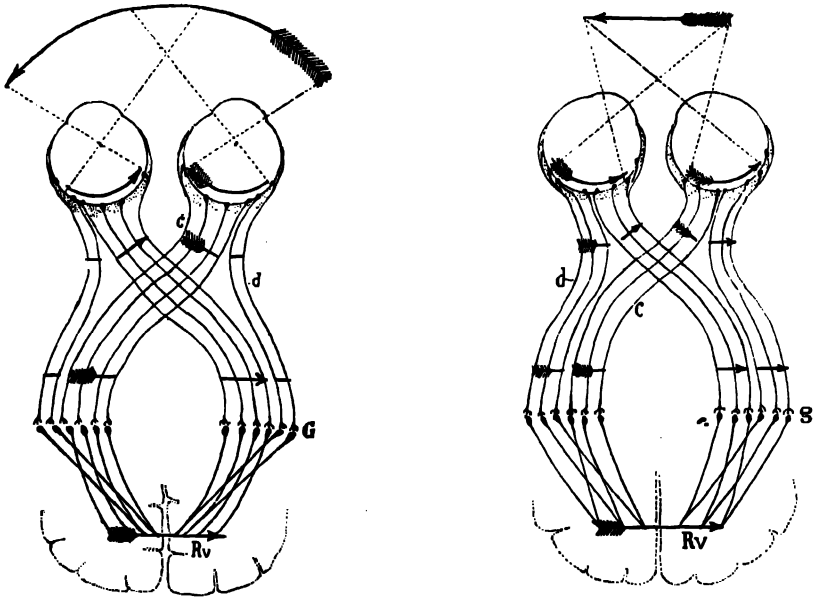

FIG. 438.—Additional sketches of Ramón y Cajal illustrating the formation of a single cerebral image in Man and in Higher Mammals which have partial decussation in optic chiasma and binocular vision. Left-hand sketch represents the visual system of a Mammal with mixed panoramic and binocular vision, the right-hand sketch that of Man and Higher Mammals with a common binocular field of view where a single central image is formed. Note that in Man the visual system also belongs to a mixed type (*see* Fig. 439). *Labeling: c*, crossed, *d*, uncrossed fibers; *g*, lateral geniculate nucleus and pulvinar of the thalamus; *Rv*, visual area of cerebral cortex with a "psychic image."

The objection to S. Ramón y Cajal's emphasis upon the "lens" of the eye as a factor responsible for the inversion of the retinal image and a consequent optic decussation made by Jacobsohn-Lask belongs in the same category, since making the effect of a *camera obscura* or "dark chamber" responsible for it would have been more accurate, even though it is probable, as will be discussed subsequently, that the chamber eye may have been merely a factor in the perfection, and not in the origin, of the decussating arrangement of the visual mechanism.

Spitzer's attempt to explain visual decussation by purely mechanical factors is highly artificial, improbable, and mechanically and logically impossible. Whereas a torsion may conceivably be invoked to explain a decussation of a single system, such as the visual, it could not account for the other numerous decussating systems scattered over the entire length of the neuraxis. Rádl's idea that "the optic nerves of Vertebrates decussate because of the inversion of the retina" lacks any basis.

Perhaps the most detailed study of the problem of nervous decussations in general is that of Jacobsohn-Lask. His conclusion is that the following factors are involved: (1) the basic form of the primitive nervous system, which is a plexus; (2) the basic form of the animal body, which is that of a tube; (3) the functional and structural adaptation of the nervous system to the tube-shaped animal body and to the bilaterally arranged inner and outer parts of the body. Besides these, there are, according to Spitzer, probably many additional factors whose interplay has produced decussations of the particular systems, varying from a total crossing to one where numerous fibers remain ipsilateral.

2. Probable causes of decussation of the vertebrate visual system.—What microdynamical factors working in the growing nervous tissue of an embryo have brought about the decussation of the vertebrate visual system, and do so during the ontogeny of every Vertebrate, remain unknown. This is a problem which should rightfully be dealt with by developmental mechanics and, in general, by embryology. Whatever these factors are, it is apparent that they are identical with, or similar to, the as yet unknown "forces of growth" responsible for the development and differentiation of the nervous system in general. An attempt to describe the working of these forces was made in the hypothesis of "neurobiotaxis" and the like (Ariëns Kappers 1908, 1916–17, 1922, 1929, 1941; Ariëns Kappers, Huber & Crosby 1936).

The functional effect of the crossing of the visual pathways is more understandable than its causes. An attempt may therefore be made to explain teleologically or in terms of a functional "purpose" what the incipient and subsequent factors may have been which caused a complete crossing of the optic nerves in the inframammalian vertebrate classes, a phylogenetical process that eventually culminated in the partial crossing that is characteristic of the Order of Primates: Tree Shrew, Lemur, Tarsier, Monkey, Ape, and Man.

It is remarkable that in all classes of Vertebrates below the Mammals the decussation in the chiasma, as far as is known, is complete (for a slight qualification of this statement *see* data on the Pigeon, chap. VI, 5 [3]). Whether or not this was an original condition present in the earliest stages of the nascent Craniate-Vertebrate Phylum or in their immediate Prevertebrate Ancestors cannot be answered, owing to an absence of information (*see* sec. 2, this chapter). However, from the above-mentioned fact it is permissible to hypothesize that, after an initial chaotic condition with a diffuse or irregular arrangement somewhat exemplified by an Earthworm (W. N. Hess 1924, 1925), at an early stage of vertebrate phylogenesis the photosensory epithelial cells tended to gather into two lateral patches at the rostral end of the body (Fig. 436, *B*).

The next permissible assumption, after what was said in the preceding section, is that, before any central nervous system was organized, the photosensory cells of the ectodermal layer may have been directly related to the muscle fibers of the mesoderm. If the primitive Prevertebrate was a creature inclined to react to any sudden photic change, be it light or shadow, negatively, as was likely, the connections had to be mostly crossed. The functional effect of such an arrangement would be a turning of the rostral end of the body away from the stimulus. Such a re-

action, while better than an entirely passive immobility, was a poor way to avoid extinction by prowling predators. For this, the development of a more efficient receptor-effector system, capable of initiating not a single or a few discordant optofugal aversion reactions but a sequence of well-co-ordinated avoidance movements, was required.

A well-organized avoidance reaction, followed by a flight from any sudden photic stimulus that indicated a potential danger, was biologically most useful. Such could be carried out if the Vertebrate Ancestor, the Prevertebrate or Protovertebrate, developed an elongated, frankly bilaterally symmetrical body, supported by a stiff axial notochord to give a hold to the segmentally arranged muscles. The anatomical requisite for the working of such a locomotor mechanism was a concentration of the nervous system into a spinal cord.

In due course of time the leading segments of the cord became condensed into an incipient brain—a *protencephalon*—to initiate and maintain a proper sequence of laterally alternating movements of the body. The brain, too, in a bilaterally symmetrical animal also had to consist of two halves, each concerned preponderantly with one half of the body. The final step would be a differentiation of a central co-ordinator regulating the activation of the right and left bodily muscles alternately.

If one imagines a Prevertebrate as resembling a Fish, the following would be its basic optomotor mechanism. First, the optic nerve fibers originating in either patch of the photosensory epithelium would have to decussate completely in order to terminate in the contralateral half of the brain. This could be considered merely as a further differentiation of the original condition, where the optic fibers terminated directly in the contralateral muscles. It certainly appears the most economical way to elicit a simple avoidance reaction, such as a turning of the head away from the stimulus, by twisting the body as the result of a contraction of the contralateral muscles.

In order to give the body a forward propelling thrust, however, activation of the ipsilateral musculature is also necessary, with the tail pressing against the inertia of the ipsilateral mass of water, again resulting in a turning of the head end of the body away from the stimulus. This appears to be a more effective response, since, in addition to a simple aversion, it gives the body an initial propelling motion in the rostral direction. In order to accomplish active, purposeful flight, the same kind of activation, alternating in time on both sides, is required, with a resulting propelling of the body in the desired direction, away from the noxious stimulating object.

The anatomical condition making possible, first, an activation of the contralateral musculature in response to an ipsilateral stimulation was a decussation of the optic nerve fibers. When a bilaterally symmetrical brain developed, the optic fibers, assembled into optic nerves, continued to be decussated, terminating in the contralateral half of the brain. The motor fiber systems originating in the two cerebral halves may, at first, have remained uncrossed, or preponderantly so, thus preserving for a while the original completely decussated optomotor arrangement.

A partial recrossing of the motor system may have taken place as the next phase, as the necessity arose for the development of alternating body movements capable of propelling the Vertebrate Ancestor forward. Eventually, as the recrossing of the motor system prevailed over the original nondecussating arrangement, with a development of alternating forward movement over the simple unco-ordinated twisting, an evolutionary change was attained which further increased the bilaterally symmetrical organization of the Prevertebrate.

In summary, the decussation of the vertebrate visual system and a preponderantly crossed arrangement of the correlated motor system may be looked upon as a mechanism originally created, first, for the inducement of a simple negative response and, subsequently, for the initiation and carrying-out of sustained escape movements.

3. Phylogenesis of the decussation of the visual system.—The development of a decussated visual pathway through which a co-ordinated motor response could be elicited apparently took place during a remote period of prevertebrate evolution, long before a dioptrical apparatus was added to the eye—in fact, before

a peripheral photoreceptor built upon the principle of a *camera obscura* or "dark chamber" was created. The decussation of the visual system may, at first, have been entirely motivated by the need for wholesale activation of the contralateral musculature, preceding a biological necessity for the perception of a detailed "figure" of stimuli "painted" on a peripheral photoreceptor surface, such as a retina.

In producing the completely decussated visual system found in most vertebrate classes, neither a narrowing of the photosensitive epithelial surfaces into hollow chamber eyes nor a closing of the latter by a refringent cornea nor an addition of a crystalline lens could have played any role, as was assumed by S. Ramón y Cajal (1899, 1909–11) and by Flechsig (1899). As a glance at Figure 436 shows, the effect of the chamber eye, with or without a dioptrical apparatus, is merely an inversion of the image, both on the retinae and in the visual centers of the brain, which by itself could not have been a factor in the creation of visual decussation. The decussation of the visual system of Vertebrates and probably of all other animal phyla wherever such an arrangement is found, especially of the Arthropods and Mollusks, appears to have been a primary or original condition caused by the bilateral symmetry of the bodily organization already present at the very inception of vertebrate phylogenesis, as discussed in the preceding section.

The bilaterally symmetrical vertebrate organization, in turn, was a result of molding forces and factors active over a long period of time. The crucial point in this process of phylogenetical trial and error may have been reached when a primitive Metazoön had evolved a tendency to move in one particular direction in preference to others. This stage may be roughly illustrated by the "gastrula" of a young developing Lancelet (*see* Parker & Haswell 1940). The next stage in vertebrate evolution was a further elongation of the body similar to that of an early embryo of the same Acranian. Such an animal obviously requires an alternate activation of the contractile structures of the two halves of its body. A regulating mechanism capable of bringing about such a sequence of alternating contractions must be arranged crosswise.

In this way the contralateral muscle fibers could be influenced by the ipsilateral stimuli. As an activating agent, any stimulus capable of eliciting a response would do, the most likely in the earliest phylogenetical stage being mechanical-tactile stimuli. The alternating activation of the two halves, in turn, was the means by which locomotion was achieved. This stage was attained as soon as the tissue became sufficiently differentiated, part of it becoming responsive to the external stimuli and part capable of conducting impulses to yet other structures that developed contractility.

When out of an initial chaos of diffusely propagated impulses and haphazard motor responses, more definitely unidirectional movements gradually developed in consequence of the differentiation of the simple sensory-motor system, a foundation was laid upon which a more efficient machine could be built. Some, possibly the majority, of the conducting nerve fibers of this sensory-motor apparatus must have been crossed, since only in this way could the physical obstacles encountered in unidirectional locomotion have been efficiently avoided.

When, as a further step in organizational perfection, the ectoderm of the rostral extremity of a Prevertebrate became photosensitive, it already had an efferent tangomotor system to use, with the help of which it could further differentiate its own optomotor system. Almost simultaneously, an integrating mechanism must have been differentiated next to the principal tangoreceptors and photoreceptors, by which the rostral extremity became the leading end of the now functionally polarized animal body.

At its phylogenetical inception the Vertebrate Ancestor was but a minute clump of loosely associated cells, a *morula*, which subsequently developed into a minute sac inclosing a cavity, a *blastula*, which in the course of further evolution, by a process of invagination, became transformed into a *gastrula*, a double-walled sac. At this stage the feeding of the creature later to become a Vertebrate was probably by some type of ciliary motion of the epithelium. By this motion, solid food particles, in addition to dissolved nutrients, were brought into its *archenteron*, or primitive gut, without the animal's need for active locomotion.

When, in consequence of an increased de-

mand for nourishment, the creature became more active, it had to develop some sort of locomotion to hunt for its food supply. This, in turn, seems to have been the prime cause of the functional polarization or differentiation of its body into a sensitive frontal end with a *prostoma*, or primitive mouth, and the rest of the body trailing behind. A Lancelet larva at the gastrulation stage may serve as an illustration (*see* Parker & Haswell).

Whether in this phase of vertebrate evolution photic stimulation contributed to a functional polarization of the sensitive front end, or whether this significant modification was wholly a product of tactile and chemical stimulation, there is no way of telling. At the least, however, photosensitiveness must have stepped in at a very early period of phylogenesis. The precociousness and the bulk of the retinal oriments in the earliest stages of a developing vertebrate embryo seem to support this view (*see* Fig. 434).

As soon as a photosensitive region developed in the Prevertebrate, its influence began to be felt. Here again, assuming a photonegative responsiveness, a decussating efferent connection seems most useful biologically. The two major influences—the sensorimotor and the optomotor—worked concurrently. Subsequently, the sense of vision and the visual system became of paramount importance.

During the remainder of vertebrate evolution, including its latest stage, the Mammals, the decussation of the visual pathways remained a fundamental factor influencing the architectural plan of the entire central nervous apparatus, as suggested by S. Ramón y Cajal (1899).

4. The chamber eye and the organization of the vertebrate visual system.—The creation of the chamber eye equipped with a dioptrical apparatus must be looked upon as the next important phase in the evolution of visual mechanisms after the differentiation of the photoepithelium. It was the most important single step in the perfection of visual discrimination, particularly of epicritic vision, requiring high visual acuity.

The chamber eye and the complex organization of the visual system of modern Vertebrates appear to be the terminal phase of a long evolutionary process, of which there is no record. It must have taken place very early in phylogenesis and must have been concluded early, since the chamber eye is standard equipment in all Vertebrates, including the most primitive, in this respect resembling the early appearance and universal presence of visual decussation.

The formation of the chamber eye must have been preceded by a whole series of intermediary stages (Fig. 441). To illustrate this, one may point, first, to the simple epithelial patches or eyespots of a Medusa or a Starfish. As the next step, the cup-shaped eyes resembling those found in some Gastropods, e.g., *Patella*, may have followed. The subsequent and more elaborate stages may have resembled the vesicular eyes provided with a dioptrical apparatus found in varying degrees of complexity in some Flatworms (*Platyhelminthes*), certain Annelids (*Nereis*), Onychophors (*Peripatus*), many Mollusks (*Chiton;* Gastropod Snails, *Triton*, *Helix*, *Trochus*, *Turbo*, *Murex*, *Limax*, and others; certain Mussels, such as *Pecten*), the ocelli of Arthropods (Crustaceans, Insects, Arachnids), the eyes of Chaetognates (*Sagitta*), the remarkably simple pinhole chamber eye lacking a dioptrical system found in the primitive Cephalopod, Pearly Nautilus (*Nautilus pompilius*, *N. macromphalus*, and others), and, finally, the advanced eyes of the Cuttlefish, Squid, and Octopus, equipped with a cornea, lens, vitreous, iris, retina, and other detailed structures, making them closely resemble vertebrate eyes. From this comparison the compound eyes of the Arthropods and others are omitted, since they follow a different pattern. (For illustrations and other details *see* Hesse, Willey, Buddenbrock, Plate, Hagedoorn, Parker & Haswell, R. Hertwig, Van der Horst.)

The preceding examples may illustrate the phylogenetical transformation of the peripheral photoreceptors from the simple epithelial patches or "dimple eyes" into efficient dioptrical instruments, "chamber eyes." These were capable of better utilization of light stimuli, manifesting itself in greater acuity, and in this way made possible further perfection of the visual system, as subsequently discussed. The fact that the eyes in most animals below the Vertebrates are close together and in a definite posi-

tion at the rostral end of the body, closely related to the cephalic accumulation of nerve cells called the brain or cerebral ganglions, indicates a certain degree of co-operation of the two sides in response to light stimulation (*see* Rochon-Duvigneaud 1933, 1943).

In the Vertebrates the tendency of both eyes to work together is manifest. In most Fishes the two monocular fields seem to approach or partly to overlap. A similar arrangement with two fields contiguous or overlapping only slightly seems to be present in most Vertebrates below the rank of Mammals and in most Infraprimate Mammals with limited sight.

In this "panoramic visual system" the two single fields of view are more or less contiguous, usually at the front end. The two laterally inverted ocular images projected in the two visual centers, the optic lobes of the midbrain, which function as "projection screens" of the brain, are oriented homonymously or in the same way and together form a single complete cerebral image. Each cerebral half-image is a natural continuation or extension of the other half, precisely as are the two halves of the visual object toward which the view is directed. A complete cerebral image, accordingly, is a fairly accurate replica of a viewed object. The only essential difference is an inversion, especially lateral, in the brain, the right end of the cerebral image corresponding to the left end of the viewed object, and vice versa.

The inversion of each of the two half-images in the two cerebral visual centers, the right and the left, and of both when looked upon as a single complete cerebral image is caused by two factors: one, the effect of the eyes acting as "dark chambers," owing to which only certain rays coming from a viewed object are permitted to enter and thus to form the retinal image, and, second, the decussation of the optic nerves in the chiasma, by which the natural order of the two half-images, disturbed by the inversion of the two retinal images, is re-established in the brain.

Obviously, without decussation of the optic nerves, each half-image of the viewed object would be projected inverted in the ipsilateral visual center, the two cerebral half-images would thus be placed in the wrong order or sequence, and the objective situation would be falsified. The effect of total decussation of the optic nerves is the preservation of a natural sequence of details of a topographical order in the visual centers of the brain as existing in the objective external world.

In a strictly panoramic visual system, with total decussation and no overlapping of the monocular fields of view, each point on the cerebral screen represents only one point in either of the two retinae or in each monocular field of view (Fig. 437, right-hand sketch). How often a strictly panoramic visual system is realized among the Vertebrates and animals in general, except in the lowliest forms (e.g., Flatworms), remains a problem for future investigation to solve. It appears that in most living Vertebrates, including the Fishes, there is some overlapping of the two single ocular fields, even though it is restricted, usually in front of the head.

Extensive binocular overlapping of both fields of view in front of the snout and great mobility of the eyeballs are found, according to our own observations, in species largely depending upon vision, as, for example, the Pike and the Trout (*see* following chapter and Figs. 450–55). The macrosmatic and macrogeusic species, e.g., Carp, principally depending upon smell and taste, have an overlapping of but a few degrees, according to Tschermak (1915). A surprisingly extensive binocular field, amounting in a vertical coronal plane to not less than 120°, is found in the Northern Brown Bullhead (Fig. 457). The minute dimensions of the eyeballs and poorly differentiated retina in this species and its nocturnal habits, however, indicate the absence of high acuity and the use of sight chiefly as a photophobic warning sense, and also probably for a rough orientation in space. (*Cf.* chap. XIV.)

In numerous Inframammalian Vertebrates entirely dependent upon sight, such as the diurnal Birds of Prey (Hawks, Eagles, etc.) and the Swallows, with eyeballs highly mobile in the horizontal plane and consequently with an extensive active and adjustable convergence of the two visual axes, there is wide overlapping of the two monocular fields of view (*see* chap. XIV). A similar situation obtains in the nocturnal Owls, except that the eyes here are permanently fixed in their sockets, with a resulting

stable forward direction of the visual axes, which are not adjustable or very little so. By what central mechanism the fusion of the "corresponding retinal points" and a stereopsis far superior to the human are here achieved and whether or not there is complete visual decussation in the mentioned species are intriguing problems yet to be solved.

In the Tarsier, a strictly nocturnal Primate, even though the chiasma is partially decussated, the eyes are almost as immobile as in the Owls. The presence of a central fovea, however, is indicative of high acuity and stereopsis, similar to that in the diurnal Primates (*see* chap. XIV, 12).

5. THE ORIGIN AND FUNCTIONAL ORGANIZATION OF THE STEREOSCOPIC VISUAL SYSTEM.—While from a wider biological viewpoint the idea of certain investigators—Uexküll, for example—that each animal species is best equipped for its own mode of living may be correct, it would be untrue to deny a manifest phylogenetical tendency of certain phyla, classes, and orders of animals to excel over other phyla, classes, and orders in organization and many types of functional performance. The same verdict is applicable with as much justice to many bodily systems, e.g., to the locomotor apparatus, the organs of generation, the circulatory system, and, above all, the nervous sytem and the sense organs.

The visual system, too, is one of the clearest examples of a gradual perfection, beginning with the simplest kind of structure—for example, the photosensory cells scattered over a part of the body surface of an Earthworm—through the various stages of simple photoreceptors in the primitive animals, culminating in the extremely complex eyes of the Higher Vertebrates, the Mammals and the Birds.

What is true of the peripheral photoreceptors is equally true of the visual system as a whole. Here, too, graded series of stages of increasing complexity may be imagined, beginning with the very simple nervous connections of primitive animals and culminating in the quite elaborate mechanisms found in Higher Mammals and Birds.

The function of such systems may also be expected to vary within wide limits. The final stage of phylogenetical perfection in the vertebrate visual apparatus, especially when appraised from our own anthropomorphous viewpoint, has been attained by the Primates, terminating in the extremely delicately adjusted stereoscopic visual system of Man.

The foremost single factor responsible for the development of primate stereopsis is the rearrangement or phylogenetical reorganization of the entire visual pathway. Whereas in all submammalian classes of Vertebrates, the infranuclear division of the visual pathway, with some slight exception in the Birds, is completely crossed, in the Mammals some optic fibers originating in the temporal segments of the retina do not decussate in the chiasma but pass to the lateral geniculate nucleus of the same side.

In the lowest ranks of Mammals, e.g., Rodents, with laterally placed eyes and little more than panoramic vision, the nondecussating portion of fibers originating in the most temporal segment of the retina represents only a fraction of the total number, accounting for a small overlapping of the most nasal segments of the monocular fields of view. In the higher orders, with more frontally placed eyes and a frankly stereoscopic vision, exemplified by the Carnivores and Primates, the proportion of the nondecussating to decussating fibers increases from approximately 30 per cent in the Cat to 40 per cent and possibly more in the Monkey and in Man (for details *see* chap. VI, 3, 4, 5). The central overlapping of the two fields of view is here correspondingly larger.

The partial crossing of the optic nerve fibers in Man amounts almost to a semidecussation. It is the basic anatomical arrangement of the primate visual system. For its proper functional employment, however, it requires the co-operation of a delicately adjusted oculomotor mechanism: the accurate converging of both visual axes upon the same point of the viewed object—the common fixation point; the influencing of the ciliary muscles to change the refractive power of the lenses and thus to accommodate the focal plane to varying distance; and, lastly, the regulation of the amount and composition of light entering the eyes through an appropriate change in the size of the pupils, in this way improving the definition of the retinal image. All three additional factors are indispensable

for bringing identical details of the two sharply defined retinal images upon the syndynamical or isodynamical localities of both retinae and for transferring these to the brain, where they are appreciated as a single mental experience.

An almost equal division of the retinal nerve fibers in the chiasma, with a resulting similar division of each field of view into two homonymous halves, and an aiming of the two visual axes at a common fixation point are two essential factors resulting in an extensive overlapping or superposition of the two monocular fields of view, which is characteristic of the Primates. The impulses from each two paired points of the homonymous halves of the binocular portions of both retinae situated at an equal distance from the dividing vertical meridians in the horizontal plane must perforce meet in the visual centers – the lateral geniculate nuclei and the striate areae—of the same side (Figs. 361, 439).

An observed object, e.g., a vertical pillar, viewed simultaneously by each eye from its own side, is seen somewhat differently, depending on the angle or distance from the common vertical meridian: parts of the mid-line of the pillar, being closest to the common vertical meridian, are seen nearer; its two sides, being at some distance from the dividing meridian, since being more distant, are seen farther away. The total effect is vision in three dimensions or in space: right-and-left and fore-and-aft, producing in our subjective or mental experience a stereoscopic impression. The two monocular wings flanking the binocular central portion of the common binocular or cyclopean field of view, by their greater dissimilarity in the horizontal sense, help further to increase the binocular stereopsis. (This observation was made and accurately described by Galen eighteen centuries ago in his book *De Usu Partium Corporis Humani; see* chap. II, 2–5.)

The phylogenetical reorganization of the afferent visual pathway and a readjustment of the accessory oculomotor mechanism have transformed the original panoramic or largely panoramic visual system of the Lower Mammals into the stereoscopic mechanism of the Monkeys, Apes, and Man. In this reorganization the eyes have been deprived of their former functional independence, in so far as they possessed any. They have been integrated into a complex machinery of a higher order, working as a single unit or team. They may be compared to a two-pronged tentacle or to two hands with their thumbs crossed, grasping a single object.

From the panoramic condition present in the Lower Vertebrates, with its two halves—two separate fields of view, two eyes, and a right and left brain center of vision, to some extent or temporarily independent—the visual system of the Primates has developed. In it both eyes and fields of view, with the two sets of centers in both halves of the brain, became intimately welded into a single mechanism working as a complex unit—a cyclopean stereoscopic visual system.

A further development of this principle is found in the sharp-eyed birds of prey, such as the Eagles and Swallows, and in some Lizards (Chameleon, Anole). Here each individual eye may be used at will; or both eyes may be directed simultaneously, as a team, at one single object in a typical binocular act of vision. The facultative independence of each eye, lost in Primates for the sake of permanent binocular teamwork, has been fully preserved in these species. (*See* chap. XIV, 7, 8.)

6. The functional plan of the primate visual system.—The central stereoscopic visual apparatus of Man and of the Higher Primates is organized upon the principle of a single cerebral screen instead of two—the two optic lobes – more or less apposited along their margins, as in the Inframammalian Fishes, Amphibians, Reptiles, and supposedly also Birds (Fig. 439).

Each retinal receptor screen (*LE*, *RE*) is cut along the vertical dividing meridian passing through the foveal center (f_1f_1 and f_2f_2) into two unequal halves, owing to a separation in the chiasma (*ch*) of decussating fibers from those that do not decussate. The smaller temporal parts of the ocular screens (f_1-x_1 and f_2-y_2) are represented in the two halves of the visual center ipsilaterally (F_1-X_1 and F_2-Y_2); the larger nasal parts (f_1-y_1-b_1 and f_2-x_2-a_2) are represented in the visual center contralaterally (F_1-Y_1-B_1 and F_2-X_2-A_2). In each half of the brain the two homonymous halves of both ocular screens—the hemiretinae—somewhat dissimilar in size and shape, are represented together, the right halves

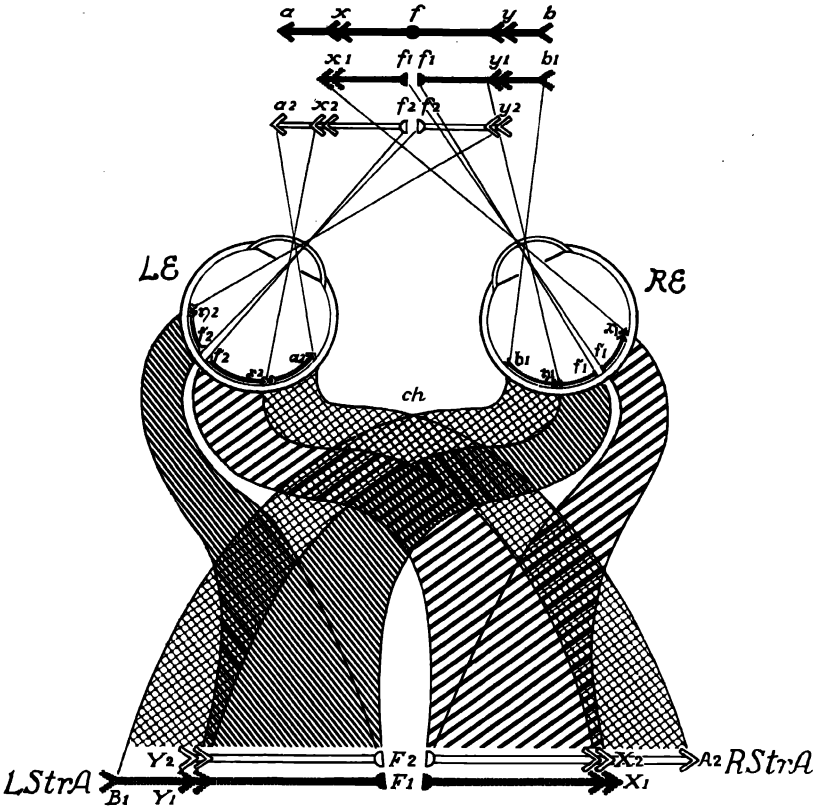

FIG. 439.—Diagram showing the intrinsic makeup and functional effect of the primate visual system, projected upon a horizontal plane (Man, Ape, Monkey). A single object a—b is focused by both the right (RE) and the left eye (LE), the right (f_1f_1) and left fovea (f_2f_2) aiming simultaneously at a common fixation point (f). A portion of an object seen by the right eye (x_1—b_1) partly coincides with (x_1—y_1), and partly differs (y_1—b_1), from that seen by the left eye (x_2—y_2, a_2—x_2, respectively). The two retinal images also partly coincide (x_1—y_1 and x_2—y_2) and partly differ (y_1—b_1, a_2—x_2). Every detail of each retinal image is transmitted along central pathways to the striate area in such manner as to preserve the original topographic relationships. Owing to a partial decussation in the chiasma (ch), each retinal image is split along vertical meridians passing through fixation points. The nasal portion of the right retinal image (f_1—b_1) is transmitted to left striate area ($LStrA$), which also receives an image from the homonymous temporal portion of the left retina (y_2—f_2). A doubling-up, however, comprises only the portion closer to fixation points (F_1F_2—Y_1Y_2), while the portion at the opposite end (Y_1—B_1) has no counterpart in the left retina. The left striate area, accordingly, sees the right half of a common field of view partly with both eyes and partly with the contralateral, right, eye alone. The temporal portion of the right retinal image (f_1—x_1) is transmitted to the right striate area closer to the fixation points (F_1F_2), where the homonymous portion of the left retinal image is also deposited (F_1F_2—X_1X_2), leaving the peripheral flank (X_2—A_2) to serve the extreme nasal segment of left retina (x_2—a_2). The right striate area, accordingly, sees the left half of a common field of view, binocularly in the portion closer to the fixation points (F_1F_2—X_1X_2), and at its flank monocularly (X_2—A_2). As a total result, each striate area sees the contralateral half of a common binocular field of view: the right area, the left half; the left area, the right half. Together, both striate areae see the entire field of view as a unit (a—b), the central portion around a common fixation point binocularly (x—y) and both flanks monocularly (a—x, y—b). The process of a cerebral fusion of two separate homonymous images into a single mental experience is prepared in the lateral geniculate nuclei and is consummated in the striate areae. An indispensable prerequisite for this is the correct working of the delicately balanced oculomotor apparatus, directing visual axes of both eyes to a common fixation point, irrespective of the distance of the observed object. The result is a union within the cerebral cortex of two slightly differing retinal images of a single object, a single subjective experience, which, in addition, possesses a three-dimensional character. (*Cf.* Figs. 361, 401.)

of the retinae (f_1-x_1 and f_2-x_2-a_2) being represented in the right cerebral hemisphere (F_1F_2-X_1X_2-A_2), the left halves of the retinae (f_2-y_2 and f_1-y_1-b_1) being represented in the left cerebral hemisphere (F_1F_2-Y_1Y_2-B_1).

Since the retina of each eye is represented partly in the ipsilateral hemisphere and partly in the contralateral one or, in other words, since each cerebral hemisphere represents ipsilateral halves of both retinae, the visual centers or striate areae of both hemispheres taken together represent both retinae or both eyes. The two striate areae, one in each cerebral hemisphere, must, accordingly, be looked upon as two halves of a single cerebral cortical center spread out in a single plane, like a screen upon which the two retinal images formed separately in the two eyes are projected as a single unit.

The portions of the cortical visual screen closer to the vertical dividing meridians and fixation points (F_1F_2-X_1X_2 and F_1F_2-Y_1Y_2) represent binocular portions of both retinae (x_1-y_1 and x_2-y_2); the two flanks of the cortical screen represent the monocular portions of only one, the contralateral, retina, the right flank (X_2-A_2) representing the left nasal monocular retinal segment (x_2-a_2), the left flank of the common cortical visual screen (Y_1-B_1) representing the nasal monocular segment of the right-side retina (y_1-b_1).

The complete cortical visual screen (*LStrA* and *RStrA*) is formed by pairs of the "corresponding cortical units" or "identical points," representing the "corresponding points" of the binocular portions of both homonymous retinal halves (thus the X_1X_2 point represents the x_1 and x_2 points, and the Y_1Y_2 point represents the y_1 and y_2 retinal points), and by the single "non-identical cortical points or units," representing points of the monocular portion of either one or the other retina (thus the A_2 cortical point represents the a_2 retinal point, and the B_1 cortical point represents the b_1 retinal point).

In this way, in the brain of Man and his primate relatives, Monkeys and Apes, is created a single stereoscopic cerebral visual screen, corresponding in all details with the entire field of view as a unit (*a-x-f-y-b*) except that, owing to a dark-chamber effect of the eyes, the correspondence is inverted, both in the horizontal and in the vertical sense; thus the left end of the viewed object at *a* is depicted at A_2 in the periphery of the right striate area, and the right end of the object *b* is shown in the periphery of the left striate area at B_1.

There are other differences also. The center of the binocular field of view around the common visual axis (*f*), corresponding to both central foveae of the retina when focusing at the common fixation point, relatively and absolutely representing but a small fraction of the total area of the field of view (roughly 2°, as compared with 180° in the horizontal meridian), is relatively magnified or inflated to roughly one-fourth of the total extent of the combined striate areae in the horizontal meridian. Conversely, the cortical representation of portions of the field of view away from the axis, especially the two flanks, representing the large monocular segments of the fields of view, are shrunken or diminished in size—facts of no immediate consequence for the present theme. (*Cf.* Figs. 225, 259, 260.)

In comparing the panoramic visual system of the Inframammalian Vertebrates, such as Fishes, Amphibians, Reptiles, and Birds which have a completely decussated chiasma (Fig. 437, right-hand sketch) with a partially decussated stereoscopic visual system of Primates (Fig. 439), the following features merit attention. In a panoramic visual system each point of the cerebral visual projection screen or "mental image" (*C*), made up of two apposited centers, represents but one point in either the right or the left retina, corresponding to one locality in one or the other monocular field of view (Fig. 437, right sketch). In a stereoscopic visual system (Fig. 439), in the greater binocular portion (Y_1Y_2-X_1X_2) around the points of fixation (F_1F_2), each single point of the cerebral screen represents pair-wise the corresponding or syndynamical points of both retinae, which under normal circumstances receive similar impulses from the same point of the viewed object (thus X_1X_2 from *x* through two corresponding retinal points x_1x_2). The flanking monocular portions of the cerebral screen of the stereoscopic visual system (Y_1-B_1 and X_2-A_2) alone, having no corresponding area in the ipsilateral retina, still preserve the panoramic character which is believed to be present exclusively in the Lower Vertebrates, or almost so.

Functionally, the middle binocular portion of the stereoscopic visual apparatus acts as a double screen made up of superimposed right and left "corresponding units" receiving more or less identical stimuli from the same point of the viewed object via the corresponding points of both retinae, and tests them with regard to their similarity or dissimilarity (intensity, hue, etc.). Conversely, the monocular flanks are to be compared with lateral guards, acting only with reference to the binocular center in the horizontal plane.

The vertebrate binocular stereoscopic apparatus is organized upon a horizontal plane, with two eyes capable of directing their visual axes to a common fixation point at any distance in that plane. The retinal fibers are therefore separated in the chiasma along the principal vertical meridians, and the stereoptic effect naturally concerns vision in the horizontal plane alone. A visual system which would be required to accomplish the same in the vertical plane would have to have two eyes placed one above the other, with fibers separated in a chiasma along the horizontal meridians of both retinae.

Since, because of the force of gravitation, the bodies of all advanced animals, certainly of all Vertebrates, are oriented vertically with respect to the horizontal plane, this plane is the principal or exclusive dimension in which such animals move, act, use, or refer to their visual apparatus—the horizontal plane of sight. A visual system which combined both horizontal and vertical stereopsis in a Vertebrate would be nothing short of a monstrosity whose problematical usefulness could, perhaps, be measured by a "fourth dimension" of the "theory of relativity" but could not be expressed in terms of present-day anatomy and physiology of vision.

Since the binocular stereoscopic visual system normally functions as a unit, it was compared by Hering and Helmholtz to the single median eye of the Cyclops, the fabled giants of ancient Homeric mythology: the *Deckauge* or "superposed eye" of Hering; and *Cyclopenauge* or "cyclopean eye" of Helmholtz. This comparison, however, is only a figure of speech, and for the following reason. A truly cyclopean visual system, containing a single median eye, it is obvious, would not be equal in its functional performance—above all, in stereopsis, that is, in tridimensional visual space perception—to the primate system as it is, even though a single cyclopean eye was imagined to have been large. The inherent defect of a true cyclopean system, with a median chamber eye, would be the single image of each point of an observed object, which, owing to the principle of the "dark chamber," would alone be formed, no matter how large the eye. Consequently, there would be only one single image projected upon the brain. There would be no central fusion of *two* similar or slightly different retinal impressions of the same object point observed from two different "viewpoints," as in binocular vision. The term "cyclopean eye" is, therefore, at best useful only as a figure of speech to indicate a unified sensory-motor apparatus possessed by Man and his primate relatives, where both eyes perforce act as a team and where the stimulation of identical or corresponding retinal points necessarily elicits a response in a single locality of the cortical visual center.

7. ULTIMATE CAUSES AND CONSEQUENCES OF DECUSSATION OF THE VERTEBRATE VISUAL SYSTEM.—A tentative explanation which may be given at present for the phylogenetical origin and physiobiological motivation of decussation of the vertebrate visual system may be summarized as follows.

At the very inception of Vertebrates a decussation of the visual system may have been forced upon them by the general character of the visual system as a nociceptor. This visual decussation may have had its parallel in a similar thigmotactic, tangofugal habit of the Vertebrate Ancestor, if, indeed, the tactile system had not preceded it. At that early stage the visual decussation may have been an instrument of a global optofugal reaction of the incipient eyes, even before these developed into chamber eyes. (*Cf.* Coghill's experiments.)

With improved visual discrimination, owing to the creation of the chamber eyes, and with the visual system changing into a positive, phototropic, analytical instrument, the same causes continued to preserve total decussation. However, its motivation now became more complex. The two retinal images required such decussation even more, since in this way alone could a normal arrangement or sequence of the details

of the total image projected in the two apposited visual centers, right and left, be established and maintained. In such a panoramic visual system, details of a central image preserve their congruous arrangement when compared with those of the observed object.

Since very early in vertebrate phylogeny a decided urge became manifest to use both eyes simultaneously as a team, a good illustration of which is the Silversides and Minnows hunting gnats above the surface of the water (*see* sec. 2, the following chapter), a gradual reorganization of the visual pathway was initiated. Of this and of the following stage, however, we still know very little. Just what the central mechanisms underlying binocular vision are in the inframammalian classes, such as the Fishes, Amphibians, Reptiles, and Birds, remains as yet imperfectly known (*see* chap. VI, 5, and the following chapter).

In the Mammals, however, the process of a gradual change from a totally or almost totally decussated panoramic or largely panoramic to a partly decussated and now frankly stereoscopic binocular arrangement may be traced step by step from the lowest orders, such as the Rodents, to the visually most progressive, the Primates (*see* chap. VI, 3–5). In the first the eyes are mounted laterally or almost so, with only small segments of the two fields of view overlapping, if at all, and with only a fraction of the optic nerve fibers, if any, originating from the most temporal retinal segments remaining on the same side.

In the higher orders the relative size of the overlapping or common binocular field increases, as does the portion of fibers that does not decussate, until in Man about 40 per cent of the fibers or more remain uncrossed. In this way a mechanism is created by which the impulses arising from practically identical points of both homonymous retinal halves are brought to the same locality of the visual cortex, the right or the left striate area, and are welded into a single histodynamical process, which is the material basis of the singleness or unity of vision. Just what the particular structures in the striate cortex are that are instrumental in this binocular fusion still remains a problem. (*See* chap. VIII, 7.)

NOTE: At this point the attention of the reader should be called to the fact that the numbers of cones or rods counted on a "stretch of 500 microns" in the retinae of various species in the following chapter (chap. XIV) are apparently correct, as indicated by recounts done on sections made available to me after Dr. Polyak's death. There appear to be some arithmetical errors, however, made by Dr. Polyak in a few instances when computing the total number of cones or rods in a circular area measuring 500 microns in diameter. I have not changed these values for various reasons, but the reader, who wishes to make use of them, may want to recompute them for the Northern Brook Silverside, Trout, and Bullhead.—HEINRICH KLÜVER.

Chapter XIV

Biology of the Organs of Sight and of the Visual System of Vertebrates

SEC. 1. THE ROLE OF VISION IN THE MAINTENANCE OF ANIMAL FORMS OF LIFE

1. GENERAL CONSIDERATIONS OF VERTEBRATE LIFE.—The essential problems with which every living being is confronted are those of being born, of successfully preserving its individual integrity, and of reproducing other beings similar to itself. If the first and the third problems, properly belonging to reproduction, are eliminated, the remaining task may be briefly defined as that of the preservation of individual integrity and welfare. Thus broadly stated, the definition of the essential problems of life applies to all living things, whether they are animals or plants.

In further limiting our theme to animals, we observe that the latter maintain themselves through two processes or acts. The first is intake of material which can be assimilated and incorporated into their bodies. The other is avoidance of being taken by other animals as food or, broadly speaking, the avoidance of annihilation. Both these biological tasks are related, being, in fact, two aspects, positive and negative processes of life. In other words, animals, unless plant-eaters, either act as predators subsisting on other animals or serve as food to other animals, the two roles being interchangeable in different situations in many cases.

The acquisition by animals of suitable food, both plant and animal, requires locomotion. This may be passive, as when the food particles are brought by currents of water or air; or food is acquired through active pursuit. The first method does not require any sense organs responding to distant stimuli and only primitive organs of locomotion. This method is widespread among lowly organisms, such as the Protozoa and Lower Invertebrates. The active method of food procurement requires sense organs capable of recognizing and locating objects of food at a distance, as well as organs of locomotion to reach and capture them. This is the standard arrangement in the Higher Invertebrates and in all Vertebrates.

The avoidance of various harmful factors may also be a passive or defensive one, as, for example, through the production of a protective armor and other means of defense, mechanical or chemical, or by various forms of camouflage or mimicry. Or it may be achieved by locomotion, that is, by active escape. Or, as in many cases, it is accomplished by a combination of passive defense and flight. A purely passive mode of defense does not necessarily require any sensory and locomotor organs. In the more advanced animals, however, efficient sense organs capable of responding to distant stimuli and a co-ordinating nervous and locomotor equipment are indispensable for executing the reaction of avoidance of the harmful factors.

In advanced animals the satisfaction of the two basic tasks of life, that of acquiring food and the avoidance of annihilation, is intrusted to two sets of bodily organs. First are the higher sense organs, those called by Sherrington "distance receptors," that is, organs of sight, hearing, and smell, while the organs of taste are of lesser importance. The other sense organs concerned with exteroceptive or superficial touch, pain, and temperature, the proprioceptive qualities of deep sensibility and sense of balance, are all also involved in various degrees. The other complementary sets of organs are an efficient locomotor equipment and a central nervous organ to sift the messages received from the peripheral receptors and to initiate, co-ordinate, and carry out purposeful actions.

Since in their multifarious relationships all animals compete with one another in their

struggle for existence, the success or failure of each particular form will depend on successful satisfaction of the basic instincts of life. This again depends directly upon the acquisition by each form of the minimum of bodily equipment essential for the procurement of food and avoidance of annihilation.

its properties, for this particular purpose, to all other factors. Its foremost properties: rectilinear propagation and great speed, its spreading in all directions from any luminous or illuminated point, its property of being reflected from evenly outlined, smooth surfaces, and, above all, refrangibility when passing through trans-

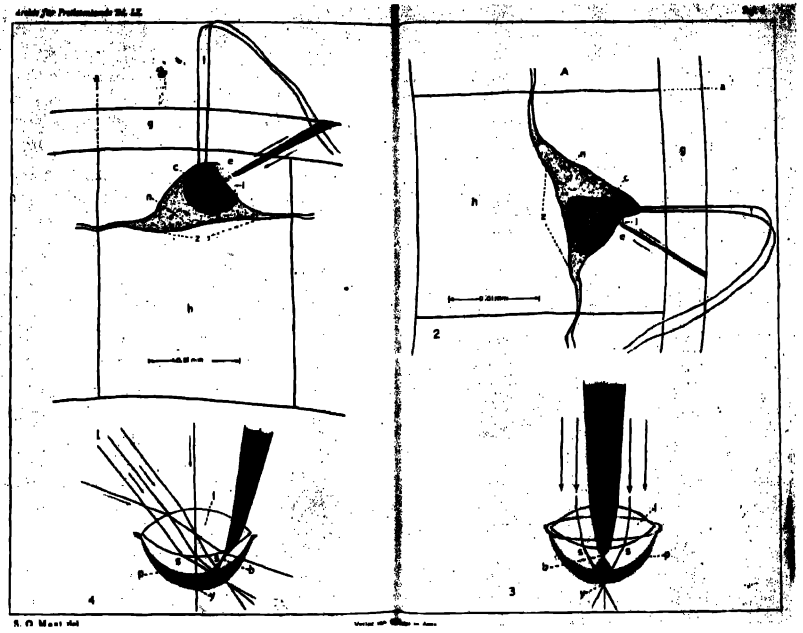

FIG. 440.—Zoöids or individual cells of a primitive colonial organism, *Volvox globator*, showing the structure of its ocelli or eyespots and their optical action, as described by S. O. Mast (Arch. f. Protistenk., v. 60, p. 197, 1927). Upper sketches represent two individual cells, each provided with one eyespot from which a narrow beam of light is reflected, with a pair of long flagella or locomotor "whips" (*f*) and with lateral expansions by means of which each cell is held in the colony. Lower sketches show schematically the respective eyespots, each made up of a shallow pigmented cup filled with a photosensitive substance and provided with a transparent biconvex lens whose presence is indirectly disclosed by the light refraction. When light enters the concavity of the cup, the yellow and the red components of the rays pass through without eliciting further biological action, whereas the bluish-green component is selectively reflected as a small beam, its direction depending on that of the entering light. This results in an altered direction of the strokes of the flagella, influencing the movement of the entire colony. The eyespots, accordingly, play the role of "directional eyes" in unicellular and colonial organisms, as they do in multicellular animals, such as the Flatworms, Leeches, and others.

2. LIGHT AND THE ORIENTATION OF ANIMALS IN SPACE.—Of the several physical factors, such as gravitation, inertia, touch, heat, and cold, the chemical stimuli, and the luminous radiation called "light," the last is the most useful orientating factor in space for the more advanced forms of animal life. Light is superior in

parent optical bodies, and none the less its composite nature, made up of a series of colored constituents which may in various ways be separated from one another and again combined—all make light the most versatile tool which Nature has given animals.

The segment of luminous radiant energy ca-

pable of being utilized by both animals and plants is rather narrow. It includes "visible light" and the "infrared" and "ultraviolet" parts of the spectrum. It represents but a small portion of the total solar radiation or energy emanated by our sun. (*See* Th. Preston 1928; C. G. Darwin 1932; R. W. Wood 1943; E. Rüchardt 1952.)

The basic qualities of visible light used by animals are rectilinear propagation, wave length, intensity, and chemical activity. It may logically be expected that living beings have developed the ability to utilize one or another or all of these properties in various combinations and degrees.

A remarkable phenomenon is the selectivity with which living beings restrict their responsiveness to one or to a few properties of photic stimuli, while remaining refractory to the others. This again is a part of a more basic phenomenon, that is, the responsiveness of all living things to only a narrow band of the solar spectrum, which, in turn, may be a proper theme for a more profound philosophic-scientific inquiry into the origins of life, into the nature of living matter, and the physical factors responsible for the creation of living substance in general. Whatever the final answer, the available knowledge points toward a basic identity of the organization and photic responsiveness of all living substances. (*Cf.* A. I. Oparin, *The Origin of Life*, 1938; also I. Lichtig 1938; J. Alexander 1948; Bertalanffy 1949; J. D. Bernal 1951; H. Shapley 1953.)

In the world of Plants the properties of light largely utilized appear to be wave length and intensity. Rectilinear propagation seems to remain little utilized. Future research may possibly qualify this statement to a much greater degree than now suspected, as indicated by the work of G. Haberlandt (*see* Naturwiss., v. 12, p. 1087). In contrast to mostly sedentary Plants, the mobile Animals have concentrated greatly upon utilization of this particular property, while not neglecting, and in some respects further developing, utilization of other qualities of light.

The beginning of the utilization of the rectilinearity of light, developed to perfection by advanced animals, especially Insects, some Cephalopods, and all Vertebrates, is already found in certain unicellular and colonial organisms. The *ocelli* or "eyespots" found in the Dinoflagellates, according to most authorities, are organs sensitive to photic stimulation, as evidenced by experiment. The individual zoöids or constituent cells of the colonies of *Volvox globator*, as described by S. O. Mast (1927), are each provided with a complex *ocellus* or a minute "eye," consisting of a hemispherical pigmented cup filled with a photosensitive substance and a biconvex lens (Fig. 440). Through the action of this eyespot, green and blue light is subjected to reflection, while red and yellow light passes through it. (*See* Pavillard 1952, on *Volvox globator*.)

Mast found similar, although somewhat simpler, eyespots in unicellular organisms which do not form colonies: *Chlamidomonas*, *Euglena*, *Leptocinclis*, *Phagus*, *Trachelomonas*, and others. In all these primitive beings the eyespots serve for orientation in space, utilizing green light, the maximum of stimulating efficiency being at the wave length of 500 millimicrons. In *Volvox*, Mast assumes the presence of a photosensitive substance and a "neuromotor apparatus," along which the generated impulses are transmitted upon the *flagella*, or whiplike locomotor organs, whose response results in the orientation of the entire colony. "The eyespots in these organisms therefore function as direction eyes, and in this respect they are similar to the eyes in Flatworms, Leeches, and many other animals," according to Mast.

It is revealing to find, from this account of Mast, already existing, on the lowest level of organismic life, complex photoreceptors, consisting not merely of an accumulation of photosensitive substances and pigment but also of a structurally differentiated dioptrical apparatus. This agrees well with the hypothesis expressed earlier, that light is to be considered the major, possibly the only, factor in the origin of life (*see* chap. XIII, 2).

Still another point in Mast's presentation appears noteworthy: the minute size of the lens of the *Volvox* zoöid, measuring only 1 micron, or one twenty-five thousandth of an inch, in diameter. The fact that even so small a lens is capable of concentrating the rays of light makes doubtful the insistence of the physicists that the smallest diameter of a lens capable of doing so cannot be less than 20 microns (which, in turn,

reminds one of the doubts raised about the possibility of individual stimulation of outer cone segments of less than 1 micron in thickness, as discussed in chapter V, 3 [5]).

In summary, the available evidence shows the great influence that physical light exerts upon organisms down to the most primitive ones, especially in their orientation in tridimensional space. A preliminary conclusion may, therefore, be permissible that, from this universal responsiveness of primitive animals to light, more complex visual organs developed in the

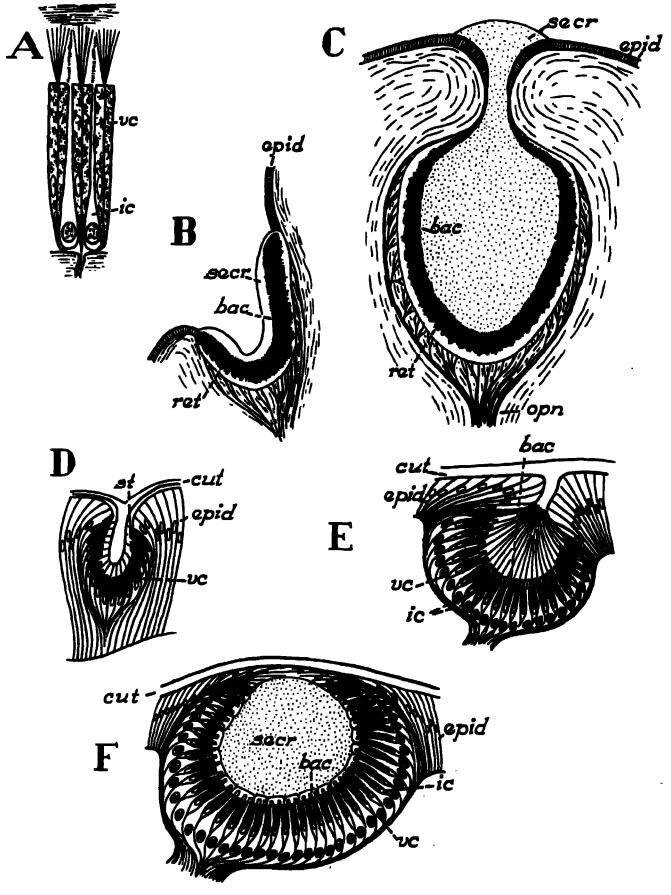

FIG. 441.—Phylogenetical stages of the eyes of Snails: *A*, visual epithelium of *Patella* at higher magnification; *B*, dimple eye of *Patella* and of *Haliotis* (*see* also *G* in the following figure). Phylogenetical stages of Annelide Worms: *D*, dimple eye of *Ranzania; E*, vesicular eye of *Syllis; F*, same of *Nereis. Labeling: bac*, bacilli or rods; *cut*, cuticle; *epid*, epidermis; *ic*, indifferent epithelial cells; *opn*, optic nerve; *ret*, retina; *secr*, secretion; *vc*, visual cells. Note the simplest eyes made up of epithelium that first becomes invaginated, then closes to form a vesicle; the latter, in turn, becomes filled with secretion, which, together with a transparent cuticle and epidermis forms a dioptrical apparatus of the eye. Redrawn from R. Hesse & F. Doflein, *Tierbau und Tierleben*, v. 1, 1935.

course of progressive evolution, when more advanced forms of animal life emerged which became the faunal population of the earth.

3. Types of eyes and visual systems and their use.—The organs of sight, peripheral and central, evolved by the animals, beginning with the unicellular and including those found in the multicellular Metazoa, are bewildering in variety. Many are very simple in structure and presumably also in function, whereas others are extremely complex in organization and per-

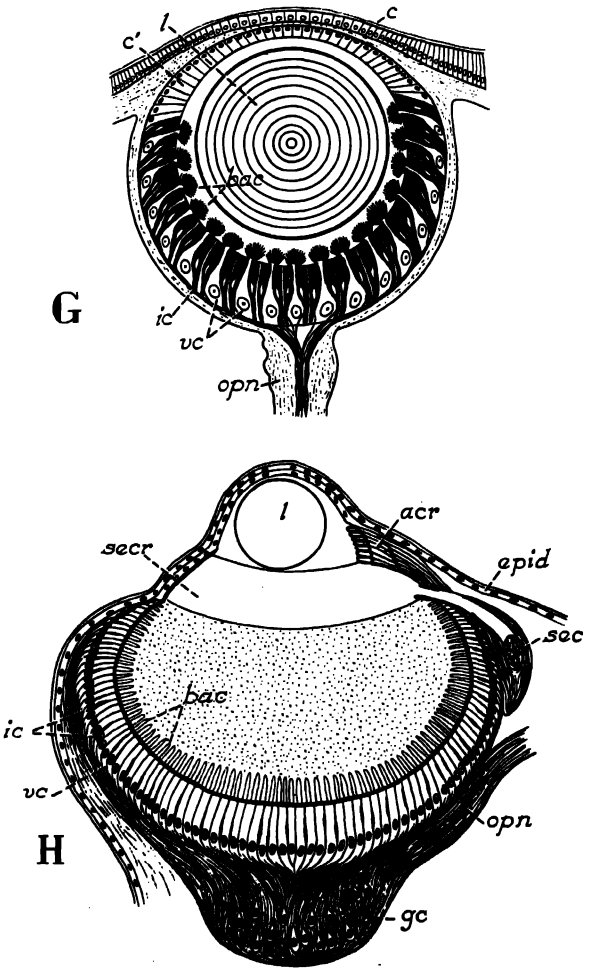

Fig. 442.—Eyes provided with a lens: *G*, of a Snail *Helix*, and *H*, of an Annelide Worm *Alciopa*. *Labeling: acr*, accessory retina; *bac*, bacilli or rods; *c*, cornea; *c'*, external epithelium of eye vesicle; *epid*, epidermis; *gc*, ganglion cells; *ic*, indifferent cells; *l*, lens; *opn*, optic nerve; *sec*, secretory cell; *secr*, secretion of same; *vc*, visual cells. formance. Between these two extremes is an unevenly graded series of an endless variety of forms.

On general biological grounds the assumption is justified that each type or special form of peripheral visual photoreceptor and its co-ordinated visual pathways and centers were evolved to satisfy the life-requirements of each particular animal form. In fact, we may be justified in assuming that each animal form is adapted to its particular habitat and mode of life in every detail of its organization.

All peripheral visual organs have certain features in common. These are a photosensitive surface, or epithelium, accessible to the direct action of light stimuli, within which the incipient photic reaction takes place. There are also structures of some sort along which the generated impulse is propagated and transmitted to the organs or structures of execution.

In many lowly animal forms, for example in the Earthworm, the photosensitive cells are rather diffusely scattered over the surface, with the greatest accumulation in the rostral segments. In others they are arranged in groups, rows, or clusters, either in the integumental epithelium or in deeper parts of the body, which remain transparent.

Photoreceptors which have the photoepithelium spread out to form a screen upon which the incident rays of light are arrested are of a slightly advanced type. In most such organs the opposite side of the photoepithelium is coated by an opaque layer of dark pigment, permitting free access only to some rays, while barring those coming from other directions. This early appearance of distinctive structures capable of responding to and of regulating the rectilinearity of light is indicative of the inherent necessity of animals to respond to this particular property of light.

Eyes resembling those possessed by Man and his nearest relatives, the Monkeys and the Apes, are present in all Vertebrates from Fishes through the Amphibians, Reptiles, Birds, and in all the Infraprimate Orders of Mammals. The structure and function of the vertebrate eye has been the object of intensive investigation during modern times by a great number of students, of whom the most prominent are Leuckart, Pütter, Plate, V. Franz, R. Hesse, Buddenbrock, Kolmer, Walls, Rochon-Duvigneaud, and Verrier. The result of these many efforts shows that, in spite of great variation in detail, the vertebrate eye in all classes is built according to the same plan.

In other animals the eyes are made according to a more or less different pattern. A notable exception are the eyes of Cephalopods (*Nautilus*, Squid, *Octopus*), animals that stand in no phylogenetical relation to the Vertebrates but whose eyes are similar to the eyes of Vertebrates in structure.

The intriguing problem of the origin of the vertebrate eye from some earlier and more primitive form, even though much debated, remains unsolved; the possible factors that have brought about the creation of the vertebrate eye are discussed in chapter XIII, 2.

The numerous types of eyes of Invertebrates described by many investigators, interesting in themselves and showing how countless animal forms have solved the problem of utilizing light as an instrument of orientation in space, are of little use in solving the question of the origin of the vertebrate eye. Some of them, however, illustrate one or another intermediate stage through which the Vertebrate Ancestors may have passed during the preceding evolutionary process.

In many of the lowermost animals the photoepithelium is accumulated at the front end of the body in patches or clusters, sometimes in rows or groups of patches, occasionally along the margins or other exposed parts of the body. The next step in the phylogenetical advancement of the photoreceptors toward the vertebrate eye is the invagination of an originally flat photoepithelium to form a dimple, as illustrated in sketches *B* and *D*, in Figure 441. A further step still is the closing of the margins of the invaginated cavity to form a vesicle (*C*, *E*, *F*). The latter is filled with a secretion, and on the outside it is coated with dark pigment, except at the transparent front end or "cornea" through which the light passes into the interior. In this way a primitive "pinhole camera" or a "dark chamber" (*camera obscura*) is created, where some sort of image is formed. Such an eye, even though producing a poor image, is somewhat more useful than an open dimple eye, and decidedly so when compared with a

patch of photoepithelium spread diffusely over the surface of the body.

Even more useful in forming an image is the eye of a *Nautilus*, an ancient Cephalopod. It is, in fact, a living "dark chamber" filled with sea water, which freely communicates through an open pupil, without any dioptrical structures but provided with a photosensitive retina which lines its interior.

crease in intensity of stimulus but also localization of the rays upon a small area of the photoepithelium lining the inside of the vesicular eye, the effect being greater brightness and better definition of the image.

The final step in the perfection of the eye in the Higher Vertebrates is the addition of minute muscles supplied with nerves and other accessory structures, by which the shape of the lens

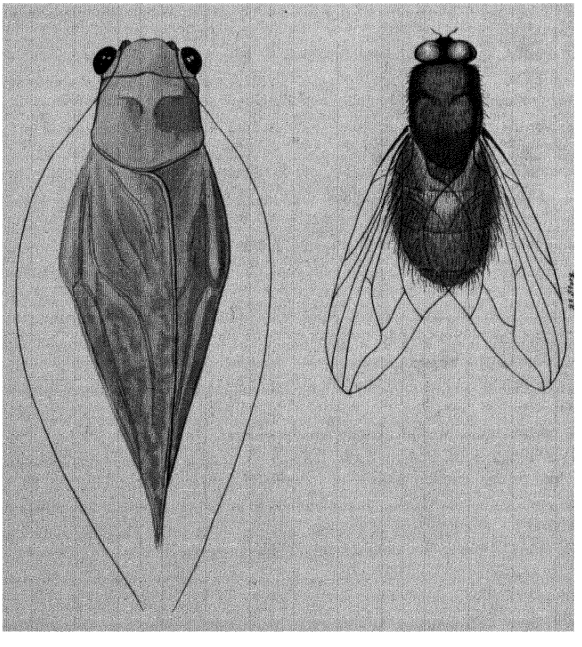

FIG. 443.— Katydid (*Pterophylla camellifolia, left*) and Housefly (*Musca domestica, right*), showing the shape, size, and position of the eyes in the two insect species. The Katydid is a large insect native to eastern North America, whose sound, made by the male rubbing its wings against each other, is frequently heard from the trees late in summer and early fall; its eyes are rather small compared with its body size and are mounted on the corners of the broad head. In the Fly, a much smaller insect, the relatively large eyes make up most of the head and are placed close together, more so in the male than in the female. Magnification 4.5×.

A further evolutionary step is represented by the addition of a transparent dioptrical body, more or less resembling a lens. In some cases there is also a vitreal body, presumably possessing a higher index of refraction, hence capable of further concentrating rays of light upon the photoepithelium (Fig. 442, *G, H*). This arrangement, in connection with the dark-chamber effect, makes possible not only an increase in intensity of stimulus but also localization of the rays upon a small area of the photoepithelium lining the inside of the vesicular eye, the effect being greater brightness and better definition of the image.

The final step in the perfection of the eye in the Higher Vertebrates is the addition of minute muscles supplied with nerves and other accessory structures, by which the shape of the lens is changed and the pupillary opening regulated. These improvements not only increase the sharpness of the retinal image in a given situation, by accommodation of the lens to the distance of the viewed object, but also make possible adjustment of the eye to varying intensities of illumination.

The perfection of the vertebrate chamber eye is one way by which the photoreceptor organ

became more efficient. Another and quite different principle is realized in the composite or musivic eyes of the Arthropods, such as the Crustaceans, Insects, and Spiders. This is a special problem to be dealt with independently (*see* **Autrum**, Exner, Hesse & Doflein, Horst, Fingerman & Brown, H. Stumpf, K. von Frisch; *cf.* Figs. 443, 444). The principles and detailed organization of the central visual mechanisms of Invertebrates, unfortunately, are but little known. Especially is this true of the very delicately organized cerebral ganglions of the Insects, as the studies by S. Ramón y Cajal, Sánchez, Hanström, Horst, and Fingerman indicate.

The organization of the vertebrate eye and of the remainder of the visual pathways and centers, in their main outlines, is by now fairly well known. A great task still remains, however. The first problem concerns the finer synaptical structures of the subcortical and cortical visual centers and their functional interpretation (*cf.* chap. VI, 9 and 10; and chap. VIII, 7). The other problem, as vast as the Vertebrate Class

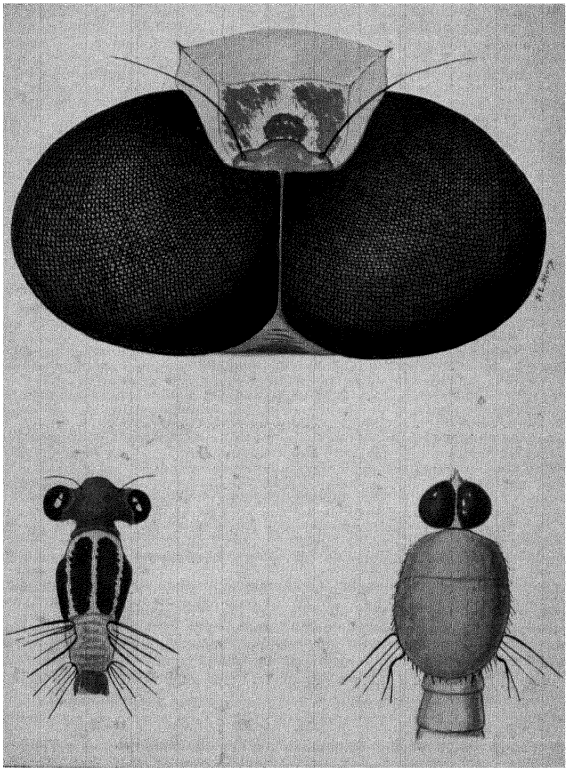

FIG. 444.—Upper sketch represents a frontal view of the head of the Big Green Darner (*Anax junius*), a large native Dragonfly, showing the huge composite eyes made up of several thousands of separate ommatidia of locally varying size. The left lower sketch represents a Damselfly of undetermined native species, showing relatively small, semiglobular eyes mounted on short stalks, hence separated by a considerable interval. The right lower sketch is that of a Mosquito of undetermined species, probably belonging to the Family Culicidae, showing the semiglobular eyes closely apposited to each other and making up most of the head. Magnification, in the same order, approximately 9×, 3½×, and 20×.

itself, is the investigation of the principal vertebrate subdivisions and noteworthy individual species in their adaptation to their particular habitats, their specific habits, and the individual and general changes that such adaptations have imposed upon their bodily organization, especially the visual apparatus, peripheral and central.

chapters an attempt is made to investigate in a few selected vertebrate species, including Man, the ways and means through which they have mastered their particular problems through bodily adaptation, especially the use they have made of their visual apparatus, and its biological consequences.

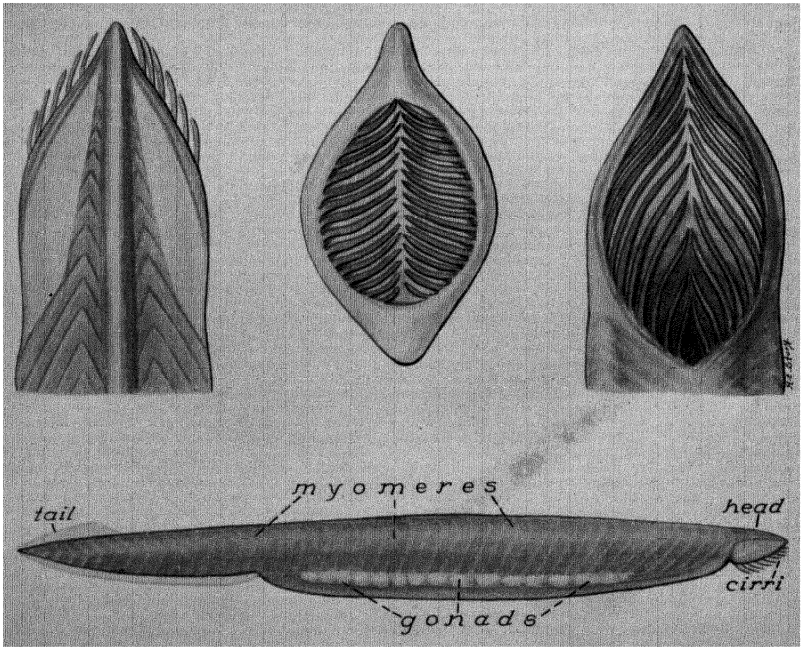

FIG. 445.—*Amphioxus* or Lancelet of an undetermined Atlantic species, the eyeless and brainless Acranian, possibly resembling one of the ancestral evolutionary stages of the Vertebrates. The lower sketch shows the general appearance of the segmented body and the eyeless head, with its oral hood and tentacles, called cirri, surrounding the mouth. The body is made up of V-shaped muscular myomeres, containing a row of reproductive organs of gonads, and terminates in a propelling tail bordered by a fin. The upper sketches show at greater magnification, from left to right, a dorsal, anterior, and ventral view of the head, with the oral hood and the arrangement of cirri encircling the mouth. Magnification of the upper sketches 18×, of the lower sketch 3½×.

Since the noteworthy writings of Charles R. Darwin and numerous other investigators that followed, it became increasingly clear that the choice of habitat and habit were the principal factors which molded the plastic animal substratum in its "struggle for existence." In the following sections of this and the concluding

SEC. 2. NORTHERN BROOK SILVERSIDE

1. TAXONOMY AND HABITS.—The Northern Brook Silverside (*Labidesthes sicculus*), also called Glassfish because of its transparency, is a small, slender, and delicate fish of clear, quiet, fresh waters of the Middle West of North America. Superficially it resembles a typical "minnow" (Fig. 447). It is, however, not related to the true Minnows of the Carp or Cyprinide Family, belonging instead to the almost exclusively marine family of Atherinidae, and a subfamily Atherinopsidae, of which it is the only representative in the Great Lakes Region of North America.

The Brook Silverside or simply Silverside, as it may briefly be called, assembles in large schools, feeding extensively close to the surface on planktonic crustaceans and small insects, according to Eddy & Surber (1947).

According to Hubbs & Lagler (1949), the Brook Silverside is a surface swimmer, found in the lakes and quieter streams, and is popularly named "Skipjack" because of its habit of skipping into the air for short distances. These authors also present a good figure of the fish in color.

In the opinion of A. R. Cahn (1924), who made a special study of the habits of this fish, its life history is more complex than that of most other fishes of the Great Lakes Region. The Brook Silverside, as Hubbs (1921) observed, is very active by day and quiescent at night. During bright, moonlit nights, however, Cahn observed frenzied activity among the fish as they darted hither and thither, skipping over the surface of the water, producing a characteristic noisy commotion that might last throughout the whole night.

The Brook Silversides, according to Cahn, inhabit the upper stratum of the water during all ages. The young subsist exclusively on plankton life, such as Entomostracans and Rotifers, gradually shifting to insect-eating as they grow older. They eventually become entirely insectivorous as they attain maturity, at which time they are 7.62 cm., or about 3 inches, long. During their babyhood they are pelagic, living in the uppermost stratum over deep water, where they are best protected against their enemies. They show daily migrations, in the morning offshore, in the evening toward shore. When adult, they settle permanently in warm, shallow shore waters and in the shoals. The Brook Silverside is strongly positively phototropic.

2. COMPARISON OF NORTHERN BROOK SILVERSIDE WITH TRUE CYPRINIDE MINNOWS.—The Brook Silverside, because of its small size,

slender, streamlined shape, habits, and food, resembles in many respects the true Minnows, with which it may be confused. "In common parlance," according to Hubbs & Lagler (1949), "all young fish regardless of kind are called 'minnows.' Technically, however, minnows are fishes belonging to the family Cyprinidae. These are all soft-rayed fishes, which, like the suckers, have toothless jaws and bear teeth in the throat only. . . ."

The Minnow Family, according to the same authors, is probably the largest of the recognized fish families, populating, in hundreds of species, almost all fresh waters of the north temperate zone and throughout Africa, the greatest diversity being found in southeastern Asia and China. Most North American forms, represented by a large number of genera and species, are built on essentially the same pattern. In the Great Lakes Region the Minnow Family is the most numerous in species and individuals. It is of considerable economic significance, even discounting the Carp transplanted from the Old World, because of its abundance, owing to which the Minnows form an important food chain for the predaceous fishes and are therefore extensively used as a bait in fishing.

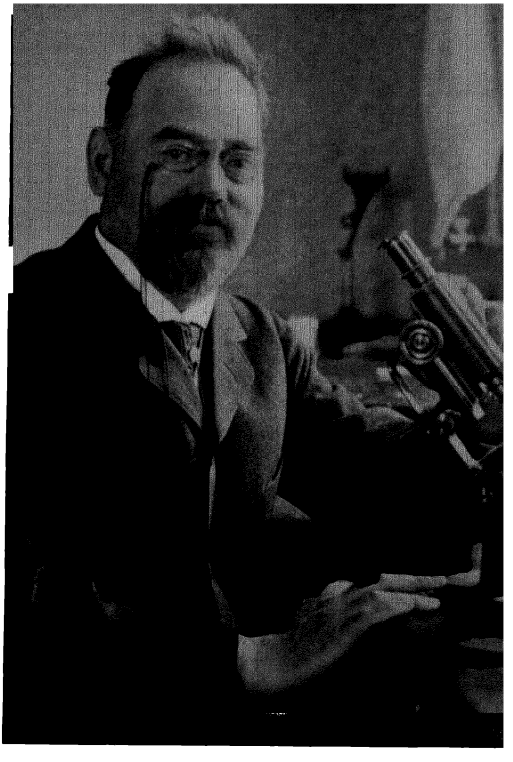

FIG. 446.—Ludwig Edinger (1855–1918), professor and director of the Neurological Institute at Frankfort on the Main, Germany, at the age of fifty-four. One of the foremost authorities of his time on the comparative anatomy of the brain (*cf.* G. Retzius; and Ariëns Kappers, Figs. 346, 467). Courtesy Dr. R. M. Strong, professor emeritus of anatomy at Loyola University School of Medicine, Chicago. (*See* for biography Neurol. Centralbl., 1915; K. Goldstein 1919; Haymaker & Baer, *The Founders of Neurology*, 1953.)

The Minnow Family, on the whole, is omnivorous in diet, the various species, however, showing considerable difference in the selection of food from the general available supply, according to Eddy & Surber (1947). The Minnows of the Great Lakes Region are mostly carnivorous, feeding principally, because of their small size, on Insects and Crustaceans, a few subsisting largely on vegetation, some wholly on the highly organic mud of the bottom of the ponds and streams.

In the words of Forbes & Richardson (1908, quoted from Eddy & Surber 1947, p. 139):

> In the general scheme of aquatic life, the native members of this family, taken together as a group, play a multiple role. They operate, to some extent, as a check on the increase of the aquatic insects, from which they draw a large part of their food supply; they make indirectly available, as food for their own most destructive enemies, these aquatic insects, many terrestrial insects also, which fall into the water and are greedily devoured by them, and the mere mud and slime and confervoid algae gathered up from the bottom of the waters they inhabit; and they rival the young to a great degree, of all larger fishes, their own worst enemies included, by living continuously, to a great degree on the *Entomostraca* and insect life which these fishes must have, at one period of their lives, in order to get their growth. They also offer a considerable means of subsistence to certain aquatic birds . . . and, through their contributions to the support of the best food fishes, they form an important link in the chain of agencies by which our waters are made productive in the interest of man. . . . From the standpoint of the predaceous species, minnows are young fishes which never grow up, and thus keep the supply of edible fishes of a size to make them available to the smaller carnivorous kinds when the young of the larger species have grown too large to be captured or eaten. . . . Moreover, by their great numbers, by their various adaptations and correspondingly general ecological distribution, and by their permanently small size, the minnows must distract in great measure the attention of carnivorous fishes from the young of the larger species, upon which, without them, the adults of these larger species would fall with the full force of their voracious appetites. By offering themselves, no doubt as unconscious, but sufficient, substitutes, they thus help to preserve—for their own future destruction, however, be it noticed—the young of many species which would otherwise be forced to feed on each other's progeny. It is not too much to say, consequently, that the number of game fishes which any waters can maintain is largely conditioned upon its permanent stock of minnows.

In summary, the Minnows and the Silversides represent the indispensable ecological link between the small aquatic life, principally insects, which they consume, and the larger predaceous fishes, which feed upon them. In general character, in adaptation to the principal biological molding factors, in feeding habits, and in the type of enemy they must avoid, the Minnows and Silversides reflect faithfully the conditions under which they live.

3. Character of the Northern Brook Silverside and its visual apparatus.—Examined under natural conditions and freshly caught, the Northern Brook Silverside appears as a small, frisky, and very alert fish about 75 mm., or 3 inches, long, sometimes attaining the length of 4½ inches. The head is short, measuring 12 mm., or ½ inch, in length, the narrow, upturned muzzle having a protractile maxillary (*see* accompanying figure). The long, greenish, and laterally compressed transparent body is streamlined relatively even more than that of the Pike (sec. 4, this chapter). On each side of it runs a composite dark-pigmented horizontal stripe along the middle, from the head to the forked tail fin, continuous over the head and across the eye and as far as the muzzle just below the nostrils. The stripe is made up of numerous minute specks of dark pigment. Similar specks, even though fewer in number, are present along the back, and fewer still along the belly. Below runs a brilliant silvery stripe which is lost in preserved specimens (hence not shown in our figure). There are two dorsal fins, the anterior fin being quite small (*dfI*, *dfII*), and a long anal fin (*anf*).

The brain, which, because of the translucency of the surrounding tissues, is clearly visible, is completely enveloped by the meningeal membranes containing similar dark pigment. The optic tecta of the mesencephalon, or visual centers, are a dominant feature in the brain.

The oversize eyes are placed laterally, with the ventral margins much closer than the dorsal margins (*cf.* three upper sketches). The optical axes, accordingly, are directed slightly downward from the horizontal plane. What the posi-

tion of the actual lines of view is must be determined by further investigation.

The corneae of the eyes shown in an optical cross-section have a slant or lopsided curve, the "corneal bulge," facing anteriorly and downward. This curvature is increased in a living fish when the upper conjunctival fold sweeps down over at least a part of the cornea in a way similar to that of the upper lid of the Advanced Vertebrates. This movement occurs rather infrequently and does so simultaneously on both sides.

In observing the head of a living fish from the front, with the fish kept freely moving in a glass jar, both pupils are clearly visible from a vantage point directly in front of the muzzle from a distance as close as 2 or 3 inches and possibly less (middle sketch). When an eye converges toward the median sagittal plane, more of its pupil becomes visible from the frontal as-

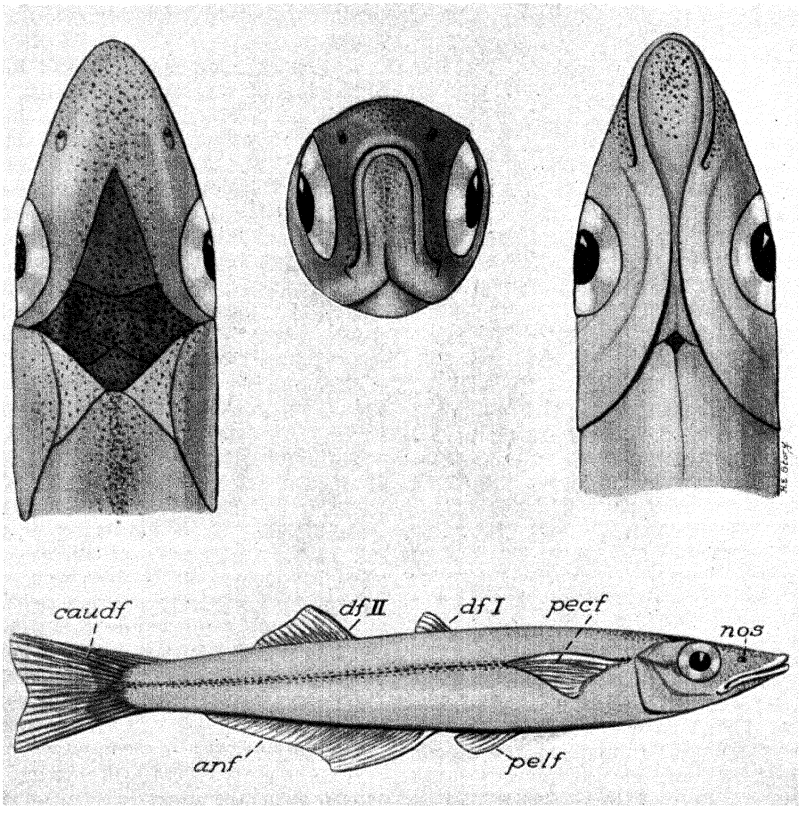

FIG. 447.—Northern Brook Silverside (*Labidesthes sicculus*), a small, slender fish of quiet fresh waters of North America, resembling the Minnows, without belonging to their family. It is noted for its habit of hunting for small insects by leaping out of the water. Upper sketches give, from left to right, an upper, anterior, and lower view of the head, showing the relatively large eyes and their slanting position, with the lower corneal margins closer and upper margins farther apart. *Labeling: anf*, anal fin; *caudf*, caudal fin; *dfI*, diminutive anterior dorsal fin; *dfII*, larger posterior dorsal fin; *nos*, nostril; *pecf*, pectoral fin; *pelf*, pelvic fin. Magnification: upper sketches, 6×; lower sketch, 2½×.

pect. Whether both eyes ever converge simultaneously, as would be advantageous for binocular vision, it was not possible to ascertain, since both eyes could not be observed at the same time. It is certain, however, that a converging movement of one eye is possible, while the other eye remains motionless, in a way similar to that sometimes observed in the Anole Lizard and in the Barn Swallow (*see* secs. 7, 8, this chapter).

4. Observation of the eye movements in confinement.—When kept in a glass jar in full light, the Silverside is continually on the move, chiefly turning round and round, occasionally sinking to the floor, and again climbing to the surface, as it tries to find a way out of its confinement. The eyes repeatedly make short, jerky movements, mostly in the horizontal plane, once or twice back, and again converging toward the point of the muzzle. The eye movements are not synchronous but alternate with similar jerky lateral movements of the head.

A change of water has an unexpected effect: the fish becomes quite frisky, the lateral eye movements become much less pronounced and difficult to observe, as if the fish were more in command of its bodily movements than before the change and hence was relying more on the movements of its head and body than on those of the eyes. The movements of the eyes are, however, present as before, but their excursions are reduced in amplitude.

5. Observation of the behavior in nature.—To describe the living habits of a small and largely crepuscular fish such as the Northern Brook Silverside in any detail would obviously require a prolonged study. In the following is given a description of the insect hunting by this fish observed on several occasions at Spirit Lake, near Frederic, in northwestern Wisconsin, during the months of July and August, 1949, 1950, and 1951.

The first note reads: As the dusk slowly descended upon the lake, its smooth surface showed small circular ripples here and there. At first my impression was that this was caused by the Sunfish in which the lake abounds. Close observation, however, revealed the cause to be the little Silversides hunting for the "gnats" which were performing their "nuptial dance" close to the lake's surface.

The disturbances appeared in the form of little blobs at the surface, soon spreading into little circles increasing in size from the disturbed center. The circular disturbances were at first few, their number increasing with the setting dusk, until at last the surface of the water was fairly boiling. Occasionally a tiny fish would emerge a little from the water, only to disappear in the next moment into its own element. In other cases the diminutive piscine hunter would make a somersault, while a few venturesome daredevils would make a clear leap out of the water and back again into it. The leaps were in each case different, some straight and vertical, others with a long and flat trajectory, or in any other possible manner. The leaps apparently depended upon the distance and the location of the hunted insects.

The second note reads: On the wooded shore of Spirit Lake it is pitch dark (August 12, 8:30 P.M. standard time). The surface of the water, however, still reflects a faint bluish light. Observed at a slant the surface appears unexpectedly alive, with silently expanding circles appearing here and there. In fact, the surface was teeming with ripples.

If one looks closely, one sees for a split second dark little objects emerging halfway into the air, to disappear again almost as quickly in the glossy water. The little Silversides are having a hunting feast. Occasionally a diminutive geyser leaps out of the water as a little body falls back into it. The air reveals to an attentive ear a fine continuous musical hum of rather low pitch, as if a swarm of bees at some distance was collecting honey from a tree in bloom. The hum is caused by a nuptial dance of uncounted "gnats" resembling minute Caddisflies or perhaps Microlepidopteran Moths of the size of Mosquitoes which are attracted to the water for the obvious purpose of depositing their eggs as soon as the wedding ceremony is over.

This up-and-down jumping of the crepuscular insects begins at about 5:00 to 6:00 P.M. and continues for quite a while into the night. As uninvited guests the little Silversides participate in it, in this way getting their protein. The feeding continues late into the night, even though there is, by human standards, little

light to be utilized. At 9:30 P.M. the surface of the water is hardly visible to the human eye, even after a prolonged adjustment to the scotopic condition, but the noise proves that the Silversides are still busy. A flashlight, confirming this, reveals the water literally swarming with tiny fish, leaping after their diminutive prey.

That, in addition to the Silversides, some other uninvited guests participated in this nocturnal free-for-all feast was indicated by certain extraneous noises probably caused by the Aquatic Birds, but, above all, by the nocturnal Bullheads: the Silversides feasting on moths, the larger fish and birds devouring the Silversides (*see* sec. 6, on Bullhead, this chapter).

The question of whether crepuscular insect hunting is a habit specific to the Northern Brook Silverside or is also practiced by other species, such as the various Minnows, as is probable, must be answered by future investigation.

6. VISUAL EQUIPMENT OF THE SILVERSIDE.— Macroscopic examination of the Silverside and its behavior indicates that the visual apparatus of this fish plays the major role in its life. Following are a few points which may be of special interest.

The eye in general conforms to the organization of a fish eye. The retina is relatively thick, with all layers, including the layer of optic nerve fibers, well developed. The regular stratification of the retina is remarkable, few ectopic elements being found outside their own layers.

The layer of optic nerve fibers is, for a Fish, unusually well developed close to the optic papilla and amounts to almost half the thickness of the entire retina.

Another remarkable feature is the accumulation of the ganglion cells in the most caudal corner of the retina, next to where it adjoins the iris membrane, in two or three closely packed tiers. This zone gradually fades to a single continuous tier in the larger portion, or *fundus*, of the eye closer to the optic papilla. A similar, even though somewhat smaller, accumulation of ganglion cells is found in the anterior or rostral corner. Hence there is, in the Silverside, a "ring-shaped area" in the periphery of the retina, encompassing the more centrally placed territory, where the ganglion cells are fewer.

The inner plexiform layer is thick and regular. It is faintly, although quite distinctly, stratified, indicating a very even, regular arrangement of the bipolar and ganglion synapses, as found in other well-organized retinae.

The inner nuclear layer, equally regularly stratified, consists of two somewhat larger and paler ventral rows of cells (which may be in part amacrine cells and in part displaced ganglion cells), and three or more rows of much smaller and more darkly stained and closely packed nuclei, which, according to their location, are bipolar cells and nuclei belonging to Müller's radial fibers. The outermost somewhat larger and paler nuclei, slightly separated from the remainder, apparently are those of the horizontal cells.

The outer plexiform layer has three zones, with zone *5-b* made up of the lower swollen ends of photoreceptors. The outer nuclear layer contains rather dark nuclei, smaller than those in the inner nuclear layer. They are very closely packed together, and their stain varies but little. Hence a certain distinction cannot be made as to which nuclei belong to the rods and which to the cones.

The bacillary layer is made up of both kinds of photoreceptors. All the cones appear to be of the principal variety subjected to the photomechanical changes. In a scotopic retina they are found about midway between the outer limiting membrane and the upper limit of the pigment epithelium. The numerical proportion of the two kinds of photoreceptors, in vertical sections, is, on the average, three rods filling the space between each two cones.

The diameter of the individual rods is about 3 microns, that of the cones slightly less. Since, according to this, the number of rods exceeds that of the cones and the total mass of the rod substance does so even more, the Silverside retina must be considered to be principally adjusted for vision in dim light, even though it is not entirely scotopic.

The number of cones counted on a stretch of 500 microns in the posterior "area," most likely used in frontal binocular vision, is 30; that of the rods and cones together, 133. The total

number of the cones, computed on this basis, in a circular area measuring 500 microns in diameter, is from 2,800 to 3,000; that of both kinds of photoreceptors taken together, from 18,000 to 20,000. This number of potentially individually stimulable units compares rather favorably with 35,000 cones counted in the rodless center of the human fovea having approximately the same areal extent (*see* chap. V, 10 [5]).

If the cones alone are considered as mediating distinct vision or acuity, the number of individually stimulable units is much less, being comparable to that in the same area of the Pike and is only about one-fourth of that found in the Trout (*cf.* sec. 5, this chapter). This is a low degree of acuity, which, however, may suffice at the close range at which the Silverside hunts insects. Whether in this it also uses the scotopic rods, as is probable, can be answered only by the application of the Golgi method. This alone may show the presence of individual bipolar synapses not only in the cones but also in the rods; hence their use in distinct vision (*cf.* sec. 12, on Tarsier, this chapter).

7. PHYSIOLOGICAL CONSIDERATIONS.—The item of particular interest in the above-described mode of catching insects by the Silversides is the use of their eyes. This, of course, can be solved with certainty only by direct observation and by experiment. For the present, the following considerations may be of some use.

It is probable that in hunting prey as mobile as the flying Moths, the Silversides would have small success unless they used both eyes simultaneously in stereoscopic vision, as a binocular team. It is, of course, possible that the fish use one eye at a time to observe the prey, as is the case with certain birds, e.g., the Robin. However, the act of aiming at the insect and the actual seizing are most likely accomplished under the guidance of both eyes, as is the case with the Robin when seizing an Earthworm (*see* sec 13 [5], this chapter).

From the regularity of the phenomenon and the number of hunters observed every calm evening and night, one judges that the fish must be quite successful. A habit as regularly observed must be well intrenched within the inherent organization of the fish, going back to the early days of Fish and Insect phylogenesis. Hence the employment of stereopsis, where both eyes are used as a functional team, must be very old.

The other related problem is that of physiological optics. The fish undoubtedly see the insects while still completely submerged in the water; hence the hunting is done in quiet weather when the surface of the water is smooth. How the fish can correctly judge not only the position of the insects but also their distance, in spite of their constant and rapid movement, can be only guessed. Whatever future detailed investigation may disclose, the preceding observation shows that the urge of the fish to get the needed supply of protein is compelling and must be old, as the fact of complete mastery of the hunting technique proves. A preliminary conclusion must therefore be made that the Silversides use both eyes, as a binocular team, in hunting insects.

The example of the Brook Silverside shows why many, perhaps most, of the Fishes must have vision good for daylight and also for at least part of the night. It explains their possession of both types of photoreceptors—rods and cones. It shows also that even in a visual apparatus preponderantly organized for scotopic use a fair degree of visual acuity is present (*cf.* sec. 12, on Tarsier).

The puzzling problem of piscine vision concerns both its dioptrics and its psychology: How do the fish compensate for the cheating rays of light, passing from a rarer medium, the air, into the denser water, which shows them the desired prey in the wrong place? To the eye of a fisherman observing the Silversides leaping above the water and actually catching the insects, the oar appears broken at the point below which it is submerged in the water, as it did to the ancient Greek and Arab naturalists, a puzzle that remained unexplained until Willebrord Snell formulated the laws of refraction (*see* chap. I, 5 [6]).

While this phenomenon is now understood by the informed, how can the Silversides, with their diminutive mentality, allow for the changed direction of the rays of light as they pass from the air into water, gauge the exact position of the jumping insects, and catch

them? And all without ever having heard of Snell and of the laws of refraction and without any cerebral cortex whatsoever, with a complete decussation of the optic nerves in the chiasma, and with a physiological myopia, all factors supposedly detrimental to acute distant vision, to binocular stereopsis, and to "psychic compensation" of errors of geometrical optics?

These problems can be only outlined here, since their working out and their solution require modern scientific technique.

SEC. 3. SUNFISH

1. TAXONOMY.--The Sunfish is one of the commonest fresh-water fishes of North America. However, in spite of this, some species, e.g., the Pumpkinseed, rival in appearance many gaudy fishes of the Tropics (*see* colored figure in Eddy & Surber 1947).

The Sunfishes populate most of the lakes and rivers in great numbers and hence are popular game for every angling schoolboy. The physiological and biological interest in the Sunfish in the present study derives from its representing the food upon which the Pike Family feeds, thus affording an insight into the relationship of a predator and its prey (*see* sec. 4, this chapter).

In the book on Northern Fishes by S. Eddy & Th. Surber (1947) the following species are described: Green Sunfish (*Lepomis cyanellus*), Orangespot Sunfish (*Lepomis humilis*), Great Lakes Longear Sunfish (*Lepomis megalotis peltastes*), Pumpkinseed or Common Sunfish (*Lepomis gibbosus*), and Common Bluegill or Redbreasted Sunfish (*Lepomis macrochirus macrochirus;* Fig. 448; *see* for other illustrations, in part colored, Eddy & Surber 1947; and Hubbs & Lagler 1949).

2. CHARACTER.--The Sunfish Family, according to C. L. Hubbs & K. F. Lagler (1949), is a diverse group of spiny-rayed fishes which have the spinous and soft-rayed portions united into a single dorsal fin (*df*), rather than separated into two distinct fins, as in the Perch Family. The Sunfishes are essentially carnivorous, feeding upon animals they can master, mostly those of small size. The dimensions of a good-sized Bluegill or Pumpkinseed, for example, may be from 7 to 8 inches and as much as 12 inches in length.

The characteristic feature of all Sunfishes is a relatively short but deep body, much compressed sidewise. The dimensions of a fully grown Pumpkinseed, for example, were found to be: length 8 inches, height 4 inches, and width, or thickness, only slightly more than 1 inch.

The head is relatively small (compared with that of a Northern Pike; *cf.* Fig. 450). The mouth in a large specimen is just wide enough to permit entry of the small finger. The teeth in both jaws and other bones of the mouth are numerous but very short. There are no barbels. The tail fin is relatively small. The dorsal fin in its anterior half contains ten stout and sharp spines. In the anal fin there are three similar spines at the anterior end, and in the abdominal fins one spine in each. The fins may be raised with the spines, making it difficult for a predator to swallow a Sunfish grabbed by its tail.

The Sunfishes are good swimmers for a short distance but are not capable of a sustained effort at great speed, and hence may be classified as rather sluggish. In summary, the Sunfishes are rather passive in character, their bodily equipment indicating an adjustment rather for defense than for offense.

3. VISUAL APPARATUS.—The eyes of the Sunfish are well developed, even though they are smaller than those of a Northern Pike of

equal size. The transparent part, or cornea, represents almost the entire visible portion of the eyeball. It has a pronounced "anterior bulge" (lower sketches in Fig. 449). This bulge, however, is flatter than in the Pike (*cf.* Figs. 450–52). The pupil is somewhat ovoid in shape, with a narrow, pointed anterior coloboma or gap; it is not certain whether another, posterior but narrower, coloboma is also present. The spherical lens, in a living specimen, protrudes into the anterior chamber, seemingly touching the inner corneal surface.

The eyes make occasional horizontal jerking movements either as a team or individually. The labyrinthine eye reflexes are pronounced and prompt. The protective visual reflexes are automatic and prompt. When a threatening movement with a hand is made over a fish lying still in a basin, the dorsal find spines are promptly raised, and the pectoral and caudal fins agitated. Whether the abdominal and anal fins are also set into motion, it was not possible to ascertain; however, when the fish is taken out of the water, these fins are also erected and the spines stiffened.

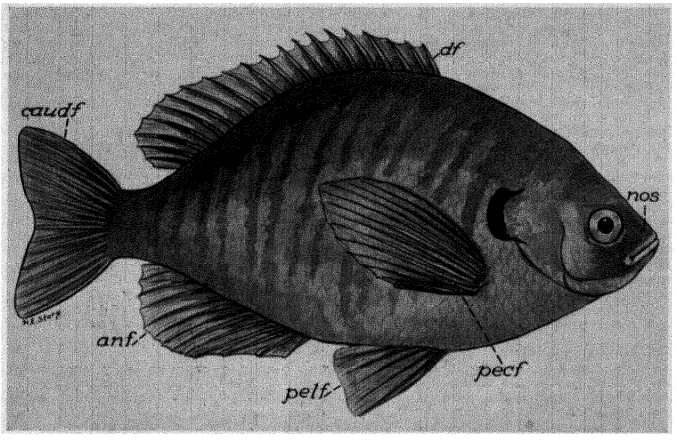

FIG. 448.—Common Bluegill Sunfish (*Lepomis macrochirus*), beautifully colored and largest of the North American Sunfishes. It is a popular "panfish," and it, together with other Sunfishes, constitutes an important food for larger game fishes, such as the Northern Pike and Bass. The Sunfishes are moderately good swimmers, with well-developed visual organs and of rather strict diurnal habit. They are somewhat inferior in their vision to their principal enemy, the Northern Pike, which defect is compensated for by their habit of swimming in schools and by the sharp, stiff spines with which their fins are reinforced. Two-thirds natural size. *Labeling: anf*, anal fin; *caudf*, caudal fin; *df*, dorsal fin; *nos*, nostril; *pecf*, pectoral fin; *pelf*, pelvic fin. (*Cf.* following figure and section on Pike.)

The "sighting grooves," described in more detail in the Pike, are present but are short, wide, and shallow and are either partly pigmented or unpigmented. They run, as usual, from the anterior margins of the eyes horizontally beneath or across the olfactory pits toward the point of the muzzle. Their extension lines converge toward a common meeting point from 1 to 2 inches in front. The anterior lines of vision from the summits of the lenses and the anterior corneal bulges seemingly fit into the "sighting grooves." The point where the lens touches the cornea seems a little posterior to the anterior corneal bulge. The lens protrudes into the anterior chamber almost as far as its equator. Normally the two eyes are held slightly turned inward with their anterior margins, the two anterior lines of vision thus being set for close vision in binocular use.

The eyeballs show great passive mobility: in the horizontal meridian for approximately 90°, in the vertical-transverse meridians almost as much. In a living fish in good condition, the eyeballs are constantly moved around the vertical axes, that is, in the horizontal plane, for

approximately 10° 30°, either simultaneously as a team or singly.

In a specimen carefully dissected so that both retinal images could be seen on the caudal faces of the two eyeballs, after removing that portion of the sclera and choroid (in a way similar to that suggested by Rochon-Duvigneaud 1922, an experiment first performed by Scheiner more

Sunfish a common binocular field of vision at least 40° wide. It is probable that, in the forming of the binocular image, the "anterior corneal bulge," even though not so pronounced as in the Pike, plays the chief role. This may indicate the ability of the cornea to collect rays passing through its marginal zone and to transmit these to the lens, approximately half of which pro-

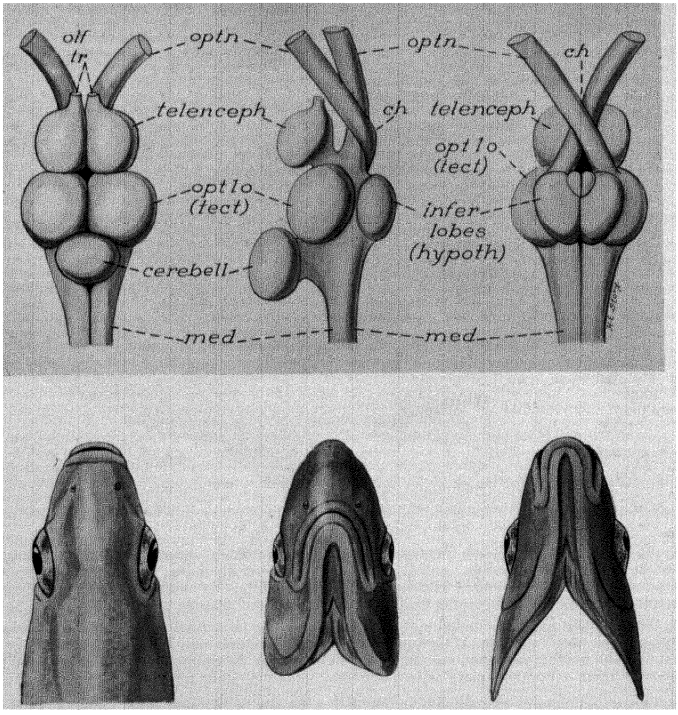

FIG. 449.—Brain and head of a Bluegill Sunfish in various views (*cf* preceding figure). Upper sketches show the brain, from left to right, in an upper, lateral, and lower view; lower sketches show, in the same order, the upper, frontal, and lower view of the head. Note the large visual centers (*optlo*) which, in fact, are the largest parts of the brain (*cf.* same in the Northern Pike); the thick optic nerves (*optn*) which are completely crossed; large eyes, their pupils visible from several aspects, best from the dorsal. *Labeling: cerebell*, cerebellum; *ch*, optic chiasma; *infer lobes (hypoth)*, inferior lobes of hypothalamus; *med*, oblong medulla; *olf tr*, olfactory tract; *optlo (tect)*, optic lobe or tectum; *optn*, optic nerve; *telenceph*, telencephalon or forebrain. Upper sketches 4 × magnified; lower sketches slightly enlarged.

than three centuries ago), it was a surprise to find the images of a single, small object held in front of the muzzle formed for approximately 20° or more on the opposite sides of both retinae beyond the mid-sagittal plane. This gives the

trudes into the anterior eye chamber—an unexpected finding in a fish in which the eyes in a relaxed condition face laterally.

The optic nerve on cross-section appears as a folded ribbon, the same as, for example, in the

kindred Black Crappie (*Pomotis nigromaculatus*). It is composed of at least 100,000 nerve fibers of mostly fine and medium caliber (1–2 microns), with a few up to 8 microns in diameter.

4. PHYSIOLOGICAL AND BIOLOGICAL CONSIDERATIONS.—In the natural habitat in which Sunfish live, in addition to the physical conditions, the principal factors to be taken into account in order to evaluate their anatomical equipment and its use are feeding habits and the enemies to be avoided.

The physical condition of the native waters indicates plenty of light and fair to good transparency, except after a heavy rainfall and during the turbidity in late summer caused by an increase in animal and plant life of microscopic and almost microscopic size. Hence the Sunfish, with only moderately developed olfactory organs, depend for food detection on vision as a distance receptor. They are good daylight animals, and, from our own personal experience, there is no indication that their vision extends much beyond the morning and evening twilight periods.

The food of Sunfishes consists of various insects, grubs, snails, slugs, worms, and other small aquatic animals, as well as frogs and small species of fish and the fry of larger fishes. Precisely how this food is acquired remains a problem that can be solved only by careful observation and experimenting. For the time being, the only guide—and a very inadequate one—is the experience gained from fishing. This suggests vision as the principal sense acting at a distance, and that the senses of smell, taste, and touch play the role of final discriminators.

When an unbaited hook is thrown into water, even though provided with a shiny or colored "spinner," there is usually no response, although there may be many Sunfish milling around. The situation changes at once when a bit of fresh earthworm is attached to the hook, which soon results in some nibbling, possibly in a lively response. However, that sight may play an important role in noticing and locating food is illustrated by the small response to a baited hook held close to or at the bottom, and in the weeds, exactly the situation where one has the best chance of catching the scotopic Bullhead (*see* sec. 6, this chapter).

The best response is induced when the bait is suspended from 2 to 4 feet below the surface of the water, provided that there is plenty of light and the bait is clearly visible. In this situation both the photic and the chemical senses are stimulated in quick succession. In very turbid or deep water and after nightfall the Sunfish usually cease to be interested in any bait, precisely when the nocturnal or scotopic Bullheads, relying on the chemical senses alone, begin to show a lively interest (*see* sec. 6, on Bullhead, this chapter).

In clear water, on the contrary, if hungry, the Sunfish pay attention to a hook and float or "bobber" from a distance of several dozen feet, beginning to flock to the center of disturbance long before any chemical sense could have had a chance to act. Also, in clear water the Sunfish prefer to keep a distance of at least 30 feet from an object of suspicion, especially if it is in motion.

Briefly, in acquiring food, Sunfish use all their senses, sight at long range, smell at close range, closely followed by the tactile and the proprioceptive senses, and taste, which require close approach or contact with the prospective food. If it is a desirable object, it is swallowed; otherwise it is spat out or disregarded. The sense of sight in the life of a Sunfish acts as a distance explorer and initiator of the alimentary function, the other senses continuing the function of feeding as the subsequent processors.

The other problem of a Sunfish, that of avoiding extinction by predators, is practically entirely intrusted to the sense of sight. Here, too, much remains unknown. If the adult individuals of the larger species, such as a Pumpkinseed and a Bluegill, alone are considered, the Northern Pike and the Muskellunge and perhaps some other fish that grow to a large size, e.g., Bass, are the only ones that come into the picture. They alone grow big enough and have sufficiently wide mouths provided with formidable teeth to be capable of mastering and swallowing a fully grown Sunfish.

The members of the Pike Family are especially to be considered the archenemies of the Sunfishes. The relationship between these two links of what amounts to a biological circle or

chain probably became established in a long evolutionary process of mutual adjustment. Under natural conditions, where there is no appreciable interference by Man or by any violent natural factors, it may be assumed that the balance is neat and even.

The principal medium by which this balance is maintained is the sense of sight of both the pursuing predator and the pursued prey. Since both are strictly diurnal fishes, the visual systems of both must be similarly organized, a slight advantage perhaps being on the side of the Pike, represented in larger eyes and in their more definite adjustment for binocular stereoscopic vision, with a more pronounced anterior corneal bulge (*see* sec. 4, on Pike, this chapter).

The same may be said about the brain in the Sunfish as in the Pike, the optic lobes being the largest single structures, each lobe as large as the entire portion of the brain in front of the midbrain (*optlo* in Figs. 449 and 454).

This fairly even balance between the pursuing Pike and the pursued Sunfish may indicate a visual competition between both in the struggle for survival. In this struggle, in each individual contest, the victory varies, the total net result being a status quo, at least in so far as the conditions now in existence can be appraised, guaranteeing a survival of both categories of fish.

It is probable that this simple relationship is, in fact, much more complicated by additional factors to be further determined. One such factor may be the habit of the Pike of preying as a solitary, freelance hunter, while the Sunfish developed a herd instinct that keeps them in "schools," representing additional protection provided by many watchful eyes. This again seems a compensation for a slight inferiority of the visual and locomotor equipment of the Sunfish as compared with the superior performance of the Pike's visual and locomotor apparatus.

SEC. 4. PIKE

1. Taxonomy.—The Northern Pike (*Esox lucius*) is a classical example of a carnivorous fish subsisting entirely on animal food mostly represented by other fish. Its other native names are Pickerel and Great Northern Pike.

The Pike is a native of the northern waters of North America. It is generally held that it is identical with the Pike of northern Europe and of Asia; it is akin to other members of its genus, such as the spectacular Northern Muskellunge or "muskie" (*Esox masquinongy*), the Eastern Common or Chain Pickerel or Green Pike (*Esox niger*), the Bulldog or Barred Pickerel (*Esox americanus*), and the Mud Pickerel (*Esox vermiculatus*). (Fig. 450; *see also* Weed 1927; Eddy & Surber 1947; Hubbs & Lagler 1949.)

2. Character.—The external appearance and internal organization of the Pike are in-

dicative of highly successful adaptation to its predatory mode of life.

Its sleek body is several times as long as it is deep or wide. On cross-section the body is almost cylindrical and varies little in diameter along its length. Anteriorly the body begins with the pointed head, the broad muzzle of which is flattened in the manner of a "duck-bill." Posteriorly the body terminates with a formidable tail provided with a broad, forked, propellent fin. The dorsal and anal fins, mounted far back, increase the propulsive action of the caudal fin. The two pairs of pectoral and abdominal fins are relatively small and, like all other fins, are soft, that is, have no sharp bony spines affording passive protection (compare with those of the Sunfishes, Perches, and Bullheads). Altogether, the shape and locomotor equipment of the Pike indicate great ability to overcome the resistance of water.

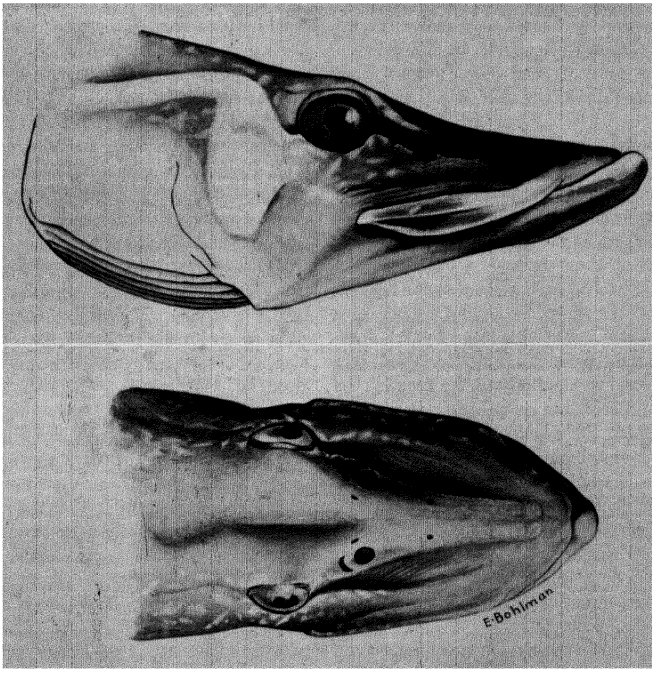

FIG. 450. Northern Pike (*Esox lucius* or *E. estor*), upper figure lateral view of the head, lower figure upper view. A predaceous, fresh-water Fish, native of North America, Europe, and Asia. Like other members of the Family Esocidae, which also includes the giant Muskellunge, the Pike is a strictly diurnal species, subsisting by preying on other fish. Hence all parts of its bodily organization—its keen visual organs, powerful propelling muscles, strong jaws armed with formidable teeth, spacious, expansible mouth and gullet, and aggressive character—are minutely adjusted to its predaceous habit. Of all equipment possessed by the Pike, vision is paramount. Indications are that the superiority of this sense is based not alone upon its keenness or acuity but as much upon binocular use or stereopsis. On anatomical grounds both ocular axes may readily converge upon a single point fixed in front of the muzzle. This is made possible by the presence of pigmented "sighting grooves" extending from the anterior margins of the eyes, in a converging direction, toward the muzzle. In the economy of nature, the Pike and its congeners play the role of a mighty factor which influences the course of evolution and adaptation of all life within its range. Structurally and biologically the Pike is the reverse of the Bullhead (*see* Figs. 456–58). (*Cf.* following two figures.)

That a Pike makes the best use of its equipment is dramatically illustrated by the behavior

of the kindred small "muskies" only 2 months old and not more than 6 inches long: "They would stalk their prey, poise, and then dart faster than the eye could follow and swallow their prey with one gulp. If the victim happened to be a large fish one slash was sufficient to sever the tail of the unlucky victim" (Eddy & Surber 1947).

The spacious mouth of the Pike, its jaws as well as the palatal bones, and even its stiff tongue are armed with numerous sharp teeth, set with the points turned toward the throat, some of them of imposing size. Any prey seized has, therefore, little chance to escape. Such chance is further reduced, according to Eddy & Surber, by the habit of the Pike and Muskellunge of swallowing the prey, usually head first.

If the prey is caught by the tail, the predator shifts it into proper position before swallowing it, according to these authors. In this way the protection offered to such species as the Sunfish and Perch by the sharp, bony, and erectile rays or "spines," especially of the frontal parts of the dorsal and anal fins, is eliminated, as the spines are pressed against the body of the prey by the jaws of the Pike: in this position the spines rather facilitate the swallowing, whereas with the tail first, the spines would stick in the mouth of the Pike and would make the process of swallowing difficult or impossible. (All species of Sunfishes and the Perch have developed a protective reflex habit of erecting and holding in such position their spiny fins when threatened or when taken out of water; *see* preceding section.)

In the habit of turning the prey head first, the Pike and Muskellunge, curiously, resemble the primate Tarsier, who does precisely the same when eating a lizard, and probably for a like utilitarian purpose. The only difference is that a Pike does the turning with its mouth, while the Tarsier accomplishes this with his hands (*see* sec. 12, on Tarsier, this chapter; a similar habit is described in the Common Shrew: *see* sec. 9, on Shrew, this chapter).

3. HABITS.—The Pike is a persistent hunter, slinking from early morning until late evening along the weedy aquatic groves, always on the lookout for suitable prey, usually a Minnow, Sucker, Perch, or Sunfish. Its activity is restricted to daylight. With increasing dusk, it slows down and ceases its search for food altogether, even though a fisherman may get an occasional "bite" after the sun is gone.

The movements of the Pike, as far as they are known, are made up of a number of straight lines, each corresponding to a short and differently oriented dart. The length of a single dart in a grown-up Pike may average 20, 25, or 30 feet, judging from the stretch along which the hunted small fry scatter on the surface of the water in order to evade their foe.

When the Pike notices an object of interest within the range of a single dart (which, in turn, may be equivalent to the average range of its sight within given optical conditions), it "freezes" for a moment, adjusts its sensory-motor apparatus to the precise location and distance of the object, and reaches it and seizes it with a single swoop. Such swift and precise action implies excellent co-ordination of the entire bodily machine: it requires, above all, keen sight to notice the potential prey and to recognize its size, shape, color, and movement—the essential qualities that elicit an attacking response.

At what distance the Pike and other fish can notice a visual object is known only imperfectly. Visibility in water depends much on its chemical composition and on the number, size, shape, and other qualities of the formed particles suspended in it, as well as on the amount, quality, and direction of light entering the water. In the fairly clear waters found in the northern lakes of North America, the object may well be seen at noontime, in summer, at from 20 to 40 feet and, under favorable circumstances, several times that distance; in turbid conditions less. On the average, it may be assumed that a fish should be able to see in good light at least 50 feet or more in the lateral direction (*cf.* Erickson 1933; G. L. Clarke 1935).

The visual acuity required to utilize in full the physical conditions of the water, accordingly, may be far below the acuity found in the keen-sighted air-living terrestrial Vertebrates, such as the Birds and some Mammals, e.g., the Primates. The true measure, however, is the average acuity found in most Fishes, the competitors among and upon which the Pike lives. Sight good enough to see objects at 50 feet

under water and under exceptional conditions at a much greater distance must be recognized as the maximum in the aquatic element. Even though there are no precise data dealing with the particular features of the Pike's sight, the available information is sufficient to warrant the assumption that its vision is fairly close to the limit imposed by the physical conditions of its aquatic habitat.

A feature characteristic of a quick-acting fish is the Pike's behavior in a basin filled with water, where for a while it keeps perfectly still and then, suddenly, for no apparent reason, becomes violently active.

4. EYEBALL.—The study of the Pike's eyes and of the rest of its visual system tends to confirm the foregoing assumption about the excellence of its sight. Its eyeball is large. In a specimen 18 inches long, the horizontal rostrocaudal diameter amounts to almost 22 mm., the horizontal transverse diameter to 12.5 mm. (*cf.* diameter of human and simian eyeballs in chap. V, 1 [2]).

In a freshly caught specimen the eyeballs are quite mobile. They may easily be moved in any direction: up or down, forward or backward, or in any intermediate meridian. This is possible, in spite of a superficial impression that the eyeball is tightly fitted in the orbit. Passively the eyeball may easily be rotated around its vertical axis for approximately 45° and somewhat forcibly to as much as 100°. How much it may be rotated under physiological conditions is a problem yet to be solved. In the specimens preserved in fixing fluids, such as formalin and alcohol, the eyeball entirely loses its natural mobility.

The few observations so far made in a living specimen under conditions far from natural indicate an exceptional ocular alertness, quickness, and extent or amplitude of the eye movements as a response to both visual and labyrinthine stimulation. For example, an eye may be rotated medially or inward so that its pupillary plane makes an angle of approximately 30° with the mid-sagittal plane. In this movement the posterior margin of the cornea is turned for a few degrees anteriorly, and the inferior margin slightly lifted, which makes the posterior retinal segment face anteriorly and the inferior segment face a little upward. Spontaneous eye movements may also be noticed in a living specimen. When the body of a Pike is moved passively, lively labyrinthine reflexes of the eyeballs in the horizontal and vertical planes, and as extensive as in a Trout, may promptly be elicited. (*Cf.* following section.)

The great mobility of the Pike's eyes is possible because of several factors: a deep conjunctival pocket surrounding the eyeball on all sides, great flexibility of the conjunctiva, well-developed and long extrinsic eye muscles, and particularly a loose, watery tissue in which the principal organs filling the orbit, such as the muscles, nerves, blood vessels, etc., are imbedded. The Pike's eyeball literally floats on a "fluid cushion," permitting easy displacement of all these structures in any direction.

5. CORNEA, LENS, AND THE SIGHTING GROOVE.—The cornea of the Pike's eye is almost as large as the visible portion of the eyeball (Fig. 450). It is pear-shaped, with its longer axis horizontal and its pointed end facing anteriorly. In a horizontal section or in an optical section in a living or preserved specimen looked upon from above, the cornea appears asymmetrically curved, the radius of curvature of the anterior portion closer to the muzzle being considerably shorter than that of the posterior portion (Fig. 451).

The anterior portion of the cornea is, accordingly, much more curved, producing an anterior or rostral protrusion or bulge. The anterior corneal bulge must, accordingly, be a more potent refractive medium than the flatter, posterior part. The rays of light coming from the front are therefore more strongly bent and more easily directed to the lens. But even if the refractive index of the Pike's cornea and that of the surrounding water were identical or almost so (an identity in Fishes now generally assumed but requiring further testing) and if no considerable refraction in the cornea were present, its anterior bulge would still be of pre-eminent importance, since it would permit a goodly portion of the lens to protrude beyond the body surface and in this way make possible collection of the anterior rays coming from the direction of the muzzle (Fig. 452).

From the anterior rim of each orbit a darkly pigmented groove extends between the nostrils of the olfactory sac and the upper jaw along the

head in a horizontal direction toward the frontal end of the duck-billed muzzle (Fig. 450). Superficially, the two grooves appear to be no more than "decorations," or elements fitting into the mottled pattern of the Pike's exterior, possibly serving as a useful and effective decoy to the finny predator.

A closer examination, however, while not disproving this interpretation, indicates that these two grooves may have another and more important function, that of sighting or aiming at the prey. Their extension lines converge anteriorly toward a point approximately 1 inch in front of the muzzle, more or less depending on the age and size of the specimen (O_1, O_2, in Fig. 451).

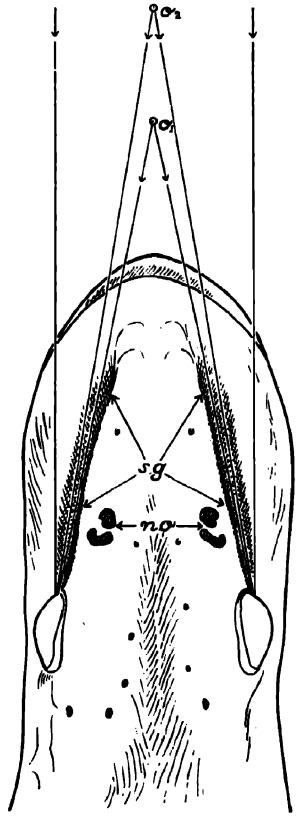

FIG. 451.—View from above of the head of a Northern Pike (*Esox lucius*) showing the position of the eyes and sighting grooves, with the anterior pencils of light rays used in binocular stereoscopic vision drawn at different angles of convergence, depending on the distance of the viewed object, beginning from approximately 5–6 inches (O_1, O_2) to infinity (*parallel lines*). *Labeling: no*, nostrils; *o*, viewed object; *sg*, sighting grooves. (*Cf.* preceding and following figures.)

It appears, therefore, that these grooves are chiefly used as channels along which the two principal lines of vision, the right and the left, have an unobstructed passage. This is made possible, in particular, when the eyes are turned slightly inward and the pupillary planes are inclined with the front ends toward the mid-sagittal plane. In this position the principal lines of vision hit the surface of the corneal bulge at a greater angle and are thus more easily inflected by refraction toward the lens, or simply pass through the cornea into the lens without refraction (Fig. 452).

The anterior pupillary notch, or "coloboma," also facilitates the passage of the frontal rays into the eye. This notch (*apn*), as observed in a living specimen, is exactly in line with the sighting groove, being, in fact, a little inward when the eye is maximally rotated inward toward the sagittal plane. In this position the notch permits the clear passage of rays passing through the caudal portion of the sighting groove into the interior of the eye.

It should also be of some interest to note that similar grooves or depressions are present in other fresh-water species of fish that depend largely on good vision, as, for example, the Trout and the Bass, and many other Vertebrates, including Mammals (*see* sec. 7, on Anole Lizard, this chapter).

6. INTERNAL EYE STRUCTURES.—The lens of the Pike's eye, as in other fishes, is spherical in shape and is only loosely fitted into the pupillary aperture (Fig. 452). It protrudes about a third into the spacious anterior chamber and almost touches the inner surface of the cornea (in the living fish the apparent interval between the cornea and the lens, when observed from above, measures 0.3–0.4 mm.).

This optical arrangement, with the considerable protrusion of the lens beyond the surface of the body, is especially favorable for the collection of the rays that pass through the marginal

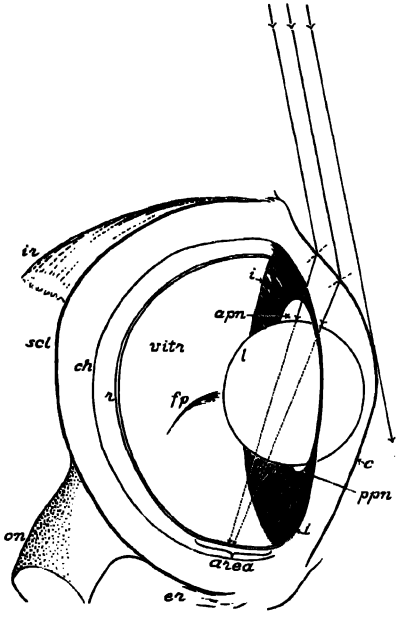

FIG. 452.—Horizontal view of the right eyeball of a Northern Pike (*Esox lucius* or *E. estor*), with upper portions of coats removed, in order to show refractive media and other structures regulating the passage of frontal rays of light used in binocular stereoscopic vision: two that hit the surface of cornea at obtuse angles, refracted into eye where they are focused by the lens (*l*) at a temporoposterior "area" of clear vision, whereas the tangential rays pass by without being inflected into the eye. Broken lines at points of contact of the rays with the corneal surface indicate verticals or "normals" to the surface with which various rays form varying angles of refraction. Note spherical lens, held in suspension by ligament and accommodating muscle, the anterior half of which protrudes through the much larger opening of the iris into the anterior chamber, where it almost touches the cornea; the latter, viewed in a horizontal optical section, appears lopsided or asymmetrically curved, its radii of curvature being shorter in the anterior segment facing the snout (*upper half* in drawing). Lens does not fill in the oval-shaped aperture of the iris (*see* Fig. 450), leaving a wider anterior and a smaller posterior pupillary cleft, through which the anterior and vitreal chambers communicate. Frontal pencils of rays, coming from the direction of the muzzle, pass through the more strongly curved anterior corneal segment and through the anterior pupillary notch (*apn*) into the lens (*l*), by which they are focused on the retinal "area" in the posterior eye corner through which distinct vision is mediated. Since the eyeballs are easily and extensively rotated in the horizontal plane, both axes of acute vision may be brought to converge toward a common fixation point, hence creating conditions necessary for binocular stereoscopic vision. Magnification 3½ ×. For other details *see* Fig. 451. *Labeling: apn*, anterior pupillary iris notch or cleft; *c*, cornea; *ch*, chorioid; *er*, attachment of external rectus or straight muscle; *fp*, falciform process; *i*, iris; *ir*, attachment of internal rectus muscle; *l*, lens; *on*, optic nerve, partly pigmented; *ppn*, posterior pupillary notch; *r*, retina; *scl*, sclera; *vitr*, vitreous.

zone of the cornea. Such are all rays that are more or less parallel with the Pike's body. Of these, however, only those that are biologically most useful are maximally utilized: the rays coming from the front. In order to permit free passage of these frontal rays into the eye's interior, the lens is pushed somewhat toward the posterior blunt margin of the oversized pupil, leaving unobstructed in front, toward the muzzle and pigmented sighting groove, a wide aphakic gap of a semilunar shape—the anterior pupillary notch or coloboma.

The shape of the Pike's pupil is oval, with the narrower end facing the muzzle and the longer axis horizontal, precisely as in the cornea. A posterior coloboma or notch is also present but is less wide. When the rostral end of the eye is turned inward for about 30° in comparison with the position at rest, the notched anterior pupillary margin is pushed inward, which brings it to lie about 1 mm. behind the back end of the pigmented sighting groove. In this position the frontal pencil of rays, after its refraction in the anterior corneal bulge, easily slips through the anterior pupillary notch and, after a further refraction in the lens, is projected as a sharp image upon the caudal or posterior segment of the retina tucked in the posterior corner of the eye near the back end of the iris.

This particular locality contains an especially differentiated "area" with an increased number of photoreceptors in the bacillary layer and the ganglion cells accumulated in greater numbers, instead of in a single and rather discontinuous tier found elsewhere in the retinal membrane. This "area" of the Pike's retina is not central but temporal, lateral, or posterior, comparable to a similar area in the Swallow, Swift, and Owl. It is the locality where a higher degree of neuroreceptive resolution of physical light stimulation takes place. (*Cf.* following subsection, and section on Northern Brook Silverside.)

7. RETINA.—The general character of the Pike's photoreceptor membrane is that of a "duplex retina," fit to function under both diurnal and nocturnal conditions of illumination. However, the impression one gains from the microscopic study is of an emphasis upon the structures instrumental in daylight vision, whereas those used in dim-light vision appear less developed. (*Cf.* the opposite arrangement in the Northern Brook Silverside and Bullhead.)

The pigment layer, packed with granules, needles, and threads of a dark-brown color, amounts to no less than one-fifth of the entire thickness of the retina. In the photopic condition it envelops the outer segments and a part of the inner cone segments.

The principal structures of the bacillary photoreceptor layer are huge cones. Their slightly bottle-shaped inner segments fill most of the space as a solid formation, leaving little between for the more numerous but much thinner rods. The long and much more attenuated outer cone segments, similar in shape to those found in the periphery of the human and simian retina, extend toward the pigment epithelium to as far as two-thirds or more of the bacillary layer.

The thickness or diameter of individual cones measured at the level of inner segments varies only a little. In the "posterior area" it is from 6 to 7.5 microns, their intercenter distance being from 9 to 10. In the extra-areal periphery the cones are 9 microns thick, their intercenter distances from 12 to 13.

The number of cones counted on a stretch of 500 microns in the "posterior area" is 30–40; in the center of the fundus it is 24–25. Computed for a circular area measuring 500 microns in diameter (same as the average diameter of the human central territory free from rods), in the "posterior area" this would give roughly 1,500 individually stimulable units (provided that each areal cone has its own midget bipolar). This number, representing less than one-twentieth of 35,000 cones found in the rodless area of the human central fovea, is still a respectable number, providing the Pike with a degree of visual acuity apparently sufficient in its aquatic habitat. (*Cf.* chap. V, 10 [5].)

The number of cones in the far more extensive extra-areal fundus of the eye was found to be about 600 in the same circular area measuring 500 microns across. This represents a rather rough "grain," in comparison with the highly efficient aerial vision of the Primates, Birds, and Lizards, but still indicates a fair degree of acuity. In this estimate the fact that the entire retina is provided with at least that many cones, hence affording a fair degree of visual resolution in the entire wide field of view of the Pike, must also be taken into consideration.

In comparison, then, the Pike's visual resolution in most of its field of view is no less than that in the extracentral parts of the human fields. The degree of visual acuity possessed by the Pike in most of its field of view appears even more serviceable to the fish in its short-range aquatic environment than the same low peripheral acuity appears to Man in his aerial vision.

Whether or not the Pike has accessory cones comparable to those found in the Trout (sec. 5, this chapter) requires further study. In routinely stained preparations none were found. According to Reich (1874), all cones are double cones; but according to our own examination, all of them appear to be single cones.

The approximate numerical ratio of cones and rods is 1:3 or 1:4, and possibly as small as 1:10. This ratio, however, is deceptive, since it does not express the relation of the total mass or substance of the two categories of photoreceptors, which may be 1:1 or even more in favor of the cones. The situation in the Pike, in this respect, is the opposite of what was found in the Northern Brook Silverside, in which the quantitative ratio of the cone and rod substances is approximately 1:10 and approximates the arrangement found in the diurnal Primates. (*See* sections on Northern Brook Silverside and on Tree Shrew, sec. 10, this chapter.)

The outer nuclear layer is quite thin, being made up of an upper row of large, pale, angular, or elliptical cone nuclei with delicate inner framework, located just below the outer limiting membrane, and of a double row of much smaller, elliptical, and vertically arranged rod nuclei. In hematoxylin-eosin or phloxin-stained preparations the rod nuclei appear almost black; in toluidine preparations, stained according to Nissl-Lenhossék's method, the cone nuclei can easily be identified by their clear, purplish hue, very different from the

dark-blue color of the rod nuclei (remarkably, the inner rod segments above the outer limiting membrane have the same purplish hue, while the inner cone segments remain unstained by this method, staining in a pink color with eosin or phloxin).

The outer plexiform layer is also thin. In spite of this, its three zones *5-a*, *5-b*, and *5-c* are easily seen. In the middle zone, as in all diurnal retinae, the row of evenly spaced so-called "granular clods" is conspicuous. These are synaptical contacts between the lower swollen ends of the cones and the upper ends of midget bipolars and horizontal cells. In hematoxylin- and eosin-stained sections these synaptical contacts are arranged in a very regular horizontal line, with small intervals separating each two adjoining contacts. Hence the number of such contacts may be used as an indication of the number of cones in a particular locality of the retina. With this as a criterion, the number of the cones in the "posterior area" was found to be fifteen, and in the extra-areal periphery about twelve, to a distance of 150 microns. This is about the number of cones found in the two localities by direct count, as mentioned earlier.

The inner nuclear layer is rather thick. It is made up of several varieties of cells, differing greatly in appearance. The bulk in the middle zones *6-b* and *6-c* is represented by small, dark, and unevenly spaced nuclei, which belong to the radial fibers and bipolar cells. In the lowermost zone are larger and paler cells, closely packed together, with a few smaller and darker nuclei interspaced. These are the classical amacrine cells, some of which, however, may be ganglion cells and Müller's "radial fibers." The uppermost tier *6-a*, next to the outer plexiform layer, belongs to the so-called horizontal cells. These are remarkable because of the extraordinary size of their bodies and horizontal expansions, with cytoplasm completely lacking a chromophile substance and inclosing a very large spherical nucleus containing a large nucleolus.

The inner plexiform layer is thick and has a granulated appearance, finer in its upper half and coarser in its lower half. Conspicuous in it are the thick, vertically arranged, and evenly spaced radial fibers of Müller, and also an even, horizontal striation.

The layer of the ganglion cells everywhere contains a single, often discontinuous, row of smaller and medium cells, with an occasional cell of giant size. The exception is the "posterior area" next to the iris in the posterior corner, where the cells form a single, solid, continuous row with an occasional tendency to accumulate into two tiers, as mentioned.

A similar but less dense increase of ganglion cells is found in the anterior segment of the retina, both "areae" together forming a ring-shaped "area" resembling that found in the Northern Brook Silverside and in the Trout (*see* corresponding sections).

The cytoplasm of the ganglion cells contains either diffuse or finely granulated chromophile substance of Nissl. In this the ganglion cells exactly resemble those in the innermost tier of the inner nuclear layer. The few smaller and darker nuclei found here may belong to the neuroglia.

The layer of optic nerve fibers is thick and horizontally striated, with thick, conically expanded, and evenly spaced lower ends of Müller's supporting radial fibers, which together form the inner limiting membrane.

In summary, the Pike's retina, with its great number of giant cones representing the bulk of the photoreceptor structures and with the diminutive, although more numerous, rods, appears to be an organ chiefly adjusted for photopic or daylight vision. Its acuity, owing to the great thickness of individual cones, must be rated as inferior to that of Vertebrates possessing a differentiated fovea, such as many Lizards, Birds, and Primates, including Man.

In appraising functionally the structures of the Pike's retina, several factors must be taken into consideration. The great number of cones, the considerable thickness of the layer of optic nerve fibers, and the exceptional thickness of optic nerves indicate that a number of optic nerve fibers may originate from the ganglion cells displaced into the inner nuclear layer. Such are present in small numbers in the primate retina and have been found in the Frog, Lizard, and Birds (*see* chap. V, 5 [1]; and S. Ramón Cajal 1911). Investigation with the Golgi method should clarify this particular point.

The giant cells found in the inner nuclear layer, located where the horizontal cells are found in other Vertebrates, appear to belong essentially to a system of neurons whose func-

tion is a lateral or horizontal association, or functional integration, of the adjacent and more distant territories of the retina. The horizontal course of the thick expansions of these cells lends itself to such an interpretation. The Golgi method should also clarify this point.

Even though the synaptical relations of the Pike's retina still remain unknown, it appears that this membrane is essentially an organ adjusted to respond with relatively low acuity but with great speed and intensity to rather feeble photic and chromatic stimuli over the entire range of its wide field of view. A locality sufficiently differentiated to act as a "posterior area," comparable to the "central area" of other Vertebrates, is present in the posterior-caudal corner, precisely where an anterior pencil of rays strikes, used in stereoscopic binocular vision. The large dimensions of the cones, furthermore, may be interpreted in terms of low threshold or high responsiveness to chromatic stimuli, which this predator certainly needs in order to notice its multicolored prey. Briefly, the Pike's retina faithfully reflects the predatory habits of this diurnal fish.

8. BINOCULAR VISION.—From the preceding there is not much doubt that the Pike's eye is well organized for its special task. This and other arrangements connected with it permit the frontal rays of light to pass along the pigmented sighting groove through the frontal bulge of the cornea and the anterior notch of the pupil to the lens, and through it to the posterior area of the retina. Here these rays are most completely utilized for detailed vision and are therefore biologically most useful for this species.

The next inference to be drawn from the foregoing fact is the likelihood of a simultaneous use of the principal lines of vision of both eyes. With the position of both lines in a relaxed specimen as stated, a relatively slight inward turn of the two eyeballs will suffice to make them meet in a single point in front of the muzzle (Fig. 451). The great mobility of the eyes described in the preceding paragraphs certainly permits this. The two eyes may, accordingly, be used simultaneously for binocular stereoscopic vision.

The organization of the peripheral parts of the Pike's visual system indicates its use in binocular convergence and stereopsis, similar to that present in the Swallow. (*See* sec. 8, on Swallow, this chapter.) However, actual observation of the use of the Pike's visual apparatus during life, particularly in catching prey, is required to confirm and to amplify, or to modify, the deductions made from the anatomical investigations.

If the answer is positive, as may be expected on the basis of some observations of the living fish, in analogy with similar observations upon Fishes made by Rochon-Duvigneaud (1933), it will be shown that the Pike has the ability to converge both eyes toward an object situated at varying distances in front of its muzzle. Likewise, a comparable range of accommodation of its dioptrical apparatus may be postulated. This, at any rate, is what one would expect in a fish depending entirely on living, moving food.

9. NERVOUS SYSTEM. —The optic nerves and centers of the Pike are no less remarkable and characteristic of this "visual animal." The optic nerves, in comparison with the small size of the entire brain, are disproportionately huge, cylindrical trunks. Each optic nerve is almost as thick as the spinal cord just behind the brain. This is the more unexpected, since certainly the somatomuscular system, whose centers are in the spinal cord, is very well developed, and its swift and powerful action of paramount importance in this species; the Pike's body, except for the relatively small internal organs, is mostly solid musculature. The ribbon-like arrangement of fibers, found in the optic nerve of other fishes, is not noticeable.

The diameter of the optic nerve of a rather small specimen is from 1.8 to 2.2 mm. In larger individuals the diameter is much larger. A cross-section shows it to be more or less round or slightly deformed. The microscopic appearance is rather uniform, thus duplicating the rather uniform size of the ganglion cells in the entire expanse of the retina. The caliber of the fibers is also rather uniform and moderate in size, the far greater majority being thin fibers of about 2–3 microns, with many smaller ones, and also a few large ones of 4, 5, and 6 microns in diameter. In this way the cross-section of the optic nerve reflects the rather uniform organization

of the retina. The number of fibers may amount to 400,000 or more.

In the chiasma the two optic nerves intercross in bulk, either the right or the left nerve being the upper one in different individuals.

The optic nerves apparently terminate chiefly in the midbrain, each nerve in the contralateral lobe. The optic lobes (*opl, optlo*), representing the optic tectum (*tect*), are of infront of the huge optic lobes (*forebr, telenceph* in same figures).

The entire brain of a Pike may be said to be a composite of the lower vital centers of the medulla oblongata (*med*), of a small cerebellum (*cbl, cerebell*), and of the relatively large mammillary bodies, upon all of which is superimposed a huge visual mechanism which dominates the whole.

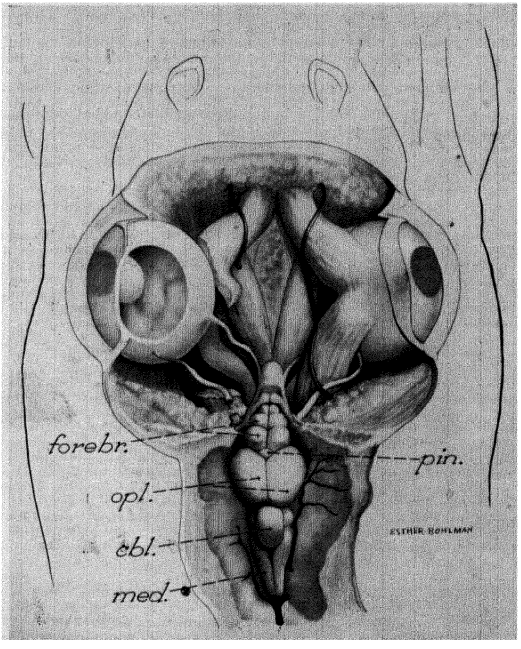

FIG. 453.— Dissected head of the Northern Pike, to demonstrate the brain (*cf.* Fig. 454), eye muscles, and nerves connected with the eyeballs. The two largest paired structures of the brain are the optic lobes (*opl*). The three other and much smaller paired structures in front of the optic lobes represent the diminutive forebrain (*forebr*). The single small structure in the mid-line, just in front of the optic lobes, is the pineal gland (*pin*). Behind the optic lobes is the cerebellum (*cbl*) and oblong medulla (*med*). Note the large eyeballs and giant extrinsic eye muscles, compared with same parts in the Northern Brown Bullhead, a Fish with small eyes and a well-developed olfactory apparatus. (*See* Fig. 456.)

ordinate size and dominate the external appearance of the brain (Figs. 453, 454; *see also* Beccari 1943, Fig. 182). They are its largest single structures. The mass of each optic lobe is roughly double that of the entire telencephalon, comprising the striate bodies, thalami, and olfactory apparatus, all these parts together giving the appearance of a small appendage in

The topographical relations of the retinal quadrants to the various fiber bundles of the optic nerve and their representation in the visual centers of the brain remain a problem for future investigation.

The highest level, or centers, of the Pike's visual system are the two optic lobes, principally made up of a cortex-like structure, poor in

cells and rather simple in structure. Here the most important processes take place, including those that may be described as "mental" or "psychic." These comprise visual orientation in space, detailed visual discrimination, visual memory, recognition of the symbolical meaning of the visual impressions of shapes and colors, and judgment and making of decisions whether, when, and how to act or not to act.

From examination of the brain alone it is obvious that the Pike is practically exclusively a visual animal. Visual impressions are of overwhelming importance in its life. The Pike, speaking in terms of human psychology, "thinks" through its sight, almost to the point of exclusion of all other senses. This may account for the fact that a Pike strikes at any shiny lure, such as an artificial minnow, if it only approximates the size, shape, and brilliance of a fish upon which it customarily preys. And it does so, irrespective of whether or not the hook is baited with some animal lure, hence without regard to whether or not its senses of smell and taste are stimulated, the condition being that the lure moves.

The role the chromatic stimuli play in the biology of the Pike, believed important by many fishermen, remains another problem that must be solved by careful experimenting. The numerous and voluminous cones may seem to be evidence of the essential function of color vision in the life of this predator (*cf.* Carter 1948). The summating apparatus, in turn, may be interpreted in terms of the extreme sensitiveness of this fish to objects in motion.

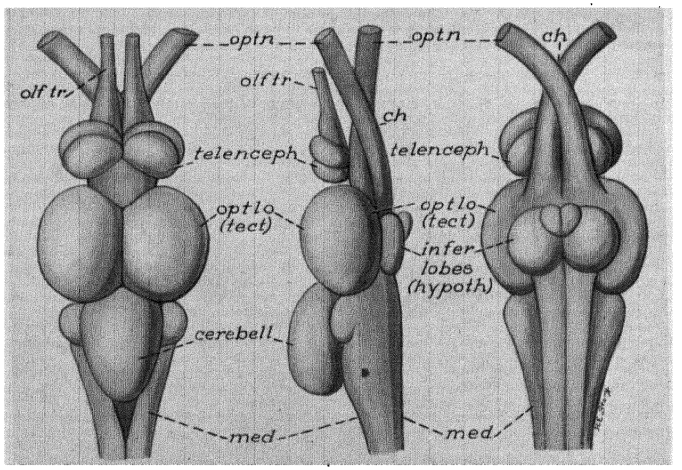

FIG. 454.– Brain of the Northern Pike in three views (from left to right): an upper, lateral, and lower aspect. Note the large size of the visual centers (*optlo*), which from every angle appear as the largest parts of the brain. The optic centers, together with the posterior parts of the brain, in this species far outweigh the diminutive telencephalon or forebrain (*telenceph*) which serves olfactory and other nonoptic functions. *Labeling: cerebell*, cerebellum; *ch*, chiasma of optic nerves; *infer lobes* (*hypoth*), inferior lobes of hypothalamus; *med*, oblong medulla; *olf tr*, olfactory tract; *optlo* (*tect*), optic lobe or midbrain tectum; *optn*, optic nerve; *telenceph*, telencephalon or forebrain. Magnification 3×.

10. BIOLOGICAL CONSIDERATIONS. From the study of its anatomical organization, its habits, and other factors of its biology, one becomes convinced that the Pike, the "wolf of the waters," or rather the "tiger of the lakes," is what it is because of its superior sight.

The visual apparatus of this predator fish has undergone remarkable increase, perfection, and specialization to serve as a daylight distance receptor. That it is precisely the sight that became specialized is accounted for by the fact

that, even in the water, light is a more certain medium of communication for a predator than any other physical or chemical form of stimulus used by the Vertebrates, such as those to which the senses of taste and smell respond.

Light, measured in terms of biological processes and events, is instantaneous, whereas the chemical substances capable of stimulating the senses of taste and smell require measurable time, even when working at close range. The fact that physical light propagates rectilinearly even in water, greatly though it is restricted and modified by absorption, dispersion, and other factors, still makes it a more dependable guide to a diurnal predator than any other external stimulus.

The sense of sight, however, had to be perfected to the limit allowable by the physical conditions of the water, particularly by its transparency, in order to be of great use. This seemingly was accomplished by the Pike and its relatives, the Esocidae. This, in turn, forced a comparable perfection of sight in other species upon which the Pike Family preys, such as the Sunfishes, Minnows, and Suckers. Without such an adjustment, they would have been exterminated, which would likewise have meant the disappearance of the Pikes.

The biological relation between the Pike and its prey may be crudely described as a perpetual, neatly balanced, war, wherein the perfection of sight of the eaten prey always closely follows that of the eating predator—a delicate relationship that in natural conditions safeguards the perpetuation of both categories of these species.

SEC. 5. TROUT

1. Taxonomy.—The Trout is mostly a small to medium-sized fish, of slender, graceful build, subsisting exclusively on small animal life, mostly insects. It is a resident of cold running streams and lakes of elevated regions of the Northern Hemisphere. It belongs to the Family

Salmonidae of which the other representatives are the salt-water Salmons.

The Trout is a popular game fish, being, in the opinion of many, a personification of all that is noble and ideal in a fish: beauty, fighting qualities, and an exquisite taste.

There are several native Trouts, the most widely distributed being the Common Brook Trout (*Salvelinus fontinalis*, Fig. 455) and other

2. Character.—As a fish subsisting on small, mobile prey, the Trout embodies all features one would expect from it: a slender body form, with a pointed and laterally flattened head, a spacious mouth well provided with medium-sized teeth, and a powerful musculature, which, with a large tail fin, represents an efficient locomotor equipment.

Of its senses, sight is superior and obviously

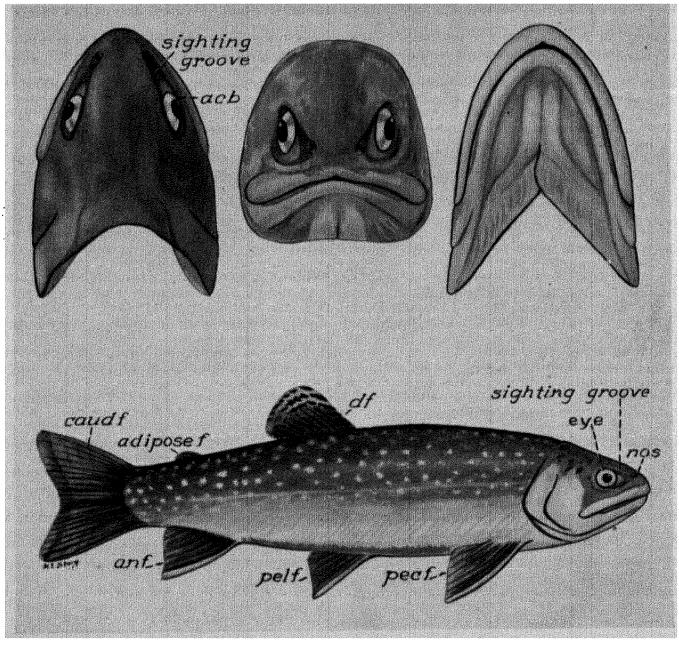

Fig. 455.—Northern Brook Trout (*Salvelinus fontinalis*). Upper sketches represent, from left to right, an upper, anterior, and lower view of the head, the lower sketch showing the full side view of the fish. Note the well-developed eyes, easily seen, including both pupils, from above and from the front, but not from below; the "sighting grooves," along which the two visual axes converge toward the common fixation point when both eyes are used together (*see* same details and interpretation in the preceding section on Northern Pike). *Labeling: acb*, anterior or rostral bulge of cornea; *adipose f.* adipose fin; *anf*, anal fin; *caudf*, caudal fin; *df*, dorsal fin; *nos*, nostril; *pecf*, pectoral fin; *pelf*, pelvic fin.

more local varieties, such as the Coast Rainbow Trout (*Salmo gairdnerii irideus*), Common Lake Trout (*Christivomer namaycush*), and the Brown Trout (*Salmo trutta fario*), the latter transplanted from Europe. (For other illustrations, some in color, *see* Schultz & Murayama 1939; Eddy & Surber 1947; Hubbs & Lagler 1949; Sisson 1950.)

the leading and dominant sense. This, with an alert nature, makes the Trout an eminently "visual animal." According to the practically unanimous testimony of anglers, its vision is exceedingly acute, the fish being quite wary, especially in much-fished waters.

The Trout's color sense also seems well developed, which harmonizes with its gaudy ap-

pearance, especially during the spawning season.

In fishing, the Trout is especially responsive if the lure is moving, simulating a moving insect, its natural food. Because of this, "fly casting" is the preferred mode of angling. As to fishing for the Common Trout, Eddy & Surber remark: "Like most other trout they are exceedingly wary, and the angler must exercise great caution, keeping out of sight as much as possible."

3. VISUAL APPARATUS AND BEHAVIOR.—A living specimen of a Common Brook Trout, 12½ inches long, examined in a basin filled with water, shows the following noteworthy features: The eye is relatively large, with a definite "anterior" or "rostral bulge," even though much less pronounced than in the Pike (*see* sec. 4, this chapter). When the cornea is viewed directly from above, with the fish in its "normal" horizontal position, in optical cross-section it appears not to be a portion of a circle or a spheroid (as in Flying Squirrel, Tarsier, or Owl) or of an ellipse or ellipsoid, a parabola, or paraboloid (as in most Primates, including Man), but more nearly resembles the outlines of a longitudinal section of a chicken egg, with its blunt end turned toward the muzzle of the fish (left upper sketch in Fig. 455). Otherwise expressed, the radii of curvature in the horizontal plane become gradually shorter as the anterior extremity of the cornea is approached. (*Cf.* Fig. 452.)

The effect of this lopsided corneal curving must be a stronger refraction at the rostral end of the cornea than at the caudal end (which observation is at variance with the generally accepted belief that in aquatic animals corneal refraction is of little or no importance). The stronger refraction in the anterior segment of the cornea is useful in turning the rays, coming from the direction of the muzzle, into the eye, which in a flatter cornea, with a tangential incidence of incoming rays, would be deflected and would pass by without entering the eye (*see* Fig. 451).

The described arrangement indicates the importance of the frontal rays, coinciding with the direction in which the fish moves and hunts. These frontal rays are of importance only if both eyes are used simultaneously, that is, as instruments in binocular stereoscopic vision. Hence the "frontal corneal bulge" is an indicator of stereopsis wherever it is present in a fish provided with laterally placed eyes, as found in all species with well-developed sight, as, for example, the Northern Brook Silverside, Sunfish, Bass, Trout, and, more so than in all species so far examined, the Pike.

Harmonizing with this interpretation are the "sighting grooves" or shallow furrows, one on each side of the head. As in the Pike, in the Brook Trout these grooves begin at the anterior corners of the eyes and run between the upper jaw and the olfactory pits. Their extension lines converge in front of the muzzle at a distance which varies with the size of the fish.

The plane of the iris membrane roughly coincides with the equator of the spherical lens. It is inclined anteriorly about 5° toward the midsagittal plane. The iris has an anterior angular notchlike coloboma or pupillary "cutout" in the anterior margin of the iris, precisely in the direction of the "sighting groove." As in the Pike, a posterior, but much narrower, semilunar coloboma or notch is also present.

In the living fish the eyes appear to be quite mobile. Spontaneous movements are present, but in narrow confinement their direction could not be made certain. The eye movements elicited by a visual stimulus, e.g., a hand suddenly approaching from the front, consist of a quick move inward in the horizontal plane, hence of a convergence. There are spontaneous movements in the horizontal plane from time to time.

When the fish, while in water, is passively moved to one side, both eyes promptly and in unison respond with compensatory movements in the opposite direction. Labyrinthine compensatory responses of the eyes, elicited by the rotation of the fish around its longitudinal axis, are also quite pronounced.

Passively, with the forceps, the eyeball can be easily moved in the horizontal plane as follows: backward or toward the tail for approximately 30°, and forward-inward, that is, toward the muzzle, for at least 45°. This makes possible total movement of the eyeball in the horizontal plane of not less than 70°–80°, which approximates the active mobility of the human eyeball.

Both pupils when observed from above are

fully visible, while they cannot be seen at all when viewed from below. This indicates an upward direction of both principal lines of vision, and in binocular vision toward a common fixation point above the horizontal plane. This would hardly be the case if the planes of both iris membranes were vertical or if they were inclined with their lower ends toward the horizontal plane, as in the bottom-gazing Perch. (*See also* Northern Brook Silverside, sec. 2, this chapter.)

The position of the theoretically disclosed lines of vision says nothing, of course, of the actual principal lines of gaze utilized by the Trout in pursuit of its usual prey, the flying insects. This must be determined by carefully planned experiments. The calculated arrangement, however, makes it at least probable that one pair of lines of view—those touching the lower extremities of both retinae in the posterior corners of the eyes—converge and meet somewhere above the head and at some distance in front of the muzzle.

The preceding description and observation were obtained from living, fresh, and preserved specimens of the Common Brook Trout, kindly provided by the Fish Hatchery in Spooner, Wisconsin. The results of the study of the Rainbow Trout, also obtained from the same hatchery, are practically a duplication. Like other Trouts, this fish, too, is exceedingly wary. The slightest move of the hand toward its head within its visibility range elicits a violent reaction of escape movements. The eyes, even when the fish is at rest, constantly make slight jerky movements in the horizontal plane, either to or from the sagittal plane, each eye being capable of an inward deviation of at least 20° or 30°. Whether both eyes make simultaneous movements of convergence, by turning inward (as observed in the Swallow), as they certainly do singly, it was unfortunately not possible to ascertain by simple observation. When the fish is passively rotated around its longitudinal axis, the eyeballs describe compensatory rolling movements in the vertical plane of almost 45° around their longitudinal axes.

The fish frequently pushes its muzzle out of the water, probably in search of oxygen. Occasionally there are periods when the fish remains unresponsive to visual stimuli, alternating with other periods when it reacts violently. As in the Brook Trout, we find a slight anterior corneal bulge, shallow sighting grooves, and a wider angular anterior pupillary notch or coloboma of the iris, together with a narrower semilunar posterior notch. In both species the lens is yellowish in color and practically touches the cornea on the inside.

4. EYE AND RETINA.—The eye of the Trout is quite as remarkable as that of the Pike and quite as characteristic of a "visual animal." In the following paragraphs are described the most important features found in the Brown Trout and the Rainbow Trout, two species closely related to the Common Brook Trout.

The shape of the eye resembles half of a sphere whose dividing side, the cornea, is slightly curved to accommodate the lens. The outer coats also deviate from a circle in the anterior and posterior extremities. Here they are flattened, to form even surfaces on which the retinal images are formed. (*Cf.* sec. 4 and illustrations of Northern Pike.)

The retina is of a pronounced diurnal type. In a photopic specimen the pigment layer represents about one-fifth the entire retinal thickness or the outer half of the combined first and second layers. In this way both outer and inner cone segments are exposed to the action of light, whereas the longer outer rod segments are entirely enveloped by the pigment.

The bacillary layer is made up of rods and cones. The rods, much longer and more numerous than the cones, hardly equal in their total mass, much less exceed, the total cone mass.

The cones are of two varieties: the much more spectacular *principal cones*, and another more slender variety which may be called *accessory cones*. The principal cones are much thicker in the inner segments, which have the shape of a champagne bottle. Their upper ends extend to the level separating the upper from the middle third of the bacillary layer. The accessory cones, on the contrary, are much thinner and shorter. Their bases rest on the outer limiting membrane, their inner segments being only about half the length of the inner segments of the principal cones.

The cones, examined on a horizontal cross-section of the eyeball, are found to be more nu-

merous and thinner in two localities. One is close to the anterior margin of the retina, the other close to the posterior. In the more extensive, centrally located territory or *fundus*, around the papilla of the optic nerve, the cones are less dense but are thicker.

In the anterior and posterior "areae," the diameter of the inner segments of the principal cones is from 6 to 7.5 microns; of the accessory cones, from 4 to 5 microns, the intercenter distance of the first being from 12 to 15 microns. The number of the principal cones counted on a stretch of 500 microns in these two areae of greatest density was from 40 to 50. This or a little less may also have been the number of the accessory cones. However, in places, two principal cones seem to alternate with one accessory cone.

In the fundus the principal cones are about 10 microns thick and the accessory cones from 6 to 7, with the intercenter distances of the first measuring 25 microns. The number of principal cones found on a stretch of 500 microns was 22; of the accessory cones, 14.

Taking the preceding numbers as a basis, the following was the total number of cones computed for a circular area measuring 500 microns in diameter: in the anterior and posterior areae, 11,000 cones; in the fundus, 4,000 cones.

This result is noteworthy in two respects. It shows, on the one hand, the number of cones in localities of greatest density to be, in the Trout, about four times that found in the Pike. This number also favorably compares with the 35,000 cones found in the rodless area of the human central fovea measuring 500 microns in diameter. (*See* chap. V, 10 [5].)

It is most likely that the anterior and posterior areae are but sections of a ring-shaped area which encircles the larger central territory containing fewer cones. This would duplicate a similar ring-shaped area found in the Northern Brook Silverside and in the Northern Pike, where, however, it is much less noticeable.

To complete this account, two other features must be mentioned. First, the ganglion cells are also found in greater numbers in the anterior and posterior areae than in the fundus. Especially in the anterior area, the ganglion cells form a closely packed row, with a tendency in many places to form two tiers. In the fundus no such tendency, but rather its opposite, was observed in occasional gaps, making the layer of the ganglion cells appear discontinuous. Second, the layer of the optic nerve fibers is conspicuous because of its thickness. Close to the optic papilla, the thickness of this layer increases to no less than half the entire thickness of the retina. The number of fibers in the optic nerve is 350,000 and may be as much as half a million.

The preceding observations, interpreted functionally, indicate a great number of individually stimulable units, beginning with the photoreceptive cones, through the optic nerves, to as far as the optic lobes of the midbrain. The number of the units in the retinal periphery is about three times their number in the larger central territory around the optic papilla. Also, the size of the receptor units in the periphery is somewhat smaller than the size of the units in the fundus. This again indicates greater visual acuity in the periphery than in the central territory of the retina.

The great thickness of the inner segments of the principal cones may be interpreted as indicating a lower threshold or greater responsiveness to visual stimuli. This greater sensitiveness of the diurnal cones most likely also includes the perception of hues.

What the presence of two different kinds of cones means functionally it is not possible to answer at present except hypothetically. It may indicate two maxima of responsiveness in the visible spectrum, possibly utilized in two different dioptrical conditions. Or it may be a device to increase sharpness of the retinal image at a distance, and again at close range; hence it may indicate the ability to accommodate.

5. PHYSIOLOGICAL CONSIDERATIONS.—A correlation of the anatomical equipment and physiological performance with the living habits of the Trout, on the basis of the preceding sketchy information, must necessarily remain incomplete. It may, therefore, suffice to consider only a few items of special interest for the understanding of vertebrate vision.

If our deduction concerning the convergence of the two principal anterior lines of view toward a common binocular fixation point situated somewhere above and in front of the head proves correct, this certainly would disclose a

very useful arrangement by which the Trout could notice an insect flying above the water or floating on its surface. In the Pike a somewhat different arrangement is present, with a fixation point straight ahead, since this fish feeds almost exclusively on other fish caught in the water, hence aimed in the direction of the Pike's body.

The use of the superior or "ceiling point of fixation," as it may be called, would represent only the initial phase of the act of insect hunting by the Trout. This would be immediately followed by a switching of the gaze of both eyes to another, the "frontal common fixation point" directly in front of the head, requiring an adjustment of the body, a binocular focusing in the frontal direction, and a propelling attack directly ahead. In this second phase the binocular use of both eyes, the fixing of the prey in a common fixation point directly in front of the head and in continuation of the bodily axis, would be the position for the best utilization of the propelling apparatus of the fish for the seizure of a flying insect by a leap out of the water, the usual way by which the Trout captures its prey.

A very much more detailed observation of a Trout in action, preferably also by using a good movie camera, combined with laboratory experimenting and careful anatomical examination, would not fail to reveal further elements of the basic activity of this interesting fish. But even with our present limited knowledge, it is justifiable to say that the perfection of the Trout's visual apparatus is the principal factor in the life of this fish. Microscopic examination of its retina showed two areae, an anterior and a posterior, where the number of cones is almost three times that in the fundus of the eye. Here the density of the cones is close to one-third of the central foveal cones of the human eye. This indicates a high degree of acuity in an animal whose biologically required usefulness of vision cannot extend more than a few dozen yards. The high acuity is made even more useful with the help of the tridimensional binocular stereoscopic vision, the existence of which seems probable, at least by circumstantial evidence.

A related problem requiring further study concerns the ring-shaped "area" and its use. If our interpretation proves to be correct and the existence of this area is demonstrated beyond doubt, it will show that the Trout is in possession of a ring in the periphery of its field of view where it sees details best. In the horizontal plane this ring would have two distinct points of higher visual acuity, an anterior and a posterior. In the vertical plane there would be a superior and an inferior point of distinct vision. Or, as might be expected from the position of the eyes, there would be no inferior point in the Trout, a fish principally subsisting on surface insects, since such would not be necessary.

SEC. 6. BULLHEAD

1. TAXONOMY.—The Bullhead or Horned Pout is a fish that is an opposite of the Pike and Trout in its anatomical and physiological organization and its biological behavior (Fig. 456). It is a member of the North American Catfish Family or Ameiuridae, closely related to the Siluridae or Catfish Family of Europe and Asia and to other Catfishes of Central and South America and of Africa. The Northern Brown or Speckled Bullhead (*Ameiurus nebulosus*) may serve as a representative; its other North American relatives are the Northern Black Bullhead (*Ameiurus melas*), the Northern Yellow Bullhead (*Ameiurus natalis*), and others. (*See*, for additional information and illustrations, Hubbs & Lagler 1949; Eddy 1945; Eddy & Surber 1947.)

2. CHARACTER.—In common with other Catfishes, the Northern Bullhead has a stout, truncated body, with a broad, flattened head decorated with one pair of shorter, and one of longer, barbels or "whiskers," partly stiff and sticking up (hence the name "Horned Pout"). Each of its pectoral and dorsal fins is armed with a strong bony spine connected with poison glands.

The mouth of the Bullhead is wide and spacious, though less so than that of the Pike. The upper and lower jaws and the gullet are armed with numerous short teeth arranged in "pads," sufficient to seize small prey and other particles of food but not fit to serve as offensive weapons against a formidable adversary.

3. HABITS.—The external appearance of a Bullhead is not that of an aquatic beauty or of a fast swimmer but rather of a fish of lowly, sluggish habits, living close to the bottom, often in muddy waters. Its food consists of anything that can be had without much effort: worms, insect larvae, snails, crayfish, frogs, and an occasional small fish, but principally decaying vegetable and animal matter. The Bullhead is no aristocrat: the sluggish, shallow, turbid waters, often poor in oxygen, and as food all kinds of detritus, both shunned by the more sensitive fish, are just right for the smaller species of Catfishes. They have been well described as scavengers.

In disposition the Bullhead is a peacefully inclined creature, not looking for the exploits of a sneaky aquatic gladiator, such as the Northern Pike, or for dainty acrobatic stunts such as those performed by a Brook or Rainbow Trout. However, when cornered or on the hook, a Bullhead is a determined fighter, well provided, as he is, with a powerful locomotor apparatus and with three long, sharp, and stout erectile poisonous spines. A Bullhead has a tenacious life: with its head almost severed, it still tries to inflict a painful wound as it wiggles in order to regain the water.

4. SIGHT.—In procuring food the Bullhead depends little on sight, and that only indirectly. Most of what it eats it finds by smell and taste, and it would not see well, even if it had better visual organs: the lower reaches of its usually weedy and turbid aquatic habitat are but little illuminated.

It is true that Bullheads may be caught on a hook and line at any hour of the day, especially if the hook is placed close to the bottom. However, they bite most readily when the traces of the setting sun have died down and dusk has descended upon the waters.

The Bullheads are pronounced nocturnal, or rather scotopic, animals. Sight, it seems, serves only a negative role in their life: to warn them during the day to hide and in this way to avoid potential enemies, particularly diurnal predators like the Pike. The sense of hearing, however, seems to be of considerable importance (*see* D. Poggendorf 1952).

Bullheads do not need illumination for the gathering of food. In the conditions of an aquarium, according to Eddy & Surber, "Bullheads become very much excited when food is thrown to them; they swim and gyrate about the food, trying to locate it. They must come close or touch it before they can seize it, and there is no evidence that they see it even then." (*See also* experiments by Schiemenz 1924.)

5. EYEBALL AND RETINA.—The Bullhead's eyes are small for a fish, both in comparison with the size of its body and when compared with the eyes of such diurnal hunters as the Pike and the Trout. (*See* corresponding sections

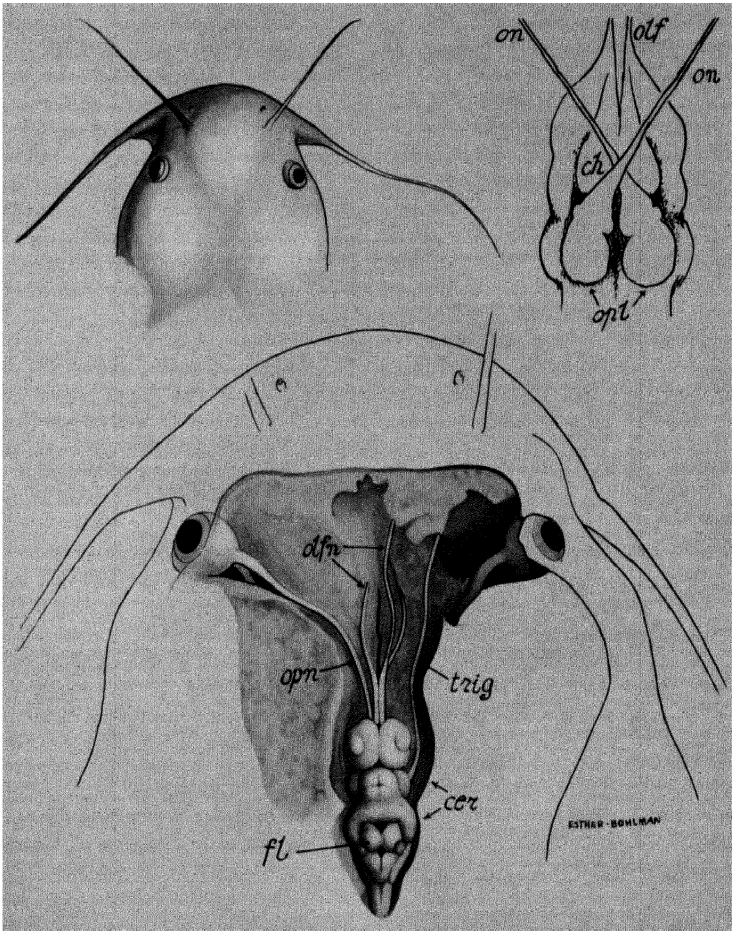

FIG. 456.—Northern Brown or Speckled Bullhead (*Ameiurus nebulosus*), a representative of the Family Ameiuridae, or North American Catfishes, closely related to Siluridae or Catfishes of Europe and Asia. A species with relatively small eyes adjusted to a life in subdued light, crepuscular and nocturnal in habit, depending practically entirely for its livelihood on the senses of smell and taste. Left upper sketch shows an intact head, lower sketch a slightly enlarged head with brain and some cranial nerves exposed. Right upper sketch shows a ventral view of the brain, together with long and slender optic nerves, decussating in the chiasma and terminating in diminutive optic lobes (*cf.* Fig. 458). Note the diminutive size of the optic lobes, in comparison with the nonoptic parts of the brain, where the olfactory nerves terminate, a situation opposite from that present in the Northern Pike, a pronounced diurnal, visual animal. Note also the two pairs of barbels, one large and one smaller, provided with taste buds, responsible for the popular name "horned pout" given to the Bullhead. Structurally and biologically the Bullhead is the reverse of the Pike. *Labeling: cer*, brain; *ch*, chiasma; *olf*, *olfn*, olfactory nerves; *on*, *opn*, optic nerves; *opl*, optic lobes; *trig*, branch of trigeminal nerve.

in this chapter.) In a well-built mature specimen 12 inches long, the average diameter of the eyeball is from 6 to 7 mm. Its shape is almost spherical. The pupil is nearly circular, and there is only an indication of a frontal and caudal pupillary notch. The extrinsic eye muscles are long but slender and poorly developed. Passively the eyeball can easily be moved in any direction.

The eye movements seen in a living specimen are of several varieties: a slight inward pull, synchronous with the action of gill musculature; an occasional slight scanning movement in the horizontal plane; and an infrequent pulling in

The field of vision of each eye is quite wide, apparently no less than 200°, judging from the shape, size, and position of the cornea (Fig. 457). The curvature of the cornea, in both the horizontal and the vertical meridians, is slightly paraboloidal. There is, however, no indication of an asymmetrical bulge, characteristic of the corneae of the Pike, Sunfish, Trout, Bass, and Silverside.

The shape of the head makes possible a slight expansion of each individual field of vision in particular directions. Dorsally above each eye a shallow depression permits the cornea to be seen from the opposite side along a straight line

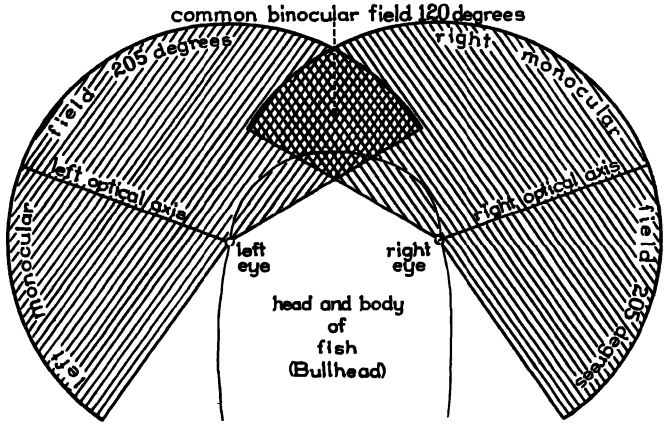

FIG. 457.—Fields of view of the Northern Brown Bullhead, a diagram showing the direction of the optical axis and the position of the monocular field of each eye and the overlapping of the two fields in front of the head, producing a common binocular field of view.

and turning down, as if compensating for the nictitating membrane which is not present in the described species. What other eye movements there are under physiological conditions remains to be determined by future investigation.

The eyes are set far apart, almost at the periphery of the broad, squat head. The distance between the vertices of the two corneae amounts to no less than 52 mm. in the same specimen. (For comparison, the interpupillary distance in Man measures 65 mm.) In the living fish the optical axis of the eye is deflected anteriorly, and it includes an angle of about 70° with the vertical sagittal plane.

that makes an angle of 60° with the sagittal vertical plane. This produces a common binocular field of view of as much as 120° above the head in the transverse-vertical plane. The two fields of view, including their monocular portions, may extend here to approximately 300°. In front of the snout, the common binocular field of both eyes is still considerable, even though it is reduced to about 60°.

The retina of the Bullhead contains all layers and elements found in other Vertebrates, but in much changed form and proportion. The pigment layer, including the bacillary layer, represents more than half the thickness of the entire retina, to which the much reduced and modified

layers *4–10* are attached below. In a photopic retina the pigment so completely permeates the entire bacillary layer as far as the outer limiting membrane that no details can be seen in ordinary, unbleached preparations.

The frame of the pigment layer in bleached preparations is revealed as a single row of epithelial cells containing large, spherical nuclei.

The photoreceptors are represented by both the rods and the cones. The rods have an outer, smooth, cylindrical segment of regular shape, with a great affinity for hematoxylin. The outer segment is linked by means of a very narrow middle zone, entirely refractory to stain, to the inner segment, whose expanded outer end, which stains well, tapers into a very narrow, long, and fiber-like portion, entirely refractory to stain. The cones are small, with a short conical outer segment attached to a relatively large and well-staining middle segment, continuing into an unstained inner segment.

Both rods and cones, as is well known, exhibit lively and prompt photomechanical movements in opposite directions: the cones toward the light, the rods away from it, opposite to the movement of the pigment.

The diameter of the outer rod segments is from 2 to 3 microns; that of the cones at their widest point, from 3 to 4. The average length of the outer rod segments is 35 microns; that of the outer cone segments, from 7 to 10. The mass of each outer cone segment, accordingly, is much smaller and is contained in the outer rod segment probably not less than ten times and possibly more.

The number of the cones, counted on a stretch of 500 microns, was found to be 60; that of the rods, from 80 to 100. Computed for a circular area of the same diameter, the number of the cones was 11,000; that of the rods, 20,000 or more. While the number of rods is comparatively small and is compensated for by their large size, the number of the cones is quite respectable, when compared with other investigated species of fish: 2,800–3,000 of the Silverside; 1,500 of the Pike; and from 4,000 to 11,000 of the Trout. The number of the cones in the Bullhead's retina, however, expresses only a

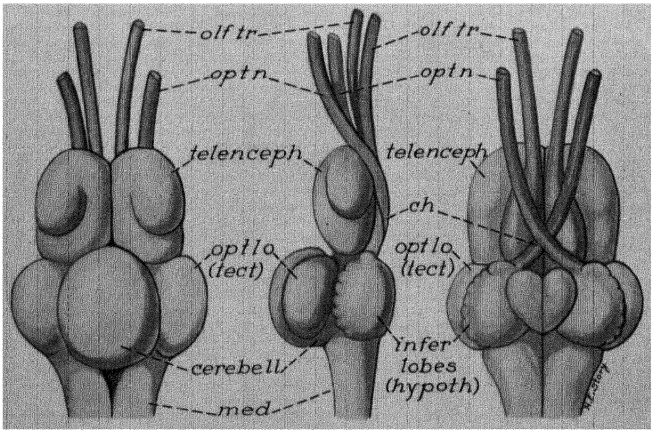

FIG. 458.—Brain of the Northern Brown Bullhead in three views, from left to right: from above, from the side, and from below. Note the relatively small size of the optic lobes (*optlo*) in this pronounced nocturnal Catfish, in comparison with the same parts in the diurnal Bluegill Sunfish, and Northern Pike (*see* preceding figures). The telencephalon, or forebrain, mainly olfactory in function, in the Catfish, on the contrary, is better developed than in the above-mentioned species. For gustatory centers *see* Fig. 456. *Labeling: ch*, chiasma of optic nerves; *cerebell*, cerebellum; *infer lobes* (*hypoth*), inferior lobes of hypothalamus; *med*, oblong medulla; *olftr*, olfactory tract; *optn*, optic nerve; *optlo* (*tect*), optic lobe or tectum of mesencephalon; *telenceph*, telencephalon or forebrain.

part of the role they may play in the visual act. This is indicated by the poor condition of the remaining layers of the retina.

The layers below the outer limiting membrane can be considered disorganized, in comparison with the well-developed and spatially well-organized ventral layers in sharp-sighted species, such as the Northern Pike, Trout, and even the Silverside. Of these layers, the best developed is the outer nuclear layer, which contains two or so rows of unevenly arranged nuclei. The outer plexiform layer is very thin and contains swollen lower ends of rods and cones. The inner nuclear layer cannot be well defined. Certain large, widely spaced polygonal cells are possibly the horizontal cells, whereas a row of rather large, darkly stained nuclei are probably those of the bipolar cells. Whether other large scattered cells are amacrines or displaced ganglions cannot be determined. The inner plexiform layer has the usual granular appearance but is much thinner than in other species. The ganglions are few, separated by long gaps. The layer of optic nerve fibers cannot be made out.

The optic nerve is thin, its diameter being 0.7 mm. The composing fibers are from 1.5 to 8 microns thick, with thicker ones predominating. The total number of fibers found is 15,000 or more. (Bruesch & Arey [1942] found 26,000; *see* chap. VI, 3 [4].)

In summary, the Bullhead's eyes and retina are poorly equipped to form anything but crude images and to analyze them in the crudest way. They are well equipped to react as a sensitive instrument of protopathic vision, responding to low intensities of light positively and to strong light negatively. But they can hardly mediate any but the crudest sort of spatial or epicritic vision, a defect which is to some extent compensated by their wide and overlapping fields of view. (*Cf.* Rochon-Duvigneaud 1925.)

6. NERVOUS SYSTEM.—The optic nerves are quite thin and flattened along part of their course. Because of the location of the eyes on the far periphery of the broad head, they are quite long (about 30 mm. in the same specimen). The optic lobes (*optlo* in Fig. 458) are absolutely and relatively small in comparison with those of a Pike of comparable size, each lobe amounting to about half the mass of one lobe of the telencephalon, or the part of the brain in front of the optic lobes, mainly concerned with smell and locomotion. The taste centers, on the contrary, are inordinately developed, being represented by four round eminences on the upper face of the medulla oblongata, the anterior

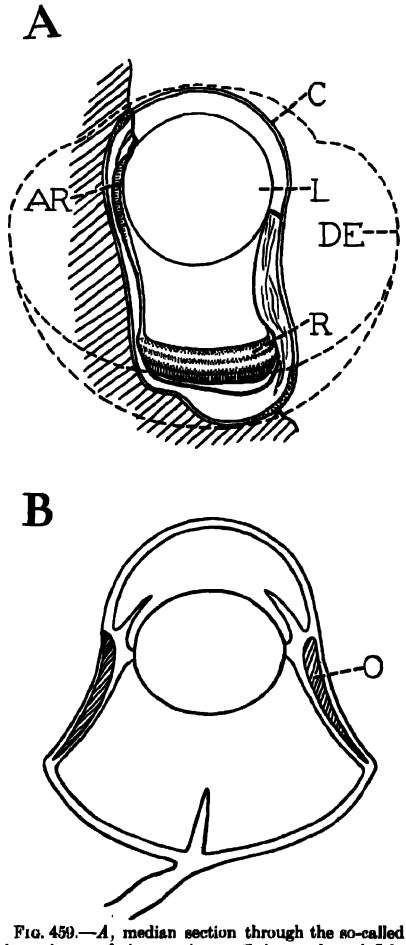

FIG. 459.—*A*, median section through the so-called telescopic eye of *Argyropelecus affinis*, an abyssal fish, drawn into an outline of a normal fish eye, to be compared with *B*, Owl's eye, somewhat similar in shape. *Labeling: AR*, accessory retina; *C*, cornea; *DE*, outline of a normal fish eye; *L*, lens; *O*, scleral ring; *R*, principal retina. being known as "facial lobes" (Fig. 456, *fl* in lower sketch).

7. Biology. — In summarizing the available information on the Bullhead, it is apparent that the anatomical organization of this fish agrees perfectly with its physiology and its behavior, and vice versa.

It is understandable that a fish which hides during the day close to the bottom of the water among the weeds and begins to forage for food only with the falling dusk is found to possess small and poorly developed eyes, degenerate retinae, thin optic nerves, and small visual centers in the brain. Sight is apparently an unimportant factor in the procurement of food. For this, the olfactory and gustatory senses are employed. These work efficiently even when a very small amount of light enters the water, either because of its depth or turbidity or because there is little light, during the night, for example, or on overcast days.

Fig. 460.— Charles Judson Herrick (1868), professor of neuroanatomy at the University of Chicago, at approximate age fifty-five. America's most assiduous student of the minute structure of the nervous system of the Primitive Vertebrates. A prolific writer on general biological and philosophical problems. Co-founder (with his brother Clarence Luther Herrick) of the Journal of Comparative Neurology. Courtesy Professor Charles J. Herrick, November 1, 1947. (For biography *see* Ariëns Kappers, Nederl. tijdschr. v. geneesk., v. 85, p. 1362, 1941.)

The Bullheads have renounced active competition with the photopic or daylight species. They retired into the darkness of the deeper reaches, where the superiority of sight of the diurnal predators is eliminated, precisely as it is in the upper layers of the water during the night. That, in doing so, they have chosen a less spectacular but nevertheless successful mode of life is proved by the fact that the representatives of the Bullhead tribe are found in every water, be it a broad river or an obscure creek, a large lake or a mudhole, within all inhabitable regions of the earth.

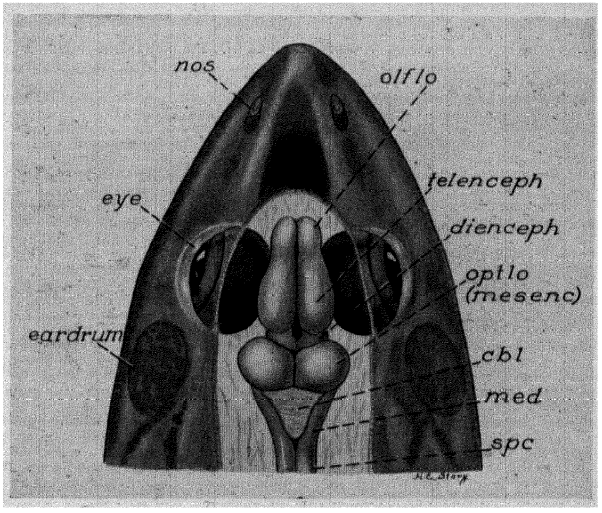

FIG. 461.—Head of a Meadow, or Leopard, Frog (*Rana pipiens*), with superficial parts dissected to show the brain and the eyes in their natural position. Note the size of the visual centers (*optlo*), which is approximately equal in mass to the telencephalon. Compare same structures in various species of Fish, in the Anole Lizard, and in the Painted Turtle. *Labeling: cbl*, cerebellum; *dienceph*, diencephalon or betweenbrain; *med*, oblong medulla; *nos*, nostril; *olflo*, olfactory lobe; *optlo* (*mesenc*), optic lobe of mesencephalon or midbrain; *spc*, spinal cord; *telenceph*, telencephalon or forebrain.

SEC. 7. ANOLE OR "AMERICAN CHAMELEON"

1. Taxonomy.—The Anolis or Anole is a small lizard, native of the southeastern region of the United States. It subsists on insects and possibly on other small animals it can catch. Because of its ability to change color, it is popularly known as the "American Chameleon," even though it belongs to the Family Iguanidae, characteristic of the Western Hemisphere, a subdivision quite different from the true Chameleons of Europe, Africa, and Asia, the Chamaeleontidae. As a type, the Carolina Anole (*Anolis carolinensis*), native of Louisiana, Florida, and other southern parts of the United States, is described in the following paragraphs (Figs. 462, 463, 464, 465).

2. Character and habits.—The general appearance of the Anole Lizard and its anatomical equipment are similar to that of other Iguanidae. The average length, when fully grown, is from 5 to 6 inches. Its graceful build makes it admirably adapted to insect hunting, which contrasts with the more robust appearance and sluggish habits of its larger relatives of Central and South America.

Following are notes that portray the functional versatility of the visual apparatus and the behavior of the Anole, observed in captivity.

November 9, 1947, at 3:30 P.M. The day was overcast, the room warm. In the terrarium, whose floor was covered with sand and scattered twigs and leaves of a southern shrub, all seemed quiet. Only the eyes of one or another Anole moved from time to time in a jerky way.

The mobility of the eyes was amazing (Figs. 463, 464): each eye could be moved independently of the other eye, and again, on occasion, both eyes could be moved in unison as a team. According to a rough estimate, the maximum excursion of an eyeball in the vertical meridian was not less than 90°, in the horizontal meridian probably somewhat less.

Occasionally both eyes converged toward the same object in front of the head. In this case the visual axes of both eyes met in a common fixation point situated somewhere in front and not far from the snout. The convergence was facilitated by the two pigmented "sighting grooves" running on both sides of the head, each in continuation of the line of view of its own eye, passing below the nostril, duplicating the arrangement described in the Pike (sec. 4, this chapter).

The way an Anole feeds, particularly how it uses its eyes in feeding, is as follows: When hungry, it first sizes up one of the meal worms, then it moves toward it a little, and then in a flash it "shoots" at it and grabs it with its teeth. An insect, for example, a fly, is attacked even more speedily, if within reach. The fly, an alert creature, always intent on a quick getaway, is not always caught. The initial phase, a prelude to an attack, is an attentive eyeing of the fly, even if it is as much as a foot or more away. The appearance of a fly within "shooting range" does not always arouse action, the inattention being even more frequent in the case of the meal worms. This happens when the activity of the animals declines and they appear drowsy toward the close of the day.

The movements of the eyes in various situations are easily studied at close range. The separate or independent movements of each eyeball are especially apparent when the head is viewed directly from the front, since in this position both eyes are seen simultaneously. This situation is represented in the right lower sketch in Figure 463. In this position the occasional direction of both eyes toward the same object, which is viewed binocularly, becomes quite apparent. In this case the two corneae and pupils are not directed forward, as in the Primates, but at a slant of about 45°. Even so, owing to a refraction in the cornea and lens, the principal frontal pencil of light passes into the eyes in such a way as to meet the central foveae, which in this lizard are quite well developed.

On November 10, 1947, a large fly was put into the terrarium. Before long, possibly because of too great heat and stuffiness in the box, the fly crawled down the side, stopping here and there, and finally coming close to a group of the lizards. Several at once tried their luck, but missed. Finally, a daring half-grown Anole launched a straight attack, shooting like an arrow, and in a split second the fly was caught, chewed up, and swallowed.

The alertness of the lizards when watching

the fly contrasted remarkably with their almost complete indifference to a number of fat meal worms crawling about in a small Petri dish in the terrarium. Hence it appears that the flies and similar moving insects probably represent the "adequate stimulus," which is wholly visual, and are the principal food.

November 17, 1947. A fresh package of Anoles arrived to be used as food for the Tarsiers, described subsequently in this chapter. The animals appeared dejected, dazed, skinny, emaciated. Evidently they had been neither fed nor watered during the many hours since they had been captured and shipped from Louisiana.

First they were given plenty of water in a flat dish (which they mostly disregarded), and more water was sprinkled over the leaves of a native shrub with which they arrived. They at once began eagerly to lick the moisture from the leaves with their tongues, and after a while seemed to be in better condition. Then half-a-dozen rather small meal worms were placed in a dish on the floor of the terrarium. For some time these also remained unnoticed.

Before long, however, possibly by accident,

FIG. 462.—Anole Lizard, or American Chameleon (*Anolis carolinensis*), a native of southeastern United States. A representative of the Iguanid Family (Iguanidae), characteristic of the Western Hemisphere. Member of the Genus Anolis, largest, most complex, and most widely distributed of the genera on this side of the globe, according to H. M. Smith (1946). A small, vivacious, alert, and intelligent Lizard of strictly diurnal and arboreal habit. An excellent climber, keen of sight, distinguished for its ability to change color under the influence of its eyes and nerves (hence its popular name "Chameleon," even though it is not related to the true Chameleons or Chamaeleontidae of Asia, Africa, and Madagascar). Anole is remarkable because of the extraordinary mobility and versatility of its eye movements, matching in this respect, and perhaps exceeding, the true Chameleons. Compare the following two figures showing Anole's ability to use each eye independently or both eyes together in a binocular visual act, as the situation requires. (*Cf. also* section on Barn Swallow.)

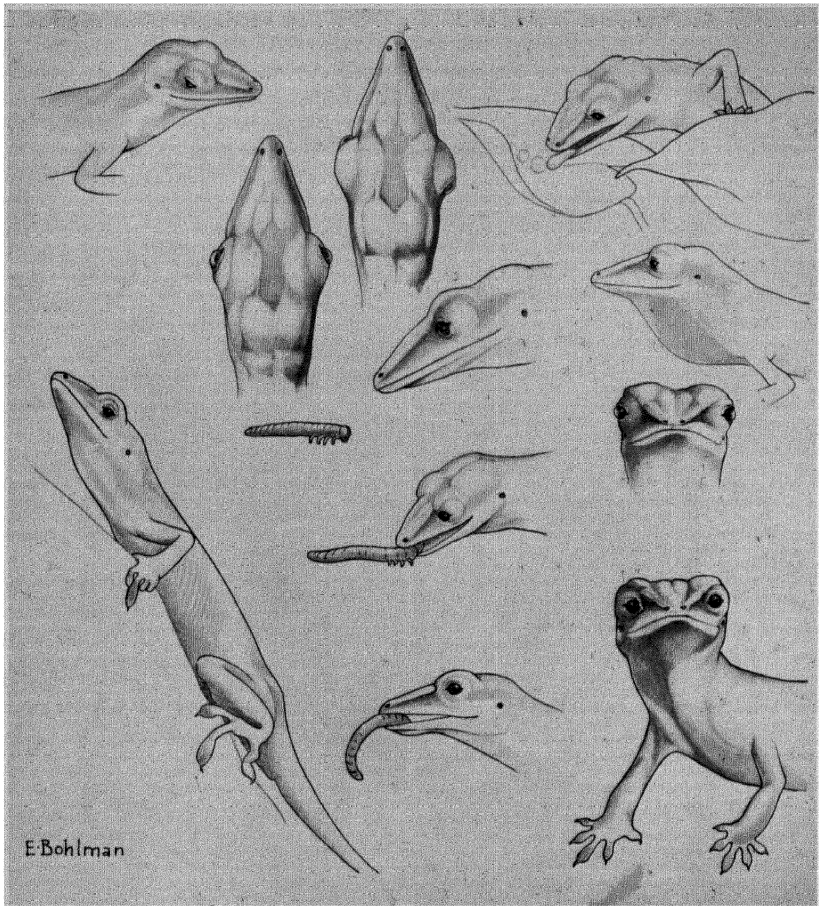

Fig. 463.— A composite figure of the Anole Lizard or American Chameleon, showing the use of visual apparatus (*see* preceding and following figures). *Upper left corner:* watching with its right eye a meal worm approaching from behind; *upper right corner:* lapping drops of water from a plant leaf, eyes directed forward; *upper center:* two views of the head from above, left view with both eyes directed laterally and slightly anteriorly ("normal" or "rest" position), right view watching other lizards, with left eye turned straight forward, and right eye turned backward; *center:* three views, upper fixing and evaluating a meal worm, middle seizing it and fixing it with both eyes, lower eating it, with eyes in an indifferent position; *lower left corner:* quiet siesta on a leaf, with left eye observing the artist; *upper right center:* expressing anger or fear, with a chin-lap, orange-red in color, expanded, as before a fight with another of its kind, with eyes attentively observing; *right middle center facing observer:* alert, watching a fly buzzing in the cage, both eyes only slightly converged (indicating use of its panoramic vision); *right lower corner:* intently watching a fly crawling on the glass pane directly between lizard and the observer, with both eyes glued on the prospective meal just before leaping to catch it (binocular stereoscopic vision). Note in last two views, pigmented "sighting grooves" converging toward the point of muzzle and nostrils, useful in binocular stereoscopic vision (*cf.* section on Pike, and Figs. 450, 451). Observed and drawn by Esther Bohlman.

or rather driven by hunger, one of the smaller Anoles cautiously sneaked toward the dish filled with unaccustomed food. After some time it finally took cognizance of the worms crawling in the dish. It slowly turned its head toward one of them and made a halfhearted attempt to nibble at it, without seizing it. Then, as if making up its mind, it resolutely tried again and seized one meal worm with its mouth. Little by little, as the Anole chewed, the worm disappeared, the deglutition movement along its throat being clearly visible. This done, possibly after 10 seconds or so, the little Anole again turned its head toward another meal worm. This time there was a shorter period of hesitation before another worm was seized, chewed up, and swallowed. Before long, a third worm was also eaten in the same way. The appetite of the little glutton seemed to grow as the feast progressed, as if to illustrate the well-known proverb. The remaining worms were devoured in the same way before the lapse of as many minutes.

This observation revealed the Anoles to be different from what one would expect from their appearance on arrival. They were not delicate and meek little animals, but voracious miniature monsters, well representing their Jurassic and Cretaceous forefathers that once held sway over the earth, and against which the humble ancestors of Mammals had to struggle to save themselves from extinction. (*See* sections on Common Shrew and on Tree Shrew, secs. 9, 10, this chapter.)

3. EYE, RETINA, AND THE VISUAL CENTERS OF THE BRAIN.—The eyeballs of the Anole are noteworthy because of their relatively large size and great mobility. In this, as in their finer structure and use, they show a degree of perfection rarely matched and hardly ever exceeded among the Lizards and among other Vertebrates, not excluding the true Chameleons, Birds, and Primates.

The diameter of the eyeball of a fair-sized adult specimen is 5 mm., or about $\frac{1}{5}$ inch. Small as this is, however, it amounts to one-fifth of the human eyeball. The two eyes together in such a small animal make up almost the entire width of the head, which measures about 12 mm. or $\frac{1}{2}$ inch across. (*See* Figs. 463, 464.)

Each eye is provided with a relatively deep and spacious central fovea. The diameter of the foveal excavation in a large specimen measures from 0.6 to 0.7 mm., which is half the foveal diameter of the much larger human eye. In other structures—the photoreceptors, bipolars, and ganglion cells—the eye of the Anole, in spite of its small size and because of its delicate build, is also capable of forming sharp images, of analyzing them, and of conveying them to the brain. Hence the eyes and the remainder of the Anole's visual system serve the species excellently as a refined instrument of sharp sight and stereopsis. (*Cf.* Rochon-Duvigneaud 1925.)

The examination of several series of sections of the retina and of the brain of the Anole stained with modified Golgi stain (*see* Technical Note at beginning of book) shows the extraordinary complexity and perfection of these organs, approaching in this respect the delicate organization described in Insects by S. Ramón y Cajal and Sánchez. Prolonged investigation would be required to do full justice to this absorbing subject. The following few observations must, therefore, suffice here.

The photoreceptor layer is made up of both rods and cones. In the extrafoveal periphery the individual cones are from $2\frac{1}{2}$ to $3\frac{1}{2}$ microns thick, their intercenter distances measuring 7 microns. At a distance of 350 microns from the foveal center, the cones decrease to a diameter of from $1\frac{1}{2}$ to 2 microns, their intercenter distance diminishing to from $3\frac{1}{2}$ to 4 microns.

The rods in this locality have a diameter of 1 micron or less and are few in number. From a point 280–300 microns from the very center, the rods are entirely absent. The rodless central territory, accordingly, measures no less than from 560 to 600 microns, which is equal to the diameter of the human central rodless area. (*See* chap. V, 10 [5].)

At a distance of 250 microns from the center, the cones are $1\frac{1}{2}$ microns thick, and their intercenter distance is from 3 to $3\frac{1}{2}$ microns. The closest cones to the center which could be measured were $1\frac{1}{2}$ microns thick, but these were still 150 microns away from the very center. The cones in the very center which were measured had a thickness of less than 1 micron. In refinement the cone apparatus of the Anole's retina

appears to be as good as the human, if not better. (*Cf.* chap. V, 10 [5].)

The remainder of the retina of the Anole is equal in refinement to its photoreceptors. The central area is conspicuous because of the great accumulation of nerve cells in layers *4*, *6*, and *8*. In the ganglion layer there are several tiers, which in the central fovea gradually decrease to four, three, two, and one tier, and in the very center, measuring about 240 microns in diameter, they disappear entirely.

There are several varieties of ganglion cells, with bodies 10 microns in diameter or less. Their delicate dendritic arborizations spread along several horizontal lines noticeable in routinely stained preparations in the inner plexiform layer. These lines indicate synapses with the lower ends of the bipolar cells. The upper delicate expansions of the bipolar cells in turn spread in the upper plexiform layer, measuring hardly 3–4 microns across. The bipolars are apparently present in several varieties whose exact classification and functional interpretation require further study.

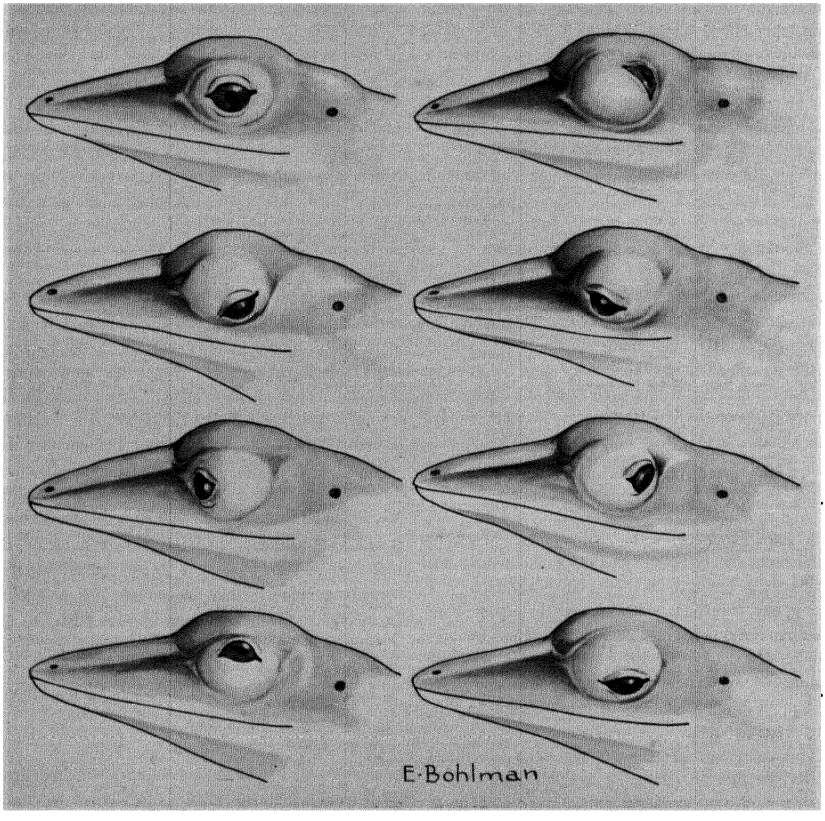

FIG. 464.—Head of the Anole Lizard or American Chameleon in left profile, approximately 3× magnified, showing relatively large eyes, their extreme mobility and the extent of their movements. Beginning with the upper left corner and terminating with the lower right corner: looking at the observer, looking down and backward, looking straight ahead as in binocular vision, looking upward, looking back and up, looking forward and down, looking straight back, looking down. Observed and drawn by Esther Bohlman. (*Cf.* preceding figure.)

The structures making up the brain are also extremely complex, delicate, and unbelievably abundant in detail. This subject may easily supply material enough to fill a series of papers matching the life-work of Santiago and Pedro Ramón y Cajal and of C. J. Herrick. Figure 465 gives magnified views of the brain of the Anole, showing the large optic lobes found in this species.

4. Physiological considerations. In the life of the Anole Lizard, primarily in the propages is its ability to use either each eye independently or both eyes together as a binocular stereoptic team in essentially the same way as do the Higher Mammals, particularly the Primates. Whereas the visual stereopsis in visually advanced Fishes, such as the Trout and Pike, was disclosed by circumstantial evidence such as the anatomical structures and organization of the visual apparatus, in the Anole the facultative binocular use of the eyes could actually be observed at work. This brings closer to our understanding the basic importance of the bin-

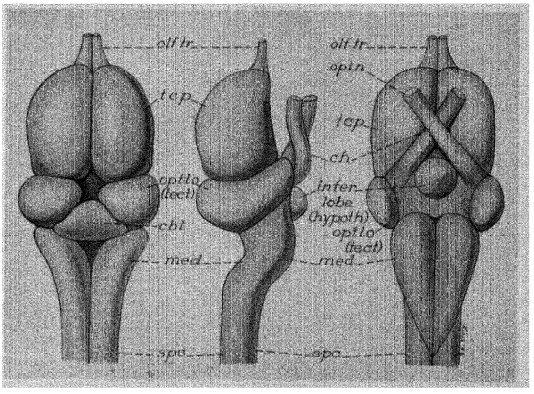

Fig. 465.– Brain of the Caroline Anole or American Chameleon, possessing a versatile visual apparatus and a large central fovea instrumental in acute vision (*cf.* preceding figures). The optic lobes of the brain are well developed, and the completely crossed optic nerves are thick. The forebrain (*tcp*), as in all Lizards, is much increased in size, in comparison with phylogenetically lower classes, the Fishes and Amphibians (*see* figures of Bluegill Sunfish, Northern Pike, and Meadow Frog). The olfactory tracts, however, are thin, owing to the lesser biological importance of the sense of smell in this pronounced diurnal visual species. *Labeling: cbl*, cerebellum; *ch*, chiasma of optic nerves; *infer lobe* (*hypoth*), inferior lobe of hypothalamus; *med*, oblong medulla; *olftr*, olfactory tract; *optlo* (*tect*), optic lobe or midbrain tectum; *optn*, optic nerve; *spc*, spinal cord; *tcp*, telencephalon or forebrain. Magnification 9×.

curement of food, the sense of vision and the visual apparatus appear dominant, almost to the exclusion of the other distance receptors, smell and hearing. Just what particular role each of these two senses plays in the acquisition of food and of mates, in the avoidance of enemies, and in other ways remains a task for further investigation.

The principal phenomenon observed in the behavior of the Anole described in the preceding

ocular team in all advanced animals, and especially the Vertebrate Phylum and the Prevertebrate Ancestors which preceded it (*see* chap. XIII, 2). The importance of stereopsis, at least as a facultative arrangement, already found in the Reptiles, phylogenetically midway between the lowest vertebrate class, the Fishes, and the highest class, the Mammals, is thus demonstrated.

In the Anole, however, the binocular use of

the two eyes is apparently resorted to only when needed. At other times each eye is used independently; or, if used as a part of the team, it is not necessarily in the stereoptic sense. We may, then, tentatively until further and more thorough investigation of this problem is carried out, indicate three particular uses of the two eyes in an Anole and many other Lizards.

First would be a static use of both eyes as constituents of a panoramic system, with both eyes functionally interrelated in a stable way, in which the two monocular fields of view do not overlap or do so only a little or are perhaps separated by an interocular gap. This produces basically panoramic vision. Its advantage is its wide scope or extent, which in certain situations or species may amount practically to a complete circle, or, in fact, to a complete sphere. The advantage of this arrangement is obvious: it permits the animal to notice any object that may concern it anywhere in its surroundings.

The second is the employment of each eye as an independent instrument, not related functionally to the other eye. This use is obviously of a higher order, since it presupposes a structural differentiation of a particular locality capable of a finer, more detailed resolution of the optical image of the retina. Mobility of the eye makes sense only when there is a differentiated area or fovea to be directed at a viewed object of particular interest.

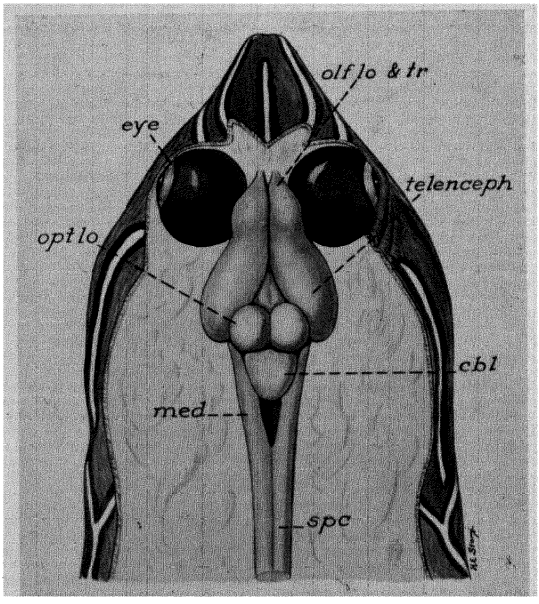

FIG. 466. Head of a Painted Turtle (*Chrysemis picta*), with upper parts dissected to show the brain and the eyes in their natural position. The optic lobes are well developed but are much smaller in comparison with the much increased forebrain (*telenceph*). (Cf. preceding figures.) *Labeling: cbl*, cerebellum; *med*, oblong medulla; *olflo & tr*, olfactory lobe and tract; *optlo*, optic lobe; *spc*, spinal cord; *telenceph*, telencephalon or forebrain. Magnification 2.5×.

The third use requires both a basically panoramic adjustment of the two single eyes to each other and a differentiation of areal or foveal vision, the first serving as a binocular functional background upon which the refined binocular stereoscopic areal and foveal vision are superimposed.

The advantage of this third use of the eyes is not only a wide scope of panoramic vision and a refinement of areal or foveal vision but, in addition, the working of both eyes, including both

areae or foveae, as a single functional team directed at a common viewed object. This is the anatomical and functional basis of stereopsis or single tridimensional vision, in so far as the peripheral organs, the eyes and their mechanics, are concerned. That this is not the entire story of stereopsis and that, in addition to these peripheral arrangements, the central factor or factors play an essential role is probable and is further discussed in several places in this book.

In the visual apparatus of an Anole, all three potentialities are skilfully realized. This apparatus permits the animal to employ at will, according to the situation, any of these three uses. Concretely, when the animal is at rest, with its visual apparatus relaxed, both eyes look in opposite directions, giving it a wide panoramic vision. Any stirring of a small object, such as a fly or a bug, or the appearance of a potential enemy, whether on the right or the left side or above, will be noticed. This is but the first phase in a process of satisfying the biological service which the visual apparatus has to render, which is to acquire food and avoid destruction.

The next step is to locate the object of attention. This is done by searching movements of one eye, that facing the object. The fly must be exactly located. This task is performed by the superior resolution of the areal-foveal vision. This is essentially an epicritic or visuo-gnosic performance. In it the entire visual mechanism of the particular side participates: the visuomotor directing the eyeball; the visuosensory controlling the retinal receptor surface in the desired position, where the foveal center corresponds exactly with the tested object, while the crude protopathic periphery "holds" it like a ring or a vise. The third and final phase consists of the employment of the visuo-gnosic substratum of the brain, which evaluates the impulses according to phylogenetically and individually acquired standards, requiring further action, if positive, and disregarding it, if negative.

If the "adequate" physiobiological impulse initiates further trains of action, the chain of events may be as follows: while the active eye fixes the prospective prey, the contralateral eye is now likewise set in motion, the motor machinery adjusting the head, possibly including also a part or all of the body, for the final action. The task of the other eye is to add that component of the subjective visual experience that underlies stereopsis or the "third dimension." This added quality, obviously, is of great importance for success, since it is paramount in estimating distance; for this a single eye, capable only of judging the two-dimensional or projectional location of the prospective prey, would be an inferior instrument.

Once the "third dimension" or distance is determined, the impetus is given to the entire locomotor machinery of the animal for the execution of the attack and the capture of the prey. The fulfilment of this depends on the balanced co-ordination and speed of all parts concerned. In this concluding act, one may judge, the visual apparatus also plays an important role as a controller of the organs of execution.

The various parts of the central co-ordinating machinery in Lizards and other Lower Vertebrates are known only in a descriptive way. So far, only a few attempts have been made to analyze it and to interpret it functionally, e.g., by Santiago and Pedro Ramón y Cajal, Coghill, C. J. Herrick, Ariëns Kappers, and some other investigators. For the most part, this problem still awaits solution.

5. The Chameleon and its eye.—It is here appropriate to give a brief summary of Rochon-Duvigneaud's description of the visual apparatus of the Old World Chameleon, an animal that has attracted much attention since ancient times. (*See* Ann. d'ocul., v. 170, 1933.) Even though taxonomically not closely related, the true Chameleon of Europe, Africa, and India, in its anatomical equipment and physiological performance, closely resembles the American Anole, its New World counterpart.

The Chameleon, according to M. F. Angel, in *La Terre et la Vie* (1931), summarized from Rochon-Duvigneaud, is an animal which avoids light. It does not like sunshine, especially when the temperature is high. It lives mostly in dense tropical forests of Africa, where the light is quite subdued by the foliage, with moderately elevated temperature and the necessary humidity. This is its ideal habitat, in which its coloring is most brilliant. (For an excellent ac-

count of the Chameleon's life *see also* Brehm's *Tierleben*, v. 5, 1913.)

According to Rochon-Duvigneaud's investigation, the Chameleon has a deep fovea (also studied by S. Ramón y Cajal and others). Its field of view is probably restricted, owing to a small cornea and retina, which is perhaps the reason for the unusual mobility of its eyes. other. The eye movements appear to be volitional and not of a reflex nature. In their movements ordinarily "they are neither synchronous nor symmetrical, each eye moving on its own account, exploring its own space independently." A synchronous asymmetric movement is possible, however, with one eye moving forward and the other backward (*see* sketch in

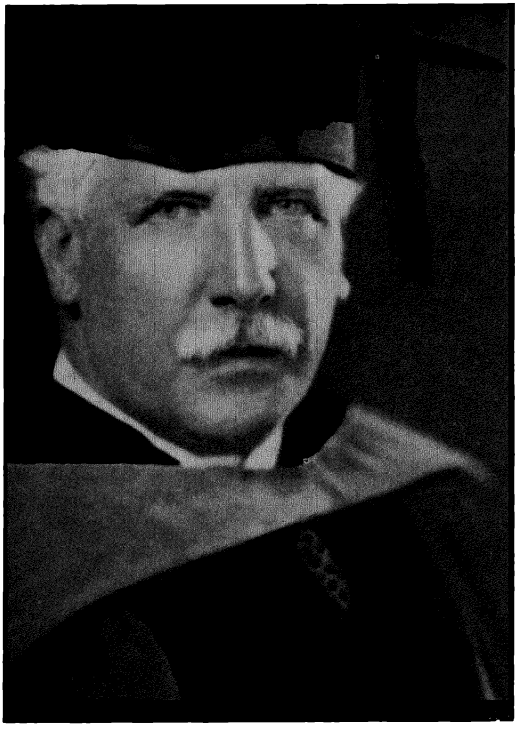

FIG. 467.—Cornelius Ubbo Ariëns Kappers (1877–1946), director of the Institute for Brain Research in Amsterdam, Netherlands, at the age of sixty-three. One of the foremost modern comparative neuroanatomists (*cf.* Edinger, Fig. 446, and Herrick, Fig. 460). Author of *The Comparative Anatomy of the Nervous System of Vertebrates*, 2d ed., enlarged and edited by G. Carl Huber & Elizabeth Caroline Crosby, 1936. (For biography *see* Psychiat. en neurol. bl., v. 38, p. 265, 1934, and Haymaker & Baer, *The Founders of Neurology*, 1953.)

"The Chameleon's retina is, in a sense, reduced to an extremely developed central fovea." The compass of its eye movements in the horizontal plane amounts to 180°, in the vertical meridian almost that (a little less upward than downward). One or the other of its eyes is constantly on the move, the eyes being independent of each the upper center in Fig. 463). When a prospective prey is within 15 20 cm., that is, within shooting range, both eyes converge toward it, the mouth opens, and the fly disappears so quickly that the movements of the tongue are barely visible.

It is probable that the convergence of the

eyes is accompanied by accommodation and certainly by constriction of the pupils (the pupillary constrictor muscle being also partly responsible for accommodation, there being no pupillary light reflex). The Chameleon has, in Rochon-Duvigneaud's opinion, according to circumstances, either double monocular or panoramic vision or associated single binocular vision. In both, the central foveae are involved, a fact difficult to comprehend, in view of the diplopia present in human vision when the two foveae are not focused upon the same object.

The central fovea of a Chameleon, according to the quoted authority, is as deep as that of the Birds. In the foveal center the retina is 280 microns thick, in its next vicinity as much as 600 microns. The cones in the fovea are 100 microns long; outside the fovea, they are 140 microns long. The nuclei of the foveal cones are displaced laterally, so none are present in the very center. As in all diurnal Lizards, in the Chameleon all photoreceptors are cones (in this respect differing from the Anole). The cone cells and their oil globules are of a yellow color, which, apparently depending upon illumination, is either clear yellow or greenish. In the foveal center, even the bodies of the cone cells are yellow, the pigmentation being most intense here. The oil droplets are present also in the foveal center. The central region, where the cones are extremely thin, is quite extensive, the cone thickness increasing only gradually toward the extrafoveal periphery. This, in Rochon-Duvigneaud's opinion, makes it probable that the minute central territory in which the acuity is highest is less pointlike than in Man. He estimated the diameter of the cones in the very center at less than 2 microns, in the extrafoveal periphery at 8 microns. (Compare much smaller values of the Anole and of the simian and human cones given in chap. V, 10 [5].)

SEC. 8. SWALLOW

1. TAXONOMY.—The common Barn Swallow (*Hirundo* or *Chelidon rustica erythrogastra*) is a small, insectivorous bird, entirely subsisting upon prey it catches in flight (Fig. 468). It and its cousin of the Old World, the Chimney Swallow (*Hirundo* or *Chelidon rustica*), in appearance and behavior are the most typical, even though they are among the smallest members of the Swallow Family (Hirundinidae) of the Order Passeres, and Suborder Oscines.

Other American representatives of the family are the well-known Purple Martin (*Progne subis purpurea: see* sec. 13, "Miscellaneous Notes," in this chapter), Cliff or Eave Swallow (*Petrochelidon pyrrhonota albifrons*), Tree Swallow (*Iridoprocne bicolor*), Northern Violet-green Swallow (*Tachycineta thalassina lepida*), Bank Swallow (*Riparia riparia r.*), and the Rough-winged Swallow (*Stelgidopteryx ruficollis serripennis*). Their better-known counterparts of the Old World are the Cave Swallow of southern Europe and Africa (*Chelidon rufula*), Cliff or Rock Swallow (*Riparia rupestris*), and Town Swallow (*Hirundo urbica*). Numerous other species populate all habitable parts of the world.

2. CHARACTER.—The Barn Swallow is a highly specialized bird, living exclusively on

flying insects which it catches "on the wing." It is an excellent flier, better than its larger relative, the Purple Martin, though somewhat inferior to the still smaller masters of the air, the American Chimney Swift (*Chaetura pelagica*), the Cliff Swift (*Cypselus melba*), and the Common Swift or Black Martin (*Cypselus apus*) of the Old World, which, however, all belong to the Family Apodidae or Micropodidae (Order Macrochires, Suborder Cypseli).

In every part of its build the Barn Swallow shows a close adaptation to its peculiar mode of living. Its body is relatively light and slender; its pectoral muscles, the source of the power that moves its wings, are comparatively huge; the wings are long, narrow, and pointed; the tail well developed, its outside feathers longer than the middle ones, making up the typical forked "swallow tail"—all features considered characteristic of a good flier. The beak of the Barn Swallow is short and as wide as the head at the root, so that the aperture of the gullet is as spacious as possible in a bird of so small a size, facilitating the capture of prey. Altogether, the anatomical equipment of the Barn Swallow is admirably suited to its particular way of living. (*See* A. A. Allen, Nat. Geog. Mag., v. 93, p. 790, and his book *Stalking Birds with Color Camera*, 1951.)

3. HABITS.—The principal features of the Swallow's living habits have been well known since time immemorial. The reason is its close association with Man, its preference for human habitations, where it builds nests of mud, and no less its gentle nature, through which it endeared itself to the people, especially to the country folk (as, for example, in my native Croatia). Its excellence in flying is appreciated even by the casual observer.

Somewhat more detailed observation reveals that the Barn Swallow spends many minutes on the wing, with occasional brief periods of rest in between. Its flight is graceful, swift, and enduring. The beats of its long wings, alternating with sailing or gliding, carry its light weight with great speed. Obstacles, be they close to the ground, near the surface of the water, or high in the air, are expertly avoided.

Conspicuous in its flight are quick turns, which make it appear irregular and zigzagging. This is understandable when one considers the purpose of the flight, which is the capture of flying insects. If the flight were along more or less straight lines, much of the prey would not be captured, even if noticed, because momentum would cause the bird to overshoot its goal. Quick, sudden turns are therefore indispensable.

How the Swallow does the trick remains a problem that has not yet been properly formulated in the minds of naturalists and aeronautical physicists and engineers. Nothing short of systematic investigation with modern technical means will solve this problem. For the time being, therefore, let it suffice to mention a few details gleaned from observation and such other facts as can be obtained from anatomy and from simple physiological tests. These indicate that the way the Swallow earns its living by means of its wings is a strenuous and complicated process.

Aside from the problem of keeping the body afloat in a medium specifically as light as air, the following questions require elucidation: determination of the leading sense by which the Swallow notices its prey; the way the leading sense reacts to the stimulus; and the way the body in general, and in particular the locomotor system, responds to make the capture of the prey a success.

4. FOOD.—Flying insects: Moths and Butterflies (Lepidoptera), Flies (Diptera), Beetles (Coleoptera), and Ant-Lions (Neuroptera) are the principal food source, evidently presenting an adequate visual stimulus, which promptly arouses the hunting instinct. The Bees and Wasps (Hymenoptera) armed with a sting, according to Brehm (O. zu Strassen), are shunned, but these and the Locusts are caught by other species of Swallows, e.g., by the Cliff Swallow, according to L. N. Nichols.

When I held in my hand a young Swallow that had never left its nest, it was alert enough to follow the insects flying around. When a big fly suddenly arrived and buzzed around, the bird made several snapping moves with the open beak in the direction of the fly, indicating the intention of catching it. This was particularly noteworthy, as only one eye was used, the other apparently having been hurt during a lengthy transportation on the preceding day.

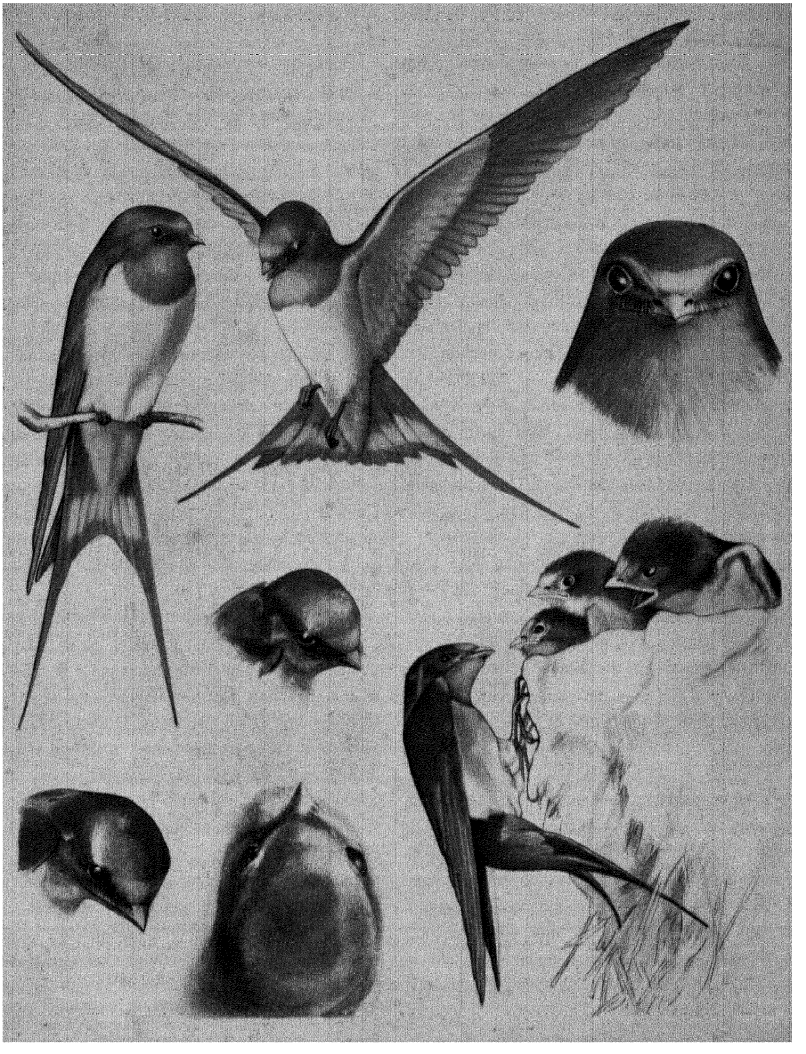

FIG. 468.—Barn Swallow (*Hirundo* or *Chelidon rustica erythrogastra*), one of the smallest and swiftest flyers of the Northern Hemisphere. Its visual apparatus, little known as yet, is marvelously developed, its sight among the best among Vertebrates. Composite plate from A. Brehm (1913), H. Harrison (1948), and others, showing an adult bird perching and in flight and various views of its physiognomy, also a nest full of young, with an adult bird clinging to the nest. (*Cf.* Figs. 469, 470.)

5. SENSE OF SIGHT.—The observation of the behavior of the Barn Swallow in nature, as well as its anatomical organization, speaks in favor of the sight as the most important, if possibly not the only, sense used.

The Barn Swallow and its relatives are diurnal animals in the sense that their activity extends throughout the light period of the day. However, they are early risers, and toward the close of the day they hunt in the evening twilight, when their twitter is still heard, while to the human eye they are almost invisible. In their intensive preoccupation with insect hunting, they remain aloft until the falling night forces them to depart, when their place is taken by their mammalian counterparts, the small, insectivorous Flying Bats (Microchiroptera).

Whether hearing and possibly smell are of any use in their hunting is not known. If this were the case, especially with hearing, it would not be astonishing, in view of the known role that audition plays in the life of the Bats and, according to Kellogg & Kohler (1952), of the Porpoises.

The available evidence favors the view that the overwhelming, almost exclusive, share in the biology of the Barn Swallow belongs to vision, while other senses play a subordinate role. The diurnality of the Swallows is also attested by the fact that they move on their annual migrations only during daylight and rest at night.

6. EYE MOVEMENTS.—In the living bird the expression of its "physiognomy" indicates a visually alert, intelligent animal. The nictitating membranes of both eyes contract either simultaneously or separately in quick moves. The pupil is of an elliptical shape, with the long axis almost vertical to the palpebral fissure. When the lids are shut, it is chiefly the lower one that covers the cornea.

When the bird is at rest, either the one or the other eye makes short, jerky motions from time to time. These are interspersed at irregular intervals with more extensive scanning movements, as if trying to fixate various visual objects. The lids, principally the lower ones, in quick winking moves, shut the eyes alternately.

Occasionally both eyes make a similar quick movement, both simultaneously converging upon a single fixation point in front of the beak. Such movements are either short and jerky or extensive, proportionately not less than in Man, amounting in the horizontal plane to at least 30°.

Such eye movements may or may not be associated with short, synchronous, ipsidirectional movements of the head. Again, the head alone may move spontaneously to the right or to the left, apparently without eye movements. On occasion, both eyes execute a quick simultaneous move toward the beak, definitely converging upon a single binocular visual object or fixation point. At other times similar movements toward the beak are made by only one eye.

When an object comes into view, that particular eye makes a quick move to fixate it, with the opposite eye remaining still. When an object that has been in view for some time is removed, that eye likewise makes a quick move as if to follow it. When the eye fixates an object turning quickly toward it, its pupil contracts, the movement of the iris apparently accompanying the accommodation (as in binocular fixation in human vision).

Unilateral fixation by one eye is often accompanied by one or two minute, jerky, ipsidirectional movements of the head, as if to assist the fixation. When the bird is drowsy, the eye in shade, away from the light, is kept shut, or its palpebral fissure is narrowed, with the other eye half-opened, executing slight exploratory moves, some definitely toward the beak, similar to those visible during binocular fixation. When after a period of dozing, the bird awakens, both palpebral fissures are suddenly opened wide, and the eyes for a while make scanning movements. These are mostly in the horizontal plane, but less extensive movements up and down as well as in any other meridian are also possible.

The two eyes of the Barn Swallow are normally placed in the head in such a way as to permit the observer viewing them from straight in front to see most of both corneae and of both pupils (Fig. 468, right upper sketch). When a visual object is offered to the bird from the front in the mid-sagittal plane, both eyes sometimes turn toward it in unison, converging upon it. Again, after a while, with the relaxation of the convergence upon the binocular fixation

point, a definite diverging movement of the two eyes toward the initial, resting "normal" position is noticed. When an object, e.g., a hand with still or wiggling fingers moves rapidly in front of the beak at an approximate distance of from 6 to 8 inches from side to side in the horizontal plane, both eyes converge upon it and the bird tries to keep the stimulating visual object in its binocular fixation point, may be elicited a dozen or more times in succession. Similar binocular eye movements, accompanied by the synchronous ipsidirectional head movements, may be induced not only in the horizontal plane but also in the vertical and in any other inter-

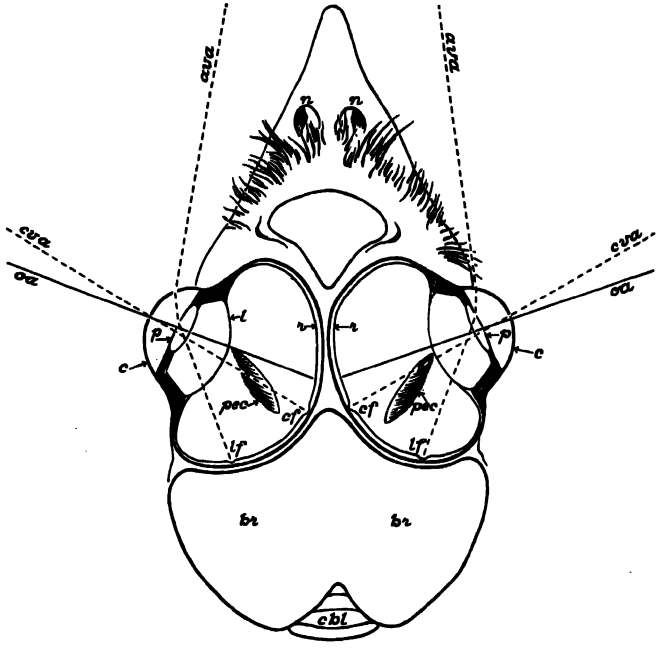

FIG. 469.—Horizontal section through the head of a Barn Swallow, with eyes and their dioptrical apparatus left in place. In each eye there are two foveae, a central, nasal or anterior (*cf*) and a lateral, temporal or posterior fovea (*lf*). A central visual axis (*cva*) incloses with the optic axis (*oa*) an angle smaller than that inclosed by the anterior or frontal axis (*ava*). The central axes of both eyes diverge from each other, forming an obtuse angle facing anteriorly; the two anterior or frontal axes, when the eyes are at rest, converge toward a common fixation point at some distance in front of the beak. This angle can be changed at will by the bird, making possible focusing at different distances when both eyes are used as instruments in binocular stereoscopic vision. In this, the two lateral foveae are used simultaneously, precisely as in human vision. However, the Swallow is also able to use each eye independently when it wishes, focusing objects with one central fovea alone, leaving the other eye at rest, exactly as does the Anole Lizard, a functional flexibility superior to that of Man and other Primates. Note considerable distance between the points at which the two anterior visual axes hit the cornea of the eyes in so small an animal. Figure drawn at 6.7×, reproduced at 4×. *Labeling: br*, brain; *c*, cornea; *cbl*, cerebellum; *l*, lens; *n*, nostrils; *p*, pupil; *pec*, pecten or "comb"; *r*, retina. (*Cf.* Figs. 468, 470.)

follow it regularly and in unison from right to left and back again.

The eye movements are automatically associated with the synchronous ipsidirectional movements of the head. These movements, by which mediate planes or meridians as well, depending on the movements of the visual object.

The fixation movements up and down are executed principally with the head, assisted only a little by corresponding movements of the

eyes. The associated eye and head movements in the horizontal plane may amount to from 30° to 40° and possibly more but are usually less (depending on the movement of the stimulating object).

7. PUPILLARY MOVEMENT.—When the bird is at rest, it shows lively spontaneous pupillary movements. Tests for direct pupillary light reaction show that the pupil responds very promptly to the stimulus, much faster than the human pupil does. A consensual reaction of the pupil on the side opposite to the eye stimulated by direct light, however, was not noticed. The pupils are regularly constricted whenever the bird makes an attempt to fixate an object binocularly and to follow its motions by corresponding movements of the head. Sometimes the pupil remains wide open, even though light falls into it after shading it off, as if kept open by a volitional inhibitory impulse.

The nictitating membrane normally closes at irregular intervals of from 2 to 5 seconds, either simultaneously on both sides or, more often, on each side independently. The membrane does not close when the pupil constricts on light stimulation, except accidentally.

8. THE EYEBALL.—In agreement with the practically exclusive dependence of the Barn Swallow upon its sight is the relatively extraordinary development of its eyes (Rochon-Duvigneaud [1943] calls them a model of structural and functional refinement).

The eyeballs of an almost fully grown young bird ready to leave the nest measure in diameter, in the vertical meridian, 7.5 mm. The central visual axis is approximately 7 mm. long, the temporal or lateral axis 7.5–8 mm. Each eyeball approximates in size one cerebral hemisphere (Fig. 469; *cf. also* Fig. 470).

The eyeballs are placed very close together,

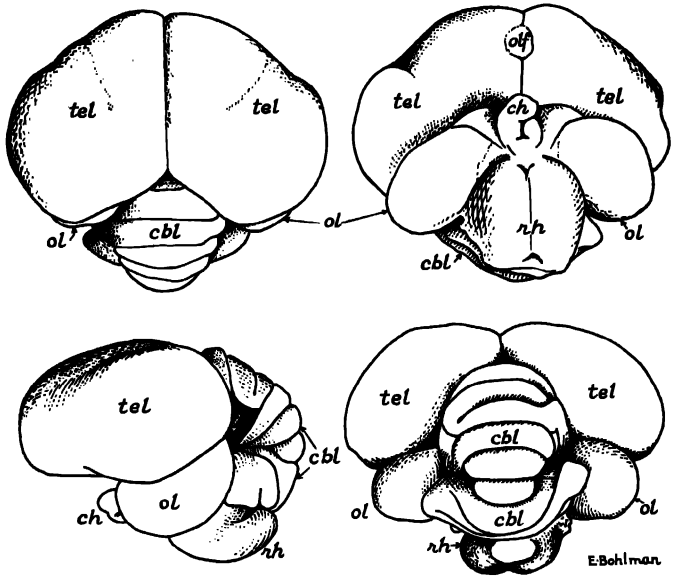

FIG. 470.—Brain of a Barn Swallow viewed from above (*upper left*), below (*upper right*), from the side (*lower left*), and from the rear (*lower right*). Drawn 9×, reproduced 5× magnified. Note relatively large size of optic lobes. *Labeling: cbl*, cerebellum; *ch*, chiasma of optic nerves; *ol*, optic lobes; *olf*, olfactory bulbs; *rh*, rhombencephalon or oblong medulla; *tel*, telencephalon. (*Cf.* Figs. 468, 469.)

back-to-back, almost touching in the mid-line, the central foveae being less than 4 mm. apart. The distance between the two lateral foveae is greater, amounting to 8.7 mm. However, the poles or summits of the two corneae are no less than 15.5 mm. from each other, a respectable distance in so small an animal. (For comparison, the interpupillary distance in Man measures about 60 mm.)

The two central lines of vision or central visual axes (*cva*), lines passing through the summits of the corneae and the central foveae (*cf*), diverge considerably, inclosing an angle of about 120° or somewhat more. Also the central visual axis (*cva*) diverges considerably more from the optical axis (*oa*), the line of rotation symmetry of the optical surfaces of the cornea and the lens, than in the human eye, the angle inclosed by them amounting to from 13° to 15°.

The two anterior or frontal lines of vision or visual axes (*ava*), lines connecting each lateral or posterior fovea (*lf*) with the anterior or nasal margin of the iris in the pupillary aperture, in a fixed specimen are approximately parallel. Slight nasal deflection of the two eyeballs, owing to their great mobility, as in the act of convergence, as described before, therefore, may suffice to make the anterior visual axes meet in a single common fixation point in front of the beak.

Such binocular convergence and fixation are further assisted in several ways. One is the position of the corneae, which face, as in the half-profile, in the anterolateral direction, conforming with the position of the central visual axes, each of which in a fixed specimen incloses, with the mid-sagittal plane, an angle of approximately 70°, or, together, 140°. The other factor is a slight distortion of the corneal curvature similar to the "anterior bulge" of the Fishes, because of which the more sharply curved anterior segment of the cornea is more favorable to the passage of rays coming from the direction of the beak. (*Cf.* sec. 4, on Pike.)

The visual behavior and anatomical arrangements of the Swallow described in the preceding paragraphs indicate the use of the lateral or posterior foveae for the simultaneous fixation of single visual objects necessary for binocular stereopsis, similar to that of Man and other Primates. In this respect the visual apparatus of the Swallow is comparable with that of the Birds of Prey (such as the Eagle, Hawk, Falcon), Gull, Cormorant, Crow, Raven, Pelican, and some Parrots (see M. Bartels). It differs from other Birds, for example, Sparrows and Pigeons, whose eyes face more laterally and have no lateral or posterior fovea.

The Swifts and the Owls represent a further step in the development of binocularity, with the exclusive employment of the lateral foveae used binocularly and an abandonment of the central foveae instrumental in single, monocular vision. (On eye movements in various Birds, *see* Bartels 1920, 1931.)

9. CORNEA, LENS, SCLERA, AND RETINA.—The cornea of the Swallow in comparison with the size of the eye is small, its diameter being only 4 mm. It is strongly curved, its radius of curvature being 1.5 mm., and it represents about half a sphere, with perhaps a slight anterior "bulge." The crystalline lens is relatively large. The scleral ring with the bulging cornea fitted into it, the small, hemispherical cornea asymmetrically deflected in the direction of the beak, the presence of two foveae in each eye—all make the eye of a Barn Swallow resemble the "telescopic" eyes of the Diurnal Birds of Prey (Eagle, Hawk, etc.).

The retina lines the much larger posterior portion of the eye, amounting to somewhat more than half the corresponding sphere. It is remarkable because of its regular structure. Its histological elements—photoreceptors, nuclear and ganglion layers, and the two plexiform layers—are very even in their outlines.

The pigment layer is rather thin but is dense in its structure. The outer segments of the photoreceptors in the examined specimen are mostly enveloped by the pigment. There are indications of photomechanical changes which depend on the condition of illumination.

The bacillary layer is very regular in its structure. It is apparently made up of both rods and cones in the entire expanse of the retina, including both foveal depressions. In the central fovea, however, the cones seem to prevail.

The outer nuclear layer contains both rod and cone nuclei in the entire retinal expanse, including both foveae. The cone nuclei are larger, elliptical in shape, with longer axes vertical to

the outer limiting membrane. They form one continuous, thickly packed tier, close to the outer limiting membrane, increasing to two tiers in the central area and to three tiers in the central fovea. The spherical rod nuclei, which in mass seem paler but, in fact, are darker, are found in three or more tiers, except in the floor of the central fovea, where they appear to be in only one or two tiers.

The outer plexiform layer is relatively thick. In routinely stained preparations it appears finely granulated. In Golgi preparations it is very accurately differentiated into three subzones, zone *5-b* being formed by filamentous cone pedicles and rod spherules.

The inner nuclear layer is remarkable because of its regularity and other features. The general arrangement of nuclei is in oblique columns, slanting from the central fovea away and down toward the inner plexiform layer. This

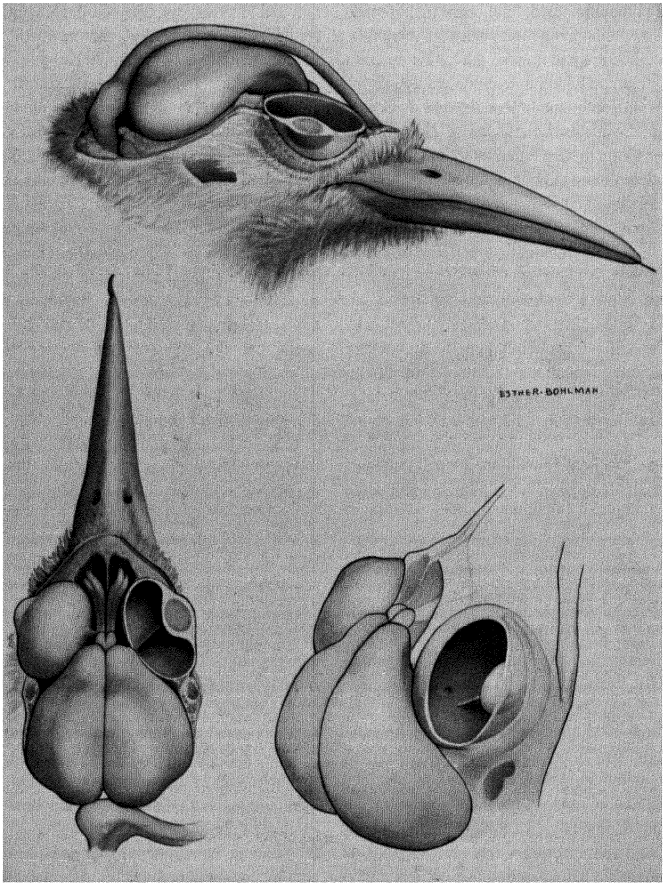

FIG. 471. Flicker (*Colaptes auratus*), a pretty-colored, sharp-sighted member of the Family Picidae or Woodpeckers. This figure shows the dissected head in various views: *above*, lateral aspect; *left*, view from above; *right*, half-profile. Note the central fovea, a small dimple next to the upper margin of the pecten, visible in the right eye, whose upper segment was removed.

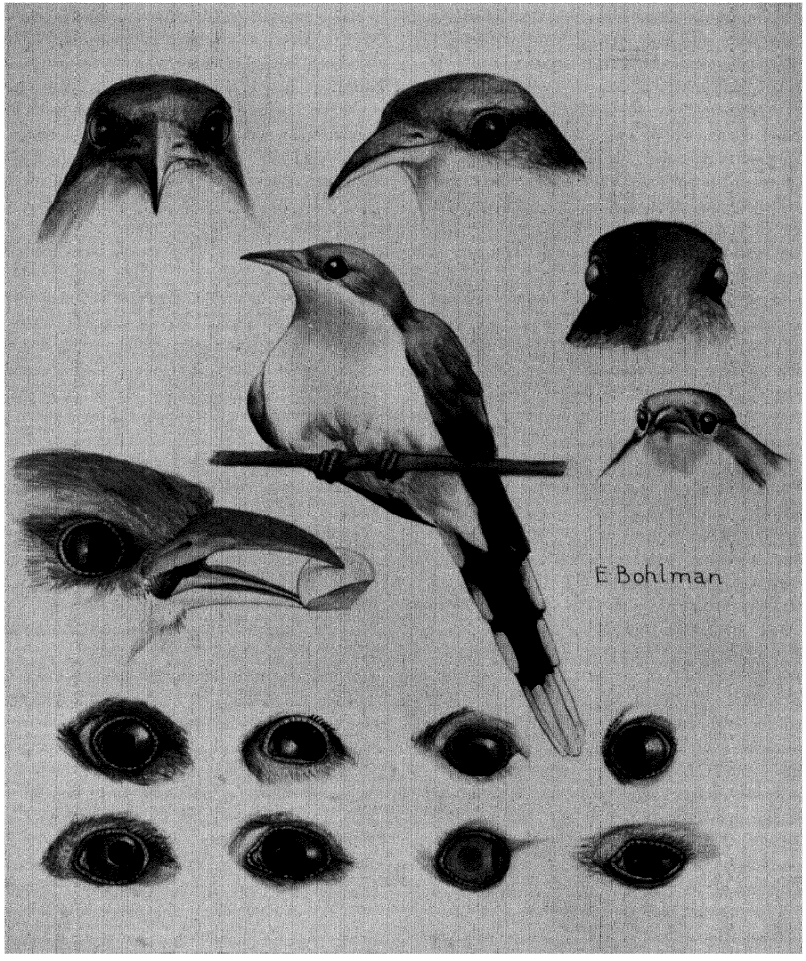

FIG. 472.—Yellow-billed Cuckoo (*Coccyzus americanus*), a sharp-sighted insectivorous bird of high intelligence, living in thickets and dense groves of eastern and middle North America. The plate portrays various views, including slightly magnified closeups of the left eye. *Left upper corner:* examining new items of food, using binocular vision; *upper center:* fixing down an object with left eye without moving head; *right upper corner:* looking backward with both eyes at a source of unexpected noise, before turning around; *just above artist's signature:* with both eyes at rest while taking a bit chilly, though comfortable, siesta after a rather soaking bath; *left center:* playing with a piece of art-gum eraser given it to observe the use of its stringlike tongue in "manipulating." Lower two rows show the left eye, beginning at the left end of the first row: expression of fear; looking up to satisfy its curiosity; looking slightly down at food when not very hungry; looking forward, using binocular vision, at a slowly moving meal worm; interest without fear; unaccounted for, probably rather indifferent; nictitating membrane drawn over cornea while killing a wiggling meal worm, this being done by running it repeatedly crosswise between its mandibles in a sort of chewing movement; slightly squinting or reducing the palpebral fissure in an affectionate mood (same observed in a Blue Jay). Observations and drawings by Esther Bohlman. Note remarkable versatility of ocular movements, depending on situation, in this bird that possesses a well-developed central fovea.

arrangement is evidently caused by the slanting bipolar cells and supporting "radial fibers" of Müller, typical of the avian retina. (*See* S. Ramón y Cajal on the fovea of Birds, in his book 1909–11, or in Trav. du lab. de recherches biol. Madrid, v. 28, Pl. VI, Fig. 16.)

The other and also quite apparent feature is the segregation of the inner nuclei into parallel zones, more conspicuous in the Swallow than in other investigated species. The nuclei of the upper and slightly thicker half are markedly different from those of the lesser vitreal half. The first are somewhat smaller and darker, while the latter are a little larger, spherical, paler, and less closely packed. This difference indicates here, as in the outer nuclear layer, a segregation of various bipolar types from one another, possibly the individual midget or cone bipolars from the common cone and rod bipolars.

The single uppermost tier of the sixth layer, made up of somewhat larger and paler nuclei evidently belonging to the horizontal cells, is again somewhat separated from the bulk by a less compact arrangement. The lowermost tier, in the same way, is somewhat separated from the rest, its nuclei belonging to the amacrine cells and possibly also to the displaced ganglions.

The inner plexiform layer is thick. It is conspicuous because of its several thicker and thinner and remarkably evenly arranged horizontal streaks. Golgi-stained preparations show that these streaks are made up of long, horizontally running expansions of "amacrine" cells and may also indicate synaptical couplings of the adjacent neurons.

The ganglion cells are very numerous and found in almost the entire expanse of the retina in at least two tiers. In the two areae their number increases to four tiers, and in the margin of the central foveal excavation to five and possibly six tiers. In the very center—the floor—of the central fovea, measuring approximately 40 microns in diameter, all ganglion cells have been displaced in a lateral direction; this ganglion-free area coincides with the minute territory where the photoreceptors are thinnest. In a narrow, peripheral belt along the ora terminalis, only a single tier of closely packed ganglion cells is present.

10. THE CENTRAL AND LATERAL FOVEAE.—Of the various features of the Swallow's retina, the most remarkable are the foveal formations, two in each eye (Figs. 173, 469). They may be observed in freshly fixed specimens, both in the enucleated eyes and in those left *in situ* or in their normal place in the head, appropriately dissected. Even though small, they may be noticed macroscopically, and even better at slight magnification (6–10×).

One is the central fovea (*cf.* Fig. 469). It is a minute, well-formed circular depression situated 1.5 mm. above the posterior extremity of the pecten or "comb" (a vascular structure protruding into the interior of the eye, conveniently displaced downward, thus leaving the spacious vitreal cavity almost free from the obstacle which would otherwise interfere with the passage of light rays). The diameter of the central fovea is roughly 0.5 mm., which is no less than a third of the human foveal depression (*cf.* chap. V, 10 [4, 5]).

The other, also circular but smaller and more shallow, is the lateral, temporal, or posterior fovea, located approximately on the same horizontal level but about 3 mm. posteriorly, behind the first, and about 2 mm. from the posterior limit of the retina.

Examined microscopically, the central fovea appears as a deep, funnel-shaped excavation, whose sides inclose an angle of approximately 40°. It is conspicuous because of its centralmost photoreceptors, whose diameter in the available preparations unfortunately could not be measured. In the zone next to the very center the inner cone segments are approximately 2 microns in diameter or less. From this a guess may be ventured that the thickness of the centralmost cones may be 1 micron or less (*cf.* sec. 7 on Anole, this chapter).

The lateral fovea is much smaller and more shallow, with all layers continuous and with only a slight thinning of the inner nuclear and ganglion layers. The grain of its photoreceptors also seems to be rougher than that in the central fovea.

The analysis of the minute structure of the Swallow's retina, with the help of Golgi staining, remains a worthy object for future research. The few glimpses we were able to obtain indicate a rich differentiation of the constituent

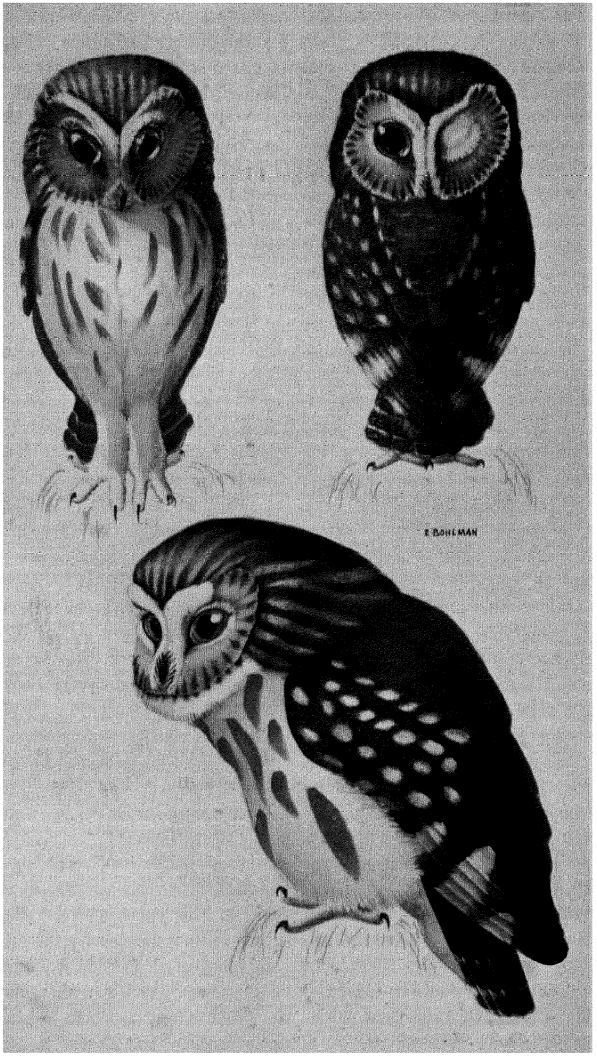

FIG. 173.—Saw-Whet Owl (*Cryptoglaux acadica*), a "little clown," smallest of the Strigidæ Family, inhabitant of dense evergreen woods of northern North America. (*Cf.* following figure.) A typical nocturnal bird of prey, with eyes adapted to its way of living. This and the following plate, made from personal observations by the artist, show the versatile use of observable parts of the visual apparatus in different situations. *Upper left:* attentively watching a live mouse, by directing both eyes straight ahead, with iris membranes moderately constricted; *upper right:* sleepily turning the head directly backward, with one eye closed; *below:* at ease, a pose often taken expressing affection or expectation of a titbit.

neurons. The problem here is not only to determine the types of neurons but most of all their synaptical relationships also. This alone may help interpret the visual functions of the Birds and of the Vertebrates in general.

Summarizing the few facts so far known, it is apparent that the Swallow's eye, in spite of its small size, is eminently capable of forming accurate images of external objects because of its delicate construction. It is further able, because of the refinement of the retina, to analyze retinal images in a most efficient way and to transmit detailed nervous messages to the brain. In its wealth of photoreceptors and other nerve cells, the Swallow's eye may be compared with the fovea and central area of the human or simian eye, surrounded by a very narrow and less efficient extra-areal periphery. In its perfection the Swallow's eye and retina may closely approach the limitations imposed by the vertebrate organization. (*Cf.* Rochon-Duvigneaud 1943.)

11. NERVOUS SYSTEM.—The brain of the Swallow conforms to the general type of avian brain (Fig. 470). The telencephalon (*tel*) is of a squat shape and smooth in appearance. What its function is, unfortunately, still remains largely a mystery. The optic lobes (*ol*) are relatively large. They protrude on both sides from under the telencephalon. The cerebellum (*cbl*), especially its *vermis* or middle portion, is also well developed for a bird, with small, stumplike cerebellar hemispheres attached to the sides.

Concerning finer structures, a glance at a few microscopic sections, variously stained with hematoxylin and eosin, Weigert, Nissl, Golgi, and Golgi-Cox methods, shows an extremely rich differentiation of the finer structures into various nuclei and layers. Nothing short of a thorough monographic study could disclose the innumerable details and interpret them functionally. This is especially true of the optic lobes, which exhibit stratification of cells and fibers in no way less elaborate than the striate area of the Primates. (*See* chap. VIII, 5–7.)

Finally, special mention must be made of the optic nerves. These were found to be no less than from 770 to 850 microns in diameter, comparing favorably with the optic nerves of Monkey and Man. This comparison becomes even more favorable when the caliber of individual fibers, generally thin, is considered. The thickest fibers, as our measurements show, have a caliber of only 3 microns, while the majority are 2 microns thick, with many being 1 micron or less. This provides the Swallow with a great number of individual conductors from the retina to the brain. Our tentative estimate of the number of fibers in the Swallow's optic nerve would be at least 500,000 and possibly as many as 1,000,000. (*Cf.* optic nerve in Man and Monkey.)

12. BIOLOGICAL CONSIDERATIONS.—The visual system of the Barn Swallow is characterized by features common to all Birds, besides others peculiar to the species. The first are the large size of the eyeballs and their peculiar shape, with completely crossed optic nerves, terminating in the large visual centers of the midbrain. The special features are: position of the eyeballs in the head and their extreme mobility; the ability of the Swallow to use its eyes either independently or together, which again may be either in panoramic vision or as a binocular stereoscopic team; the extraordinary wealth of photoreceptors and other nerve cells, which make most of the retina resemble the "central area" of the Primates; the presence of both rods and cones everywhere, probably even in the very center of the central fovea; the presence of two specially differentiated foveae, a central and a lateral or posterior; relatively thick optic nerves, made up of a great number of fine and very fine fibers; huge optic lobes of the midbrain, showing an elaborate structural makeup. These features undoubtedly indicate the dominant role of vision in this species. What the importance of smell is, as indicated by the unexpectedly large and contorted turbinates, and of hearing remains an object for further investigation.

The manner in which the Swallow probably gets food, which almost certainly consists exclusively of flying insects caught on the wing, is somewhat as follows. It is apparent that the entire visual mechanism, beginning with the rods and cones of the retina and terminating in the brain, and minutely co-ordinated with the entire remaining bodily machine, is organized in its gross and detailed structures and properties to respond instantly to the minute visual stimu-

li characteristic of particular species of insects.

It is likely that most prey is first noticed monocularly by any part of the extrafoveal retina. The next phase is the fixation of the object by the central fovea of that particular eye, permitting a more detailed, even though extremely rapid, critical examination. This impression is or a negative urge. In the first case the two eyes, assisted by the appropriate movements of the head and neck, converge upon the prey, which is sharply focused binocularly; its position is appraised tridimensionally and stereoscopically by means of the two lateral or posterior foveae and their parts of the visual cen-

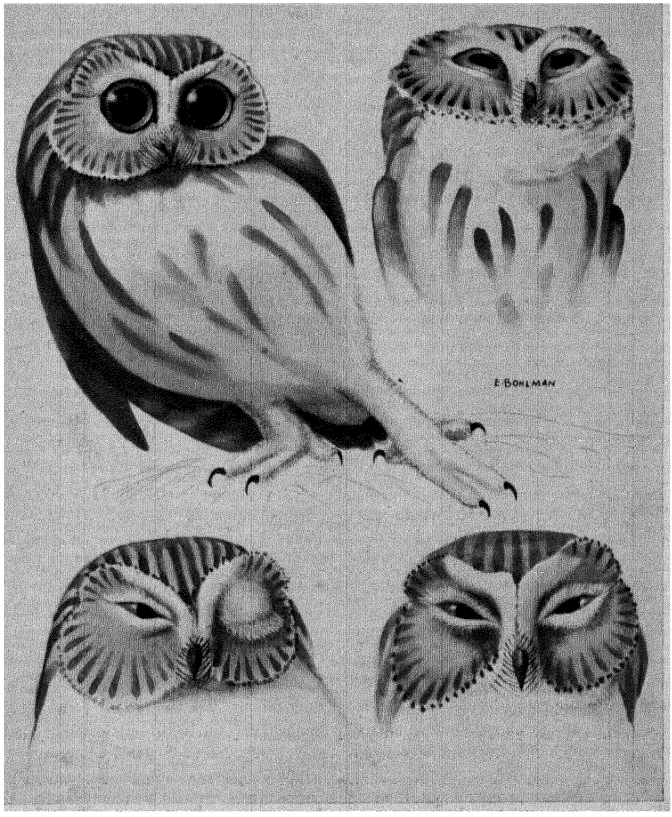

FIG. 474. Saw-Whet Owl, showing various manifestations of the observable visual behavior. (*Cf.* preceding figure.) *Upper left:* awkwardly and slowly leaning away, with eyes and pupils wide open, distrustfully avoiding the hand attempting to pet it, until it seemed it would topple over; *upper right:* looking at the ceiling in a drowsy, contemplative mood; *lower figures:* two attitudes taken while being admired by the visitors.

at once "mentally" digested on the basis of inherent instincts and past experience.

The third step in the process of hunting, also practically instantaneous and automatic, is a "decision" which is colored as either a positive

ters. In this act the binocular convergence must be conceived as extremely rapid and, at the same time, elastic, capable of following the insect in its erratic movement, accurate focusing being essential for the success of the capture.

The accurate binocular stereoscopic appraisal and tridimensional judgment of the prey's position and distance in space, itself constantly on the move, facilitates proper regulation of the locomotor mechanism in pursuit and in the final capture of the prey. In all this exceedingly rapid process, there is little left to chance, invoked by some students of this problem (*arabesques du vol* of Rochon-Duvigneaud). It is an exceedingly fast and precise co-ordination of many systems for the single biological purpose of feeding.

It is hardly necessary to add that all these acts have to be performed in a definite order, according to a definite formula, almost mechanically, even though permitting great variation in detail, in order to adapt the pursuit and capture of the prey to the conditions of each particular instance. In this way alone is the biological demand satisfied and the survival of the species and of the whole family guaranteed.

How the details of the entire process are carried out and how the exceedingly complex retinal, cerebral, and neuromuscular apparatus works in performing the necessary functions is a worthy subject of investigation with modern scientific methods and technical means.

Of special interest is the visual system of the Barn Swallow and similar Birds in possession of two foveae in each eye, in comparison with the arrangement in Man and other Primates with but a single central fovea. The problem which arises here is both anatomophysiological and psychological. How does a Swallow, Hawk, or Eagle utilize the two foveae of each eye for the purpose of single vision, and how must their central visual apparatus be organized in comparison with the human, in which the slightest discrepancy in the "correspondence" of the two homonymous halves of the visual system causes most acute discomfort in Man, owing to diplopia?

SEC. 9. COMMON SHREW

1. TAXONOMY.—The Shrews that form the Family Soricidae, among the smallest of the Mammals, are spread over most of the inhabitable earth (Figs. 475, 476). They are akin to the subterranean Moles or Talpidae, and the flying Bats or Chiroptera, in particular to the

insectivorous suborder of Microchiroptera or Small Bats.

Scientific interest in the Shrews derives from a realization that they closely resemble the primitive, generalized animals of past ages, the Pantotherians, from which all Mammals, past and present, originated, and that the earliest linear ancestors of the Primates, including Man, were shrewlike. The purpose of this section, accordingly, is briefly to summarize available information on the anatomical characteristics of the Shrews and their habits and to consider to

Northern Hemisphere, both in the Old and in the New World, including all of India and the island of Ceylon. In the Southern Hemisphere the Shrews are present as far as South Africa, being absent from the southern portion of South America and from the entire Australian continent.

Of the Old World species, A. Brehm (L. Heck) mentions as the most common the Forest Shrew (*Sorex araneus* or *vulgaris*), further the Alpine Shrew (*Sorex alpinus*), Pigmy Shrew (*Sorex minutus* or *pigmaeus*), the aquatic or Water

FIG. 475. *Pachyura etrusca*, smallest terrestrial Shrew, insectivorous, nocturnal, body length 4 cm., tail 2.5 cm., inhabitant of countries adjacent to the Mediterranean and Black Seas. A type of primitive, generalized Mammal, resembling the Early Insectivores of the Cretaceous Period of the earth's prehistory, which lived from sixty to one hundred and twenty-seven million years ago. From A. Brehm's *Tierleben*, 4th ed., *Säugetiere*, v. 1, p. 291, 1912, with special permission of the Bibliographisches Institut A.G. (Dr. E. List), Mannheim, Germany. (*Cf.* Figs. 476–79, 482–88.)

what extent these characteristics, especially the senses, and under what influencing circumstances, could have served as a starting point for the rise of the Primates. (*See* sections 10 and 12 on the Tree Shrew and the Tarsier.)

The now living Shrews are grouped by systematic zoölogy into numerous genera, in turn subdivided into hundreds of species and subspecies, variously adapted to their particular habitats, including the aquatic. As far as is known, the Shrews seem to inhabit most of the

Shrew (*Neomys fodiens*), House Shrew (*Crocidura russulus*), Mediterranean or Ciliated Shrew (*Pachyura etrusca*), and others. (*See*, for additional illustrations, Brehm 1912; English; and Lydekker 1916.)

The North American Shrews are subdivided, according to H. E. Anthony, into the following genera: Shrew (*Sorex personatus* or *S. cinereus*), Water Shrew (*Neosorex palustris*), Pigmy Shrew (*Microsorex*), Little Shrew (*Cryptotis*), Short-tailed Shrew (*Blarina*), and Gray Shrew

(*Notiosorex*). (*See*, for illustrations, H. E. Anthony 1928; H. H. T. Jackson 1928; and T. Surber 1946.)

2. CHARACTER. The external appearance of the Shrews, their anatomical organization, physiological performance, and biology are remarkably similar, no matter what their particular mode of life. They are small in size, externally resembling small Rodents, with a pointed muzzle and small eyes and ears. Their metabolic rate is high, requiring great quantities of food. The Shrews eat various small animals, including insects. They are rather nocturnal and secretive in habit and do not hibernate. Their dentition is of a primitive, little-differentiated, sectorial type, resembling that of the Inframammalian Vertebrates, from which the dentition of the more advanced Mammals has differentiated in the course of evolution.

The length of the representative domestic species in inches, given by H. E. Anthony (1928), is as follows: *Sorex personatus*, total 4, including tail 1.6; *Neosorex*, total 6.4, including tail 2.7; *Microsorex*, total 3.3, including tail 1.3; *Cryptotis*, total 3.1, including tail 0.64; *Blarina*, total 5, including tail 1; *Notiosorex*, total 3.6, including tail 1.24.

The measurements of the smallest species of Shrew, also one of the smallest Mammals in existence, that of the Mediterranean Shrew (*Pachyura etrusca*, *see* Fig. 475), inhabiting southern Europe and North Africa, are: body length 1½ inches, and tail length 1 inch, according to L. Heck (*see* A. Brehm's *Tierleben*, 4th ed., v. 10, p. 292, 1912). Several African species, thus the Giant Shrew (*Praesorex goliath*), of the

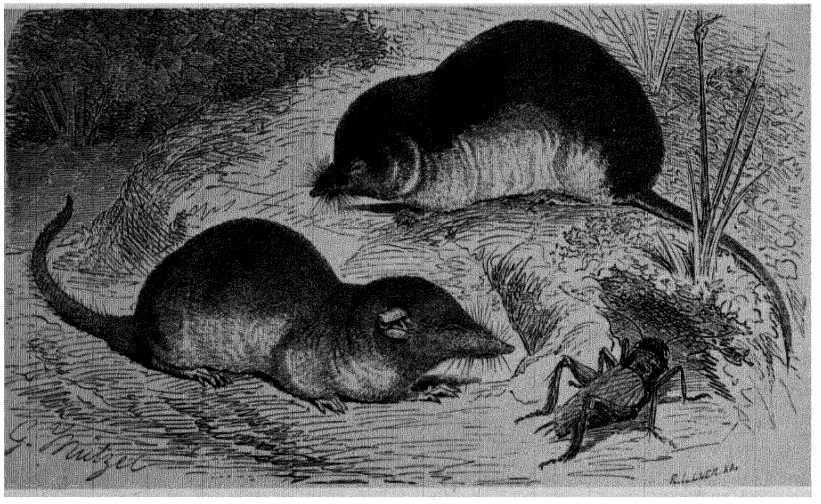

FIG. 476. *Sorex araneus* (*above*) and *Crocidura russulus* (*below*), two somewhat larger representatives of the terrestrial and nocturnal Shrews of Europe. Approximate body length 6½ cm., tail length 4½ cm. Note minute eyes and pointed snout, shriveled ears and long bristles, indicating poor vision and well-developed tactile and olfactory senses. From A. Brehm's *Tierleben*, 4th ed., *Säugetiere*, v. 1, p. 276, 1912, with special permission of the Bibliographisches Institut A.G. (Dr. E. List), Mannheim, Germany. (*Cf.* preceding and following figures.)

size of a Rat, are mentioned by Malbrant & Maclatchy (1949).

The diameter of the eyeball, both in *Crocidura russulus* and in *Sorex araneus*, measures 1.5 mm. in the sagittal axis and a little less in the transverse, according to Rochon-Duvigneaud, and in the *Sorex minutus* a little more than 1 mm., according to the same investigator. In comparison, the eye of *Pipistrellus*, a small European Bat, is a little larger, measuring 1.75 mm. across, whereas that of the European Mole

and the European Hedgehog, both much larger animals, measures from 0.8 to 0.9 mm., and from 5 to 6 mm. across, respectively.

Small as the eyes of the Shrews are, they are nevertheless in all particulars fully developed, possessing all usual structures: a transparent cornea, iris, biconvex lens, chorioid, retina, and blood vessels. Of the photoreceptor cells, in *Crocidura* both rods and cones are present, in *Sorex araneus* only the rods. In comparison, in the Mole both categories have been found by the same investigator, and in the Hedgehog and in the Bat only the rods.

The eyes of the Shrew, because of their small size, do not form images with sharp details and must be considered as largely lucifugal, directional organs of sight adjusted to respond chiefly to the varying intensities of light stimuli (*see* Rochon-Duvigneaud 1925, 1943; *see also* Verrier 1935; Walls 1942).

The eyes of the European Shrews *Sorex* and *Crossopus* have been examined by Kolmer, with the following results: diameter 1.5 mm., well-developed retina, photoreceptor layer made up of rods and cones in the ratio of 3 to 1, numerous ganglion cells, rich supply of blood vessels belonging to the central arterial system, and an optic nerve containing approximately 2,000 fibers (*see* Kolmer & Lauber 1936).

3. HABITS.—The habits of the Shrews, even though the animals are widespread and important in the origin and phylogenesis of Mammals and have been much investigated, unfortunately still remain in many respects little known because of the animals' secretive habits. In the following paragraphs is given a digest, first, from the important older publications, followed by the more recent ones, based on first-hand observation.

Perhaps the best presentation of the biology of the Shrews in general, especially those of Europe and near-by parts of the Old World, even though largely based on older sources, is found in the celebrated work on the life of animals by A. Brehm (*Tierleben*, 4th ed., v. 10, revised by L. Heck 1912). In it are recorded the observations not only of the German and other European investigators but also of some earlier American writers.

The Shrews, according to Brehm, inhabit both the lowlands and the elevated regions, climbing high into the Alps. They prefer dense woods and thickets, meadows, gardens, and buildings. Most of them love damp places, some taking to an aquatic life, a few burrowing into soil in which they dig passages or use those made by other animals, such as Mice and Moles, which they may have chased away. They prefer darkness and shade, avoiding dryness, heat, and light, being quite sensitive to sunlight, of which many perish. Their movements are exceedingly quick. In their behavior the Shrews resemble the Martens among the beasts of prey: like the latter, they also are adapted to various conditions of life and exhibit a daring, ferocity, and cruelty quite out of proportion to their diminutive size.

Among their senses, smell seems to be foremost, the next being hearing, whereas sight is poorly developed. Their intelligence is rather modest. Toward small animals they are merciless killers, while from more powerful adversaries they run as fast as they can.

The Shrews subsist almost exclusively on animal food: insects and their larvae, worms, mollusks, young birds and mammals, occasionally fish and their eggs, crayfish, and the like; they do not eat fruits, seeds, and other vegetable matter.

Immensely voracious, they daily consume food equal in amount to their own body weight; hence they cannot stand long hunger and, because of this, are unable to hibernate. In an experiment made by Rorig, a Shrew (*Sorex vulgaris*) weighing only 12 gm. had consumed, during 88 days, 3,733 meal worms (614.6 gm.), 4 grubs, 3 frogs, and 1 mouse. The dry weight of the substance was 200.58 gm., the daily ratio being one-fifth of the body weight of the living Shrew. There are, however, other experiments that make it doubtful whether the Shrews must eat continuously to remain alive. (*See*, for a modern study of the Shrew's physiology, Morrison *et al.* 1946, 1953.) The Shrews are able to produce a high-pitched, chirping twitter.

The archenemies of the Shrews are the Owls, against which their musky odor is no protection. The Storks and the Snakes, whose sense of smell is also poor, eat them with relish. Cats, Dogs, Foxes, and other Mammals who live by preying, on the contrary, avoid them.

While most of the observers emphasize the terrestrial habits of the Shrews, except of the aquatic species, a few mention having seen them climb low tree trunks to collect insect eggs or even build a nest.

There are few animals that are so unsociable toward their kind as the Shrews, except perhaps the Moles. Not even the opposite sexes live with each other in peace except during the mating time. Wherever two Shrews meet on their rambles, a duel is inevitable. However, even among the Shrews, there are occasionally peaceful relations, as the one reported of a gathering of about one hundred of them which were seen merrily scampering around.

The Water Shrews, as could be expected, are adapted to their peculiar mode of life: their fur is thick and impervious to moisture; their toes are provided with special hairs that are used as the web is used by the aquatic birds; their external ears can be folded, and the external auditory meatus may be closed; and the hairs along the underside of the tail are arranged in a ridge which possibly makes this limb usable as a propelling organ.

The Water Shrew is described as an extremely vivacious, clever, and agile creature, swimming and diving exquisitely, and with a remarkable ability to float either with the head alone above the surface or with the entire body. When swimming, its body appears flattened and usually also covered with a layer of minute, brilliant air bubbles which act as an insulator (possibly also adding to its buoyancy).

C. H. Merriam, in his book *The Mammals of the Adirondack Region* (1884 or 1886), has given us an interesting record of his personal observations on the habits of the American Shrews, of which the following excerpts are quoted from his description of the Cooper's Shrew:

> Like its congeners, it manifests a predilection for the immediate vicinage of old logs and stumps, and its holes can frequently be found, both in summer and winter, in these places, and about the roots of trees. Underground life does not appear as attractive to it as to its relatives, the moles, yet it avoids too much exposure and commonly moves, by night and by day, under cover of the fallen leaves, twigs, and other *debris* that always cover the ground in our northern forests. . . .
>
> Its ceaseless activity, and the rapidity with which it darts from place to place, is truly astonishing, and rarely permits the observer a correct impression of its form.
>
> Whenever a tree or a large limb falls to the ground, these Shrews soon find it, examining every part with great care, and if a knot-hole or crevice is detected, leading to a cavity within, they are pretty sure to enter, carry in materials for a nest, and take formal possession. Hence their homes are not infrequently discovered and destroyed by the wood-chopper. . . .
>
> Not only are these agile and restless little Shrews voracious and almost insatiable, consuming incredible quantities of raw meat and insects with great eagerness, but they are veritable cannibals withal, and will even slay and devour their own kind. I once confined three of them under an ordinary tumbler. Almost immediately they commenced fighting, and in a few minutes one was slaughtered and eaten by the other two. Before night one of these killed and ate its only surviving companion, and its abdomen was much distended by the meal. Hence in less than eight hours one of these tiny wild beasts had attacked, overcome, and ravenously consumed two of its own species, each as large and heavy as itself!

Merriam found the weight of a grown-up Shrew to be hardly more than half a dram, or not quite 2 gm., the largest specimen weighing 2.85 gm.

Further interesting observations of the habits of the Short-tailed Shrew in Michigan have been reported by A. F. Shull in the *American Naturalist* (1907). He found it catching Meadow Voles, mostly at night. It stores up piles of snails of the genus *Polygyra* and, with ease, like a miniature athlete, digs burrows and underground nests. Its food consists of Snails, Voles, House Mice, May Beetles and their grubs, Moth larvae and other insects and their pupae, Earthworms and Sow Bugs. Vegetable food, such as carrots, crackers, and grass roots, it never touched, which contrasts with the Common Shrew (*Sorex personatus*), which apparently also eats plant material (*see* Merriam's experience below). Its appetite is prodigious: a day's fare, for example, consisted either of two-thirds of a Meadow Vole, 1 Mouse, 15 May Beetles, 13 larvae of the same beetle, or 35 small Earthworms. It eats many other insects, the Ground Beetles and Sow Bugs being preferred. Beef was eaten by it readily. The method by which it captured its prey was to grab it by the ears and hold it until tired, then to

pierce its skull with a quick bite. It ate the brain and the cranium first, then the neck and the shoulders, while the snout, skin, legs, and tail were left unconsumed.

Of the senses of the Short-tailed Shrew, Shull found touch to be very fine, but sight poor, its principal role being to distinguish light from shadow. Its sense of smell is acute: "When the shrew was above ground, it was always going about with its nose slightly elevated and its nostrils dilating and contracting rapidly in unison with movements of the sides of the body, as if sniffing the air."

Hearing is also very well developed. A loud noise repeated often, however, would not elicit any response, but a response was obtained from slight sounds heard for the first time. Most persistent response was obtained from the flutter of the wings of a Pigeon, which "always sent the shrew scurrying into its burrows." "This particular sound must have been heard hundreds of times during that period [five weeks], yet even at the last could not be heard with equanimity by the shrew"—which may indicate an instinctive reaction to the noise of an owl.

"Sufficient evidence has been offered that most of the shrew's work on snails is done at night." The Shrews, it appears, are physiologically intolerant of bright light and of considerable heat. This seems to be the reason for their being active chiefly during the night, even though they are not entirely nocturnal, as evidenced by their capture by the Hawks. This last observation by Shull was substantiated by V. Bailey (1926), who was able to catch the Short-tailed Shrews as often during the day as during the night, even though the animals are not seen except when trapped.

The Short-tailed Shrew is universally present and in great numbers, the ratio in its range being four Shrews to one acre. The Shrew is well protected against the predators, Hawks and Owls, by its constitution and habits; compared with Mice, few Shrews are caught by Snakes, Foxes, Minks, Skunks, or Red Squirrels.

On the Common and other species of Shrews, much interesting observation, including that from the older literature, was gathered by Seton (1909). In the words of Cope (1873): ". . . the strength, ferocity, activity, and courage of the Blarina are such that if it were increased to half the size of a tiger it might quite logically make tigers its habitual prey." As it is, its preferred food, according to the same writer, was Field Mice. According to Morden (1884), *Blarina* eats about twice or three times its own weight of food every twenty-four hours.

From Seton's own experience, the Common Shrew (*Sorex personatus*) is not capable of climbing. It is never found far from the water, even though it is not aquatic. In character it is unsociable to the point of ferocity. "Whenever two of them fell into one of the pitfalls that I used for their capture, the stronger one invariably attacked and devoured his weaker brother." However, he quotes Herrick (1892), who found the Shrews to be sociable among themselves.

The mating of the Shrews, in Seton's experience, takes place during any season except the winter. Their voice is high pitched, at the limit of audibility. They are active during both day and night. Their eyes are useful only "to tell them when they are emerging from safe shadow into the open light with its great increase of danger." The Shrews are active during the whole winter, running in minute tunnels just under the surface of the snow.

The food of the Common Shrew consists chiefly of insects and worms and of flesh of any kind. It is extremely voracious and even cannibalistic. It needs an enormous quantity of food, and, to satisfy its appetite, Merriam and Seton believe that it may also eat vegetable products such as beechnuts, seeds, and roots.

Its enemies are Hawks and Owls. The Weasel, Cat, and Mink, even though they will kill it, do not eat it on account of the repugnant "musky" odor emanating from its glands.

Seton reports that the Short-tailed or Mole Shrew (*Blarina brevicauda*) preys under conditions where eyes are of little use, as in brush, moss, and among fallen leaves. Its home is in woodlands, among the tangles of brush and sedgy grass, under log piles, along streams, and in hardwood bush. In general, it prefers conditions similar to those favored by the Field Mouse, but it also digs tunnels in a way that recalls the Moles. It also digs beneath the leaves. Referring to *Blarina*'s way of life, Seton says that "this little inter-world betwixt floor and carpet was for him; and thus I learned why

he had bartered his eyesight for keener powers of smell and touch."

The Short-tailed Shrew, according to Seton, lives very close to water, in fact, "on the water's edge." It subsists chiefly on insects, worms, and any other living food, and prays largely on the Field Mice, equal to it or larger in size. In a pinch, it also eats beechnuts, corn, and oats. Merriam (1884) reported about one which he fed for a whole week with beechnuts, which it liked very much and on which it thrived. According to Eadie (1944), Field Mice, however, form a large part of its diet, possibly to some extent those weakened by disease or dead.

All Shrews, in Seton's opinion, are heavy drinkers, which is the reason why they live close to the water. This close attachment to the water is even more pronounced in the Water or Marsh Shrew (*Neosorex palustris*), which, according to Herrick (1892), resembles "a miniature otter."

The senses of the Shrews, in Seton's experience, vary much. While hearing is extremely acute, their eyesight is reduced to the point where the animals are practically blind. Sight apparently is useful only to distinguish light from shade. The sense of touch is exquisite. Smell, in his opinion, strangely enough, seems not to be well developed. *Blarina*'s motor functions also seem not to be out of the ordinary, the animal not being capable of climbing or running fast. In Seton's words, *Blarina* "offsets all its shortcomings by a superlative development of hearing and touch, and a restless energy combined with indomitable courage, great muscular powers, and tireless activity, an equipment that makes it a fearsome beast of prey, a terror to all wild creatures of its small world, that are less than double its weight."

The Shrews, according to H. E. Anthony's *Field Book of North American Mammals* (1928), may be quite abundant in a given region but, for all that, are rather infrequently observed.

> Their small size, quick movements, and habit of working under cover do not give one much opportunity to see these least of all mammals. Although these tiny creatures seem to be most active at night, they are often abroad in full daylight. . . . When one does see a Shrew it is usually but a glimpse as the animal rustles among fallen leaves or darts from under one log to another. . . . They are such highly organized, nervous creatures that they give instant response to any stimulation. Live Shrews which I have trapped have started violently when I have attempted to give an imitation, rather crudely I fear, of their fine, high-pitched squeak, and I have actually had one die in my hand from nervous shock.

Anthony, together with other observers, emphasizes their predatory, courageous nature, not hesitating to attack animals several times larger, even though hunting mostly for insects that are not able to put up much resistance.

> Mice put into cages with Shrews are dispatched with a celerity that indicates this is by no means a new experience for the Shrew at least; and as a further index to the Shrew character there are accounts to tell us that a cage can not contain more than one Shrew at a time for one will kill and eat the other if two are confined.
>
> Shrews require an abundance of food and consume a surprising amount because of a very rapid rate of digestion. Deprived of food for even a few hours they starve to death.

For their abode Shrews choose humid localities on the banks of small streams overgrown by rank vegetation and shrubbery, except the Pigmy and Gray Shrews, which prefer dry clearings instead of dark woods or damp, marshy places. "Shrews are active throughout the year and do not hibernate. Cold has no terrors for them and they range north of the Arctic Circle." Of their home life, very little is known.

The genus *Neosorex* or Water Shrew is well adapted to its aquatic mode of life, with its close pelage, partly webbed hind feet, and long tail. This Shrew lives along small streams and on the shores of marshes.

The activity of the Shrews apparently extends over twenty-four hours a day, with a decided preference for the night. *Blarina*, for example, is about during the daylight hours, even though it is seldom seen.

"The Short-tailed Shrew usually has five young in a litter and the nest is in an underground den or under rocks or stumps. The female makes a warm nest and lines it with shredded material such as grass and leaves. The young may be born from April to fall or even later."

Thaddeus Surber, of the Minnesota Department of Conservation, gave additional valuable information on the habits of the Shrews (*Con-*

servation Volunteer, v. 9 [July–August], p. 20, 1946). According to him, the Shrews

are largely nocturnal in habit and live just beneath the surface debris of the earth, the leaves, the moss and the wild grasses, so they are usually unobserved unless one is versed in their habits and has acquired the patience to watch for their occasional appearance above the surface. While they utilize the runways of the voles to a certain extent, in the damp cold sphagnum bogs they form tiny runways of their own and in the hardpacked snow often form tunnels just beneath its surface, from which it must be inferred they are active throughout the year. . . . Gifted with an insatiable appetite and a powerful digestion, they are extremely active in their endless search for food and it requires an enormous amount of insects and their larvae, earthworms and flesh to sustain them. As they occur in considerable numbers throughout the state, it can be readily seen they perform an important part in the economy of nature in holding in check myriads of insects. With the exception of owls, their enemies are few as these tiny beasts are provided with a peculiar nauseating odor that no doubt repels most animals. . . .

The largest species . . . , the water shrew, about equals the house mouse in size. It is almost as aquatic in habits as the muskrat and inhabits the same character of surroundings—peaty marshlands—as the star-nosed mole.

While all the shrews are very active, vicious and quarrelsome, the long-tailed species are the most pronounced in this respect. Savage and unsociable in disposition, they seldom encounter each other without engaging in a fight. Where two or more are taken alive and placed in confinement it means a fight to the death. Individually they do not hesitate to attack woods mice several times their weight.

The water shrews are the only mammals actually capable of running on the surface of still waters. Living as they do in the vicinity of ponds and small brooks, they play and search for their food with all the activity of the otter, even catching small minnows. Speaking of their ability to traverse water surfaces, Jackson (*N. A. Fauna*, No. 51, page 9) relates the following: "They can swim, dive, float, run along the bottom of a pool or creek, or actually run on the surface of the water with the greatest ease. In a bog near Rhinelander . . . the author saw one run a distance of about five feet across a small pond, the surface of which was glassy smooth. The body and head of the animal were entirely out of water, the surface tension of the water supporting the shrew, and at each step the animal took there appeared to be held by the fibrillae on the foot a little globule of air, which was also discernible in the shadow at the bottom of the pool, exactly as one might notice in the case of the water strider (*Gerris remigis*)."

On the Little Short-tailed Shrew (*Cryptotis parva*) there are several informative papers published in the past few years. This species, studied by W. J. Hamilton (1944) in northern Indiana, lives in leaf-mold tunnels in damp woods but also in the open grassy clearings along the forest margins. Its diet consists of Insects, Earthworms, Centipedes, Mollusks, and a small amount of vegetable matter. It is a glutton, consuming more than its weight of food in 24 hours, also eating Amphibians, Lizards, and Mice. In captivity it eats almost any animal food, but also cooked vegetables in the amount of three-fourths of its weight a day. Under natural conditions it probably consumes less. It is fond of apples. Its digestion is exceedingly rapid: the time required for the food to pass through the alimentary canal is, on the average, from 3 to 4 hours, sometimes as little as 114 or even 95 minutes. It likes water and drinks it freely. Under these circumstances, it is not surprising that it becomes fully grown at the age of one month. Sight appears to play a minor role in the life of this Shrew, the movements of the animal apparently not being under the guidance of the eyes. The sense of smell also seems not to be particularly well developed, the animal seemingly relying chiefly upon the tactile sense of the snout and the vibrissae (Edinger's "oral sense"). Its hearing is likewise not very acute, unless for the ultrasonic sounds. The animal sleeps well but is active at all hours, more during the night.

Additional information was gathered on the Texas variety of the same Little Short-tailed Shrew (*Cryptotis parva Texas*) by Davis & Joeris (1945). This Shrew is proficient in digging burrows in soil and making nests of shredded blades of grass in them. It is sociable, never fighting with its kind, except when given a single morsel of food. A prominent trait of this Shrew is meticulous personal cleanliness, which it keeps up by "washing" and combing its fur with its forepaws. It sometimes uses a special locality for defecation. The animal is active at all times, but the peak is attained during the night, with most of the day hours spent sleeping or resting in its nest, curled up on its side. Most of the specimens were caught during the early

winter, when the natural food was reduced. Its preferred food was the softer kinds of insects, such as Sow Bugs, Grasshoppers, and Crickets, while the hard-shelled Beetles were avoided. It also was fond of hamburgers, and it relished skinned Mice, while it was afraid of a live Mouse. On occasion it proved cannibalistic, as when confined with a dead comrade or when two found themselves in a trap.

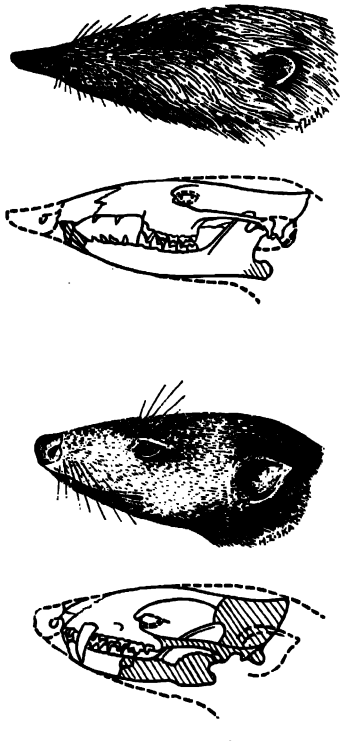

FIG. 477.—Skulls and restored heads of the ancient Cretaceous Placental Mammals which lived approximately one hundred million years ago and are believed to have resembled generalized types from which modern Orders of Mammals have developed: *above*, "insectivore" *Zalambdalestes lechei*, or an ancient Hedgehog; *below*, the "little carnivore" *Deltatheridium pretrituberculare*, a generalized type "not far removed from the base of the entire placental stock," according to Romer (1945). Discovered by Walter Granger, of the Third Asiatic Expedition of the American Museum of Natural History, near the Flaming Cliffs at Shabarakh Usu, in the Gobi Desert, in Mongolia. The petrifacts represent, according to W. K. Gregory, the "veritable missing links in the story of mammalian evolution." From W. K. Gregory, "Mongolian Mammals of the 'Age of Reptiles,'" Scient. Month., v. 24, p. 225, 1927. Slightly reduced. (*Cf. also* R. C. Andrews, W. Granger, *et al.*, *The New Conquest of Central Asia; Natural History of Central Asia*, v. 1, pp. 271–74, 1932.)

Concerning the sense of smell, the importance of which Hamilton questioned, Schorger (1947) relates his own recent observation in the field, which showed that, in situations where vision was practically eliminated, the sense of smell was used very well to find food, concluding that the Shrew's sense of smell is much better than it has been considered to be by recent observers.

Whereas observers are unanimous about the poorly developed sense of vision in the terrestrial Shrews, in the aquatic genus of *Neosorex* this may be different. There is the observation of a Rocky Mountain Water Shrew (*Neosorex palustris navigator*) catching small fry of Salmon parr, 2½ inches long, in the water, reported by Ben Hur Lampman (1947).

4. SHREWS AND THE ORIGIN OF PRIMATES.—The modern Shrews and other living Insectivores, exemplified by *Centetes* or *Tenrec*, aquatic *Potamogale*, *Solenodon*, *Chrysochloris*, Mole, Hedgehog, *Gymnura*, and Elephant Shrew, are the most ancient of living Placental Mammals (*see* description in Brehm, v. 10, 1912). Even though they are in many respects modified from the ancestral placental type, the Shrews are the best living example of how the ancient Placental Mammals of the early Jurassic Period of roughly 125 million years ago looked before they became differentiated into various orders of Modern Mammals. (*See* Fig. 468 in Parker & Haswell, *A Text-Book of Zoölogy*, v. 2, 1940, for the appearance in time and probable relationship of mammalian subclasses and orders; *see* Fig. 83, in Zeuner, *Dating the Past*, 1946, for a table of subdivisions of the past geological epochs; *cf. also* Fig. 257, in Romer, *Vertebrate Paleontology*, 1945.)

In anatomical features and living habits, the Shrews may be characterized as the most primitive living Placental Mammals of small to diminutive size, of principally terrestrial habits, with subterranean and nocturnal leanings, largely carnivorous in diet. In order to gauge the early phase of primate evolution, it is neces-

sary, first, to examine the character of the shrewlike animals in their role as the ancestors of Primates and to fit together the results with the subsequent phases, of which the Tree Shrew and the Tarsier may be an illustration. (*Cf.* Figs. 475, 476, 478, 479, with Figs. 482–85, and Figs. 497–500; *see also* figures in subsequent sections, this chapter.)

If the Primates developed from forms roughly resembling present Shrews, these ancestors must have possessed anatomical and biological characteristics sufficiently pliable to develop into features characteristic of the Primate Order. Of these features, the most salient are the dominance of diurnal vision, grasping hands, omnivorous diet, and superior intelligence. On general, speculative grounds, it may be hypothesized that these features have a common genetical basis, caused by common conditions that created them.

The first characteristic—superior vision, with an emphasis on diurnality—is a far cry from the micropic and scotopic type of vision found in practically all terrestrial Shrews. There are few cues to indicate whether this is an inherited or a secondarily acquired characteristic. It would be easy to take refuge in a general thesis that, under the influence of changing conditions of life, almost any feature could be modified, even to its extreme. But this explanation, applied to the nocturnal habits of the Shrews, may appear somewhat strained. For this the nocturnalism of the Shrews is too universal and has been in existence at least since the Eocene Epoch or during the last 50–60 million years. Hence it is more likely that this nocturnalism is a characteristic closely related to the very origin of the Mammals.

Among the modern Insectivores, small eyes, poor vision, and terrestrial and nocturnal habits are practically universal (*see* Brehm 1912). From this fact it is legitimate to hypothesize that similar features may have been the original condition of the incipient Mammalian Phylum, during which some Vertebrates began to differentiate into forms eventually terminating as Placental Mammals. This time may very crudely be identified with the Triassic Period, the first of the three periods that make up the Mesozoic Era, dating roughly 175 million years in the past, according to Zeuner (1946).

The causes that imposed nocturnalism with its consequences continued during the following and much longer Jurassic and Cretaceous Periods. These two periods were coextensive with the climax of the Flying Reptiles and Dinosaurs. It is apparent that during these long periods the lowly ancestors of the Mammals passed through a severe testing, during which they were transformed from reptile-like diurnal animals with good vision into true Mammals.

In this critical "bottle-neck" time of trial and error, compelling factors must have worked to bring about a radical transformation and, with it, survival. Extinction was always threatened by the Dinosaurs or Dominant Reptiles, endowed with good sight. The only way for weak creatures to survive and become Mammals was to hide in darkness and behind camouflage. In doing this, the ancestors of the Mammals lost the precision of diurnal vision. (In the absence of light, the development of photopic vision is suppressed, as experiments by Birukow & Knoll [1952] showed.)

To compensate for reduced sight, other senses had to develop. In the case of terrestrial Shrews, the senses of smell, hearing, and touch competed for priority. In the Insectivorous Bats the sense of hearing combined with touch became dominant, at the expense of both smell and sight (*see* Polyak, J. f. Psychol. u. Neurol., v. 32). For the ancestors of the Mammals, including those of the Shrews, this meant a flight into darkness, a realm dominated by odors and sounds. This, in turn, imposed other profound changes: reduced body size, an increased demand for animal food in order to maintain high metabolism, and so forth.

Of these changes, macrosmia or dependence upon the sense of smell may have been most fraught with consequence. It was a keen nose that led the primitive Mammals to food, which, of necessity, was the "small life" that lives close to and in the ground: insects, grubs, earthworms, and other creatures of small size and their eggs. In fact, any "flesh" was very welcome to them. Eggs of all sorts were a delicacy, since they represent the best combination of nutritive material. The Ancient Mammals must have been especially eager to locate this prize. The facilitating factor was the poor protection of reptilian eggs afforded by their soft

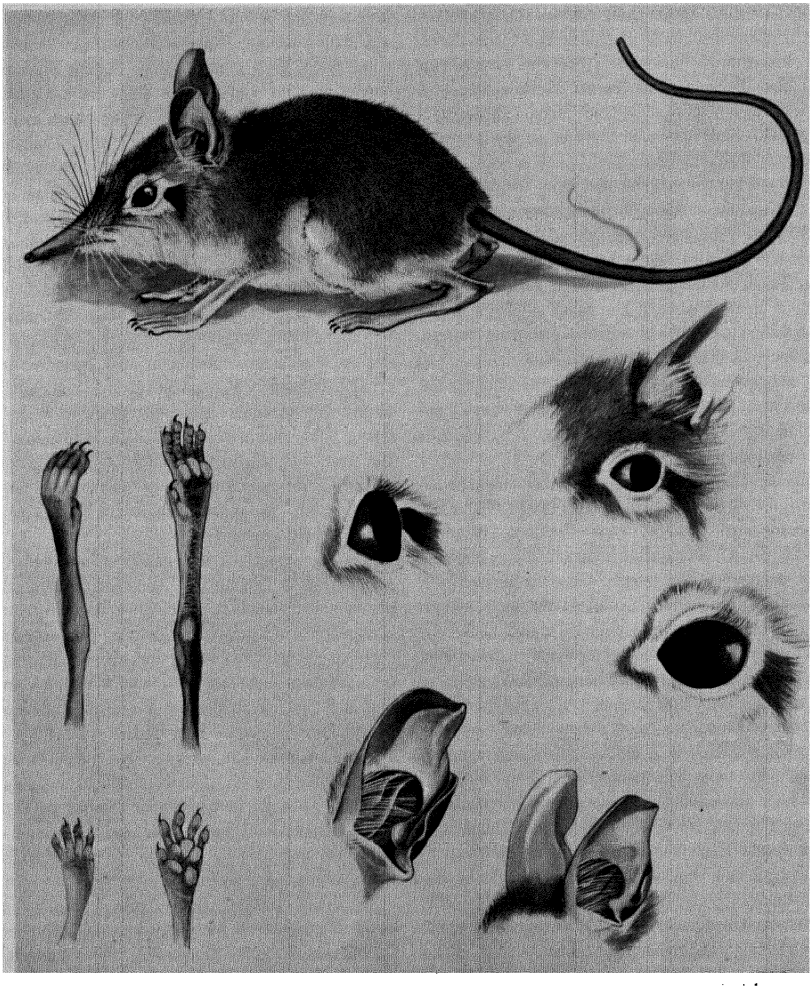

FIG. 478.—African Elephant Shrew (*Elephantulus rufescens*), one of the Jumping Shrews or Macroscelidae of the African Sudan, a suborder of Insectivora. A terrestrial relative of the Tree Shrews or Tupaiidae of Asia (*see* subsequent figures), the modern representatives of the ancient Mammals from which the ancestors of Primates have developed. This and the following plate have been prepared from a preserved specimen with the help of A. Brehm's *Tierleben*, 4th ed., *Säugetiere*, v. 1, 1912. Details show, in addition to a restored animal, views of the hind and front foot, of the eyes in plain view and in half-profile, and of the auricles. (*Cf.* Figs. 479–81.)

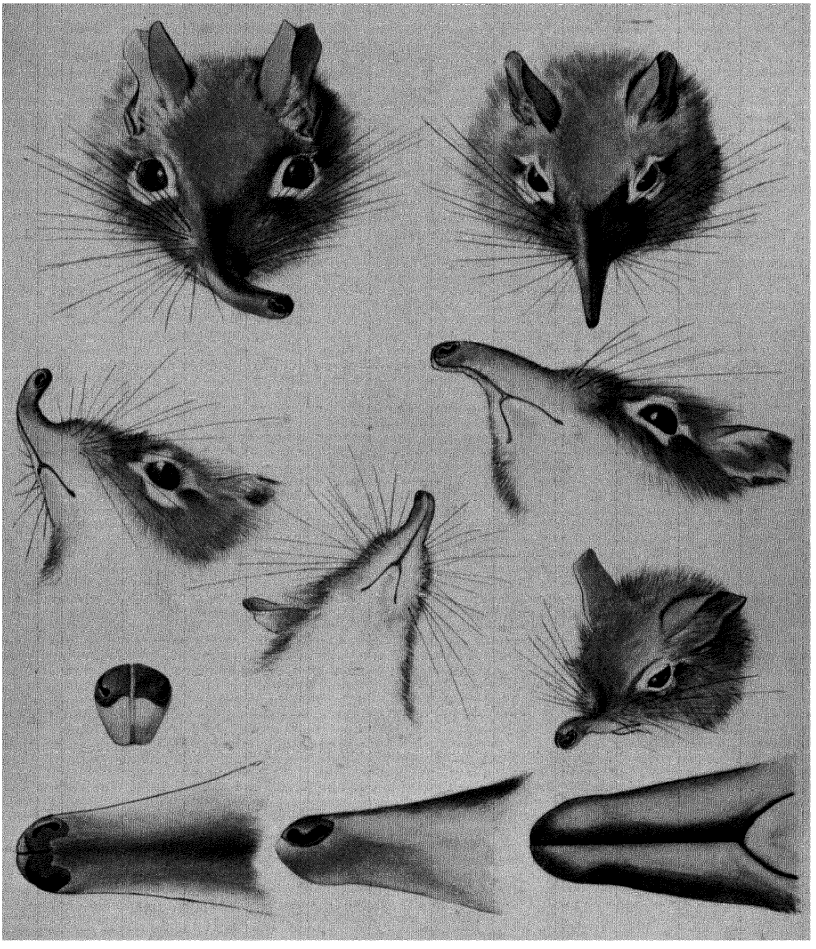

FIG. 479.—Views of the head and parts thereof of the African Elephant Shrew, a primitive terrestrial insectivorous relative of the Tree Shrews of Southeast Asia, the *Tupaia* (Figs. 482, 483), *Ptilocercus* (Fig. 484), and *Urogale* (Fig. 485). The eyes, even though quite laterally placed, indicate by their position some slight overlapping of both fields of view in front of the head. The pupils, when contracted, form vertical slits, the iris providing a protective screen against excessive insolation, an arrangement useful in a tropical habitat with scanty vegetation. Large, delicate, and movable auricles, a long flexible snout, and numerous long vibrissae all bespeak the great importance that hearing, smell, and the "oral sense" of touch have in the life of the Elephant Shrews. This contrasts with the small auricles and well-developed eyes of the Tree Shrews, which, from the viewpoint of primate phylogenesis, appear to be a more advanced division of menotyphlous suborder of Insectivora. (*Cf.* Fig. 478.)

envelope. When a clutch of these was destroyed, another chance for survival of the mighty Dinosaurs was lost.

It is obvious, however, that this presentation of cause and effect—the rise of the Mammals and the downfall of the Reptiles—is too simple to do justice to a very complex process of factors and circumstances that extended over many millions of years. Of these, nothing now remains but the final historical result, which we see in the disappearance of practically all large Reptiles and their replacement by Mammals. It is an outcome of the "struggle for existence," where the lowly, but not weak, and better-adaptation to a secretive, mostly nocturnal, mode of life. Their scotopic obscurity, evidently, must be advantageous to them, even in present conditions, and they may continue in this way indefinitely. In their way, they are as successful as are the subterranean Moles or *Chrysochloris*, even though they do occasionally use daylight, mostly negatively, by shunning it and consequently are not able to respond to colors, which play a large part in the lives of the diurnal Fishes, Lizards, many Mammals, and most Birds.

The Shrews continue their existence in the darkness into which they were driven by bio-

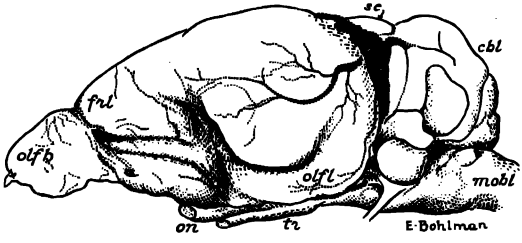

FIG. 480.—Brain of the Elephant Shrew in side view, 4× magnified. Note the large olfactory bulb and lobe and absence of the occipital lobe, indicative of the dependence of this insectivore animal chiefly on the olfactory sense and on hearing (as the long snout and large, flexible auricles in the preceding figures show). (*Cf.* following figure.) *Labeling: cbl*, cerebellum; *frl*, frontal lobe; *mobl*, oblong medulla; *olfb*, olfactory bulb; *olfl*, olfactory lobe; *on*, optic nerve; *tr*, trigeminal nerve. Venous sinuses and a few other blood vessels also shown.

equipped Shrews won over the mighty, but less adaptable, Dinosaurs.

The rise of the Placental Mammals from their Jurassic and Cretaceous obscurity into a Cenozoic luxuriance did not appreciably affect the modern Shrews. They may have changed somewhat, retaining, however, the essential organization and habits which we may assume their ancestors possessed at the end of the Jurassic Period: small size, short limbs, clawed feet, small brain, large olfactory bulbs and lobes, small eyes and poor vision, and little differentiated dentition. For this the blame may be put upon the larger Mammals and Birds, which meanwhile developed and replaced the Dominant Reptiles.

According to the competent observers quoted in the preceding pages, Shrews populate most of the globe in great abundance, contrary to the superficial appearance caused by their perfect logical necessity more than 100 million years ago and in which they have been kept ever since. In their adaptation to obscurity they parallel the Microchiroptera or Insect-eating Bats, depending, however, principally upon a combination of senses: smell, touch, taste, and hearing, instead of upon hearing alone, as their flying relatives do.

During the Cretaceous Period, when the downfall of the large Reptiles was initiated, very likely assisted by the rising Shrewlike Mammals, many of the latter took the opportunity to emerge from obscurity. From these, almost like an explosion, developed practically all now living orders of Mammals, which very soon spread over most of the earth. This was a "Sturm und Drang period" for the Class of Mammals (*see* Fig. 257 in Romer's *Vertebrate Paleontology*, 1945; also Parker & Haswell, *A Text-Book of Zoölogy*, v. 2, Fig. 468, 1940).

This period may be described as the unshackling of a class, hitherto living in darkness under perpetual terror and threat of extinction, to new freedom and opportunity. This miracle was mediated by a return to the full diurnal vision of their reptilian ancestors, a vision far superior, in its precision and reactions to radiant stimuli, to any nocturnal adaptation, no matter how superlatively utilized (*cf.* sec. 12, Tarsier). In its significance for the further advancement of Mammals, this rebirth was on a par with the transformation the sense of vision made the major contribution. We have a glimpse of this in a few insectivorous representatives whose vision seems definitely improved over the blindness of the Moles and the extremely poor vision of most of the Shrews. Such examples are the Hedgehog, *Gymnura*, probably *Potamogale*, and our native Water Shrews. Except for the well-observed Hedgehog (*see* Herter & Sgonina 1933), the record on these, unfortunately, is less than meager. This is also true of the many exotic

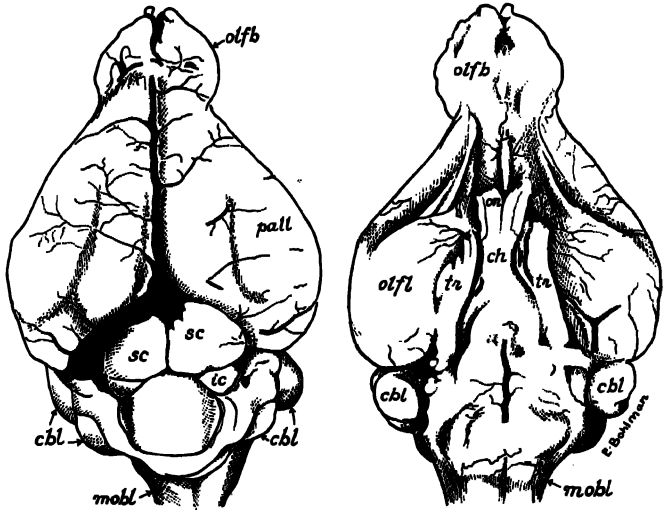

FIG. 481.—Brain of the Elephant Shrew, left figure a dorsal view, right figure a ventral view, 4× magnified. Note the large superior colliculi (*sc*) of the midbrain or primitive mesencephalic centers of sight entirely uncovered by the still undeveloped occipital parts of the great hemispheres; prominent olfactory bulbs and lobes interconnected with marked striae; optic nerves which are much thinner than the trigeminal nerves; asymmetry of venous sinuses, the left sigmoid sinus much larger than the right one. (*Cf.* preceding figure.) *Labeling: cbl*, cerebellum; *ch*, chiasma of optic nerves; *ic*, inferior midbrain colliculus; *mobl*, medulla oblongata; *olfb*, olfactory bulb; *olfl*, olfactory lobe; *on*, optic nerve; *pall*, pallium or forebrain cortex; *sc*, superior midbrain colliculus; *tr*, trigeminal nerve.

"invention" of photoreceptors by the early Prevertebrate; the change that made possible the initial rise of the Vertebrate or Chordate Phylum, as described in section 2, in the preceding chapter.

How from this evolutionary stage and under what influencing factors the grasping hands and superior intelligence of the Primate Order gradually evolved is a theme treated in the following sections of this chapter and in the final chapter. However, it may be mentioned here that in this little-observed and poorly described Shrews of Asia and Africa.

The next step, that represented by the Elephant Shrews (Figs. 478, 479) and the Tree Shrews (Figs. 482–86), is a great advancement over the soricide Shrews. It may illustrate the real beginning of the emancipation of the Mammals from their inherited nocturnality and their readoption of daylight habits, an absolute requisite for the rise of Primates.

Other habits occasionally noticed in the

Shrews, such as adding plant products to their diet and making short excursions up trees, may also have been the first timid attempts which, in favorable circumstances and in due course of time, developed into the arboreal life of the Tree Shrews, from which the true Primates eventually evolved.

SEC. 10. TREE SHREW

1. Taxonomy.—The Tree Shrews are Mammals the size of a good-sized Rat, which they superficially resemble (Figs. 482–86). In their anatomical organization and living habits they closely emulate the primitive, generalized type of Mammals of the Cretaceous Period of the earth's prehistory, roughly estimated as having started 127 million years ago and terminated 58 million years ago.

The Tree Shrews at present are found in India and Assam, in Farther India (Burma, Siam, Indo-China, the Malay Peninsula), southern China, Malaysia west of Wallace's line (Sumatra, Java, Borneo), and in part of the Philippines (Mindanao).

At least seventy-five species have been described so far (Lyon 1913). Best known in the literature are the Dusky Tree Shrew (*Tupaia ferruginea*), Tana (*Tupaia tana*), Anathana (*Anathana ellioti*), Midget Tree Shrew (*Tupaia minor*), the Philippine Tree Shrew (*Urogale everetti*, "Tarra-Bahbooey" of the natives), and the Pen-tailed Shrew (*Ptilocercus lowii*).

Systematically, the Tree Shrews belong to the Family Tupaiidae, which, together with the closely related African Elephant Shrews or Macroscelidae (Figs. 478, 479), form the suborder Menotyphla or Tupaioidea, one of the subdivisions of the Order Insectivora. Other suborders representing the Lipotyphla are: the extinct Deltatheroidea (Cretaceous *Deltatheridium*, Fig. 477, Eocene *Didelphodus*), Centetoidea (Tenrecs of Madagascar, *Solenodon* of Cuba and Haiti, the African Otter Shrew or *Potamogale*), Chrysochloroidea (Golden Moles of South Africa), Erinaceoidea (Zalambdalesti-

dae of Upper Cretaceous, Leptictidae of Upper Cretaceous to Oligocene, the still living Erinaceidae or Hedgehog Family of the Old World, represented by the Hedgehogs and *Gymnurae*), the Soricoidea or the common terrestrial and aquatic Shrews (Soricidae) and the Moles (Talpidae).

2. Character.—In its general appearance and in its size and behavior, the Tree Shrew somewhat resembles the Squirrel, for example, the native Red Squirrel or Chickaree (*Sciurus*

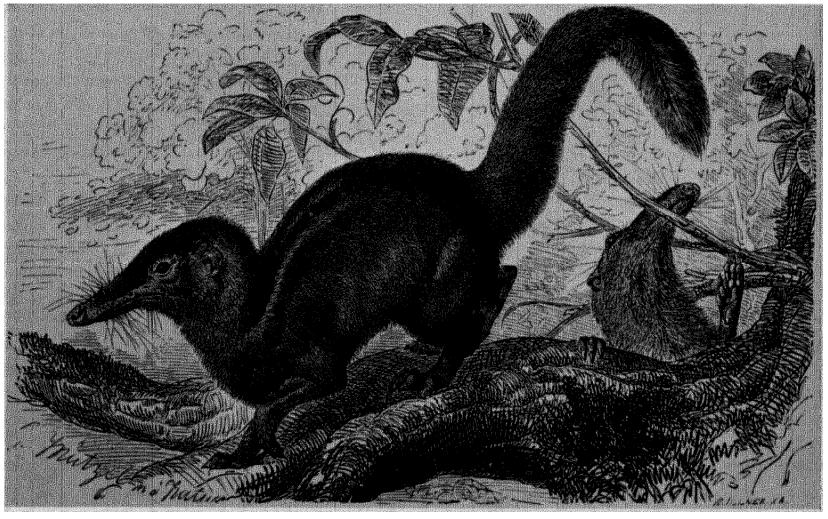

Fig. 482.—Long-nosed Tree Shrew (*Tupaia tana*), a native of Sumatra and Borneo, representative of advanced Insectivorous Mammals or Tupaiidae. Measurements: head and body 25 cm. long. Habit partly arboreal, diurnal, insectivorous, and probably also fructivorous. From A. Brehm's *Tierleben*, 2d ed., v. 2, p. 224, 1880, with special permission of the Bibliographisches Institut A.G. (Dr. E. List), Mannheim, Germany.

hudsonicus, Fig. 494). However, when more closely observed, the Philippine *Urogale* seems more like a typical soricide Shrew, such as the Old World House Shrew (*Crocidura russulus*, Fig. 476), except for its larger size and eyes which are relatively much larger.

The fairly stout body of the Tree Shrew rests upon shorter forelimbs and longer hind limbs, all provided with five toes armed with curved claws. The elongated head terminates in a pointed snout covered with naked, moist skin. The eyes are moderately large, relatively much larger than in the small terrestrial Shrews (Soricidae). A row of fine eyelashes sticks out from each eyelid, especially the upper, an additional protection being a few long, stiff bristles growing above and below the eyes (Figs. 488, 489). Similar bristles adorn both the upper and lower jaws and the snout.

The external ears are unlike those of almost any other Mammal. They are reduced in size, and, instead of having the usual shovel shape, they appear shriveled, markedly resembling the auricles of the higher Primates: Monkeys, Apes, and Man. As in the latter, they are almost immobile. (*Cf.* Polyak *et al.*, *The Human Ear in Anatomical Transparencies*, 1946.)

The tail is fairly long and is covered with rather scanty hair; it usually is carried half-raised, often with its tip curled to one side or the other (Fig. 486).

3. Specific features.—The preceding description is that of the Philippine Tree Shrew observed during life and studied in detail by the author. While it may in general be true of the entire family, greater or lesser deviations from

it are seen in numerous species scattered over many lands of southern and southeastern Asia and the near-by islands. In *Tana* (Fig. 482), e.g., the snout is longer than in *Anathana* (Fig. 483), which makes the latter approach some of the Lemurs in appearance (Figs. 524, 525). On the other hand, because of the abundance of hair, the tail in both species resembles rather more that of the Squirrels, whereas in the Pen-tailed Tree Shrew (Fig. 484) the hairs are limited to somewhat less than the distal half of the tail, with the hairs of the tuft arranged distichously or in two rows, one on each side.

4. Habits.—There are many notes about the living habits and character of the Tree Shrews, scattered in the observations of numerous travelers and explorers since their discovery. They were first mentioned by Ellis, one of the surgeons of Captain Cook's expedition (1780), and thereafter by Leschenault de la Tour (1807), Diard (1820), Raffles (1822), Schlegel & Müller (1841), Gray (1848), W. Elliot (*ca.* 1849), Whitehead (*ca.* 1879), and O. Thomas (1892). However, all of them are casual or sketchy, none giving a sufficiently complete picture of the animal.

There is general agreement that, except for *Ptilocercus*, which is nocturnal, all Tree Shrews are diurnal in habit, arboreal, and rather omnivorous in diet, with a preference for insects, such as ladybirds and other small beetles, flies, crickets, grasshoppers, ants, earthworms, and cockroaches. They are also reputed to be partial to birds' eggs, small birds, mice, lizards, and the like. In all species fruits, seeds, and buds form part of the diet, while some species seem to be almost entirely frugivorous. Food is taken both from the ground and from trees.

According to Wharton (1948), who gathered his information from the natives of Mindanao, the Philippine *Urogale* lives in holes in the ground or under rock cliffs and bears about five young in a leaf-lined nest. It is strictly a diurnal animal and sleeps all night, curled into a tight ball. It feeds in the morning hours, regularly visiting certain fruit-bearing trees growing on steep, moist hillsides along river gorges.

About the Dusky Tupaia, Cantor (1846) wrote that at times it sits on its haunches, holding its food between its fore-legs; and, after feeding, it smoothes its head and face with both forepaws and licks its lips and palms.

According to some observers, the Tree Shrews are alert, fast animals, climbing almost with the agility of a Monkey. Others, on the contrary, question this, since Tree Shrews are often caught by cats and dogs. Young ones are easily tamed, and many live in and around the huts of the native villages in semidomestication, which strangely contrasts with their alleged inclination to quarrel with their own kind.

Tree Shrews live under widely differing conditions, in dense jungle, as well as in bamboo thickets, among scattered trees and bushes in human settlements, and in Burma also as house pets. They are found both in flat country and in mountains, where they climb to 6,000 feet and more, for example, in the Himalayas in India and in Assam, and on Mount Apo, on the Philippine island of Mindanao.

What proportion of time the Tree Shrews spend in the trees and how much on the ground is not quite clear from the scanty information. It seems that in this respect there are considerable differences in various species and genera. The Dusky Tree Shrew and *Anathana* may be more arboreal, the Pen-tailed Tree Shrew entirely so (Le Gros Clark 1926, 1927), whereas *Tana* and *Urogale* possibly are more ground dwellers, although *Tana* and *Urogale* may also frequently climb small trees and bushes. According to Ridley (1895), the Dusky Tree Shrew is more terrestrial in its habits than a squirrel.

According to Robinson & Kloss (1909) and Kloss (1911), only a few species of Tree Shrews are truly arboreal, the majority of them living and feeding mostly on the ground and only occasionally climbing low bushes. Some species, e.g., *Tupaia* of the Nicobar Islands, according to Abbott & Kloss (1902) and Kloss (1903), are undoubtedly arboreal. They are common in the heavy jungle and are found only in the treetops, where they are "as active as squirrels in running along branches, or climbing about amongst smaller twigs in search of insects." Their voice is a sort of trilling squeak.

5. Observation of Tree Shrews in captivity.—Until recently, Tree Shrews have on very few occasions been observed alive under more or less civilized conditions (Brehm, v. 10;

FIG. 483—Anathana (*A. ellioti*), a Tree Shrew native of India south of the river Ganges. The figure represents an adult male specimen. Dimensions: from the tip of the nose to the root of the tail about 8 in., tail 9 in., from the nose to the ear 1½ in. Note relative shortness of the head and larger eyes compared with most other species of the same genus. (From G. R. Waterhouse, in the *Proceedings of the Zoological Society of London, Mammals*, plate XIII, y. 1849.)

FIG. 484—Pen-Tailed Tree Shrew (*Ptilocercus lowii*), the most arboreal of the genus, native of the Malay Peninsula and nearby islands (Sumatra, Borneo, etc.). (From J. E. Gray, in the *Proceedings of the Zoological Society of London, Mammals*, pl. II, y. 1848).

Le Gros Clark 1926, 1927). The following notes were made by the author from observations of a pair of Philippine Tree Shrews, acquired in the summer of 1947 and held in captivity for many months. Additional valuable information was obtained from observing several living animals of the same species in the Brookfield Zoölogical Garden, Brookfield, Illinois. All these Shrews came from the slopes of the 9,690-foot-high Mount Apo, the highest elevation in the Philippines, along the river Sibulan.

FIG. 485.—Philippine Tree Shrew (*Urogale everetti*), a native of the island of Mindanao, Philippines. A Graflex camera flash photo, reduced to two-thirds natural size. The primitive Mammal from which, or from a similar form, the Primate Order, including Man, originated. Note the well-formed eye and the auricle not unlike that of the Monkeys and Apes. (*Cf.* Fig. 477 and following figures.)

The Tree Shrew, according to our own observation, is an active, nervous, fussy, intelligent, and inquisitive creature. Most of the time during the day, the Shrews run about their cages, jumping here and there, constantly examining everything, even when not hungry, climbing up and down the sides, and occasionally hanging for a moment from the ceiling, pushing under the cardboard box given them as a hideout, and poking their long noses everywhere — in short, born busybodies.

They are omnivorous. They eat oranges, bananas, apples; like lettuce; nibble at carrots, peanuts, and other vegetables; and love fresh, soft white bread. They have a "sweet tooth." Fresh fruit, such as grapes, is relished by them, while sour oranges and carrots are only nibbled

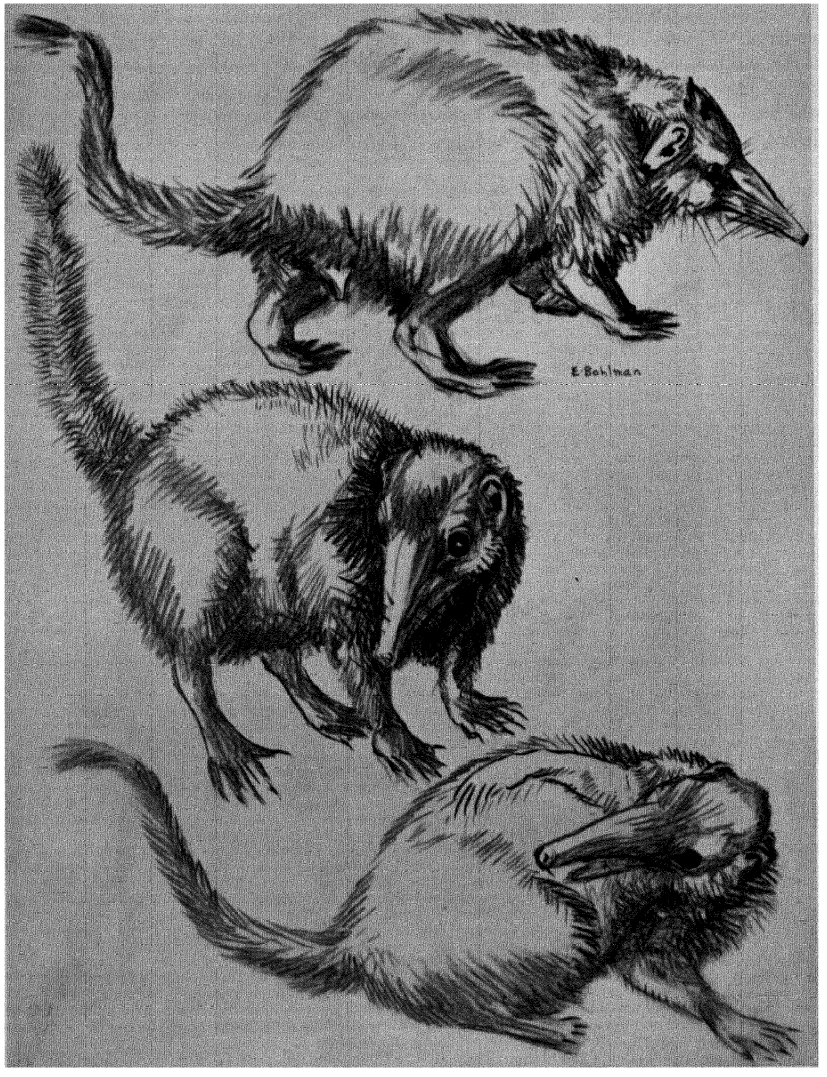

FIG. 486. Freehand sketches of the Philippine Tree Shrew. Upper sketch shows its usual appearance when running around the cage investigating, with the characteristic posture of its tail; middle sketch with a raised and bushed-up tail, observing with its left eye (an expression of mild curiosity or slight apprehension); lower sketch shows a characteristic attitude when scratching its fur with one of its forepaws and often "combing" it with the teeth of the upper jaw at the same time.

at. However, they do not care much about dry raisins. Fresh milk they like, but there are individual differences: while one Shrew drinks it by lapping it up to the last drop, another Shrew takes but little.

They are very fond of fresh and frozen meat and, in general, animal food. Any part of a rabbit, guinea pig, or rat they eat avidly, be it

first, the Tree Shrew usually gives the lizard a quick poke with one of its forepaws, always ready to run away if the situation appears dangerous. If the repetition of the trick finally convinces it that the prospective meal can be conquered, it quickly snatches it and carries it away to devour it.

The tidbit these living Cretaceous gourmets

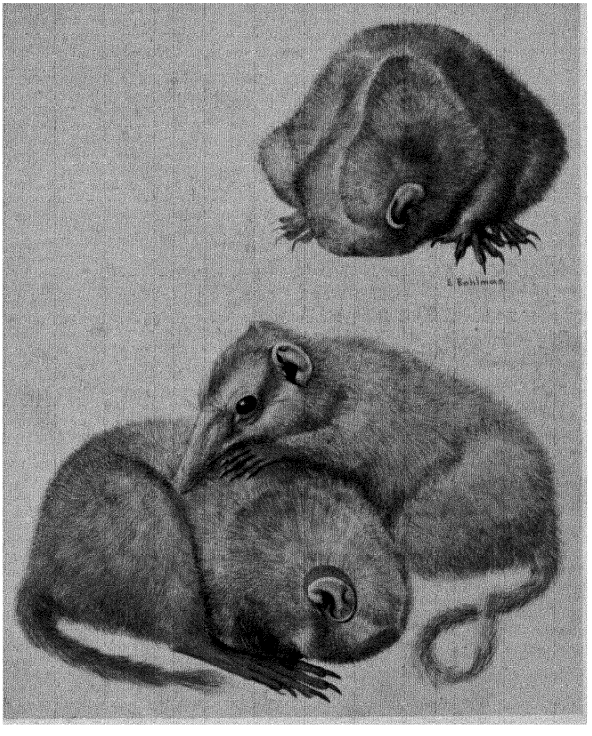

FIG. 487.—Sleeping and resting postures of the Philippine Tree Shrew. Upper figure alone, sound asleep. Lower figure represents a typical pose during an afternoon nap, taken regularly as a matter of daily routine, with one of the pair soundly asleep, the other dozing and keeping vigil.

muscles, internal organs, brain, or fat. Softer bones, cartilage, and tendons are also all consumed.

Anole Lizards are devoured whole with relish, although they are apparently afraid to tackle them alive. When a live lizard is offered to them, it rarely is attacked with a rush, as by the Tarsiers, but rather approached timidly. At

prefer to every other food, however, is meal worms. Two dozen of these given them at each meal are gobbled up in no time. When the meal worms are put in the same dish with fruit and vegetables, the first thing the greedy Shrew does is dig for the worms. In this process the pieces of fruit are disdainfully scattered over the floor of the cage and are partly eaten only after

the more tasty morsels have been consumed. Other insects, such as cockroaches, are also eaten with gusto.

One day a fresh pigeon egg was placed for the first time on a dish in the cage. After taking a look at it from some distance and without any preliminary olfactory exploration, in a surprisingly quick rush, the Tree Shrew attacked it and, with a single bite, opened the shell and eagerly lapped its contents, which were running over the floor, and finally it licked off its front paws which had been soiled. In a very short time nothing remained except empty pieces of the shell. Whether or not the animal had had a previous similar experience with eggs in its native jungle, the display indicated that in the wild state bird and lizard eggs may be a frequent fare eagerly sought by the Tree Shrews.

Judging from the greed with which animal food is eaten, Tree Shrews seem to be more carnivores than fructivores or omnivores. On the other hand, considering their timidity when attacking living prey and their liking for certain vegetable products, such as sweet grapes, the foregoing statement must be qualified: Tree Shrews, while partial to animal food, cannot be rated as true, aggressive, bloodthirsty carnivores, such as members of the Weasel, Dog, and Cat tribes, or even like the Tarsier, not to speak of ordinary Shrews (Soricidae), whose greed for animal food in captivity sometimes culminates in cannibalism. (*See* preceding sec. 9, on Common Shrew.)

The principal animal food of the Tree Shrews in the state of nature, it seems, is a variety of insects, grubs, worms, slugs, snails, and other small animals, including vertebrates which, because of their helplessness, can be easily captured, as, for example, young birds, lizards, frogs, and the like, as well as their eggs. For the rest, they have to be satisfied with whatever else nature provides for them in the form of various fruits, which they also like, the sweeter the better, their taste in this respect being substantially not different from our own.

In eating, being no altruists, each Tree Shrew had to look after its own interests. This naturally caused a reaction, which in German is succinctly called *Futterneid* or "competition at the fodder trough." Such rivalry erupted especially at the offering of meal worms. On this occasion the difference in individual character was clearly manifested. The more aggressive and more agile Shrew usually got the better part of the bargain, whereas the other more clumsy and more timid Shrew, which perhaps had been hurt by rough handling when it was caught, had to be satisfied with the leftovers. In a scramble for tidbits, the slighted Shrew was driven off or frightened away, giving expression to its offended feelings by squealing in protest as it ran around the cage.

Outright squabbles or fights, however, were not observed, possibly owing to the abundance of food which the animals had at all times. The squealing was occasionally also elicited on teasing the animals by offering them a desired morsel, and then taking it away.

6. BEHAVIOR.—The captive Tree Shrews became fairly tame very shortly after their arrival. In the course of a few weeks, they were quite confident and could be easily handled, if a certain amount of circumspection was used. However, even after many months of gentle treatment, they still maintained a certain reserve and could not be taken with an unprotected hand. Whenever anything unusual happened in the animal room, they became alarmed and ran quickly behind their cardboard hideout.

Their daily cycle showed two maxima of activity, one early in the morning, the other higher one in the late afternoon. During these two periods they were most active, ate most, ran about, and did exploring. Toward the end of the afternoon period, with the falling dusk, their activity reached its peak: for a few minutes and without an apparent cause, they ran about their cage in confusion, squealing aloud at the same time, gradually quieting down with the coming of night. During the noon hours they usually were quiet, partly resting curled up, one dozing while the other kept watch (Fig. 487). It is interesting to note that the two maxima of activity are the same as those when, according to Ridley (1895), the animals in the Malayan jungle also are "brisk and on the alert."

7. USE OF THE LIMBS.—Throughout many months of captivity special attention was paid to the use of the forelimbs. Ordinarily, the Tree

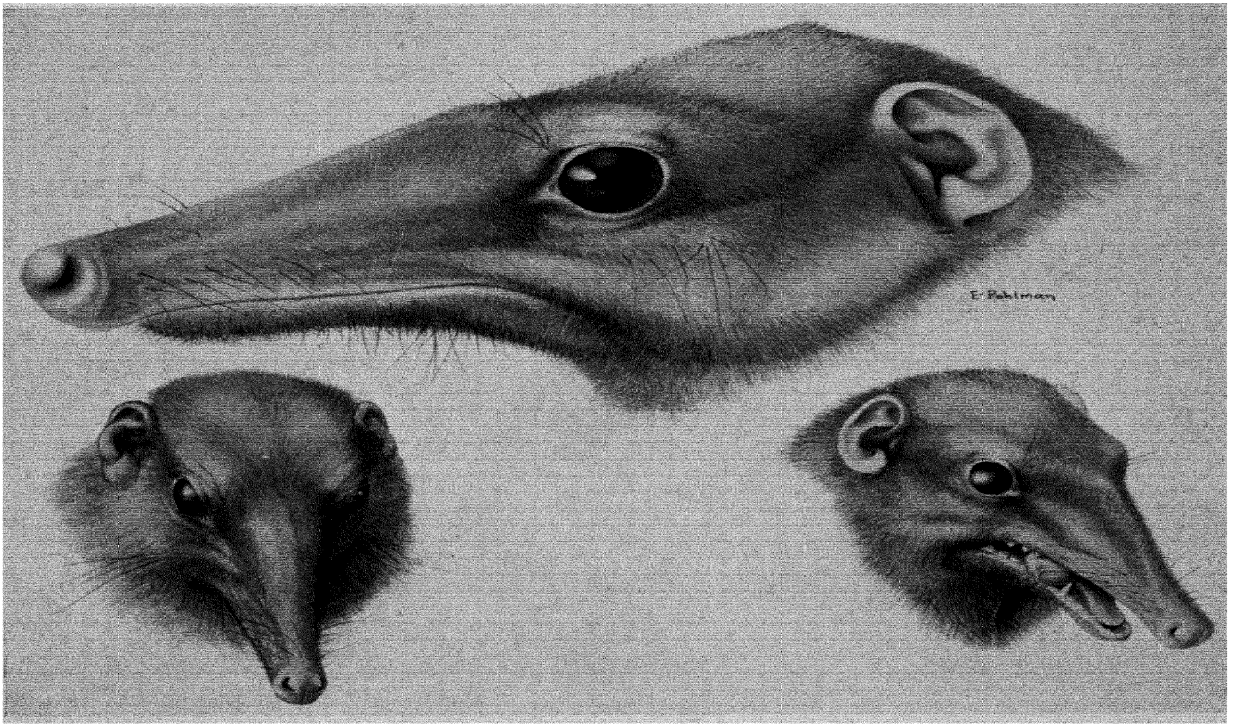

FIG. 488.—Philippine Tree Shrew, close-up views of the head and of the physiognomic expression. Upper sketch, left profile magnified almost two times normal size, shows details of the eye, auricle, muzzle with nostrils, etc. Note the long protective vibrissae above and below the eye and under the chin; tiny lashes along both lids; circular, centrally placed pupil; remarkably human shape of the external ear, with an indication of a "Darwin's tubercle." Left lower sketch is almost a frontal view, slightly from above, of the head, a pose induced by rattling the cage, showing both eyes, ears, and nostrils, together with the protective bristles. Right lower sketch shows animal chewing a small Tokay grape, of which, as of other sweet fruit, it is very fond. Lower sketches of approximately three-fourths normal size.

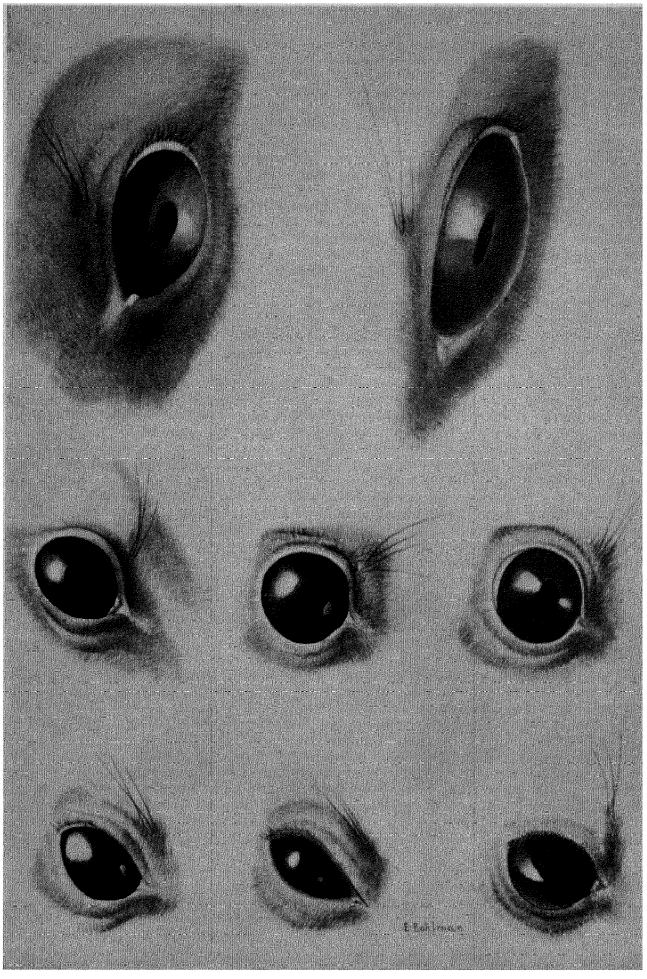

FIG. 489.—The eyes and the surrounding parts of the head of the Philippine Tree Shrew at varying magnifications, expressing different moods and uses. *Upper left*, left eye in three-quarters view, listening to an unfamiliar noise; *upper right*, same, viewed directly from the front. The smaller sketches show the right eye, beginning with the left end of the second row, as follows: animal at rest, looking slightly backward; expression of curiosity, smelling something new, gaze of both eyes directed down the nose toward the explored object; puzzled at an unfamiliar object close to and directly in front of it, with the inner canthus almost out of sight, a part of sclera visible as a semilunar zone along the blunter outer canthus, and with the lashes of the maximally drawn-up upper lid mingling with the fur of that lid, hence indistinguishable from it; dozing in sunshine; very sleepy and unafraid; resting and looking at something at the far end of the cage. Note the varying size and shape of the palpebral fissure, the varying position of the lids, hair, and pupil, indicating unexpected variety of movements of which the eyeball and other parts of the eye are capable. Upper sketches approximately 3× magnified, lower sketches almost twice natural size.

Shrews seized morsels of food with their teeth. Even then, however, they frequently assisted the chewing process by holding the morsel or by pushing it into the mouth with one forepaw. Occasionally they assumed a squirrel-like posture, sitting on their haunches while manipulating a piece of food.

Probably the clearest demonstration of manual dexterity was exhibited when catching a meal worm offered to them with a forceps a few inches outside the cage. This was accomplished usually with a single, quick, and well-aimed stroke of a forepaw. If one attempt failed, it was repeated until the desired morsel was secured.

When a meal worm accidentally fell through the screen floor of the cage into the tray, 3 inches below, even this difficult problem of recapturing the worm was usually mastered with a single forepaw after two or three attempts. The crawling meal worm was clutched with the claws and fingers and carried nimbly, by the same hand that had seized it, to the mouth.

The peak of the performance was reached, on rare occasions, when a fly carelessly sat close to a Tree Shrew and was caught by a flashlike movement of one forepaw and carried with it to the mouth. (*See* for similar actions by the Baboons, chap. XV, 5 [2].)

8. CLIMBING.—The climbing ability of the Philippine Tree Shrew was another item of special interest, as much as it could be observed in the limits of confinement. The general impression was that, while the animals were on the ground most of the time, they climbed the sides of the cage and the ceiling frequently and easily, seemingly for the fun of it, out of sheer exuberance, often remaining for a few seconds suspended from the ceiling before jumping down again. The incessant climbing seemed to be part of their "nature," just as when on the ground they rarely rested but ran around, or at least turned their heads one way or another, looking and observing.

All movements of the head, body, and limbs were quick, including scratching the exact spot that itched with one paw (parasites? *see* Fig. 486, lower sketch). In its vivaciousness the *Urogale* may approach or equal the Red Squirrel or Chickaree and seems more frisky than the Eastern Gray Squirrel. There may, however, be individual differences in disposition or other influences that may make one a better climber than the others.

In the Brookfield Zoo the male, living in his own fairly large compartment, with a branched tree mounted in it, was quite active, whereas the female and the baby were more restrained. Time and time again he climbed up the stem and, like a squirrel, hopped from branch to branch and jumped back again to the ground, 2 or 3 feet below. Occasionally he would squat for a while in the crotch of a branch, then start again on his climbing tour from branch to branch, down and up again. The almost ceaseless activity, the ease with which he climbed the smooth stem and the branches, the way he clutched the thinner twigs with his digits and claws, and the easy leaps he made, all gave the impression that the Tree Shrew feels at home in the trees, being in this respect not much inferior to the Red Squirrel. Whether it compares to the latter in negotiating large gaps in the treetops, observation in its native habitat alone could determine.

The claws apparently are principally used for climbing the stem. When holding small twigs, both the claws and the phalanges of the paws were employed. When on the ground, the animal stepped on the entire palm, both of fore and hind extremities, thus exhibiting a typically plantigrade gait, never digitigrade. Concerning the opposability of the big toe and thumb to other toes and fingers, more observation is required; the impression, however, is that, if present, it is rather limited.

9. VISION.—Judging from the observation of their behavior, the leading sense of Tree Shrews in all activities is undoubtedly sight. They watched attentively the activities about them and got excited when their food was prepared. They recognized, located, and to some extent selected at a distance, by sight, food offered them, whether it was fruit, a lizard, meal worms, or milk.

In puzzling situations, such as when they had to tackle a live lizard, their vision was the only criterion on which they acted. The same was true in locomotion, where the direction of the course, the distance of the jumps, and so forth were principally or exclusively judged by sight.

The sense of smell and Edinger's "oral sense," however, definitely seemed of importance, since the Shrews often "nosed" the morsels before eating them (which the Tarsiers never did), except in the case of meal worms, which they grabbed at once. Their pointed muzzle seemed to be quite an instrument of exploration, its naked, moist tip and delicately shaped nostrils always being in motion when searching about.

They often drank water after meals, and likewise fresh milk, lapping it up by rapidly dipping in and pulling out the tongue.

Last but certainly not the least of their outstanding traits was their cleanliness: as a rule, they performed their natural functions in a restricted locality, in this way keeping most of the cage clean.

10. FIELD OF VISION.—The position of the eyes of the Tree Shrew in the head is lateral, with, however, a slight deviation of the anterior margin of the cornea toward the mid-sagittal plane. In certain situations, for example, when the animal expected a tidbit, it turned its head straight forward, both eyes facing a common fixation point in the mid-sagittal plane in front of the muzzle. Obviously, both eyes were then used together, binocularly, the two corresponding ocular images being depicted on the posterior temporal segments of the two retinae. A rough estimate of the common binocular overlapping of the two fields of vision is from 50° to 60°, in this respect practically duplicating the condition in the Red Squirrel. (*See* sec. 11, on Squirrel.)

11. EYEBALL AND THE RETINA.—The eyeball of the Philippine Tree Shrew is remarkably similar in shape to, but is slightly smaller than, that of the native Red Squirrel (*Sciurus hudsonicus*). Its optical axis is 8.5 mm. long, its transverse horizontal axis 9.3 mm.; in the Squirrel the same dimensions are 9 mm. and 10 mm.

The diameter of the cornea in the horizontal meridian is 7 mm., both in the Tree Shrew and in the Squirrel. In the first, accordingly, the cornea is relatively larger. The corneal curvature in the horizontal plane in the Tree Shrew is paraboloidal and is considerably flatter than in the Squirrel.

The shape of the pupil is fairly circular in both. The lens, both in the Tree Shrew and in the Red Squirrel, is relatively larger and much thicker than in diurnal avian eyes of comparable size, as found, for example, in the Barn Swallow. In both Mammals the anterior lens surface is much flatter than the posterior, the latter in the Tree Shrew being almost hemispherical, in the Squirrel slightly paraboloidal. Both lenses are clearly colored with yellow pigment, less intensively in the Tree Shrew. The optic nerve of the latter is about 1.5 mm. thick, while that of the Squirrel is slightly more.

Ophthalmoscopic examination of the eyes of the Philippine Tree Shrew did not reveal much. No certain sign of a central area—much less of a foveal depression—was found in the locality temporal to the disk, where they could be expected. The only visible feature was a delicate striation radiating from the disk, indicating bundles of nerve fibers, and possibly a slight difference in coloring. Larger blood vessels seem to avoid this area, however, which may be suggestive of an early stage in the phylogenetical differentiation of the central fovea.

A noteworthy feature is a long, thin "cone," similar to that found in the Lizards. It is a residual formation, left after obliteration of the embryonic hyaloid artery. The wider base rests in the optic papilla, the sharp point protrudes into the vitreal cavity. The "cone" consists almost entirely of neuroglial tissue.

The iris, including the stroma, is heavily pigmented, the constrictor well developed, the dilator muscles discernible. The ciliary body, both the muscular part and the folds, is well developed. The chorioid membrane is heavily pigmented.

The retinal membrane lines almost the entire and larger posterior portion of the eyeball. The bacillary layer is made up almost exclusively of cones. The inner cone segments, measuring about 6 microns in thickness, make up a continuous formation as far as the ora terminalis, with hardly any intervening spaces between the adjoining cones. The number of the cones varies little in different localities, being almost uniformly from 20 to 23 cones to a stretch of 150

microns, or from 65 to 75 cones to a stretch of 500 microns (the diameter of the rodless central area of the human eye).

The outer nuclear layer is also remarkable, in that it is composed of a single continuous row of pale, oval nuclei, arranged with their long axes vertical. These nuclei undoubtedly belong to the cone cells, with which they agree in number and arrangement. There are, however, a few rod nuclei, as the employment of oil-immersion objectives shows. These stain much darker and are but a fraction of the cone nuclei, the numerical proportion being about 1 rod nucleus to 5 or 10 cone nuclei.

Still another notable feature is the "granular clods" of Dogiel (*cf.* chap. V, 4 [10, 11, 15]). These are found in the middle zone or *5-b* of the outer plexiform layer as a single, discontinuous row, corresponding exactly with the cone nuclei and the cones. These "clods," as elsewhere, may indicate individual synapses of the cones with midget bipolars (*b* & *h* synapses), besides those of the cones with the horizontal cells (*b* & *c*) and other bipolars.

A further notable feature is the thick inner nuclear layer made up of six or seven tiers. The ganglion cell layer is remarkable, since it is continuous in the entire retina, including the extreme periphery. In places, in particular in the posterior segment of the eye, there are, contrary to the statement of Woollard (1926), two or three tiers of ganglion cells. In accordance with this, the layer of the optic fibers is also thick, especially on the temporal side of the papilla. Here fibers collect from the posterior or temporal segment, which is smaller but richer in ganglion cells, owing to which the fiber layer next to the optic papilla increases to no less than half the total thickness of the retina.

In an attempt to appraise the functional efficiency of the eye and retina of the Tree Shrew, the following points must be considered. The first is an almost exclusive presence of cones (an anticipation made by Walls 1942). Interpreted according to the "duplexity theory," the Tree Shrew must be considered as specialized almost exclusively for photopic conditions or daylight vision. The rods, while not entirely absent, are found in only insignificant numbers. This is a reversal of the conditions found in the nocturnal Vertebrates, even more extreme than in the Northern Brook Silverside or Bullhead, and, above all, in the Tarsier (sec. 12, this chapter). It resembles the conditions found in the Pike, but even more to the detriment of scotopic vision. The observation of the behavior of the Tree Shrew in nature, especially during nocturnal illumination, should be of great interest.

The other point of interest is the practically uniform size of the cones in the entire retina. There are no significant differences in this respect between the posterior parts, where ganglion cells are accumulated in two or three tiers, and other localities, where they are found partly in a single tier. If the functional "grain" varies, it does so because of the synaptical arrangements, for example, the presence or absence of the polysynaptical variety of midget bipolars and midget ganglion cells. Only the application of the Golgi method of staining to the retina could answer this question.

The computation of the functional receptor "grain," on the basis of the number of cones, gives from 4,000 to 5,000 units in a circular area measuring 500 microns in diameter. This is only about one-eighth of the number of cones found in the rodless area of the human central fovea (chap. V, 10 [5]), but is three or four times greater than the number of cones found in the posterior area of the Pike (*cf.* sec. 4 [7], this chapter).

The visual acuity of the Tree Shrew, accordingly, is much below the acuity of human vision. It must, in the biological sense, also be rated as inferior in an arboreal Mammal in comparison with the Pike, considering the much shorter effective distances at which a fish must be able to see in its aquatic habitat. This inferiority of acuity, however, is much compensated by the fact that in the Tree Shrew practically the entire retina, with its huge number of cones, acts as a crude "central area," superior as it is to the extra-areal periphery of the human retina.

In addition, if the good structural development of the cones in the entire expanse of the retina is interpreted physiologically, one is forced to concede that the Tree Shrew has good color vision in the entire field of view, compared with the color perception restricted to the cen-

tral portion of the human field. This, in a diurnal and arboreal Mammal living in a brightly illuminated tropical habitat and largely subsisting on fruits, is understandable. (*Cf.* K. Guenther 1931; *see* chap. XV.)

12. COMPARISON OF THE RETINA OF THE TREE SHREW WITH THAT OF THE RED SQUIRREL AND OTHER MAMMALS.—Since the Tree Shrew in its arboreal habit is similar to the arboreal Rodents, it is of great interest to compare the ocular structures of these two taxonomically so widely different species. (*See also* sec. 11, on Squirrels, this chapter.)

In the Red Squirrel the cones are somewhat smaller, but more numerous, and are found in similarly close formation as far as the ora terminalis. In the extreme periphery, the number is from 22 to 25 cones, in the temporoposterior area 30–35 cones to a stretch of 150 microns, with a very gradual variation. No morphologically discernible rods in the bacillary layer are present. However, in the outer nuclear layer there are two tiers, the upper consisting of larger nuclei and the lower tier of smaller, rounder, but darker nuclei, which may possibly belong to the rods, in a ratio of about 2 to 1.

There is a very definite areal formation in the lateral posterior segment of the eye. Its features are a greater number of smaller cones, a thick inner nuclear layer made up of ten tiers, and an accumulation of ganglion cells in four tiers, instead of two, as in the remainder of the retina.

The "grain" of the cones is surprisingly high. Computed for a circular area 500 microns in diameter, there are at least 10,000 cones in the lateral posterior area, the cone diameter here being from 3 to 4 microns. This is almost one-third of the entire cone population of the rodless territory of the human central fovea, which has the same areal extent. It is about twice the number of the cones found in the posterolateral area of the Tree Shrew, as mentioned in the preceding subsection.

Since the cone apparatus is so well developed, with the cones spreading in close formation as far as the ora terminalis, it is fair to assume good color vision in the entire extent of the field of view, both in the Squirrel and in the Tree Shrew. Both species are examples of strong diurnal adaptation. In contrast, in the Tarsier, Cat, and Guinea Pig no cones can be found in the bacillary layer or assumed on the basis of the cone nuclei in the outer nuclear layer. Hence it is necessary to assume that these largely nocturnal species are color-blind. (*See*, however, Locher 1933; Walls 1942.)

13. THE OPTIC NERVES.—The optic nerve of the Tree Shrew is a round and relatively thick cylinder (*on* in Fig. 492). It is made up of bundles of various sizes, held together by neuroglial septa in a way similar to that found in the Monkeys, Apes, and Man. In Weigert-stained sections it measures from 1.2 to 1.5 mm. without the dural sheath. On cross-section it is circular, whereas the optic nerve of the Red Squirrel is more elliptical (*see* following section).

The fibers appear to be well provided with myelin sheaths. Their caliber varies from approximately 1 to 2.5 microns, with a few as much as 3 microns or a little more in thickness. The coarser fibers are absent.

The number of fibers is quite considerable. According to a rough count, it amounts to 300,000 and probably more. Their caliber must be rated as thin. The total number of cones in the retina, according to a rough count, is 2 million, making the cone-fiber ratio 7:1. This indicates that in less favored regions of the retina many cones are synaptically related to a single optic nerve fiber, in order to reduce the functional units to the 1:1 ratio in the region with the greatest visual acuity.

The comparable numbers in the Red Squirrel are: the total number of fibers in the optic nerve, 200,000 or more; the total number of cones in the entire retina, roughly 3 million; the cone to fiber ratio, 15:1. Since the same ratio in the Tree Shrew is only 7:1, the slightly smaller eyes of the latter are better supplied with optic nerve fibers than those of the Squirrel.

In the Elephant Shrew (*Elephantulus rufescens*), a native of the Sudan in Africa, the number of cones is but a fraction of the rods, at least five of the latter filling the space between the two adjoining cones. The numerical ratio of the cones to rods, roughly estimated, may be 1:25. The total cone number in the retina is approximately 1 million. Since the optic nerves in this Insectivore are much thinner than in either the

Tree Shrew or the Red Squirrel, the number of the optic nerve fibers is also much smaller. There are apparently coarser, well-myelinated fibers and possibly also thinner and poorly myelinated ones in the optic nerve. The total number of coarse fibers is approximately 15,000. The cone to fiber ratio, computed on this basis, is 70:1. This indicates a coarse photoreceptor and conductor "grain."

How the biological requirements of the Elephant Shrew are satisfied must remain a problem for future investigation. The good development of the cones agrees well with the diurnal habits and great affinity for light and strong sunshine, emphasized in this species by observers (*see* Brehm's *Tierleben*, v. 10, p. 349, 1912). The great number of rods in the retina, on the other hand, indicates that the animal must be equally at home in scotopic and semiscotopic conditions, in contrast with the *Urogale*, which, judging from the latter's poorly developed rod system, must be expected to be almost entirely photopic.

14. THE BRAIN.—The brain of the Philippine Tree Shrew, in all essential details, is identical with that of the Midget Tree Shrew (*Tupaia minor; see* Le Gros Clark 1924, 1933). Like the latter, it has the appearance of the brain of a small Placental Mammal (Figs. 490–92). From the tips of the frontal lobes to the back of the oblong medulla it measures 28 mm., of which 19 mm. is the length of the cerebral hemispheres. At the widest, its diameter measures 18.5 mm. In shape and dimensions it may well stand comparison with that of the Red Squirrel, being, however, both in the great hemispheres and in the brain stem, rather more slender, less full and rounded, and hence containing less substance. It is a typical lissencephalous brain, with few faint dents and depressions on the external surface of the neopallium, except for the marked ectorhinal fissures (*rhfiss*) and sulci separating the olfactory bulbs (*olfb*), tracts, and lobes (*olfl*) from the rest of the hemisphere.

There are certain features in which the brain of the Tree Shrew differs strikingly from that of the Red Squirrel. The olfactory bulbs (*olfb*) are roughly three times in volume, and the olfactory striae much broader, passing over to the slightly larger olfactory gyri or tubercles and the piriform areae, amygdaloid nuclei, and hippocampal gyri that are of about the same volume.

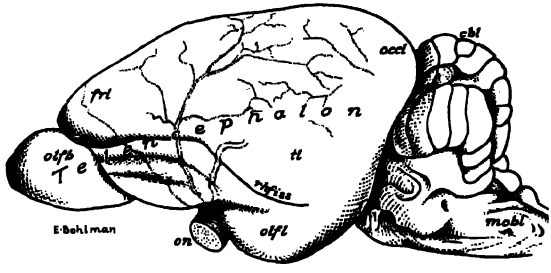

FIG. 490.—Brain of the Philippine Tree Shrew, lateral view, magnification 3×. Note the beginning of a posterior expansion, or occipital lobe (*occl*), which, even though small, is quite noticeable when compared with the blunt end in the Elephant Shrew (Fig. 480), while the olfactory parts are about equally well developed in both. *Labeling: cbl*, cerebellum; *frl*, frontal lobe; *mobl*, oblong medulla; *occl*, occipital lobe; *olfb*, olfactory bulb; *olfl*, olfactory lobe; *on*, optic nerve; *rhfiss*, rhinal fissure; *Telencephalon*, forebrain.

Another marked difference is found in the cerebellum (*cbl*). In the Tree Shrew this organ amounts to barely half the volume or mass of that of the Red Squirrel. Its configuration is much simpler, the hemispheres much less prominent, the elemental *folia* thicker but numbering hardly one-third, altogether giving the impression of a structurally and functionally more primitive, less elaborate, and less efficient organ.

The distribution of the blood vessels over the lateral face of the hemispheres in both species is roughly the same. The exception is the meeting line between the territories of the middle and

posterior cerebral arteries, which is more rostrally located in the Tree Shrew, about 5 mm. in front of the occipital poles. (*Cf.* similar arrangement in the human fetus and in the Monkey; *see* chap. X, 7.)

15. OPTIC PATHWAYS AND CENTERS OF THE BRAIN.—Like the eyes and optic nerves, so the highly developed central parts of the visual system betray the Tree Shrew as a "visual animal."

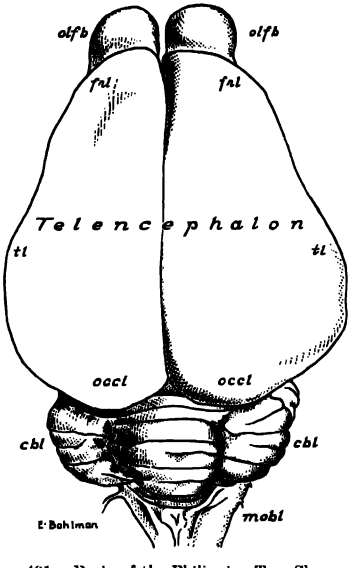

FIG. 491.—Brain of the Philippine Tree Shrew, dorsal view, magnification 3×. Note the complete covering of the midbrain colliculi by the posteriorly expanded occipital lobes, the same colliculi remaining still uncovered in phylogenetically less advanced Elephant Shrew (*see* Figs. 480, 481). This change indicates further "migration," in the *Urogale*, of gnostic visual functions from the superior colliculi of the midbrain to the cerebral cortex of the telencephalon. *Labeling: cbl*, cerebellum; *frl*, frontal lobe; *mobl*, oblong medulla; *occl*, occipital lobe; *olfb*, olfactory bulb; *tl*, temporal lobe; *Telencephalon*, forebrain.

The chiasma or intercrossing of the optic nerves is quite thick and is made up of numerous small intertwining bundles. Unfortunately, it was not possible to determine, in our Weigert-stained series, whether all fibers decussate or whether a part does not and, if it does not, what proportion of the total it represents. This can be determined only in suitable experiments, e.g., by the application of the Marchi stain after enucleation of one eye.

From the upper margin of the chiasma, a great number of less intensively stained fibers ascend into the ventralmost part of the hypothalamus, entering the floor of the third ventricle and the near-by portions, in the way found in other species of Mammals of low phylogenetical standing (Figs. 191, 192).

There are at least two other and, according to size, more important subcortical visual centers, where the greater majority of optic fibers terminate. One is the superior colliculi of the midbrain, the other the lateral geniculate nuclei of the betweenbrain.

The superior colliculi are exceptionally large and elaborate in structure. They form huge caps surmounting the ventral portion of the midbrain, being almost equal to it in the quantity of substance. Laterally, each colliculus overhangs the sides of the midbrain to the middle. In substance it contains about four times the volume of both subdivisions of the lateral geniculate nucleus. The large size is an indication of the relative preponderance of the mesencephalic over the diencephalic and cortical centers of the visual apparatus of the Tree Shrew.

The internal organization of the superior colliculi also indicates their great functional importance. The optic tract fibers enter from the side in great numbers, forming a thick medullary layer. The upper cortex-like gray cap is rich in nerve cells, except the superficial zonal stratum, where there are but few of them. Just beneath this stratum numerous small nerve cells are condensed in such a way that they resemble the outer granular layer in the striate cortex (chap. VIII, 5–7). Following this is a zone with fewer cells and again, just above the medullary stratum, a layer of more numerous and larger cells, with many cell clusters in the latter. In the ventral layers of the cap appear large cells, as well as smaller ones. The large size and elaborate organization of the superior colliculi are indicative of the important role these mesencephalic centers play in vision in this species. As in the Inframammals, they probably are of greater importance than the striate areae of the cerebral cortex.

The lateral geniculate nucleus, in general, resembles that of the Lower Mammals (*cf.* Fig. 191). As in these, it is made up of two subdivisions—a dorsal and a ventral—attached to the lateral side of the thalamus. The slightly larger dorsal nucleus consists of two thicker laminae and a thin medial one, separated by thin sheets of fibers entering from the optic tract. In some sections there are four laminae, with two slightly thicker lateral and two thinner medial laminae, arranged like the skin of an onion, parallel to the lateral contour of the thalamus. In other sections the laminae are not exactly parallel, resembling the somewhat twisted laminae found in the Higher Primates.

The smaller ventral nucleus is of roughly triangular shape, with many thinner fibers from the tract entering and undoubtedly terminating here (as was found to be the case in the Rat and Cat; *see* chap. VI, 4, 5). The bulk of the fibers of the tract, as in all Lower Mammals, on the lateral side proceeds to the superior colliculus. These also are thin.

Both subdivisions of the lateral geniculate nucleus are filled with closely packed nerve cells, those in the dorsal nucleus being slightly larger. Whether the cells are arranged in laminae in the dorsal nucleus must be examined in well-stained Nissl series of sections. The vascular supply, especially the capillary network, is somewhat denser in both subdivisions of the nucleus than in the adjacent thalamus.

The striate area in our series was difficult to identify. Its exact boundaries can be determined only with a series of well-stained Nissl sections. According to Le Gros Clark (1931), this area is located in the posterior extremity of the occipital lobe. It extends on both the lateral and the medial faces (Fig. 279, *C*).

In our own Weigert-stained sections this area appears to extend on the lateral face of the lobe down as far as the boundary of the second and third fifth, indicated by a slight dent and a blood vessel. On the medial side, the striate area extends over the interhemispheric surface and a little over the so-called cerebellar surface, which, however, faces the superior colliculus.

The medial geniculate nucleus is much less developed. In volume it represents only approximately one-eighth or one-tenth of the lateral geniculate nucleus. This difference indicates the lesser importance of hearing for the Tree Shrew, as do also the reduced and deformed external ears (*see* Figs. 485, 488).

The oculomotor apparatus of the brain stem is very well developed. The oculomotor nerve is quite thick, and its nuclei, both somatic and vegetative, are large nests of cells. This is also true of the trochlear and abducent nerves and nuclei.

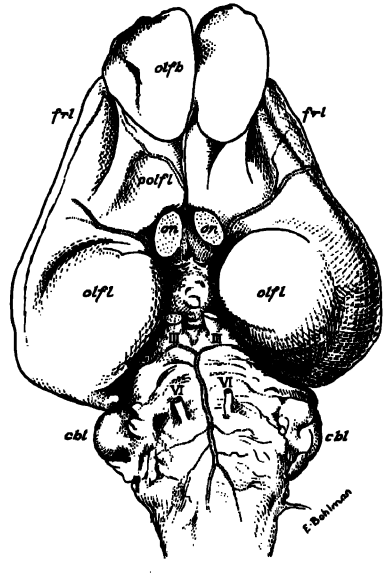

FIG. 492.—Brain of the Philippine Tree Shrew, basal view, magnification 3×. Note the thick optic nerves (*on*) which make possible high visual acuity in this diurnal species, which is in agreement with the numerous cones found in its retina. Well-developed oculomotor nerves (*III*) and the abducent nerves (*VI*) also indicate good motility of the visual apparatus, while the large olfactory centers (*olfb, olfl*) indicate that smell is an essential sense still relied upon by this species. *Labeling: cbl*, cerebellum; *frl*, frontal lobe; *olfb*, olfactory bulb; *olfl*, olfactory lobe; *on*, optic nerve; *polfl*, parolfactory lobe; *III*, oculomotor nerve; *VI*, abducent nerve.

16. THE PHYLOGENETICAL AFFINITIES OF THE TREE SHREWS.—The habits and anatomical peculiarities of the Tree Shrew described in the preceding paragraphs offer an opportunity to appraise the biological importance of their several faculties, to speculate how they could have evolved in the past, to compare them with

those of the Rodents similarly adapted to an arboreal life, and to make tentative deductions concerning the role of the Mammals similar to the Tree Shrews in the origin of the Primates.

The eye of the modern Tree Shrew, especially the retina, is that of a Mammal strongly, almost exclusively, specialized for photopic conditions or daylight vision. Since in it the overwhelming majority of photoreceptors are cones, its retina, by no stretch of the imagination, can be considered to represent a "generalized type" from which, on the one hand, the photoreceptors of Monkey, Ape, and Man have evolved and, on the other, those of the preponderantly nocturnal Lemurs. (Such assumption was made by Woollard 1926, 1927, and others.)

It is, then, more appropriate to hypothesize that the original generalized condition, developed by the Vertebrate Ancestors and inherited through the Fishes, Amphibians, and Reptilians by the Early Mammals, was taken over directly by the Primate Ancestors which subsequently gave rise to Monkeys, Apes, and Man. Such a duplex retina and visual system may be somewhat exemplified by the Elephant Shrews. The Tree Shrews, strongly adapted for photopic conditions, almost opposite to the entirely scotopic Tarsiers, illustrate only in a general way the stage just preceding the coming of the true Primates after their ancestors had successfully squeezed through the "phylogenetical bottleneck" during the early mammalian "struggle for existence," as discussed in the preceding section. But the Tree Shrews represent a good argument for the assumption that a modicum of duplex visual apparatus may have been salvaged by the Primate Ancestors even during times of stress, a condition keeping balance between the photopic Tree Shrews and the scotopic Soricide Shrews.

Other features of the anatomical equipment also necessitate caution in accepting the Tree Shrew as an illustration of the beginning of primate phylogenesis. Its lateral geniculate nucleus, with a larger dorsal and apparently laminated division, appears advanced beyond the condition found in the Rat and Guinea Pig, approaching one found in the Lemurs and Lower Simians. But, again, this advancement is qualified by the huge superior colliculi of the midbrain, which rather recall Inframammalian Vertebrates, where this visual center preponderates or is definitely supreme. It is a feature altogether characteristic of all lowly Mammals except those in which, as in the Mole and Bat, vision has receded in importance or is abolished.

From its well-developed olfactory centers, it would appear that the Tree Shrew depends greatly upon the sense of smell, more so than do the arboreal Squirrels. As compensation, one would logically expect a lesser development of other senses, especially vision. The behavior of the Tree Shrew, while definitely showing the importance of smell, however, indicates vision to be superior.

Another puzzle is the much inferior development of the cerebellum, the part principally concerned with the delicate regulation of postural movements, especially important in a tree-dwelling animal. While this would agree with the observations of some naturalists, it does not harmonize with the testimony of other travelers or with our own observation of the captive animals, even though some inferiority of the Tree Shrew to the best climbers among the Squirrels, such as the Chickaree, may be conceded (*see* following section).

A tentative interpretation may be suggested, that the relatively underdeveloped cerebellum of the Tree Shrew is compensated for by better development and working of its sight. A similar situation is found in the Barn Swallow, certainly an excellent flier, in which the relatively small cerebellar mechanism is compensated for by an exquisite visual apparatus (*see* sec. 8, on Swallow, this chapter). Obviously, more observation of the behavior of the Tree Shrews in their native habitat is required, with a careful comparative evaluation of the arboreal habits of the different species, correlated with a systematic study of their sense organs and brain, and all compared with that of other arboreal and terrestrial animals.

Whereas the comparison of the brain of the Tree Shrew with that of the Red Squirrel is useful, since it concerns species of similar arboreal habits belonging to different orders of Mammals, a comparison with such ground-dwelling representatives of the order of Insectivora as the Old World Hedgehog, Mole, and Common Shrew is likewise of interest. This may give some indication of the hypothetical initial

form and function of the visual equipment of the brain, and hence the habits, of the original ancestors of the Tree Shrews or Tupaiidae, from which have evolved the Primates: the Lemurs, Monkeys, Apes, and Man.

The first striking feature noticeable in the brains of the now living primitive Insectivores is the extraordinary development of their olfactory apparatus: olfactory bulbs, tubercles, piriform lobes, and the rest. In the brain of *Centetes*, *Solenodon*, *Microgale*, Hedgehog (*Erinaceus*), *Gymnura*, *Blarina*, *Crocidura*, *Scalops*, *Talpa*, *Chrysochloris*, and *Macroscelides* not less than half of the whole organ, judging from the surface aspect, is olfactory (*see* Le Gros Clark 1932).

In the Jumping Shrew, for example, the neopallium or "new cortex" concerned with nonolfactory functions, such as vision, hearing, and skilled movements, is represented by a minute cap mounted over the huge olfactory parts (Fig. 279, *A*). Since most of these species are highly specialized for a particular mode of life, e.g., subterranean in the case of the Moles, where the senses of smell, touch, taste, and hearing, are the only ones that matter, the excessive development of the olfactory system must be considered as a secondary adaptation.

The original condition of the early mammalian ancestors may be more truly represented by the terrestrial Shrews, such as the native *Blarina* and the Old World *Crocidura*, in which the neopallial cortex is somewhat better developed. Compared with the brain of the Short-tailed Shrew (*Blarina brevicauda*), the brain of the Philippine Tree Shrew is far advanced. In it the entire mass of the olfactory parts amounts to hardly more than one-third, the neopallium to two-thirds. The small extent of the neopallium in *Blarina* and the large olfactory apparatus agree well with the small eyes, poor sight, and principal dependence upon smell. The recession of the olfactory apparatus and the sizable development of the neopallial cortex in *Urogale* again fit well the greater role that vision plays in its life, whereas audition may have remained on the same level or receded somewhat.

The increased size of the neopallium in *Urogale* compared with *Blarina* is noticeable in three directions: frontal, temporal, and occipital. Whereas in *Blarina* there are hardly more than the beginnings of the frontal and occipital expansions and none of the temporal, in *Urogale* the three poles of the hemisphere, in particular the frontal, are well formed (Figs. 490–92). In the development of adequate cortical centers for the higher senses: sight (*occl*, occipital lobe), hearing (*tl*, temporal lobe and Sylvian region), and the more elaborate sensory-motor functions (*frl*, frontal lobe), the Tree Shrews excel all other Insectivores. It is because of this that they are regarded as the "progressive" representatives of an insectivorous stock from which the Primate Order may have evolved. (*Cf.* Figs. 274, 275.)

The objections made to this interpretation, because of the presence of claws on the hands and feet of the Tree Shrews (Lorenz 1927), seem of less weight when one considers, first, that all primitive Insectivores possess claws, even though the assumption must be made that the Primates must have arisen from similar forms; and, second, that in certain species which are unquestionably Primates, the nails still either resemble rudimentary claws or actually are claws (e.g., *Hapale*, Tarsier; *see* following section).

Altogether, most of the available evidence points in the direction of some insectivorous Mammals, more or less resembling modern Tree Shrews, as the probable form from which the Primates originated. In Le Gros Clark's words (1932): "It may be deemed appropriate that special emphasis should be laid on the highly developed condition of the cerebral mechanisms of vision in *Tupaia*, for it evidently indicates that in this animal the visual sense exerts a predominating influence over its behavioural reactions, and this is precisely what Elliot Smith has held to be fundamentally characteristic of the Primate phylum as contrasted with other mammalian groups."

In support of his thesis Le Gros Clark points out the following features in which *Tupaia* approximates the Primates: large brain size, the presence of an incipient calcarine sulcus, a distinct temporal pole, a richly differentiated and laminated cerebral cortex, differentiation of cortical areae, thick optic nerves, large lateral geniculate nuclei with incipient lamination, large and well-laminated striate areae, well-differentiated oculomotor nuclei which also in-

clude a distinct median group of cells, and a nuclear differentiation of the thalami.

All these distinct anatomical features indicate that the Tree Shrew has made at least the first evolutionary step beyond the undoubtedly more primitive Soricide Shrews toward the true Primates—the Lemurs, Tarsiers, Monkeys, and Apes—irrespective of whether or not it is to be classified in the technical sense as a Primate. "Many of the features of the brain of *Tupaia* are remarkably 'progressive' and certainly confirm the opinion of those authors who are disposed to regard the *Tupaioidea* as representatives of an insectivorous stock which may well have given rise in Palaeocene times to the early Primates." Hence, "the Tree Shrews," in Le Gros Clark's opinion, "should logically be classified as primitive Primates and grouped with them," even though "they are still much more primitive than any recent member of this order. . . ."

In summary, the modern Tree Shrews, in the light of past and present investigations, are revealed as strongly diurnal Mammals, with an acute sense of vision and a structurally well-differentiated visual system that has definitely assumed the leading role in their life. This is a far cry from the nocturnal Soricides, largely depending on olfaction, audition, and the tactile sense.

However, because of their excessive photopic specialization, a doubt must be raised whether modern Tree Shrews represent more than a general example of the actual forms which gave rise to the Monkeys, Apes, and Humans, most of which possess a more balanced duplex visual mechanism. In any case, the Tree Shrews may illustrate the first decisive step in the emancipation from the lowly olfactory level of the terrestrial existence which led toward the arboreal life and intellectual development of the Primates. (*See* following sections in this chapter and chap. XV.)

17. Prehistory of the Tree Shrews.—The reason for the great scientific interest in the Tree Shrews is their kinship with the Early Insectivores that lived during the Cretaceous Period of the prehistory of the earth. Such was the *Deltatheridium*, which lived from 80 to 100 million years ago and which is considered to be the ancestor of all extinct and modern orders of the Placental Mammals, including the Primates (Fig. 477). These Early Insectivores, in turn, developed from still older and more primitive Mammals, the Pantotheria or Pantotheres of the Jurassic Period, which lived approximately 127 to 152 million years ago, from whom they inherited many anatomical features.

The modern Tree Shrews apparently derived from forms whose scant and somewhat archaic remnants are represented by *Anagale* of the Asiatic Oligocene Epoch of 35 million years ago. They may not be identical with their predecessors in all anatomical details. However, they retain the essential characteristics of their bodily organization and presumably also of their living habits: small body size, sharp-cusped insectivorous dentition, five toes on all four extremities, which are short, a plantigrade gait, diurnal vision, omnivorous taste, and numerous other features reminiscent of their reptilian ancestors. Together with other Insectivores, therefore, the Tree Shrews represent the most primitive living Eutherians (Le Gros Clark 1933).

Even so, the Tree Shrews or Tupaiidae definitely represent an evolutionary upgrade, perhaps tied by an intermediate stage of Gymnurae to ancestors which resembled the modern Ground Shrews or Soricidae, which subsist almost exclusively on animal food and depend chiefly upon the sense of smell and not on vision (*see* preceding section on Common Shrew, this chapter).

In fact, in anatomical makeup—the skeleton, muscles, intestinal tract, and other parts—the Tree Shrews have been found by some to be closer to the Lemurs than to the typical Insectivores, such as, for example, the Hedgehog. Hence they are regarded by a number of authorities as "forms transitional between the primitive insectivore ancestors and more typical primates," and are included by them in the "primate stock" as its "basal members," the Tupaioidea (Gregory 1910; Carlsson 1922; Wood-Jones 1929; Le Gros Clark 1934; Romer 1945).

Other investigators, however, basing their opinion particularly upon cranial development, continue to adhere to "the classical inclusion of the Tupaioidea with the Insectivora," especially the Macroscelidae or Elephant Shrews (Henckel 1928; Klaauw 1929), and deny the possibility of

development of the Primates from the Tree Shrews assuming the latter became separated from the Primitive Insectivores long after the differentiation of the Primates (Roux 1947).

18. Arboreal life and the origin of Primates.—In the speculations concerning the origin of Primates from the early generalized Mammals, the arboreal mode of life has been the center of attention. The necessity of adaptation from the original terrestrial existence to the very different and more exacting conditions of life in the trees, according to this view, was the compelling factor that, in a long course of evolution, created the advanced types out of the humble forms of Mammals, a process that eventually culminated in the arrival of *Homo sapiens*, or Modern Man. Thus, broadly stated, the foregoing thesis may at present not meet with much opposition. The difficulty, however, arises when it comes to identifying and evaluating all the probable factors that were at work and to link these in a causal chain of events. (*Cf.* chap. XV.)

The first question is: Why should there have been any need for some of the early Mammals to leave the ground and to climb the trees? Keeping in mind the familiar picture of a cat taking to the tree when it meets a dog, as the better part of valor, one may think of the relative safety the trees offered against ground-dwelling marauders. From what we know of conditions during the Jurassic and Cretaceous Periods, the time called the "Age of Reptiles," there certainly was no lack of rapacious beasts to make life miserable for the small and weak ancestors of the Mammals.

Granting that the factor of safety played its role, it could hardly have been decisive. This is demonstrated by the success of the modern terrestrial Shrews or Soricidae, smallest among the Mammals, which, since their appearance at least 50 million years ago, have not only held their own but managed to spread over the greater part of the habitable globe. And this they achieved in spite of remaining strictly ground dwellers, while some have also taken to the water. Most other Insectivora likewise are ground dwellers, and somehow or other have survived. The only exception is the Flying Bats or Chiroptera, which alone of the Mammals had developed the ability to fly, through which they acquired an abundant source of food and comparative safety.

In their ground-dwelling mode of life, most modern Insectivora resemble the early land Vertebrates, which, of necessity, must have been terrestrial. Paleontological studies show that the treelike plants were still in their evolutionary infancy during the emergence of these land Vertebrates approximately 300 million years ago, during the Devonian Period. During the subsequent Triassic Period, dating 175 million years ago, when the Ferns, Cycads, Ginkgos, and Conifers already had a long history, the nonplacental Mammals appeared.

Much later, by the time the Placentals had already arrived, during the Paleocene and Eocene Epochs of the early Tertiary Period, from approximately 30 to 60 million years ago, the modern Angiosperms, with their abundance of blossoms and fruits, attained their full development. This appears to have been an opportune time for some of the early terrestrial Insectivores to make more frequent excursions up into the trees. In this light, the thesis that the ancestors of the Mammals, the ancient Pantotheres, which flourished principally during the late Jurassic Period (*ca.* 120 million years ago), were originally arboreal and that the Tree Shrews and the true Primates merely continued their ancestral pattern by keeping to the trees does not look plausible, in spite of such anatomical evidence as the insectivorous dentition and the divergence of the thumb and the big toe found in the Pantotheres.

The next task is to identify the compelling factors which brought about the change from a terrestrial to an arboreal life, with its concomitant reorganization of the body, in particular of limbs, sense organs, and the brain. There seem to have been several of such factors at work in a complex cause-and-effect relationship.

An abundance of fruit in the trees does not seem to have been a direct inducement, at least not during the early phases of arboreal adaptation. The principal lure appears to have been the teeming insect and other small life subsisting on and from the trees. To a venturesome ground-dwelling Insectivore the bugs, slugs, and grubs picked from the trees merely repre-

sented a welcome extension of a diet to which it was already accustomed.

An additional and largely new factor was the improvement in the quality of fruit brought about by the co-operation of the winged insects and birds (*cf.* H. N. Ridley 1930). The winged insects appeared during the late Carboniferous Period (225 million years ago), and the birds toward the end of the Jurassic Period (127 million years ago).

Fruits and seeds, as well as animal food, may have been an additional lure that influenced the transformation of the original insectivorous ground dwellers into omnivorous semiarboreal or entirely arboreal Tree Shrews. These, in turn, may have contributed their share to the selective improvement of their own diet and thus prepared the way for some of their members to evolve into fructivorous, tree-dwelling Primates—the Lemurs, Monkeys, and Apes.

For life in the trees an animal requires efficient grasping limbs, good sight, and well-developed brain centers. The first may be obtained by developing either claws that can dig into bark or pads capable of adhering to the surface or digits for clasping twigs. Any of these may be quite efficient, as the examples of the Squirrels, Tree Frogs, Birds, and Primates show.

The Tree Shrews obviously must originally have used claws and still chiefly use them. Only gradually, as some of them became transformed into Lemurs, much bigger in size and with considerably longer digits capable of clasping smaller branches and boughs, did claws become of less importance and, in the Tarsiers and Monkeys, with few exceptions, were transformed into flat nails, giving a better hold. The grasping quadrumanous extremities of the Higher Primates, in turn, helped to establish them firmly in their arboreal habitat.

The present Tree Shrews have not yet achieved this stage. Their grasping ability is rather limited. In climbing they mostly use their claws. Their hands and digits have not become, as yet, grasping instruments with finely diversified movements of tentacles, fit to hold small objects and examine them by vision, smell, and taste, useful though they already are for carrying morsels of food to the mouth. In this respect, the Tree Shrews are but little above some Rodents, particularly Mice, Squirrels, and Chipmunks, distinguished by their ability to manipulate food with their forepaws (*see* sec. 11, on Squirrel).

The other requisite—well-developed sight—is also indispensable for a successful life in the trees. This concerns not only visual acuity but also correct space perception, especially distance judgment. The large central area found in the eyes of Tree Shrews indicates the beginning of a differentiation of the locality of acute sight instrumental in epicritic vision and in binocular stereopsis. Stereopsis, or good tridimensional vision with both eyes, seems to be a prime necessity in such a life. This requires at least some overlapping of the two monocular fields of view, creating permanent binocularity. This may not be entirely absent in the Tree Shrews but seems to be inferior to that found in Monkeys.

The third factor necessary to a successful arboreal existence—the brain—is still primitive in size and organization in the Tree Shrews. Nevertheless, it is superior to that of the Soricide and Elephant Shrews, in that it is relatively much bigger, with large, elaborately organized visual centers of the midbrain and betweenbrain, and with a better-developed cortex, larger striate area, and relatively reduced olfactory apparatus. Altogether, it is a more efficient regulating central organ, though less so than in any of the true Monkeys, or even in the Lemurs.

In the evaluation of the importance of arboreal adaptation for primate evolution, many other factors must also be considered. The arboreal habit alone, obviously, is not a magic formula guaranteeing phylogenetical progress. The proof of this is the Sloth (*Bradypus*), probably one of the most arboreally adapted animals in existence. By restricting its diet to the foliage of the trees, in which it spends its lazy, immobile life, it reduced its senses and intellect to one of the lowest levels in the entire realm of Mammals. The strictly arboreal adaptation in this case was a potent deterrent directly responsible for the low sensory and mental abilities, and it also exerted a deleterious influence upon the entire organization of this Mammal. The arboreal habit alone, therefore, could never have sufficed to start some of the early Mammals toward becoming Primates, which eventually culminated in Man. (*See* for the continu-

ation of this subject the following sections in this chapter, and chap. XV.)

SEC. 11. SQUIRREL

1. Taxonomy.—The Squirrels are mostly small Mammals of terrestrial, semiarboreal, or entirely arboreal habit, belonging to the Order of Rodents (Rodentia). In common with other Rodents, such as Mice, Rats, and Beavers, they are distinguished by a dentition adapted for cutting and grinding hard vegetable substances, such as wood and nutshells, with two prominent, sharp, chisel-like upper and lower incisor teeth, one pair in each jaw, and with molar teeth with flat crowns adapted for grinding. In anatomical and physiological constitution, they are, of all native Mammals, best adapted to life in the trees and bushes.

In the following, only the semiarboreal and arboreal genera, the Chipmunks (*Eutamias*) and the Tree Squirrels (*Sciurus*) are considered, in particular the Western Chipmunk (*Eutamias quadrivittatus*) and the Red Squirrel (*Sciurus hudsonicus*), or Chickaree.

The paleontological age of the Sciurides is much more recent than that of the Tree Shrews described in the preceding section, which they emulate in habit and appearance. The earliest record, which is doubtful, according to Bryant (1945), is from the Upper Eocene, dating roughly 30 million years ago, becoming definite in the Lower Eocene of approximately 25 million years ago, the family becoming more numerous only in the Upper Miocene and later, estimated at 20 to 25 million years ago. The ancestral prototype of the Squirrels has not

yet been determined, being probably most closely related to the Family Paramyidae.

The first animal whose behavior was observed by this writer in its native habitat was identified, with the help of the authoritative description given by H. E. Anthony in his *Field Book of North American Mammals* (1928), as the Western Chipmunk (Fig. 493). It is a smaller and more slender species than the Eastern Chipmunk (*Tamias striatus*). It is conspicuously striped with five dark and four buff-colored narrow longitudinal stripes, is of an alert, active disposition, and is semiarboreal in habit. Its total length is from 8.5 to 9.5 inches, more than one-third of this belonging to the bushy tail. Its food is seeds, nuts, buds, fruit of many varieties, some insects, and occasionally birds' eggs. Its enemies are Snakes, Hawks, Weasels, Foxes, Coyotes, Badgers, and Wildcats. The genus *Eutamias* is very large and diversified into no less than fifty-seven forms inhabiting western North America. The probable species observed and described in the following is either the Least Chipmunk (*Eutamias minimus*) or the Timber-Line Chipmunk (*Eutamias minimus oreocetes*).

The other animal observed was probably either Bangs Red Squirrel (*Sciurus hudsonicus gymnicus*) or Minnesota Red Squirrel (*Sciurus hudsonicus minnesota*). According to H. E. Anthony, it is the smallest of the North American diurnal arboreal Squirrels (Figs. 494, 495). In summer its upper parts are pale rusty red, its underparts clear white, with a moderately bushy tail. Its total length is 12.5 inches, the tail accounting for 4.6 inches. It is strictly diurnal and arboreal. It is alert and inquisitive in disposition, feeding on plant and tree products and occasionally on animal food. It inhabits the coniferous forests of North America. Its enemies are Hawks, Owls, Pine Martens, Foxes, Wildcats, and others.

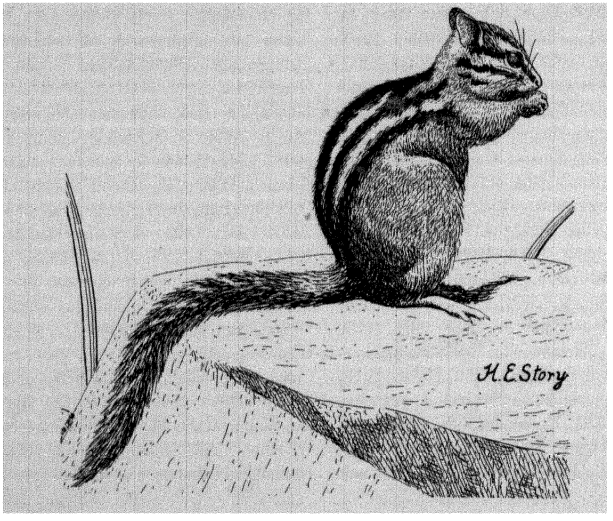

FIG. 493.—Western Chipmunk (*Eutamias quadrivittatus*), a small terrestrial and semiarboreal Squirrel. Inhabitant of western North America, differentiated into many species, especially numerous in the Rocky Mountain Region. A keensighted, alert, intelligent little Rodent of diurnal habits. It subsists on a variety of fruits, seeds, nuts, and buds and on some insects, grubs, slugs, and bird eggs. It frequently rests on its haunches when consuming food, which leaves its forepaws free to pick fruit or to carry it to its mouth. Redrawn from A. H. Howell, *Revision of the American Chipmunks*, etc. ("North American Fauna," No. 52, 1929).

2. HABITS. Both the Chipmunk and the Red Squirrel, in their bodily equipment, appear to be admirably adapted to their particular

modes of life, which in the first may be characterized as semiarboreal, in the second as completely arboreal.

The western or *Eutamias* genus of Chipmunks are of more slender form and more agile than the eastern *Tamias* genus and are far more "plastic" in their adaption to the many locally varying conditions of the Rocky Mountain Region. In the words of H. E. Anthony, they are bright, alert, active, and inquisitive creatures, moving about during most of the daylight hours. Those living in the open plains are shyest, since most exposed, whereas the well-protected forest-dwelling species, with avenues of escape at every turn, are bold and curious and are often heard calling, chattering, or scolding the intruder. They store up food in underground nests, to be consumed during the winter. Their habit is terrestrial, although they climb readily when pursued by an enemy or to get fruit or nuts from the shrubs. The Eastern Chipmunk, on occasion, climbs trees of considerable height, though not so well as the Red Squirrel.

The Red Squirrel or Chickaree, the commonest Tree Squirrel, is essentially a denizen of the evergreen forests, not being found out of the timbered areas. It is active throughout the year, taking only temporarily to a shelter during inclement winter weather. It subsists on a plant diet of nuts, seeds, and buds and stores up food for winter. This practice makes it an important reforestation agent.

Chickarees "have gained an unsavory repu-

FIG. 494.—Red Squirrel or Chickaree (*Sciurus hudsonicus*), a small, strictly arboreal Squirrel, alert, intelligent, and vivacious, an inhabitant of the coniferous forests of North America. It is the smallest of the native arboreal Squirrels, strictly diurnal in habit, and the best climber of them all. It subsists on various fruits and buds, seeds and nuts, especially pine cones. It has the reputation of being a robber of birds' nests and is considered "the most carnivorous of our Squirrels." Its character is bold and daring, its curiosity insatiable. The arboreal Squirrels, even more than the semiarboreal Chipmunks, have the ability to manipulate objects in a way similar to that of the Monkeys. In this, however, the Squirrels are greatly handicapped by the absence of thumbs, which forces them to use both of their hands together (as in this figure). This, in spite of their dexterity, is a disadvantage, contrasting with the ability of the higher Primates, including Man, to oppose the thumb to other fingers of the hand, which makes it possible to use each hand independently for delicate grasping movements (the exception is the Primates, which have secondarily lost their thumbs). Redrawn from A. B. Klugh, "Ecology of the Red Squirrel," J. Mammal., v. 8, p. 1, Pl. 1, 1927.

tation as robbers of birds' nests, suckers of eggs, and eaters of fledglings, and many naturalists have written accounts of how the animals were caught in the act. They appear to be the most carnivorous of our Squirrels," according to Anthony.

"The unquenchable curiosity of these Squirrels makes them a conspicuous mammal. Upon the appearance of a man or a Dog they begin a violent harangue and scold and chatter for long

comys volans, which, even though the most arboreal of all Squirrels and also forest dwellers, are strictly nocturnal in habit (Fig. 496).

The "Chickarees," according to Anthony, "are good swimmers and have been known to cross bodies of water a mile in extent." In this respect they resemble their larger relatives, the Eastern Gray Squirrels, which also do not hesitate to take to the water during their migrations across the country.

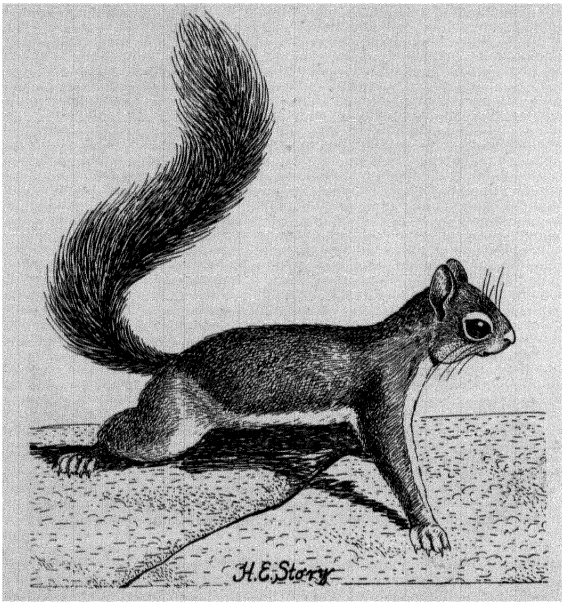

FIG. 495. Red Squirrel, a young, not fully grown animal, in a pose expressing intense curiosity. The Red Squirrel represents, in its climbing dexterity, the keenness of its higher senses, and its supple sensory-motor co-ordination, a high degree of adaptation of a pure quadruped to an arboreal mode of life. Redrawn from A. B. Klugh, "Ecology of the Red Squirrel," J. Mammal., v. 8, p. 1, Pl. 2, 1927.

periods of time. Instead of being shy and secretive, like most wild mammals, they attract attention and seem to feel that nothing on the ground will be able to catch them in the trees."

The most important characteristic of the Chickaree is its strict diurnality. In this respect it is like the rest of the Arboreal Squirrels, the Eastern Gray Squirrel (*Sciurus carolinensis*), the Tuft-eared Squirrel (*Sciurus aberti aberti*), and the Fox Squirrel (*Sciurus niger*). It differs from the Flying Squirrels of the genus *Glau-*

3. NOTE ON THE BEHAVIOR OF WESTERN CHIPMUNK.—The observation of the behavior of the Western Chipmunk recorded in the following was made on August 12, 1950, in Jackson Hole, in Grand Teton National Park, in the western part of Wyoming, just south of Yellowstone National Park. The time was about 8:00 A.M., along Cottonwood Creek, a tributary of the Snake River. The window of the cabin overlooked a little patch extending to the arm of the creek, overgrown by tall grass, with a few

trees and shrubs in it. The campers were mostly gone, and the camp was quiet.

There was a slight stir among the vegetation only a few feet from the cabin window. A little Chipmunk appeared along one of the slender stems of a berry bush whose fruit was just beginning to turn red. This shrub was later identified as Shadbush or Juneberry (*Amelanchier*

ripening at that high elevation, from 5,000 to 6,000 feet, as late as the second half of the month of August.

Observing the striped, rusty, and alert little Rodent, it was difficult to imagine a Mammal more nimble and better adapted to an arboreal way of life. The manner in which it climbed and fed may well illustrate the beginnings of the

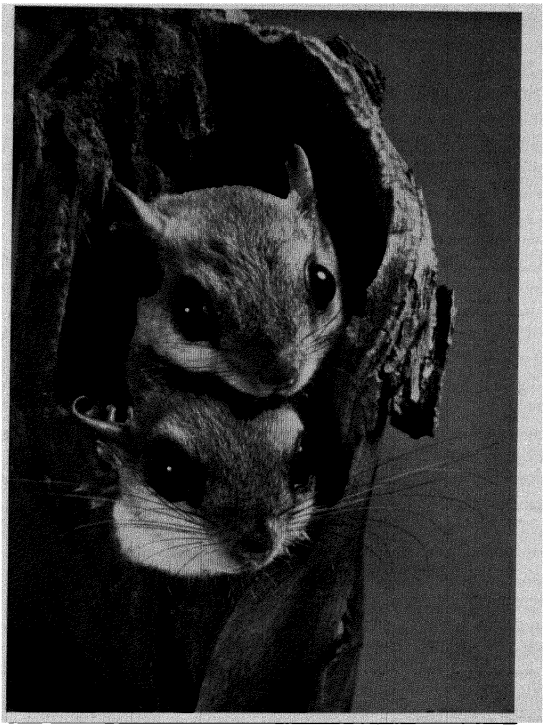

Fig. 496.—Flying Squirrel (*Glaucomys volans*), a native North American, strictly arboreal rodent of nocturnal **habit, possessing lateral** skin folds extending between the fore and hind legs, by means of which it can glide from one **tree to another. Phylogenetically,** this mode of locomotion may be considered the first step in the evolution of flight, fully developed by the Birds, Bats, and the extinct Flying Lizards. The picture shows two young squirrels peeking from a hole in a dead branch of a tree, their usual home. Note the large, spherically curved corneae of the eyes and **the long whiskers, both characteristic** of the nocturnal Mammals. Courtesy R. C. Hermes, Buffalo, **New York.**

canadensis), or a kindred western species (*see* F. S. Mathews, *Field Book of American Trees and Shrubs*). Its fruit is described as "a dry, edible berry, lacking distinct flavor, resembling a huckleberry, varying in color from crimson through magenta to dark or black purple, according to the stages of development," and

arboreal adaptation of the early insectivorous ancestors of the Primates. Since the clusters of berries hung at the ends of the branches, the animal had to reach for them with its forepaws, sometimes stretching itself as far as its body and limbs would permit. The principal instruments to secure its hold on the twig were its

hind limbs. This freed its forelimbs for "manipulation," to gather the terminal berry-bearing twigs, to pluck one berry, to retreat to a stronger limb in order to assume a more comfortable position on its haunches, and to nibble on the fruit which it dexterously held and turned in both "hands."

The process of picking a berry and consuming it was repeated about a dozen times until hunger was satisfied. In order to get to the fruit, the Chipmunk had to reach for different branches, always holding its bushy tail in a certain position, indicating that this part may be used less as an "organ of balance" than as a "tactile organ" in order to maintain precise orientation in space by means of the tactile rather than the vestibular sense. When it wanted to climb another stem of the bush, the Chipmunk would easily leap a foot or so, commensurate for his size with the average leap of two or three feet that the Red Squirrel usually makes when not hard pressed.

The Western Chipmunk appears to be as perfectly adapted to life in the shrubs as is the Red Squirrel to life in larger trees. If measured by an absolute standard, the Chipmunk appears hardly less arboreal than the Philippine Tree Shrew or *Urogale* described in the preceding section of this chapter, at least as far as it is possible to judge by observing the latter in captivity.

The Chipmunk is adapted to a semiarboreal way of life, that is, in shrubs, because it gathers food from smaller plants, whence an important part of its sustenance derives, instead of in tall trees, as is the case with the Sciuride Squirrels. The Chipmunk seems to be an earlier, more primitive type, less emancipated from terrestrial habit, hence representing an earlier, less advanced phase of arborealization than do the Sciuride Squirrels.

In locating and recognizing the fruit on the shrubs and in gathering it, it is fair to assume that the Chipmunk's eyesight is not only the most important, but the only, guiding sense. The fruit of the Juneberry and of similar shrubs does not make a noise, nor does it produce an odor that would be effective at any considerable distance. It acts upon the sense of sight alone before it is selected and put into the mouth, after which other senses, those of smell, touch, and taste, are used to determine edibility.

Hearing plays no direct role in the procurement of plant food, even though it performs a biologically important role as an active and passive warning sense. Hearing is of capital importance as a distant warning sense to so small an animal, living mostly in tall and dense vegetation, which restricts or eliminates sight. In these circumstances hearing is the only sense through which the animal is alerted to an approaching, invisible predator. Only when a Chipmunk climbs up a shrub or a tree, as it often does, does sight become useful as an important distance receptor, warning of approaching danger, which makes the ability to climb an important avenue of escape and eventual survival.

In this appraisal of the factors which make the Chipmunk's "world," the diurnal Birds of Prey, moving about above the level of the obstructing vegetation, are an exception; these can easily be noticed both by sight and by hearing. On the other hand, the diurnality of the Chipmunk and its instinct to retire at nightfall to the relative safety of its underground burrow appear to be sufficient protection against the silent nocturnal Owls. As a means of survival, sight is of capital importance to a diurnal animal like the Chipmunk in view of its role in acquiring food and, in open country, also as a warning sense.

4. Note on the behavior of Tree Squirrels.—The Squirrels, both the Eastern Gray Squirrel and the Red Squirrel or Chickaree, especially the latter, become very excited when they notice a potential source of danger, for example, a human intruder. From a safe vantage point, such as a high branch, they chatter loudly, scolding at the intruder for quite a while, shaking body and tail violently, and occasionally pounding on the branch on which they stand. All the while they attentively observe the object of their ill will, using only one eye, and shifting occasionally from one side to the other.

Or, when sensing danger or when perplexed, they "freeze," that is, remain perfectly still while looking at the object of their suspicion

with one eye only. In this they behave just as other Rodents, such as the Guinea Pig, Gopher, Chipmunk, and Woodchuck, do in similar situations. Monocular vision alone is used as an epicritic sense.

When, however, the Chickaree becomes truly inquisitive about an object, it quiets down and turns toward it, facing it squarely with both eyes, binocularly (as does the Tree Shrew). It also uses both eyes when it climbs a tree trunk or runs along the limb or branch of a tree to the very end and leaps to the opposite branch of an adjoining tree.

Crossing the gap from the tip of a branch to the opposite branch of another tree is the most dangerous of the many superb antics which these accomplished acrobats are capable of performing. The reason is obvious. The twig is thinnest at the end. It is least able to support the weight of the heavy body of a running animal. It bends just at the moment when it receives the additional push necessary to give a sufficient momentum to the leaping animal, which, in turn, increases even more the gap between the terminal twig and the opposite tree it wishes to climb onto. The unsteadiness of the support and the obscuring of the opposite branch by leaves make a leap from one tree to another perilous. A miss in grabbing the opposite twig by the forepaws would result either in a serious injury or death, depending on the distance from the ground. Frequent near-misses may be observed, especially when the animal is frightened by a pursuer.

In ordinary circumstances a Squirrel does not seem to pay much detailed visual attention to the surface of the bark of a trunk or limb as it climbs or runs. Its head is carried rather high, and its eyes are directed straight ahead. Even though it does not seem to examine the path carefully, it is certain that its eyes are directed upon the course along which it runs so that it is able to modify its movements according to need. For this purpose the numerous cones, in close formation extending almost as far as the ora terminalis of the retina, are most useful to the Squirrel, as they are to the Tree Shrew.

In difficult situations, such as negotiating a long gap between the opposite branches of two neighboring trees, the Squirrel must use all its superb powers of vision to measure the distance and the position of both takeoff and point of landing and probably other matters, such as the thickness and the position of the twig on which it is to land, as well. Binocular stereoscopic vision must then be utilized to its full capacity if it is to render satisfactory service and accomplish its biological purpose, which in most cases is either the saving of individual life, the acquisition of a mate, or the procurement of necessary food.

The Red Squirrel shows inherent and unmatched powers of co-ordination of stereopsis and motility, especially when hotly pursued. Then it runs with amazing speed up or down a tree trunk or along a crooked limb to the very end or makes, without the slightest hesitation or miss, an astonishing leap of 3–4 feet or more, as recorded by Klugh (1927).

The performance of the Red Squirrel may be close to the peak of arboreal locomotion of any Mammal of its size. In its way it is comparable to the performance of the best climbers among the Monkeys. A thorough functional analysis of its movements by means of modern photographic techniques would undoubtedly furnish the basis for an objective scientific appraisal of the arboreal mode of life, and what it meant in the evolution of Primates. (*Cf.* sections on Tree Shrew and on Tarsier, this chapter, and also chap. XV.)

5. Squirrels, arboreal habit, and the origin of Primates.—The factors responsible for the phylogenetical emergence and molding of the Primates, in spite of profuse literature on this subject beginning with the classical writings of Charles R. Darwin, are difficult to understand even now.

Two factors especially have been prominently discussed. One is the pre-eminence of primate vision, which is of diurnal type; the other is the arboreal way of life adhered to by most of the Primates, with the notable exception of Man. But although both these factors have been much analyzed, the way in which they have worked together to produce Primates remains unexplained. Above all, the initial phylogenetical stimulus which transformed some of

the early insectivorous Mammals into Primate Ancestors remains still unknown.

If arboreal life and the pre-eminence of vision it imposed were the prime factors in the rise of Primates, one may well ask: Why have not the Sciuridae and even more the modern Tupaioidea progressed beyond their present state, which they attained long ago?

With respect to the Squirrels, the basic difference between the presumable insectivorous ancestors of the Primates and the early Rodents in anatomical equipment, diet, and probably other more elusive factors may be emphasized. This difference may have been sufficient to allow further perfection in one, while limiting the progress in the other. Such difference may have been essentially dietary. The Primates, as far as our knowledge goes, originated in the tropics, the arboreal Squirrels in colder climates. Their food, even though grown on trees, was markedly different. For the Primates it was soft, succulent fruits, varied in appearance, especially in color, while for the Squirrels it was nuts and seeds, rather uniform in their dull coloring and incased in hard shells. In their nutritive value, fruits rich in carbohydrates also differed substantially from the seeds of the north, filled with proteins and fats.

Both diets, even though imposing an arboreal adaptation, must have had a different effect. The primate ancestors, in order to exist, had to develop manipulative ability and good color vision, whereas the ancient Squirrels had to specialize in gnawing shells and husks and in extracting the seeds with their teeth, while developing but little their manipulative ability and color vision. The Primates had, therefore, to develop the grasping hand with an opposable thumb, capable of holding objects without the use of the other hand, while their dentition remained fundamentally archaic. The Squirrels in turn, relying on their rodent dentition in feeding, went so far as to abandon their thumb. This loss, although detrimental to feeding, made their hands more useful for their mode of climbing by digging with claws into bark, instead of grasping the boughs with the fingers and the opposable thumb, as the Primates do.

In the retardation of the Squirrels, their late appearance during the Miocene, or 25 million years ago, may also have been some factor, compared with Primates, which had already begun their evolutionary ascent from a generalized stock during the Eocene and Paleocene Epochs, or from 40 to 58 million years ago.

There is no such phylogenetical excuse, however, that could be cited in favor of the Tree Shrews, which have had plenty of time since the origin of Mammals, during which they seem to have remained practically stationary. A thorough appraisal of past and present factors alone may answer this question. (*Cf.* Bryant 1945; Romer 1945.)

In conclusion, while one must accept arboreal life and superior vision as factors responsible for the rise of Primates, the complete story of their origin and of all major factors responsible for it still remains to be told. (*See* chap. XV.)

SEC. 12. TARSIER

1. Taxonomy.—The Tarsier was first described by the noted French naturalist G. L. L. de Buffon in the year 1769. Ever since, because of its unique zoölogical position, it has been an object of scientific interest. According to G. Elliot Smith, the Tarsier is "the most primitive living primate" which undoubtedly represents a definite advancement toward the Higher Primates, the Monkeys and the Apes, in comparison with the Tree Shrews and Lemurs. The Tarsier is considered to be the residue of a side branch of the Early Primates which was wide-

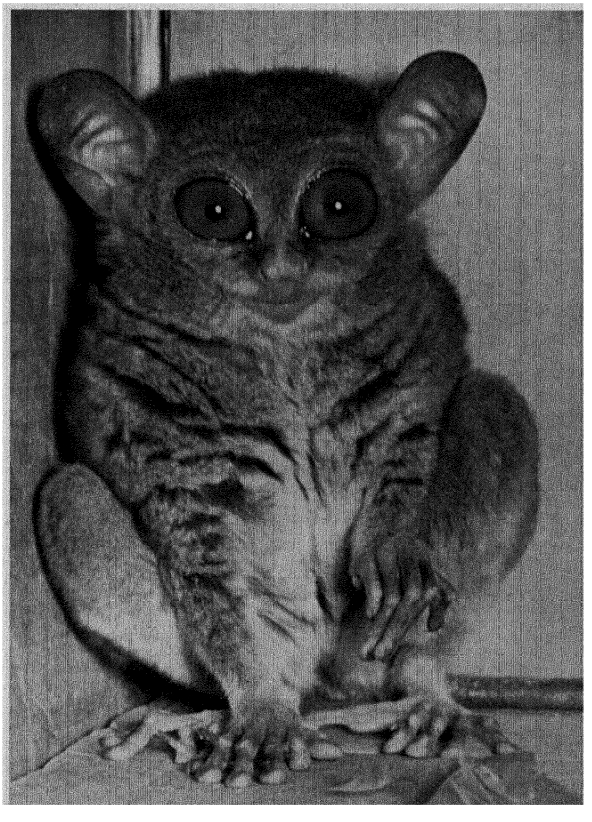

Fig. 497.—Philippine Tarsier (*Tarsius philippinensis* or *T. carbonarius*), a strictly nocturnal and carnivorous Primate from Mount Apo, of the island of Mindanao, Philippines. A Graflex camera flashlight photo, slightly reduced, of an adult animal showing the normal resting posture on flat ground, in the attitude of alertness. The characteristic features are the huge, almost circular eyes, set in a large head, which, together with the soft, fluffy, mottled, grayish-colored fur and the retiring habit, make it markedly resemble its avian counterparts, the Owls. Note the slight difference in the size of the two palpebral openings; the "mongoloid" or oblique position of the lines connecting the inner and outer canthi; the horizontally oval, miotically constricted pupils in daylight, which become widely distended during the night; and the "platyrrhine position" of the nostrils facing laterally, resembling the New World Primates. (*Cf.* following figures.)

spread over Eurasia and North America during the Paleocene and Eocene Epochs, which cover a period from 58 to 20 million years ago.

The Tarsiers (Tarsiidae, Tarsioidea) are at present restricted to the islands bordering on southeastern Asia and near-by regions. One species, the Spectral Tarsier (*Tarsius spectrum*), inhabits the Malay Peninsula, Java, Sumatra, Celebes, and Borneo; the other species, the Philippine Tarsier (*Tarsius carbonarius* or *philippinensis*), is found on the islands of Mindanao and Bohol. These and perhaps some other less-known species, e.g., *Tarsius fischeri*, represent the Tarsioidea, which systematically are the second suborder of the Order of Primates (Primata), the first and older suborder being the Lemurs (Lemuroidea), the third and more advanced being the Monkeys, Apes, and Man (Pithecoidea or Anthropoidea). (*Cf.* Woollard 1925; Gregory 1951, p. 464.)

FIG. 498. Philippine Tarsier, a primitive Primate, of predaceous habit, survival of an ancient epoch of earth's prehistory, remarkable for its overdeveloped vision strictly adapted to nocturnal life. A resting attitude. Graflex photo.

2. GENERAL CHARACTER. The Tarsier is a small, shy, retiring, monkey-like animal of peculiar appearance (Fig. 497). It has a relatively large, round head, with a short muzzle and a pug nose, the nostrils facing laterally, as in the South American platyrrhine Monkeys.

The dentition of the Tarsier is essentially that of an Insectivore. Conspicuous is the sharp V-shaped angle formed by the two branches of the lower jaw, characteristic of the Lower Monkeys and only slightly so of Man, whereas in the large Apes the two branches become parallel (*see* Fig. 499).

The Tarsier's large, bulging eyes and big ears are conspicuous and, together with its solemn expression, soft, fluffy fur, and nocturnal habits, make it resemble, especially when in a sitting position, a native Screech Owl (*Otus asio*).

The other conspicuous parts of the anatomical equipment of the Tarsier are its long hind legs, adapted for leaping, and a long, almost naked, tail that likewise assists in locomotion (Fig. 503).

When it is wide awake, its huge eyes are wide open, with the palpebral fissures widened to al-

most full circles. When the animal is at rest, the large corneae are all that is visible of the eyes, a narrow pericorneal margin of the sclera becoming visible only when the attention of the animal is aroused (Figs. 503, 505).

In ordinary daylight the pupils usually are reduced to small elliptical openings whose longer axes are horizontal (Figs. 497–99). In darkness the pupils expand to the corneal margins. Fine lashes are attached to the palpebral margins, especially those of the upper lid. A bunch of long bristle-like hairs sticks out from each eyebrow. Similar bristles protrude lateral to the eyes from the cheeks and from the upper lips not far from the base of the nose.

The auricles are large, shovel-shaped, and very flexible in shape, resembling those of some Lemurs, such as the African Galagos, the Aye-Aye (*Daubentonia* or *Chiromys madagascariensis*), and some insectivorous Flying Bats. Horizontal wrinkles on the inner face of the auricles are a characteristic feature (*see* Polyak *et al.*,

FIG. 499.—Philippine Tarsier (*Tarsius philippinensis*), a Graflex camera snapshot at rather close range, showing a typical reaction of moderate fright: palpebral fissures maximally open, eyebrows drawn up, mouth half-opened showing typical "insectivorous" sectorial teeth, with auricles widely distended and turned frontally, all features indicating a high degree of preparedness to receive a maximum of visual and auditory stimuli and a readiness for self-defense. Other numerous anatomical details may also be noticed, such as the horizontally elliptical shape of the pupils, here miotically reduced because of the photopic conditions; iris structure when expanded; well-marked lashes on upper lids; platyrrhine position of the nostrils; and the marked foldings of the auricular surfaces. (*Cf.* Figs. 497, 498.)

The Human Ear in Anatomical Transparencies, 1946).

The hands and the feet are perhaps the most remarkable features of the anatomical equipment of the Tarsier. Whereas the ears and the eyes, even though of an uncommon appearance, are duplicated in some other Mammals, the terminal parts of the four extremities are truly those of a full-fledged Primate. Even though typical grasping organs. Even though there is not, as yet, as much diversity in their use as is found in the true Monkeys, they already approach simian hands and feet.

The usefulness of the Tarsier's hands, however, is still largely limited to crude prehension and locomotion. To this end the tips of the fingers and, far more, the tips of the toes have spread into flat, soft pads which can adhere

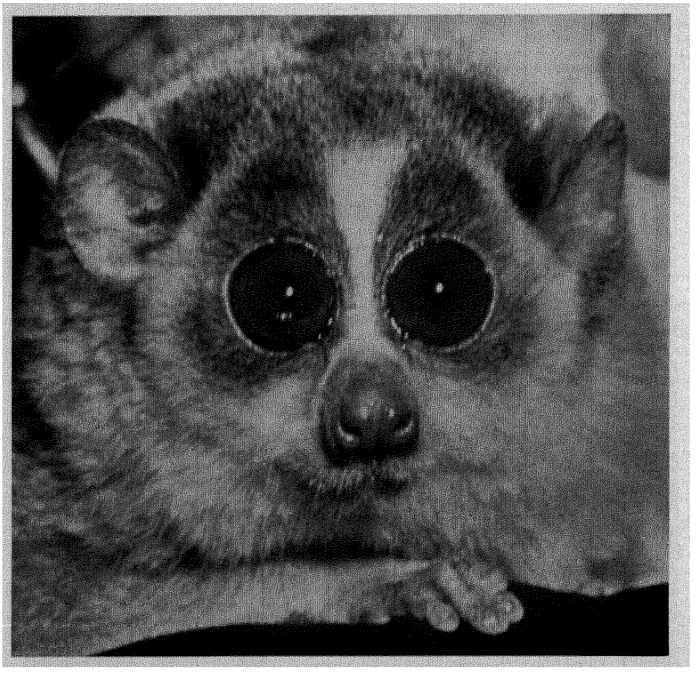

FIG. 500.—**Slender Loris** (*Loris* or *Stenops gracilis*), native of South India and Ceylon, one of two small, nocturnal, slow-moving Lemurs of Asia. Inhabitant of the forests, feeding on fruits, insects, birds, and other small life. Note perfectly appositied eyes oriented in a frontal plane; large, round corneae, and almost vertical pupils, indicative of a nocturnal habit; small interval separating the inner margins of the cornea caused by the large size and approximation of the eyeballs; perfect binocular fixation, making for a large overlapping of both monocular fields of view, a sure sign of excellent stereopsis. *Cf.* preceding photos of the Tarsier. With the permission of Wide World Photo, 1951. (*See* Fig. 524.)

specially adapted to the Tarsier's peculiar mode of living, they retain their original, primitive features, most important, the five digits. While the "hand" and "foot" of a Tree Shrew are still essentially the "paws" of the Infraprimate Mammals, of limited use as prehensile organs (Figs. 485–87), in the Tarsier they have become firmly to the surface of the grasped object, such as the upright bamboo stems, which is especially useful in the Tarsier's rainy habitat.

The nails of almost all fingers still are definitely narrow, pointed claws, closely adhering to, and about the same length as, the terminal phalanges, except in the second and third toes,

where the claws are long and turn up. The big toes alone possess flat nails resembling those found in most other Primates (Figs. 513, 514).

The root of the long tail is stiff, being a continuation of the spine, and affords support to the body when the animal hangs suspended from a stem. The greater part of the tail, however, is flexible. The hairs on the tip of the tail are slightly longer, thus making up a scanty tuft.

habitat little or almost nothing was known until modern times. But even after the recent reports by Hoogstraal (1947) and Wharton (1948), much remains obscure. A thorough scientific study of the Tarsier, just as of the Tree Shrews, in their native country, considering every angle of habit and habitat, still remains to be done.

From the early travelers Raffles (1822), H. Cuming (1838), S. Müller (1855, 1857),

FIG. 501.—Philippine Tarsier eyeing a meal worm, immediately before making a leap to snatch it. Insects, lizards, and other small animals are the food of this carnivorous Primate, which entirely disdains fruits and other plant products.

The entire bodily organization of the Tarsier is closely adapted to its hopping locomotion in dense undergrowth, probably mostly represented by the bamboo thickets of its tropical home, and to its nocturnal habit.

The anatomy of the Tarsier has attracted a great deal of interest since the early period of modern research and has been worked out in great detail, first by Burmeister (1846) and again by Woollard (1925).

3. HABITS.—About the living habits of the Tarsier and, indeed, about the character of its

Jagor (1873), and H. Rosenberg (1878), one learns that the Tarsiers inhabit dense forests in flat parts of their native countries. By daytime they hide in the dark, humid recesses, in thick foliage, or in the holes of trees. Or they are found between the roots and brambles in the densest bamboo thickets, usually a male and a female together. They make leaps of 3 feet easily.

Their food consists mainly of insects or of lizards, although in need they eat shrimps and cockroaches. The information about vegetable food is contradictory. According to S. Müller,

the Tarsier eats various fruits as well as insects, but in Jagor's opinion, it dislikes plant food but eagerly eats grasshoppers. The animal is nocturnal, drowsy during the day and lively during the night, leaping noiselessly here and there, its pupils wide open. The young, carried on its mother's belly, clings to her fur with its hands.

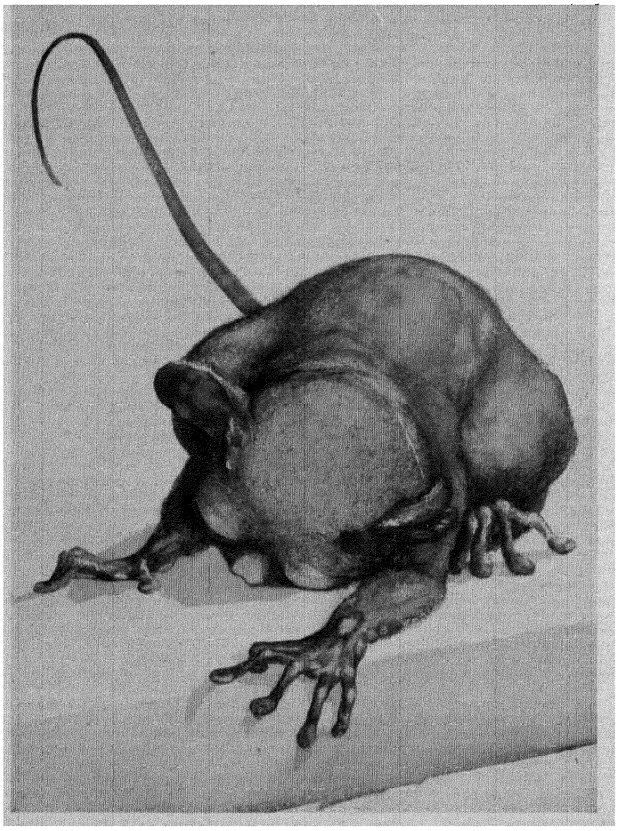

FIG. 502.—Philippine Tarsier, in the typical act of seizing a meal worm, by mouth alone or by mouth and both hands, after a quick leap toward it, during which both eyes are closed, with one ear folded up, and an upraised tail.

The information obtained during the past few years is more abundant and reliable, even though some gaps and contradictions still remain. Le Gros Clark (1924) presented quite an exhaustive report about the Tarsier's habitat, locomotion, use of limbs, food, and eating habits, all observations made on the Island of Borneo. The taxonomic affinity of this primate suborder to Man is not clearly revealed by blood serum precipitin reactions.

Raven (*see* Tilney 1928, p. 90) found the Tarsier extremely active during the night, "probably the quickest jumper of all mammals." According to G. C. Lewis (1939), the Tarsier's eyes possess great mobility and roll extensively sidewise and vertically in their sockets, "exposing great expanses of white eye ball in the faint light in a way reminiscent of a southern pickaninny hearing a ghost story." In

the experience of N. Cook (1939), the sight of the Tarsier in daytime is very poor, the pupils of the eyes reduced to mere pinpoints. The sense of smell is little developed, while hearing is more acute. The animals begin to move "about the time chickens go to roost."

The first successful attempt to bring living Tarsiers to the United States was made by Eckman, and the first scientific study of the living animals was undertaken by Catchpole & Fulton (1939).

A much richer picture of the life of the Philippine Tarsier and its native country is obtained from the firsthand observation of Hoogstraal (1947). While hunting with a headlight at night, he several times saw Tarsiers hopping from branch to branch in the thick second-growth forest in the lowlands of Mindanao, occasionally making long jumps on the ground. The animal apparently is much more abundant than heretofore believed. During the daytime it is usually found in dense, deeply shaded thickets, tightly clutching slender trunks or branches from 4 to 10 feet above the ground. When the animal notices an intruder, it usually moves its head slightly, with a fanlike opening, closing, and twitching of the ears.

Not infrequently a pair, a male and a female, is found in the same tree, sometimes a baby with its mother. During the day they apparently rest, and jump only when the tree in which they sit is cut or violently disturbed. When picked up, they are ready to defend themselves with their sharp, needle-like teeth.

In crowded cages the Tarsiers may fight among themselves, uttering a single, loud, shrill-pitched trill, whereas when they are surprised in the forest they are always silent. Instead of being a scourge of the forest, for which they have been decried by ignorant, sensationalist publicity-seeking writers, they are, in fact, timid little creatures, easily frightened, and Hoogstraal saw some topple over and die of fright. According to his experience, Tarsiers are never found under the roots but always on the branches or slender trunks of the trees.

The Tarsiers search for food only during the night. This consists largely of lizards, insects (mostly orthopterous), beetles, and spiders. Small rodents such as mice are not natural food, at least not for the Philippine Tarsier, these animals not being present in Mindanao. The epithet *carbonarius* or "coal-eater" in its scientific name is, of course, founded upon a baseless myth believed by the local natives, refuted long ago by Jagor (1873).

The manner in which the Tarsier secures its food by leaping upon it and reaching for it with one or both hands is peculiar. The morsel is held in the hand while the Tarsier eats it. The head of the prey is always eaten first, and the remainder gradually pushed into the mouth.

The female Tarsier gives birth to a single baby that arrives fully formed, with open eyes. The baby clings to its mother's belly until quite large. (*Cf.* Fig. 515.)

The latest and equally valuable information about the living habits of the Tarsier is from Charles H. Wharton (1948). He found this "exceedingly specialized" little Primate in the region surrounding the Davao Gulf at the southern end of the Philippine island of Mindanao. The animal thrives best in the second- and third-growth, vine-tangled thickets, along the coast and in the valleys, and sometimes in the gardens of native settlements.

Its favored haunts are thickets of small trees, where it clings to the upright limbs with its long fingers which are equipped with little, round, tenacious pads, especially advantageous in the rainy country where it lives. As night falls, the Tarsier leaves its hideout in a series of rapid leaps from branch to branch. Some of these leaps measure as much as 6 feet. When jumping, it holds its ears extended, hands and feet drawn to the body, with the tail trailing behind. "An instant before landing, the tail swings upward, and the long hind legs come forward to touch first and break the impact."

Its large eyes "can be moved only slightly in their sockets," owing to which "the tarsier must pivot its head about, even to inspect something a few inches to its right or left." Just how good the sight of this entirely nocturnal animal is during the night is not clear from the report.

The large and extremely mobile ears can be folded, betraying an acute sense of hearing, apparently adjusted to the sounds produced by the various insects upon which the Tarsier preys. When its sharpened ears catch a faint noise made by the potential prey, e.g., a large

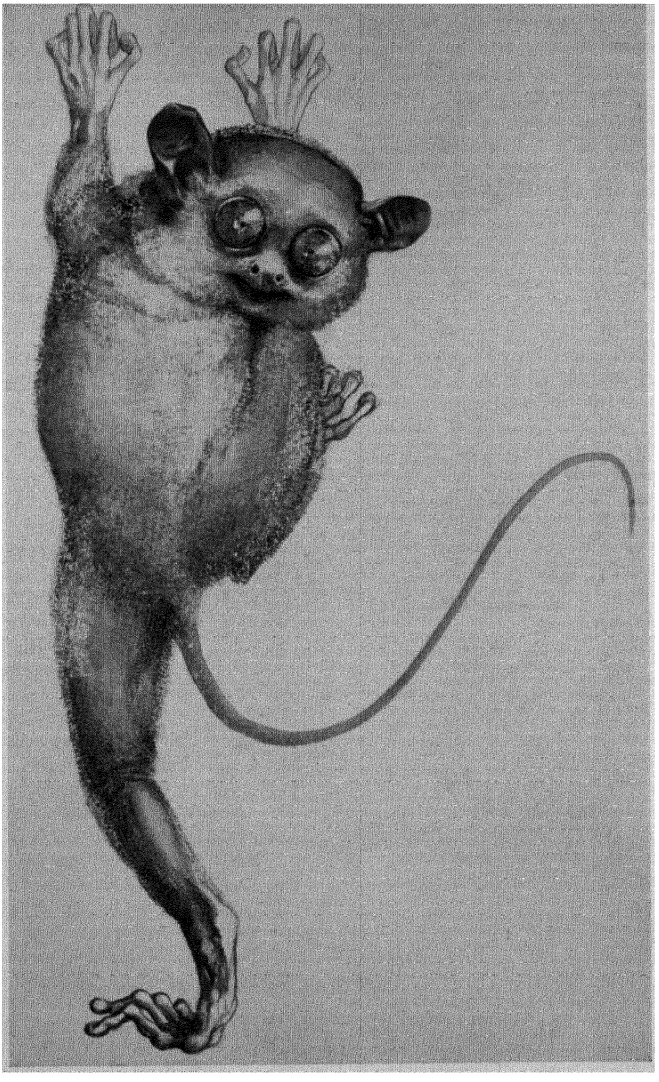

FIG. 503. Philippine Tarsier scrambling up a twig or a branch, holding on to it with both hands, the right foot fastened to a stem, the left leg maximally extended, the head turned backward (in the manner of an owl), with its eyes fixing the object of suspicion, its lids maximally drawn back, making the huge eyes appear even larger, and with its pupils reduced to minute, horizontally placed elliptical openings.

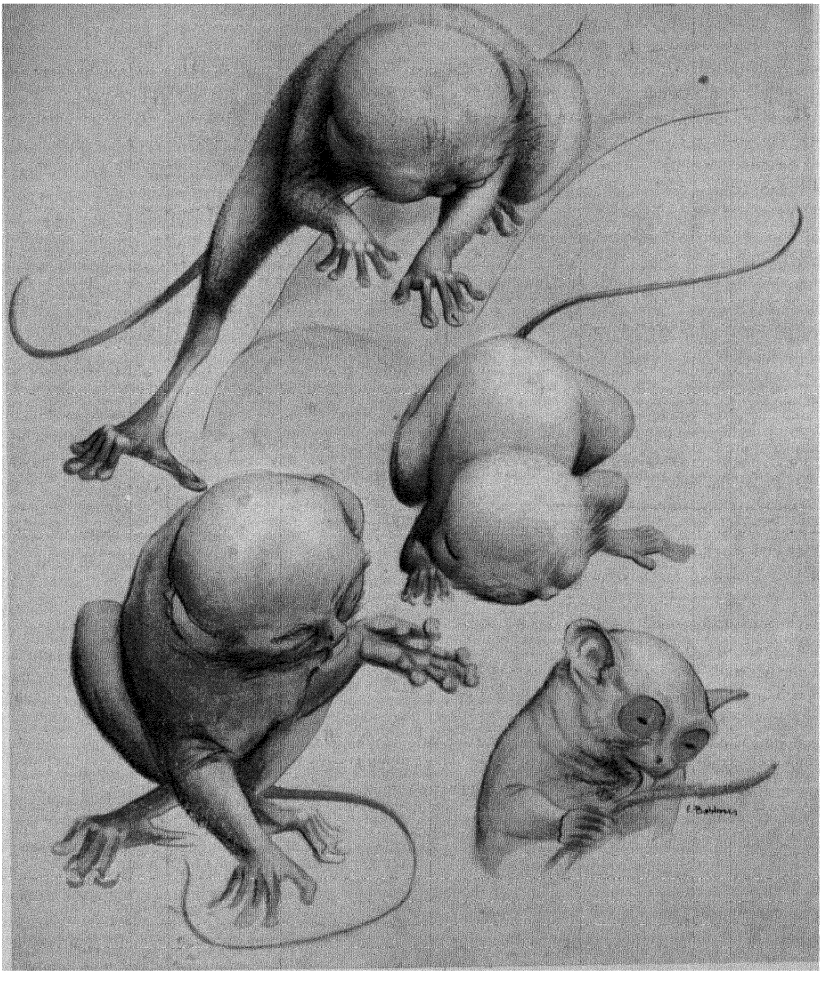

FIG. 504.—A female Philippine Tarsier in various characteristic attitudes of grooming: *above and at left below*, licking fur of her left forearm; *center*, rubbing face against the floor; *right lower corner*, preening and licking the tip of her tail which she holds with her right hand, while gazing at it attentively and with great interest. The Tarsier's preoccupation with its own appearance is interesting in a nocturnal Mammal, the instinct and manipulations resembling those of the true Monkeys.

beetle crawling not far behind, its head slowly turns around until it looks backward, the large eyes widen to the maximum, the pupils expand to the corneal rim, the ears move back and forth until the source of the noise is located, the eyes turning toward the prey. An instant after the eyes have detected the slight stir of the beetle, the Tarsier leaps "across the intervening space faster than the eye can follow," and lands on a near-by branch. The next moment it catches the beetle in its hands and eats it, head first.

How the Tarsier likes the final phase of the hunting drama just described, repeated many times every night in its native jungle, it shows by closing its eyes, now for a while out of action, down to the size of "mere furry slits, completely covered by the russet eyelids."

The food of the Tarsier in the wild state, according to Wharton, consists of insects, lizards, and probably mice(?); in captivity, of grasshoppers, lizards, raw meat, wild birds, beef, liver, meal worms, crabs, mice, June beetles, all to be furnished in abundance to this most carnivorous of the Primates.

The Tarsier's voice, when at peace, is a "beautiful birdlike trill or twittering," resembling "a series of locustlike chirps," or a loud shrill when alarmed.

The pairs like to sit together and hold each other for hours when they are not hunting.

The fable of Tarsiers eating charcoal, which is believed by the natives, apparently has its source in the fact that the animal is frequently found in burned-over places. Connected with this is the story told by the natives that the *amas*, or the "Old Man of the Mountains," in the native language, is attracted by fire and lamp "in order to warm himself."

4. Behavior in captivity.—The two living specimens bought from Mr. Wharton arrived in Chicago via airplane in good shape in July, 1947. They were a pair, a male and a female. In order to give them enough room for exercise, they were placed in a large cage, about $2\frac{1}{2} \times 3 \times 3$ feet. A shelf was put in the back, 18 inches above the floor, together with several fresh leafy oak branches to climb on and to hide in. A small cardboard box was also placed in the cage to serve as a hiding place and as sleeping quarters. The floor tray was covered with dry sand, and care was taken to have fresh water at all times. Following are a few notes from my personal observations (*see also* accompanying figures).

During the day the animals, when undisturbed, were usually found sitting on their haunches, hiding behind the leaves, either on the shelf or perching on a branch. They were like two fluffy, round, brown little balls, almost perfectly motionless except for an occasional, barely perceptible, twitching of the tips of the auricles and a slight rotation of the head.

The female in particular, as she clung to a twig, resembled a little owl more than a mammal. The two pairs of big, round, bulging, brown eyes were motionless, intently glued on the intruder. The pupils were small ovals, 1×2 mm. in diameter, with the longer axis horizontal. No movement of the lids was observed for a long while. When a pencil was moved behind the back of the male as he sat on the shelf, he slowly rotated his head until he faced directly backward, and fixed the object with his protruding eyes, as if puzzled, also moving both auricles in the direction of the gaze. After the pencil was withdrawn, he again resumed his former statue-like pose. A similar experiment with the female sitting on a branch a few inches above her companion produced the same effect. Otherwise, when unmolested, both animals were motionless, as if drowsy or asleep, their eyes kept wide open, their gaze directed past the observer, as if oblivious of his presence. In this frozen pose they continued after the observer moved away.

One October afternoon when the room was filled with sunlight, both Tarsiers were found concealed behind the leafy branches. The female was facing the door of the room, quietly watching in that direction. Her pupils were reduced to minute horizontal slits. A live Anole lizard was placed on a branch in front of her, about a foot distant. The lizard, evidently not recognizing danger, leaped toward her, landing close in front of her on the shelf. First she slowly turned her gaze toward the lizard and watched it for a little while, then, her eyes popping out a bit as the lids retracted, holding both hands close to her face she threw herself at the lizard but missed it. She apparently misjudged the distance, possibly because daylight

conditions were unnatural to her. On a second attempt the lizard was caught, crushed, and left on the shelf.

Remarkably, the female did not take further notice of the dead lizard. Possibly she was not hungry or, more likely, she was in a state of drowsy stupor, as might be expected in a strongly nocturnal animal during the daytime. Only when the lizard was moved by a long forceps did she repeat the attack and grab it. For a while she held it in her mouth without eating it, as if absent-minded, then she retired into a corner and began to munch on it.

While eating the lizard, the female held it in her right hand, and occasionally stopped chewing for quite a while. In holding it, all five fingers of the hand, including the thumb, were in apposition (Fig. 511). On this occasion she began chewing the tail, an exception to the usual procedure, which is quickly to bring the head of the live prey into the mouth and crush it. Both hands are used in this action, and they move too fast for the observer to analyze precisely how the manipulation is carried out. This is especially true when the prey is caught by the tail and must be turned quickly.

During all this activity the male Tarsier remained perfectly motionless behind the leaves.

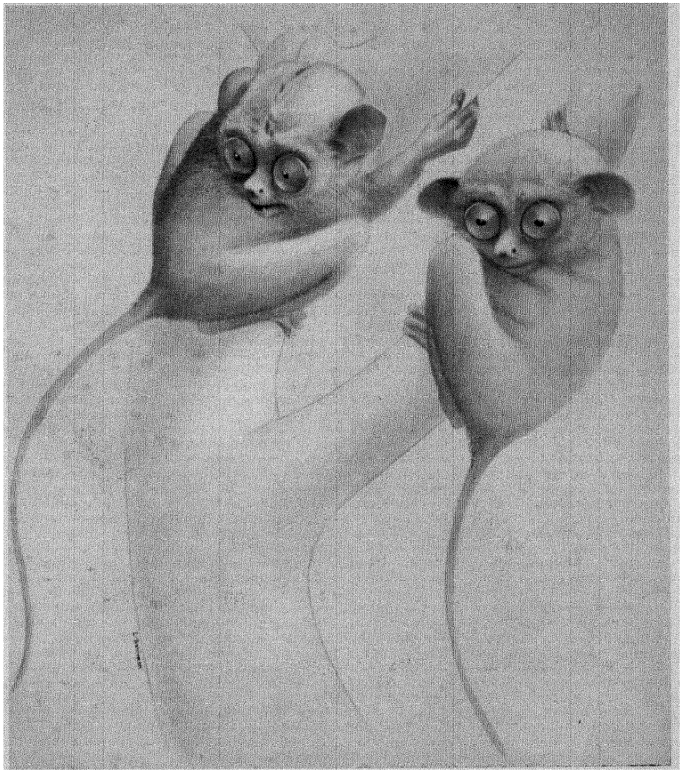

FIG. 505. A pair of Philippine Tarsiers showing a male (*left*) and a female (*right*) the moment after both scrambled up a limb when the door of their cage was suddenly opened. Their physiognomies, turned toward the source of trouble, reflect fear, their eyes intently fixing the object of their apprehension, their lids maximally pulled back, baring part of the sclera normally not visible, with the mouth of the male slightly opened.

A live lizard was placed where he could see it. As soon as he noticed it, he began to shake off his drowsiness. He soon became very attentive and slowly stretched his head toward the prospective meal, retracting his lids and popping out his eyes. Then in a flash, he rushed in the same way, headlong at the lizard. He promptly caught it and quickly put it into normal position, head first, into his mouth, and began to chew, while both hands worked very fast in helping the jaws.

Thereafter he began the slow, deliberate, measured process of chewing his meal, stopping periodically, the left hand holding the lizard,

FIG. 506.—Male Philippine Tarsier impersonating human attitudes. Left-hand sketch depicts the animal in the act of "chinning" or raising himself by the strength of his arms alone until his chin was above the level of the limb. Right-hand sketch shows the same animal resting on a limb, in a pose not unlike that of "a cowboy on a corral fence," with his right hand and right foot firmly gripping the limb, his left upper arm partly supporting the body weight, his left forearm and hand nonchalantly crossed, his left leg and foot dangling in midair, his face expressing the perfect equanimity of a person "gazing out of the window."

while the right was used as a prop. During the slow process of chewing he would occasionally turn his head to one side or the other, while his large auricles made scanning motions, apparently caused by the constant racket made by the Tree Shrews in a near-by cage. As he chewed, with part of the lizard's body still hanging out of his mouth, he would occasionally push it farther into his mouth with the back of one hand.

Even after the tip of the tail disappeared, he went on chewing for a few more minutes. All the while he was enjoying his repast, he continued to stare into space. Only rarely did he shut his eyes, "winking" by slowly pulling his upper lids over his bulging eye globes. Sometimes this did not occur in both eyes simultaneously, one lid occasionally closing, while the other eye was still completely or partly held open, in the manner observed occasionally in Cats and Owls

FIG. 507. A male Philippine Tarsier in a characteristic pose and facial expression, indicating a mild emotional dilemma between apprehension from a possible danger and interest in a meal worm offered to him and held between the thumb and index finger. Note the wide-opened eyes, with the mouth opened only slightly, the legs, feet, and body facing away, as if making ready for a quick leap in the opposite direction.

(Fig. 509). After finishing his meal, the male again retired behind the foliage, keeping a watchful eye, however, for another possible tidbit.

Fights between the two little animals were not observed. At the most, when one was served a lizard the other would try to grab it away, usually unsuccessfully if the first Tarsier already had it securely in his mouth. Most of the time they showed themselves to be gentle, peaceful creatures, glad to be left alone. Frequently they were found huddled together.

Only once could the voice of the Tarsier have been identified for certain. Late one afternoon the animals were in the little cardboard box in a corner of the large cage in which they usually spent the day. Suddenly there was a somewhat shrill and extremely high-pitched sound heard, not intensive or loud, and sustained for 3 or 4 seconds; it began with a somewhat lower pitch and terminated on a higher note. Its acoustic quality was decidedly that of a "reed" (that is, not of a "flute"), resembling the song of a Hooded Nun Finch of India, the so-called "Java" or "Love Bird." The sound was repeated two or three times.

5. FOOD AND EATING HABITS.—The diet of the Tarsier, as observation in captivity shows, is entirely animal. The Tarsiers are, in fact, the only truly carnivorous Primates in existence. They never touched vegetable products and fruits, such as bread, carrots, peas, lettuce, bananas, oranges, grapes, raisins, apples, peanuts, and the like—all things which the Tree Shrews ate well or fairly well.

During the day they were given one or two Anole lizards each, in the morning and the afternoon, depending upon the size. Other meat, such as fresh or frozen parts of a rat, guinea pig, pigeon, and the like, they ate only during the night, this food apparently not representing a sufficient stimulus to attract them in the daytime. Usually much of this meat was found on the next morning untouched and dried.

The preferred food, to which they responded at any time, as did the Tree Shrews, was meal worms. No matter when it was offered, and even after they had eaten a sizable lizard, the sight of a dish full of crawling worms placed in the farthest corner of the cage was a potent visual stimulus which aroused interest and action. This happened even when the animals were dozing, concealed among the leaves, and seemed to be uninterested.

Sometimes the reaction would come after a considerable lapse of time, during which it was doubtful whether the dish had been noticed. The fleeting image of the dish, always the same size and shape, that meant great enjoyment for them, however, must have registered on their minds. At last the leaves would be pushed aside, and their large eyes would appear, looking about. After the dish was located, there was usually a meditative pause. But the sight of crawling meal worms evidently was too much to resist.

At long last, one of the Tarsiers would finally come out of his lair and jump down to the floor of the cage close to the dish. After another brief moment of scanning the dish, one of the fat worms was selected and a quick attack made on it. This was always done in a particular way, by precipitated, headlong "diving" in such a way that both the hands and mouth touched the prey at the same time. This manner of eating was maintained even while, from the human viewpoint, there was no need for a double assurance of success and the hands were not needed and not used. Actually, most meal worms were seized with the mouth alone, or the hands were used only to assist in the capture. In any case, the mouth was the principal, usually the only, instrument used in picking up the worms (Fig. 502).

6. EYE, EAR, AND HEAD MOVEMENTS.—The process of catching and eating meal worms offered a favorable opportunity to observe in some detail the behavior of the eyes. When the animal sat quietly and there was nothing to attract its attention, the eyes seemed absolutely immobile. No movements either of the lids, eyeballs, or iris could be detected for long periods of time.

As soon as a dish with the meal worms was offered, the Tarsier turned his head toward it and retracted his eyelids, which made the eyes seem to pop out. A slight convergence of both eyes, to bring both lines of vision toward the common binocular fixation point, seemed to take place (Fig. 501). When making searching

movements with the eyes, in either the horizontal or the vertical plane, definite but slight jerking movements, simultaneous in both eyeballs, were noticeable. They were, however, very small, these movements amounting to hardly more than 1 mm.

A counterpart to an almost complete immobility of the eyes was the ability of the Tarsier to rotate his head almost 180°, as if it were on a pivot. This enables the Tarsier, as it does the Owls, to look behind him without turning his body (Figs. 503, 508).

In contrast to the rigidity of the eyes was the extreme mobility of the ears, which could be moved in almost any direction and changed in size and shape in an almost infinite variety of

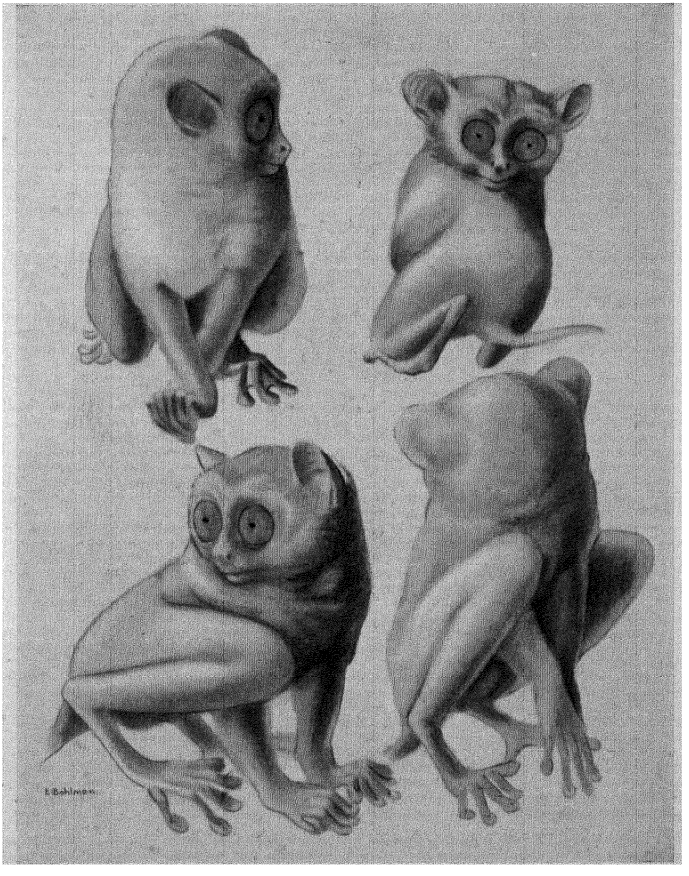

FIG. 508.—A male Philippine Tarsier, showing characteristic poses when observing and examining his surroundings: *upper left*, looking to his left, showing the face in profile, with his body weight chiefly resting on his left foot and leg; *upper right*, the body turned away from the observer, the head turned toward the same, with his eyes wide open, expressing a mixture of inquisitiveness and doubt; *lower left*, quietly and attentively observing something, possibly the noisy Tree Shrews in the adjoining cage; *lower right*, with his face turned away, his body weight entirely supported by the legs, his hands barely touching the ground. The great flexibility of the neck and the ability to turn the head backward strikingly resemble the same trait in the Owls.

ways. Such auricular mobility undoubtedly indicates a refined hearing, that evidently plays an important role in the life of the Tarsier (Fig. 514).

7. Use of limbs.—The use of the extremities is definitely more advanced toward the condition found in the Pithecoid Primates in the Tarsier than is the case in the Tree Shrew (Figs. 498, 503, 504, 506, 510, 511, and esp. 513, 514).

To begin with, the palms of the hands and the soles of the feet are much larger and the digits longer and more flexible than in the Tree Shrews. The upper extremities are true hands with differentiated fingers and thumbs; the lower extremities, in spite of the inordinately elongated tarsal bones, exhibit the essential features of the prehensile hind feet of the Monkeys. Such extremities represent a great advance from the more primitive conditions in the Tree Shrews.

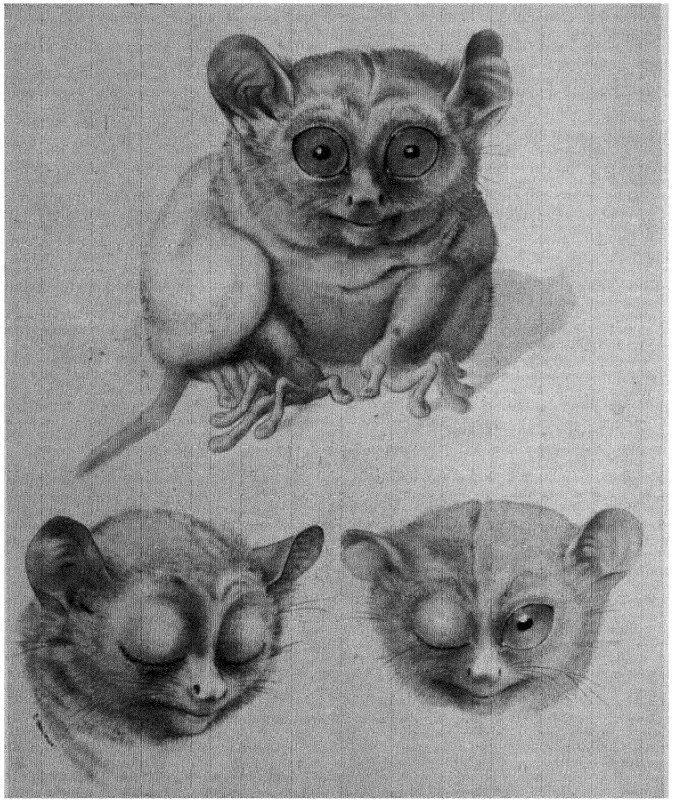

Fig. 509.—Facial expressions and body posture of a male Philippine Tarsier when in a good mood. Upper figure portrays rapt attention under the spell of quiet, gentle, friendly talk. Lower sketches show the effect apparently caused by continuous, friendly talk made in order to hold his attention while somewhat tired, during which he occasionally shut either one or both eyes, as if in hypnosis. The closing of only one eye occasionally takes place when the animal rests, as is the habit of his avian counterparts, the Owls.

An object of great interest was the opposability of the thumb and the big toe. In the Tarsier this movement could more accurately

be defined as an abductibility and adductibility of these two digits from, or to, the rest of the fingers and toes than as true opposability. The big toe was usually found about 45° abducted from the axis of the second toe It was more difficult to ascertain the rotation of the big toe, which became apparent only in certain situations. There was a certain amount of true opposability of the big toe to other toes.

aligned with, the rest of the fingers (Figs. 497, 504, 506, 511, 514). When the hand rested on flat ground, with the fingers sprawled, the thumb usually was kept farther away from its neighbor than the average distance between the remaining fingers (thus in right lower sketch in Fig. 510, and in right upper sketch in Fig. 513).

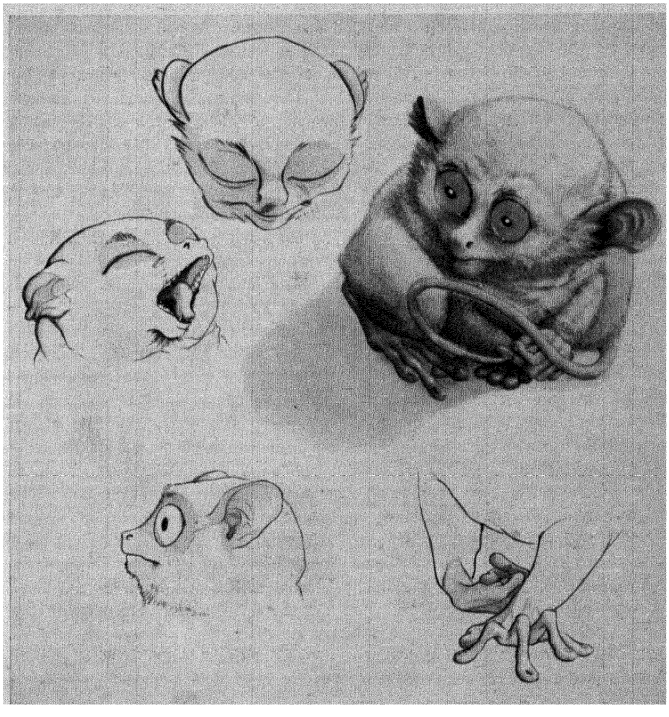

FIG. 510. Various poses and attitudes of a female Philippine Tarsier: *upper center*, dozing; *right upper sketch*, just wakened from sleep; *left upper sketch*, yawning; *left lower sketch*, showing full profile after turning the head to right on slight sound from that direction, with both ears cocked; *right lower sketch*, showing a peculiar position of the hands, left hand broadly spread, resting on the ground, and supporting a part of the body weight, right hand curled up as in "embarrassment."

The evidence in favor of the opposability of the thumb was much more difficult to obtain. Most usually, when holding an object or a piece of food for example, a lizard or clutching a branch or holding the tail during the process of grooming, the thumb was apposited to, or This may indicate a certain amount of rotation of the thumb around its axis and the ability to use it in opposition to other fingers. But the opportunity of securing positive evidence of this was given only rarely, as, for example, when the thumb was adducted to the index finger and at the same time rotated around its axis for about 90°, practically duplicating the condition pres-

ent in the human hand (right middle sketch in Fig. 513).

How frequently the Tarsier uses his thumb in this fashion and whether it is capable of true opposition of the thumb to all fingers of the hand remain to be further investigated. In any case, the squatting position, with partial or complete release of the upper extremities from the task of supporting the weight of the body, readily assumed by the Tarsier; the flexibility of the fingers and some opposability of the thumb; and the ease of pronation and supination of the forearm and of rotation and other movements of the upper arm—all these contribute to the emancipation of the upper extremities from the exclusive or principal function of locomotion, making them available to a greater degree as instruments of feeding and of manipulation in general.

The hind extremities are the principal instruments of locomotion and are adapted to a hopping gait. This adaptation has been achieved by the general strengthening and lengthening of the legs. This lengthening has been accomplished chiefly by the inordinate prolongation of the tarsal or ankle bones, the calcaneus and navicular or scaphoid (hence the name "Tarsier"), greatly resembling the conditions found in Birds, but not in the Kangaroo, in spite of a superficial resemblance. Nevertheless, true to the arboreal habit and the inherent pithecoid organization, the hind limb has been developed into a grasping organ, with padded terminal phalanges and opposable big toe.

8. Eyeball.—The eyes of the Tarsier are remarkable. In absolute size they are large, and in proportion to the size of the animal they can hardly be matched anywhere among the Mammals. In order to meet a like relationship, one must look among the Birds and Fishes with the best-developed sight.

The eyelashes, arranged along the margins of both lids, up to 5 mm. long and bent away from the palpebral fissure, at close view give the eye a human appearance. Each eye is protected above by a matted brow, a part of the general pelage, with a few 15-mm.-long vibrissae or bristles arising in a bunch above the inner canthus. The outer canthus is sharp, the inner one blunt, and there is a relatively large third lid. The length of the palpebral fissure is about 12 mm. The fundi of the upper and lower conjunctival pockets run just behind the corneal margin, but, because of the great expanse of the lids, the pockets are roomy.

The transverse axis of the eyeball measures about 18 mm., the longitudinal axis about 17.5 mm., which approaches the 24-mm. diameter of the human eye, all strangely contrasting with the enormous difference in weight of the Tarsier (*ca.* 150–200 gm.) and Man (75,000 gm.).

The cornea is spherically curved and, as in most nocturnal animals, is relatively large, measuring about 18 mm. from margin to margin, which is nearly equal to one-third of the ocular circumference. The root of the iris is attached to the cornea along the margin and is visible through it as a dark-brown, 0.7-mm.-wide circular stripe.

The lens is very large and proportionately thick, its diameter being 10 mm., its longitudinal axis or thickness in the center 6.5 mm., compared with the 8-mm. diameter and 3-mm. thickness of the human lens. Both surfaces of the lens are spherically curved, the anterior having a shorter radius of curvature.

The anterior chamber in the axis is relatively shallow, the distance from the lens to the cornea measuring only 3 mm. However, owing to the great expanse of the cornea, amounting to almost half the corresponding sphere, the anterior chamber is quite roomy, since its main extension is along the sides of the huge lens. The depth of the vitreal chamber in the axis is 6.5 mm.

The ciliary body is well developed, being made up of 1.5-mm.-long, and 1-mm.-high ridges that are thinner but more numerous than in the human eye. The iris is a brown and thin curtain inclosing a pupillary aperture and pressing upon the anterior lens surface. It and the chorioid membrane are heavily pigmented.

The optic nerve with its sheaths is only 1.3 mm. in diameter; without the sheaths, barely 1 mm. From the point of its implantation slightly nasal to the posterior pole, it runs closely along the eyeball for a short distance before it turns nasally, making an angle of almost 45° with the sagittal plane.

The six extrinsic eye muscles, four straight and two oblique, are relatively little developed.

Together they form a small cone around the optic nerve. The four straight muscles are quite short and are attached to the eyeball well behind the equator, a factor that further reduces their effectiveness as an oculomotor agent. The levator muscle of the upper lid is a thin, broad slip, whose bundles spread fanwise before mingling with the orbicular muscle; these bundles are partly attached to the aponeurosis of the eyeball.

the bundles arranged meridionally (Brücke's muscle) and radially. These are all attached, on the one hand, to the well-developed scleral roll at the root of the iris and, on the other hand, to the chorioid membrane. In meridional sections, almost all ciliary muscle bundles show a straight or slightly curved course, only a few, close to the inner corner of the body transversally cut, representing the circular portion (Müller's muscle).

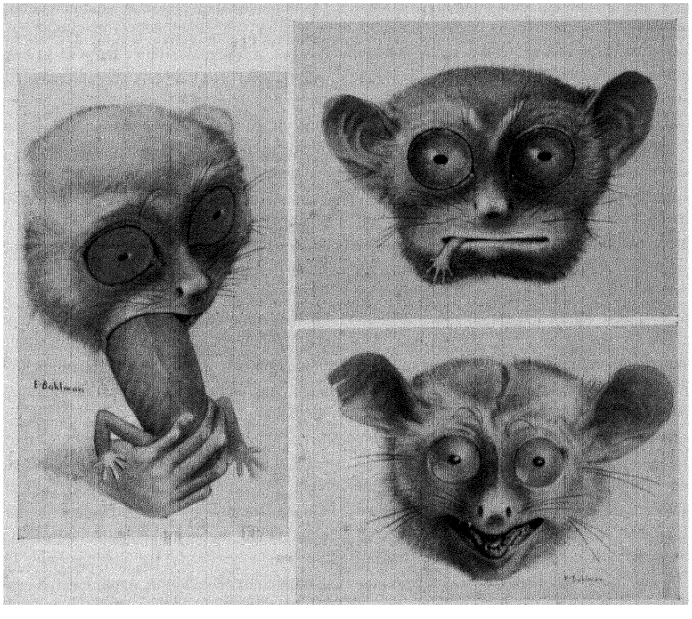

FIG. 511.—Various expressions of the physiognomy and of the eyes of a Philippine Tarsier: *left sketch*, contentedly munching on the tail of an Anole Lizard, a reverse situation from the usual procedure of starting with the head, since in this instance a decapitated specimen was offered; *upper right sketch*, showing a startled expression caused by observer's loud laughter; *lower right sketch*, an expression of fear rather than ferocity, with the mouth half-opened, the baring of the teeth, and the tip of the tongue just visible.

A study of microscopic preparations of the eye reveals further noteworthy details. The cornea is relatively thin, its structure very homogeneous, its two surfaces very even and smooth. The ciliary body, directly continuous with the chorioid membrane, is well developed. It contains, besides the smooth-muscle fibers, numerous chromatophore cells filled with brown pigment.

Best developed of the ciliary muscles are

The fibers of the ciliary zonule of Zinn are numerous; some are thin; others, formed by the merging of several thin ones, are quite thick. Peripherally they are attached directly to the ciliary processes and body and in this way to the chorioid membrane and also to the hyaloid membrane and through it to the retina. Inwardly, they merge with the lens capsule along the equator.

The iris contains blood vessels and heavily

pigmented stromal cells of a light-brown color. This color contrasts with the dark-brown, almost black, color of the pigment filling the cells of the iridial portion of the retinal epithelium that lines the inner face of the iris, while the pigment filling the ciliary portion of the blind, nonnervous portion of the retina, as well as that in the ciliary chromatophores, is of an intermediate-brown intensity.

The sphincter muscle is a well-developed layer close to the pupillary margin. The dilator muscle may be identified as a thin, distinct layer next to the pigment epithelium, best seen in the outer half of the iris closer to its root.

The hyaloid membrane is a thick, structureless sheet, distinct and separate from the actual inner limiting membrane, from which it can be easily detached without tearing off the lower ends of Müller's radial fibers.

The nervous or functioning portion of the retina extends almost to the ciliary body. There is no ora serrata or serrated margin, since the line along which the nervous part of the retina terminates is quite even, representing the ora terminalis. Small cystic cavities along the terminal margin are a reminder of similar, but much larger and more numerous, cavities in the human ora serrata. A small neuroglial "cone" filled with nuclei, a remnant of the hyaloid artery that functions during embryonic life, protrudes from the vitreal face of the disk. The chorioid membrane is well developed, being especially thick in the territory of the central area, and is rich in heavily pigmented chromatophores.

To summarize, the eye of the Tarsier appears to be an organ highly adapted to its nocturnal life. The cornea and lens are huge dioptrical light collectors, and the large iris is an efficient regulator of the amount of light to be admitted into the eye: as much as possible during the night and very little during the day.

The well-developed ciliary muscle is necessary to counteract the strong pull by the thick fibers of the ciliary zonule and thus permit the huge crystalline lens to accommodate for close range through an increase in its sphericity. Such accommodative mechanism can be fully utilized only in an eye whose retina allows for a high degree of visual acuity. This is possible in the Tarsier, in spite of the subdued nocturnal illumination during which it is active, in virtue of a good development of the central area and fovea of the retina, as described in the following subsection. The most economical utilization of nocturnal illumination is further assisted by the heavy pigmentation by which most of the interfering stray light is eliminated.

Finally, in view of the poorly developed extrinsic eye muscles, whose effect in turning the eyeball is small, as shown by observation, the question may be raised as to whether in some way these muscles may not assist in accommodation, a function obviously of great biological importance for the survival of the species.

9. RETINA.—The retina of the Tarsier is as remarkable in its structure as is the rest of the eyeball. For this, above all, two factors are responsible. While, in general, it conforms in its makeup to the structure found in other Primates, it stands apart from most species of this order in the absence of cones.

The bacillary layer is made up entirely of rodlike photoreceptors (Fig. 512). In this respect it is homologous with the rod-bearing retina of the Cat and of the prosimian *Galago* and *Nycticebus* (Detwiler 1938, 1939, 1940, 1943). But unlike the prosimian species, the Tarsier is remarkable in its possession of both a central area and a fovea (whereas a central area alone is found in the Cat). Hence the Tarsier breaks the rule by which these two specially differentiated structures are found only where cones are present. In this respect the Tarsier agrees with the South American Night Monkey (*Nyctipithecus* or *Aotes trivirgatus*), in which a central area and fovea are also present.

The Tarsier's retina is relatively thin. In the axial region it measures 220 microns or slightly more, being gradually reduced to 35 microns along its terminal margin. Its layers, for a Mammal, are regular, the boundaries being mostly quite sharp and even, with very few ectopic or displaced nuclei found in the two plexiform layers and none in the bacillary layer.

The absolute and relative thickness of the layers varies markedly from the periphery toward the axial region, where it is most pronounced in the formation of the central area. Taking as a criterion the increase in the ganglion layer to more than a single tier of cells, the

diameter of the central area measures 2,000 microns or 2 mm. across. Its center is little more than 2 mm. distant from the temporal margin of the disk; hence the central area is relatively smaller in extent than, for example, in a Rhesus Macaque. However, the increase in the number of ganglion cells and other refinements in a zone immediately surrounding the central area proper indicate that the pericentral zone is also on a higher functional level than the periphery.

The pigment granules of the pigment layer are brown. This contrasts with the chorioid pigment, which, although also brown, appears almost black because of its abundance. The granules in the specimen examined were confined to the pigment layer.

The thickness of the bacillary layer increases from about 40 microns at the equator to 70 in the periphery of the central area and to as much as 140 in its center (Fig. 512). The arrangement of its structural elements is remarkably smooth and even, just as the underlying outer limiting membrane is smooth. There are no "convolu-

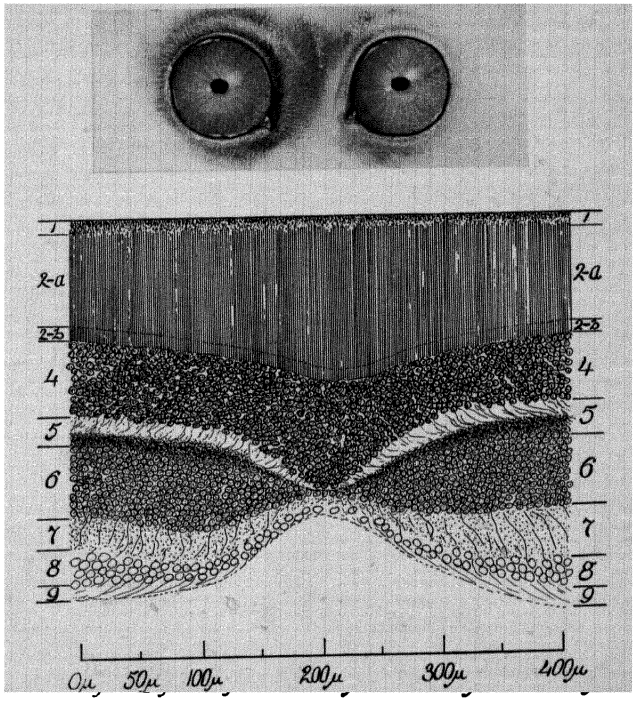

FIG. 512.—Tarsier's eyes and structure of central fovea. Upper sketch represents a close view of the eyes, showing the huge corneae in the almost maximally extended palpebral fissures, which are oriented with a "mongoloid" slant, the horizontally elliptical pupils almost maximally contracted, as in full illumination. The lower sketch represents, at medium magnification, a vertical section through the center of the Tarsier's central fovea, showing the layers described in detail in the text. Note the extraordinary length and thinness of the foveal photoreceptors, longest in the very center and resembling the rods (layers *2-a* and *2-b*); swollen outer nuclear layer *4* in the very center and attenuation of all layers from *5* to *9* in the same locality. These features are in harmony with the strictly nocturnal habit of the Tarsier, which, in spite of this, preserved the central fovea, a common heritage of all Monkeys, Apes, and Man. It is the possession of the central fovea that, in spite of the Tarsier's nocturnalism, affords this Primate a high degree of visual acuity. The layers of the retina indicated along the sides, the actual magnification in microns indicated on the scale below. (*Cf.* Figs. 129, 161.)

tions" or "plications," as described by Woollard (1926); these artifacts, where found, are caused by an inadequate technique of fixation.

The photoreceptors making up the bacillary layer, both in the extra-areal periphery and in the central area, including its very center, are exclusively rods. They are very thin in diameter, all alike, arranged remarkably uniformly, and vertical to the limiting membrane. Where they are found bent or otherwise displaced, the original vertical arrangement can easily be restored.

The caliber of the individual rods differs little in the central fovea and area and in the extra-areal periphery. In the first it is 0.5 micron, in the latter about 1 micron. The intercenter distance between the adjoining rods measures from 1 to 1.5 microns.

Whereas the difference in thickness is insignificant, the rods vary considerably in length,

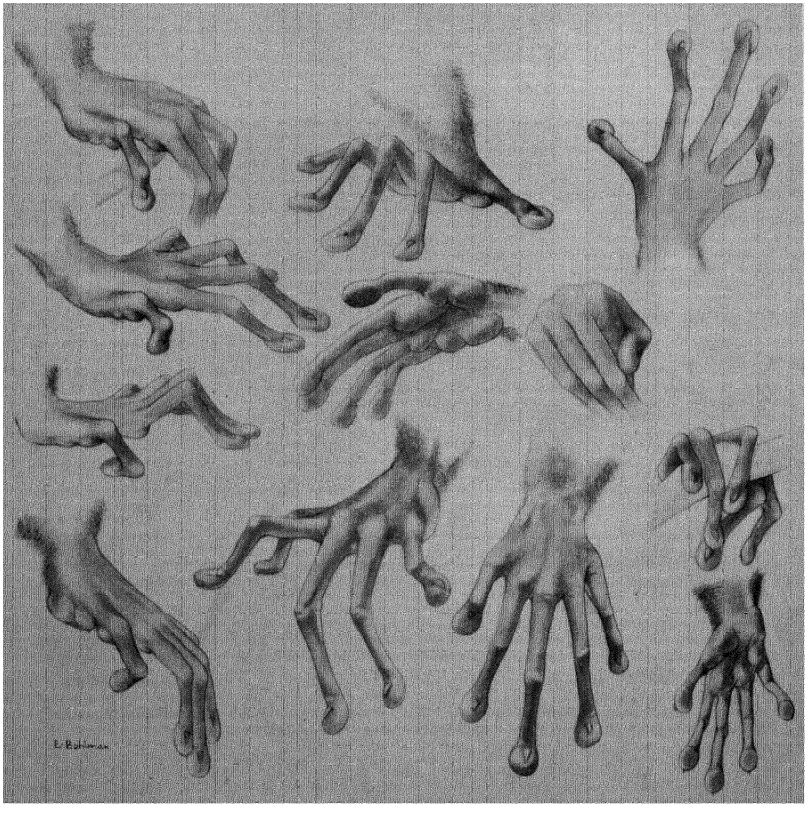

FIG. 513.—Hands of the Philippine Tarsier and their use. The hands are typical, even though somewhat modified, primate hands, the figure showing the form and relative size of the fingers, thumb, and palm and their various employment. The two sketches in the right lower corner are drawn on a slightly smaller scale. The sketch under the one in the right upper corner depicts the right hand with its fingers bent and the thumb held adducted to the index and middle fingers. The sketch in the center of the upper row and the one in the right upper corner show the thumb abducted from the other figures. (*Cf.* following figure.)

as expressed by the increased thickness of the bacillary layer. They are shortest in the periphery and gradually lengthen toward the center, where they are longest. The greater length of the central rods is caused entirely by the relatively greater lengthening of the outer segments, especially apparent in the center of the outer fovea (Fig. 512, layer *2-a*).

The outer nuclear layer is thick and is made up of a great number of closely packed nuclei. This layer attains its maximum thickness in the areal periphery and just outside the area, where up to sixteen tiers of nuclei may be counted. In the very center of the fovea the number of nuclei increases to eighteen or more tiers. The nuclei are all of the same appearance; they are small, dark, containing coarse framework and granules—in other words, they appear as typical rod nuclei found in the human and simian retinae, where both rods and cones are present.

A row of larger and paler nuclei stained in a different hue, located just underneath the outer limiting membrane, found in the cone-containing retinae, is absent in the Tarsier. However, the uppermost tier of the nuclei, while of the same hue as the rest, contains slightly larger elements, which, however, is an insufficient criterion by which to consider them true cones. It is therefore possible that, with the adoption of a strict nocturnal mode of life by the Tarsier, the original primate cones were transformed into rods, while their nuclei still retained their former location below the outer limiting membrane and remain slightly larger. Hence, if there are cones in the Tarsier's retina, they cannot be demonstrated with the hematoxylin and phloxin stain or with the toluidine blue stain of Nissl & Lenhossék. Other methods, such as Golgi and perhaps modifications of Klüver's Luxol fast blue cell-fiber stain, may furnish a decisive answer to this particular question.

The outer plexiform layer attains almost half the thickness of the outer nuclear layer. As in other Mammals, it is made up of three zones: *5-a*, fibrous; *5-b*, inner swollen ends of photoreceptors; and *5-c*, outer expansions of the bipolars and horizontal cells. In the Tarsier this layer is more uniform, chiefly consisting of photoreceptor fibers in the upper half and, in the lower half, an ill-defined granular mass, identified in other species as made up of rod spherules and outer expansions of various bipolars and horizontal cells. A continuous line of "granular clods," especially prominent in the central area and fovea of the Macaque and Man, identified with the outer dendritic expansions of midget bipolars individually attached to the lower faces of the cone pedicles, is missing in the Tarsier. This again harmonizes with the absence of true cones. (*Cf.* Figs. 512 and 128, 129.)

The inner nuclear layer contrasts with the outer nuclear layer by its paler stain and larger nuclei. A discontinuous row of slightly larger nuclei surrounded by a fair amount of cytoplasm immediately adjoining the outer plexiform layer, apparently belonging to the horizontal cells, is conspicuous here. Another zone where larger nuclei are present is close to the inner plexiform layer. Other nuclei of a more or less angular shape and slightly darker in color, belonging to the radial fibers of Müller, are present in the vitreal half of the layer.

The inner plexiform layer contains numerous fibers arranged vertically, the space between being filled with a granular mass. Owing to a condensation of the granules, several parallel horizontal zones may be distinguished.

The ganglion layer is composed of cells varying considerably in size but, in general, being larger than in either of the two nuclear layers. Their nuclei, as usual, are of a spherical shape, with a delicate chromophile framework in which a number of smaller and a few larger granules are inclosed, one of which, the largest and of a round shape, occasionally appears as a nucleolus. Chromophile Nissl substance either is present as minute granules or is more diffusely distributed over the cytoplasm of the body and larger dendrites. Outside the central area the ganglion cells form a single, almost continuous row; in the central area they gradually accumulate in several rows until, close to the fovea, they form five or six tiers. The size of the ganglion cells does not vary much, only a few somewhat larger cells being found in the extra-areal periphery scattered among the smaller ones.

The layer of optic nerve fibers in most of the retina is thin but distinct. Close to the disk it increases in thickness, amounting to as much as

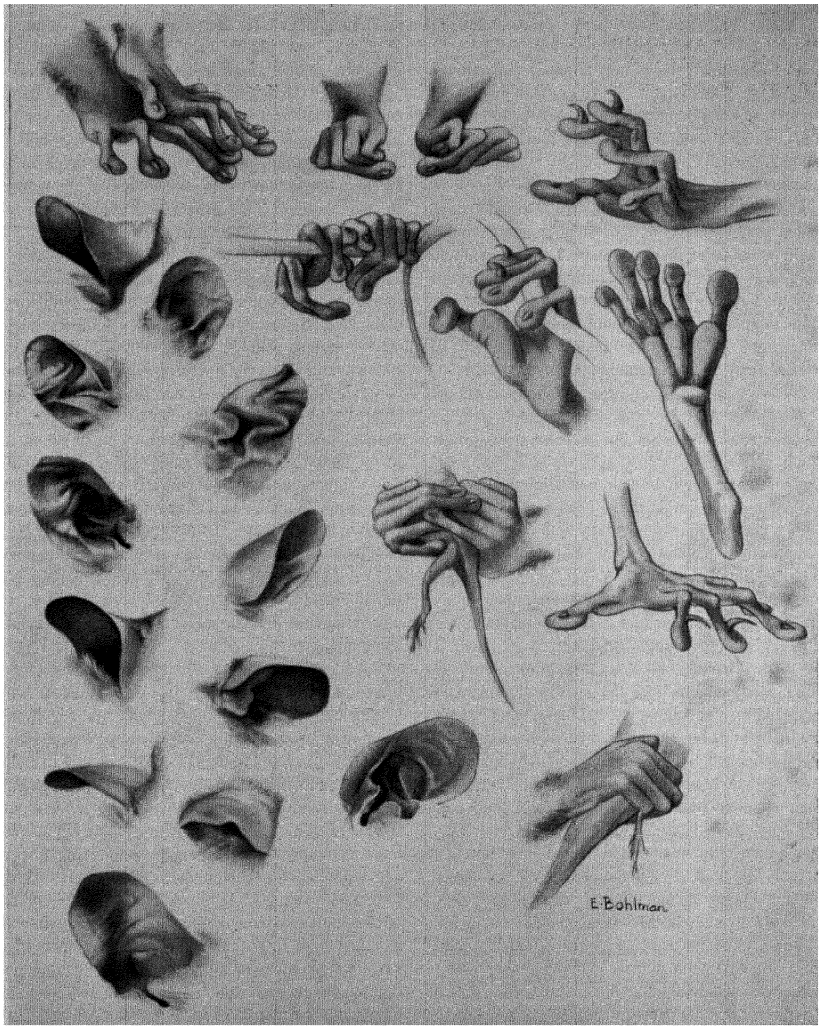

FIG. 514. Hands, feet, and auricles of a Philippine Tarsier expressive of various moods, acts, or manipulations. Hands and feet, beginning with the left upper corner: both hands as the animal sits intent and alert, while talked to; typical position of both hands when the animal is about to pounce upon a meal worm; both hands resting on a twig when the animal is at ease, though alert and interested; both hands firmly gripping the body of an Anole Lizard whose head is being held in the mouth; right hand holding a lizard during the meal; two views of the left foot, as the animal in a leisurely way climbs the side of the cage; plantar view of the left foot and its long "hock"; left foot sprawling on the ground, with its big toe abducted. Ears, from the top: right ear seen in front view while the animal was asleep; left ear while listening to gentle talk; right ear at a moment of catching a meal worm; left ear while the animal was getting ready to pounce on a meal worm; right ear expressing fear, with the head in profile; left ear while preening his fur; right ear when the animal was at rest; left and right ear as the animal pounces on a meal worm; left and right ear while eating; left ear while the animal rests, with his head in profile.

one-fourth or more of the thickness of the retinal membrane.

The neuroglia is well developed. Radial fibers of Müller are present everywhere, including the foveal depression. They are particularly conspicuous in the inner plexiform layer, whence many of them can be followed through the ganglion and fiber layers to the inner limiting membrane formed by the joining of the widened vitreal ends.

The central retinal artery and vein enter through the optic disk, whence, imbedded in the retinal substance, their branches spread over this membrane. The endothelial nuclei of the capillaries are met with in layers ventral to the outer plexiform layer. Abundant capillaries, but no large vessels, are present throughout the central area, including the fovea. In the areal periphery an occasional medium-sized vessel is found.

The chorioid membrane in the central area and fovea is thicker than outside, a feature found in all primate eyes where area and fovea are present.

Ophthalmoscopic examinations of the eyes of the living Tarsier made in our laboratory by Dr. F. S. Ryerson, of Detroit, in both ordinary and red-free light, revealed the presence of a well-developed yellow spot or "macula" temporal to the disk (*see* color Fig. 149, and *cf.* with color Figs. 148 and 165–70). This locality is distinguished by an arrangement of blood vessels typical in other primate species in which a central area and fovea are present. That is, the larger arteries and veins follow an arching course above and below the central area, in this way avoiding the locality of the retina instrumental in central vision. A small macular artery or vein may pass over, either directly from the disk or, branching off from one of the larger vessels, toward the center of the yellow spot.

The territory containing yellow pigment is large and somewhat pear-shaped, beginning almost immediately temporal to the disk and spreading laterally for about 4 disk diameters. The pigmentation is most intensive in a small, circular, approximately centrally located area about the size of the disk and 2½–3 disk diameters temporal. Small blood vessels converge from all sides toward this area, but only the terminals enter it, without, however, reaching the center, which appears to be free of all blood vessels. The pigmentation in this circular area appears to be much finer in grain than that outside it. In the very center a minute, faint, foveal light reflex was seen occasionally.

The presence of a central fovea, found ophthalmoscopically, was confirmed by the ex-

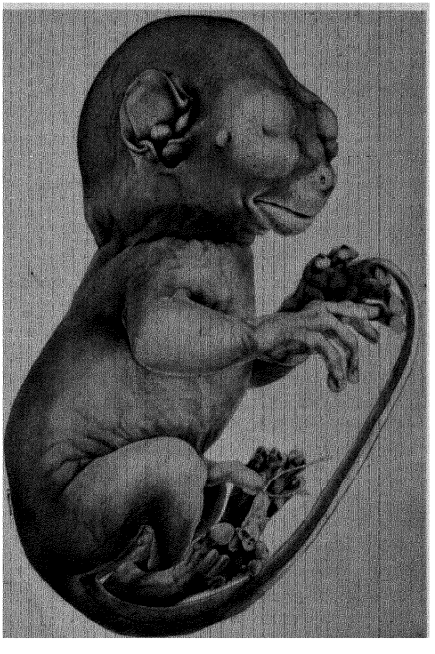

FIG. 515.—Fetus of a Philippine Tarsier during a late stage of development. Note the large size of the eyes, whereas the external auricles are still some distance from their full development.

amination of preserved specimens at slight magnification (2, 4, 8×). It was, however, the microscopic study that finally corroborated its presence and gave detailed information.

The fovea of a Tarsier is small in comparison with that found in other Primates. Its diameter is about 250–300 microns. Its small size and shallowness may be the reason that it was not found by the preceding investigator (Woollard 1925, 1926). Small though it is, it exhibits all the principal features characteristic of a pri-

mate fovea: lengthening of the photoreceptors in the center and a greater or lesser reduction of other layers (Fig. 512).

In particular, the outer limiting membrane shows a dip, or "outer fovea," in the very center, to accommodate the rods, which attain their greatest length in this locality. The outer nuclear layer is increased in the very center for about half its thickness in the immediately adjoining region, whereas the outer plexiform and the inner nuclear layers barely remain continuous. The inner plexiform layer is reduced to almost half, and in the ganglion layer a single discontinuous row of cells remains. In all three cellular layers the arrangement of the nuclei shows a slant down and away from the center. A similar slant is maintained by the fibrous constituents wherever visible, this being most conspicuous in the two plexiform and the optic fiber layers.

The arrangement of the cellular and fibrous elements indicates the process of lateral displacement, least advanced in the outer nuclear and most in the ganglion and optic fiber layers. From this it is apparent that the factors which form the Tarsier's fovea are the same as those responsible for the formation of the fovea in all other Primates and in Vertebrates in general. The only difference is the degree of the lateral displacement, which, in the Tarsier, amounts only to approximately half or less of the displacement found in the diurnal Primates and is most pronounced in the center of the human fovea, where practically all layers in front of the photoreceptors have been removed (*see* chap. V, 10, and accompanying figures).

In evaluating the physiological significance of the Tarsier's central fovea, we must first consider the photoreceptors. This layer, according to accepted histological criteria, is made up exclusively of rods. All the nuclei of the outer nuclear layer also possess features characteristic of rod nuclei of such definitely duplex retinae as those of the Rhesus Macaque, Chimpanzee, and Man. A continuous zone *5-b*, made up of relatively large chromophobe cone pedicles with the more numerous and smaller chromophile rod spherules squeezed in between, is absent in the outer plexiform layer, and zones *5-a* and *5-c* have a more uniform fibrous or granular aspect. A discontinuous row of "granular clods" of Dogiel, indicating synapses of midget bipolars with the cone pedicles, or *h* & *b* synapses, is absent in the Tarsier.

The available evidence favors the view that the only photoreceptors in the Tarsier's fovea are the rods. True to the functional purpose of the fovea, the centralmost rods in it are as thin as the building factors could have created them. Thus individual stimulability of the rods, through the reduction of rod diameter in the foveal center, and consequently acuity in night vision are increased. On the other hand, the great lengthening of the outer rod segments, hence the increase in the mass of the photosensitive substance, may be interpreted as meaning a greater increase in functional responsiveness or a lowering of the threshold in the very center. In the Tarsier's fovea we have, then, the same factors contributing to maximal visual acuity as in the diurnal Primates, but adapted to nocturnal vision.

The synapses are the next object in the functional histoanalysis. This problem cannot be solved except through well-stained Golgi preparations. Until this is done, a few general remarks must suffice. What the synaptical relationships of cells making up the inner nuclear layer are, may only be guessed. If the true cones are absent, it is probable that the well-differentiated midget bipolars are also absent. The true midget ganglions, which form such a conspicuous feature in the diurnal Primates (Macaque, Chimpanzee, Man), are likely to be absent also. But whatever the particular variety of the ganglions in the Tarsier's fovea, their synapses must be considerably restricted in space, almost individualized, in order that their great numbers may be used adequately.

The great number of ganglion cells in the fovea and its immediate vicinity permits the assumption of the presence of at least 10,000 functional units in this locality. These, together with the units in the remainder of the central area, represent a formidable apparatus making for a high degree of visual acuity. In any case, the number of ganglion cells, if the majority of these are capable of an independent response (as they are in the fovea of the diurnal Primates), would permit a high degree of physiological resolution probably approaching the maximum possible under conditions imposed by

scotopic vision. That this is somewhat below the maximum of the most developed photopic vision of Primates is understandable. The dimensions of the Tarsier's fovea, smaller than those in a Rhesus Macaque, would indicate this.

Another Primate adapted to a nocturnal life, in which a central area and fovea have been found, is the South American Night Monkey (*Nyctipithecus* or *Aotes trivirgatus*). According to reliable unpublished investigations of Dr. H. Klüver, visual acuity and form vision in this species are not much below human. It was, therefore, of special interest to compare the dimensions and structure of the fovea of the Night Monkey, on the one hand, with those of the nocturnal Tarsier and, on the other hand, with those of the diurnal Primates, Man, Rhesus Macaque, and Chimpanzee.

The central fovea and area of the Night Monkey show features essentially similar to those in the Tarsier, with, however, certain peculiarities. The area is larger, the fovea shallower, the bacillary layer thinner. The diameter of the area measures about 2,500 microns, or 2.5 mm. across; that of the fovea, 600–700 microns, or 0.6–0.7 mm. The thickness of the photoreceptor layer in the fovea is from 63 to 70 microns, with a slight dip of the outer limiting membrane in the very center. Other peculiarities are: the bacillary layer, as in the Tarsier, is composed exclusively of rods, the outer nuclear layer showing ten tiers in the center, and twelve tiers outside the fovea, with all nuclei exhibiting characteristic rod appearance and uniform arrangement, while the typical cone nuclei are absent; the outer plexiform layer in the very center is very thin, increasing outside it to 40 microns and showing three well-differentiated zones in the central area—*5-a* (fibrous, with a slant away from the center), *5-b* (dark, granular, but with cone-pedicles absent), and a thin and poorly structurally differentiated zone *5-c;* the thick inner nuclear layer, measuring 100 microns outside the fovea, is reduced to 30 microns in the very center; the inner plexiform layer, finely granulated, is 35–40 microns thick outside the fovea and in the very center is reduced to 20 microns; the ganglion layer, consisting of three tiers outside the fovea, is reduced to a single continuous tier in the foveal center.

The rods of the Night Monkey, as of the Tarsier, are thinnest in the foveal center, their thickness being reduced here to 1 micron or less, with the intercenter distances measuring 1.5 microns. Approximately 400 rods could be counted along the foveal diameter of 600 microns. The total number of the foveal rods, computed on this basis, would be from 150,000 to 200,000.

The general conclusion which may be drawn from the preceding structural peculiarities and considerations is that a Primate, in adapting himself to a nocturnal mode of life, may achieve a degree of visual acuity and over-all utilization of the visual stimuli comparable with the best achieved by the members of the same order adapted to the photopic habit. The limitations of scotopic vision appear to be chiefly in hue discrimination, whereas visual space perception, notably acuity, seems to be less affected.

10. THE OPTIC NERVES AND THE VISUAL PATHWAYS AND CENTERS OF THE BRAIN.—The optic nerve of the Tarsier is a symmetrical cylinder, circular in shape on cross-section and 1.5 mm. in diameter. It is relatively rich in fine and very fine fibers, with only a few coarser ones interspersed, while very coarse ones are entirely absent. The caliber of most fibers measures from 1 to 2 microns only, a few even less, with some 3 microns thick and almost none thicker. The total estimated number of fibers is at least 150,000, approaching 200,000. Even this figure, because of the difficulty of counting, may fall far short of the actual number.

The chiasma is remarkable because of the great number of fibers which do not decussate. The nondecussating fibers, according to a rough estimate, may amount to at least one-fourth, and possibly to as much as one-third, of the total. Any certainty of this, however, can be had only through experimental evidence, preferably by the employment of the Marchi method of staining.

The brain of the Tarsier, primitive though it is, definitely bears marks common to all Primates (Figs. 516–18; *cf.* Figs. 270, 279, 280, 282, 284, 306, 307). These marks are the three distinct lobes of the great cerebral hemispheres: frontal, temporal, and occipital.

For the size of the animal, the brain is rela-

tively large. Its dimensions are: total length from the frontal to the occipital poles, 16 mm.; from the frontal poles to the summit of the cerebellum, 17.5 mm.; and across the two great hemispheres in the widest place, 17.5 mm.

The squat shape and the location of the brain in the posterior half of the head are caused by the inordinate size of the eyeballs. Because of this, the brain is pushed back and compressed, just as the facial part of the skull is squeezed and pushed down by the huge orbits. These changes have been made by the same temporal lobe is much the thicker. The occipital lobe has the shape of a broad, curved, but quite attenuated, spoonlike plate. A sharp, deep dent —the primordium of the lateral fissure of Sylvius—separating the frontal from the temporal lobes, provides enough space to accommodate the fundus of the huge orbits.

The external surface of the brain is typically lissencephalous or smooth, except for a delicate filigree of shallow furrows in which the blood vessels are lodged. On the inner face of the occipital lobe, overhanging the midbrain and cere-

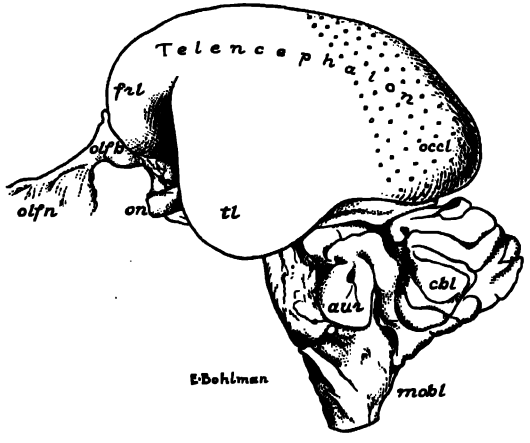

FIG. 516.—Brain of the Philippine Tarsier in a lateral view, 4× magnified. Note the relatively enormous development of the temporal (*tl*) and occipital lobes (*occl*), which is in line with the extraordinary development of the auricles and eyes, both being indicative of a highly specialized mode of living, with nocturnal adaptation of sight and hearing. The olfactory apparatus, becoming of secondary importance, is reduced. The striate area stippled with circles. *Labeling: aur*, cerebellar auricle; *cbl*, cerebellum; *frl*, frontal lobe; *mobl*, oblong medulla; *occl*, occipital lobe; *olfb*, olfactory bulb; *olfn*, olfactory nerves; *on*, optic nerve; *tl*, temporal lobe.

mechanical factor that determines the configuration of the head and brain of the Birds, most of which also have large eyes (*see* Figs. 469, 470, 471). Another contributory factor may have been the center of gravity of the body and of the head, important in a leaping animal. It is the same factor which caused the shortening of the brain of the Insectivorous Bats (Microchiroptera), in spite of their diminutive eyes.

The cerebral hemispheres can be roughly subdivided into three lobes, with little substance to spare. The beak-shaped frontal lobe (*frl*) is the smallest, the larger temporal (*tl*) and occipital lobes (*occl*) representing the bulk. The bellum, is a deep furrow resembling the letter Y. The posterior limb of that furrow is the orimental or incipient calcarine fissure, the principal landmark indicating the visual cortex of the Monkeys, Apes, and Man (*c* in sketch *E*, Fig. 279; *cf. also* Figs. 306 and 307; *see also* Woollard 1925). The two frontal limbs facing the corpus callosum are the arcuate or hippocampal sulci. Along the lower face of the temporal lobe an irregular furrow is found that has yet to be identified. The corpus callosum reaches back only as far as midway of the longitudinal extent of the hemispheres.

The olfactory bulbs (*olfb*) are small and are

almost completely overhung by the frontal lobes. They resemble small, triangular, flattened seed kernels standing vertically, side by side, along the mid-sagittal plane. From the anterior angle of each bulb a single, thin, flattened olfactory nerve arises (*olfn*). The two nerves, closely attached to one another, coursing between the two orbits, enter into the posterior upper corners of the small nasal cavities whence they take their origin. The inferior-posterior extremity of each olfactory bulb gradually attenuates to become the olfactory tract that connects with the rest of the brain.

The principal parts of the brain concerned in vision are the same as in the Monkeys, Apes, and Man: the lateral geniculate nuclei, the superior colliculi, and the striate areae of the cerebral cortex. Whether there are any hypothalamic connections remains a problem to be further investigated.

Both geniculate nuclei—the lateral and the medial—are proportionately quite large. The lateral geniculate, where it is best developed, on coronal sections represents at least one-fifth and perhaps as much as one-fourth of the area of the entire betweenbrain. It is made up of a larger dorsal laminated nucleus and a smaller ventral or "pregeniculate" nucleus. The dorsal nucleus is composed of somewhat larger cells of various sizes arranged in contorted laminae resembling the superior olive, whereas no distinct lamination is recognizable in the ventral nucleus. The lamination pattern is complicated, requiring further careful study and interpretation. This is especially necessary in determining which of the laminae belong to the ipsilateral homonymous halves of the fields of view, and which to the contralateral. This problem may best be investigated experimentally, with the removal of one eye and a subsequent examination of Nissl-stained sections through both geniculate nuclei. The exact number of the laminae also remains to be determined. It appears probable, however, that there are at least two, and probably as many as four, cell laminae.

The ventral geniculate nucleus consists of slightly smaller and paler cells when stained by the Nissl method. It is best developed on anterior oral levels. Its cells and fibers are continuous with the subthalamus, the subthalamic connections apparently predominating. This, in view of the nocturnal habit of the Tarsier and, in this connection, of the importance of the pupillary function and accommodation, may be of significance. (*See* chap. VI, 10.)

The medial geniculate nucleus is also quite well developed. Its cells and fibers are very clearly organized into laminae and groups, according to a special pattern to be further worked out. In view of the acute sense of hearing in the Tarsier, this is understandable.

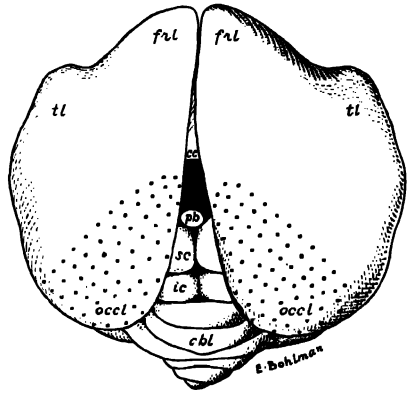

FIG. 517.—Brain of the Philippine Tarsier seen from above, with both hemispheres slightly separated in order to show the midbrain colliculi and other parts normally not visible, since they are overhung by enormously expanded occipital lobes. The striate areae marked with small circles. *Labeling: cbl*, cerebellum; *cc*, corpus callosum; *frl*, frontal lobes; *ic*, inferior colliculi; *pb*, pineal body or gland; *sc*, superior colliculi; *tl*, temporal lobes.

The colliculi of the midbrain are likewise well developed (Figs. 517, 518). However, the gray cap of the superior colliculus is much thinner and structurally less elaborate than in the species where the midbrain predominates (Rodents, also Tree Shrews). In agreement with this, the number of optic nerve fibers terminating here is but a fraction of those entering the lateral geniculate nucleus.

The inferior colliculus is proportionately large and rich in nerve cells. These in part are arranged into layers, indicating an elaborate organization of this internode of the auditory system.

The oculomotor nerve and nucleus are surprisingly large. In fact, the entire gray sub-

stance lining the Sylvian aqueduct of the midbrain is thick and elaborately differentiated into numerous cell nests, made up of nerve cells of various sizes, shapes, and staining properties. Whether this is because of the well-developed parasympathetic functions of the eye, indicated by a large iris, and probably also because of accommodation, as might be expected with such strongly adapted nocturnal vision, or because of the presence of the central area and fovea remains a problem to be solved by future investigations.

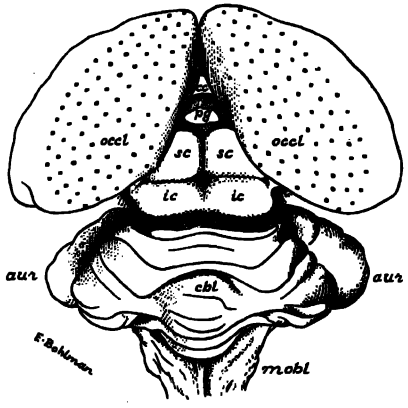

FIG. 518.—Brain of the Philippine Tarsier in back view, showing also the midbrain colliculi between the separated hemispheres. The striate areae marked with small circles. *Labeling: aur*, cerebellar auricle; *cbl*, cerebellum; *cc*, corpus callosum; *ic*, inferior colliculus of midbrain; *mobl*, oblong medulla; *occl*, occipital lobe; *pg*, pineal gland; *sc*, superior colliculi of midbrain.

The lower auditory centers, represented by the dorsal and ventral nuclei of the acoustic nerve, were found to be large, their cells indicating stratification and folding of the layers—all testimony to the excellence of the sense of hearing. (*Cf.* S. Poljak, J. f. Psychol. u. Neurol., v. 32, p. 170, 1926.)

The cerebellum (*cbl*) is fairly well developed, although it has perhaps a more primitive aspect than in the Tree Shrew (*cf.* Figs. 490, 491). Its two hemispheres extend considerably in the lateral direction, though less so than the auricular portions. As in the Higher Primates, the occipital lobes of the great brain, extending far backward, almost completely cover the cerebellum from above.

The striate areae of the occipital lobes or those parts of the cerebral cortex in which fibers of the visual radiation conducting impulses from the homonymous halves of both retinae terminate are relatively very large.

The location and the general structural makeup of the striate area are similar to those of the other Primates. There are, however, features peculiar to the Tarsier. Possibly the most outstanding is its relatively enormous extent. Examined in a continuous series of Nissl-stained coronal sections, the area stretches from the occipital pole to midway between the latter and the frontal pole. However, it is oriented somewhat differently than shown in Woollard's diagram (*see* Fig. 279, sketch *E*).

The striate area, on the basis of our own study, resembles a long flat cap, similar to, but proportionately larger than, that in the Tree Shrew, determined by Le Gros Clark (sketch *C* in same figure). Its ventrolateral boundary, instead of being vertical, however, slants. Hence the area extends anteriorly much farther along the dorsal margin of the hemisphere than posteriorly, where it envelops the entire occipital lobe only as its pole is approached. Most of the lateral face of the hemisphere above the temporal lobe, accordingly, does not belong to the striate area (stippled in Figs. 516, 517, 518). Even so, a substantial portion of the pallium or cerebral cortex, roughly amounting to one-fifth or more, is visual.

The boundaries of the striate area where it passes over into surrounding areae are, in histological sections stained with Nissl–toluidine blue, quite sharp, the transition abrupt. It is an area richer in nerve cells than the extrastriate areae. It is elaborately differentiated into layers and sublayers in the same way as in the Monkeys, Apes, and Man. The notable feature is the splitting of the inner nuclear layer into three sublayers, the thinner outer *4-a* and the much thicker inner sublayer *4-c*, both filled with numerous "granules," and an intermediate zone *4-b*, less rich in cells, in which a few outer solitary cells of Meynert are found. The inner and larger solitary cells are located in layer *5*, which, as in other Higher Primates, is less rich in cells. Even finer distinctions may be identi-

fied as, e.g., *4cα* and *4cβ*, suggesting an advanced structural and functional differentiation. The details, as well as the synaptical organization, must remain a problem for future research.

In summary of the most important facts of the visual system of the Tarsier, it is no exaggeration to say that it is relatively more indicative of the supremacy of the sense of sight than in any other Primate of which we have sufficient knowledge. The Tarsier's huge eyeballs and extraordinarily developed subcortical and cortical centers of vision indicate this. The retina, with its multitude of extremely delicate rods and absence of cones, indicates complete adaptation to the nocturnal mode of life in which color vision is abolished. In spite of this, the visual acuity of the Tarsier, because of its possession of a small, but well-organized, fovea and yellow spot and a fairly thick optic nerve, may be assumed to be rather high. The partial decussation in the chiasma, in turn, may indicate an organization of the visual pathways and centers of the brain which, together with the frontal position of almost immobile eyes, indicates a high degree of tridimensional binocular stereopsis. Finally, the extraordinary size of the striate areae, together with the relatively small size of the superior colliculi, may be interpreted in the sense of a preponderance of cortex over the lower, mesencephalic, centers in the visual apparatus. Briefly, more than any other Primate, the Tarsier is a "visual animal."

11. Relative importance of the Tarsier's senses.—The comparison of the brain of the Tarsier (Figs. 516, 517, 518) with that of the Elephant Shrew (Figs. 480, 481), the Philippine Tree Shrew (Figs. 490, 491, 492), and the native Short-tailed Shrew demonstrates the extent of the reduction of the olfactory system in the Tarsier. The olfactory bulbs of the Tarsier represent hardly more than a fraction of the mass or volume of the same bulbs in the Tree Shrew, perhaps 5 per cent. Even in comparison with the *Blarina*, a much smaller animal, the Tarsier's olfactory bulbs may amount to hardly more than one-fifth. The great difference in the size of the olfactory centers in these species is related to the varying size of the nasal cavities. In the *Blarina* the length and width of the cavities is double the nasal cavities in the Tarsier, a much larger animal.

These anatomical facts merely confirm the extent of the reduction that the olfactory sense suffered in the Tarsier. This reduction is caused by the extraordinary development of the Tarsier's vision, which in the micropic Soricide Shrews, with their keen sense of smell, plays but a minor role. The Elephant Shrews and the Tree Shrews maintain an intermediate position in this respect. The behavior of the Tarsier and of the Tree Shrew confirms this, in that the Tarsier was never seen to use its sense of smell in testing food, whereas the Tree Shrew used it regularly.

The deductions concerning the faculties of the Tarsier that can be made from the study of its brain and sense organs are almost self-evident. From the diminutive size of the olfactory centers it is safe to conclude that the sense of smell in this suborder plays an insignificant role, apparently even more so than in other advanced Primates: Monkeys, Apes, and Man. The well-developed subcortical centers of sight and hearing, the fact that at least one-fifth of the pallium or cortex of the cerebral hemispheres is directly related to vision and probably as much to audition, are all self-explanatory. This all agrees with the inordinate development of the externally visible peripheral organs of these two senses—the eyeballs and the auricles.

The only question that could reasonably be raised concerns the supremacy of sight over hearing. Obviously, an answer could be given only after a thorough observation of the Tarsier in its native habitat and upon valid experimental evidence. The presence of a large yellow spot and a well-developed central area, with a well-formed, though small, central fovea; converging lines of vision; and a partially decussated chiasma, in opposition to the opinion of some recent investigators (Elliot Smith, Woollard, Tilney), favor the view that the tridimensional stereoscopic sense in the Tarsier is not absent but is, in fact, quite well developed. This is the more remarkable, since its retina is that of an entirely nocturnal animal.

The stereopsis of the Tarsier shows that this sense is not necessarily restricted to the diurnal animals but is also compatible with a nocturnal

mode of life, depending on the degree of perfection of vision (the Cats and the Owls are a good example of this).

The behavior of the Tarsier observed during life shows that it possesses a keen sense of sight, good visual memory, accuracy in gauging the distance and direction of its leaps when catching its prey; that its various motor actions, such as moving the head, eyes, auricles, and upper extremities in perfect harmony with the movements of the trunk and of the hind extremities are well co-ordinated, and all guided by sight, as described in subsections 4–7 of this section. All this favors the view that the sense of vision in all its manifestations, except color perception, has apparently been brought to the highest state of perfection compatible with the nocturnal mode of life in this suborder.

In its dependence upon the two higher senses, especially sight, the Tarsier is like the rest of the true Primates, whether they are chiefly nocturnal, as are the Lemurs, or almost entirely diurnal, as are the Monkeys, Apes, and Man.

12. The Tarsier and the problem of the origin of Primates.—In the attempts to answer the following questions—Which of the Early Mammals first showed bodily features characteristic of the true Primates? What were the external factors influencing the evolution of the Primate Ancestors? And how and why did their organism react in the particular way that resulted in primate evolution?—the Tarsier has played a conspicuous role.

The reason for the intensive interest in this suborder is the fact that even superficial observation reveals the true primate nature of the Tarsier. Its numerous other characteristics, on the other hand, link it with the phylogenetically older Order of Insectivora. Again, while it resembles the more primitive Lemuroidea in many ways, in others the Tarsier appears close to true Monkeys and Apes (Pithecoidea or Anthropoidea), owing to which an intermediary suborder, Tarsioidea, has been established. Finally, in paleontological chronology, the Tarsiers and the Lemurs appeared as early as the Paleocene (*ca.* 50–60 million years ago) and Eocene (*ca.* 35–50 million years in the past). This indicates that the Tarsiers preceded the true Monkeys, which developed, probably from a primitive, nonspecialized tarsioid stock, by the beginning of the Oligocene Epoch, 30 million years ago.

The Tarsier, in the words of G. Elliot Smith, "is a remarkably generalised creature which in many respects is akin to the Menotyphlous Insectivora [Tree Shrews], and has persisted with extraordinarily little change from the beginning of the Eocene period," or about 45 million years ago. Yet every part of its anatomy, according to Smith, "reveals its affinity to the higher Primates and affords evidence of its differentiation from the Lemuroidea."

Some of the extinct Tarsioids, known as Anaptomorphidae, particularly *Tetonius* of the American Lower Eocene (*ca.* 45 million years ago), had a skull whose general structure was "quite similar to that of the living *Tarsius*, with a very short face and huge, forwardly turned orbits . . ." while the older forms, e.g., *Necrolemur* of the Upper Eocene of Europe (30–35 million years ago), quite properly, "appear to have been rather more lemur-like, with a somewhat less reduced snout" (Romer 1945).

The brain of the Tarsier, according to Cope (1885), also resembles that of the extinct Anaptomorphidae, which he believed were the most simian Lemurs yet discovered, and probably represented the family from which the Higher Monkeys, Apes, and Men derived. Notable authorities, such as Gregory (1922) and Simpson (1950), however, have raised a voice of dissension in the chorus glorifying the Tarsier as a close kin of Man, and admit at most a very remote common ancestry of both.

The intermediate position of the Tarsier in primate evolution, according to Woollard (1925), is manifested by the following anatomical peculiarities: (1) Primitive—smooth brain, small corpus callosum, large ventral commissure, simple subdivision of cerebellum resembling that found in the Marsupials, a large third eyelid containing a plate of cartilage, a well-developed Harderian gland, and alimentary viscera that are of the simplest among the Mammals, approaching in this respect those of the Reptiles and Amphibians. (2) Lemurine—arrangement of the cortical areas, absence of a pigmented macula, "specialisation of vision, the nocturnal habits, and a general retinal pattern of the nocturnal type" (the second statement

concerning the absence of a "macula" and of a foveal excavation is obviously an error; *see* par. 9, this section). (3) Anthropoid—reduction of the face, eyes directed forward, erect posture, orbits almost completely separated from the temporal fossa, facial muscles highly differentiated. "With all the evidence of its anatomy marshalled," Woollard somewhat incongruously concluded, "there can be no doubt that *Tarsius* is a Lemur of the Lemurs and is annectant to the early Eocene primitive placentals, and that standing at the base of the Primate stem it reaches forth to the Simian forms and is annectant to the Anthropoidea."

The information so far mentioned indicates the great antiquity of the Tarsiers. This view, in the light of available evidence, seems reasonable, whether or not the Tarsier is to be regarded as "the oldest mammal inhabiting the earth, since no other mammalian form of the Eocene period is now extant" (Fulton 1939). As soon, however, as an attempt is made to evaluate definite anatomical features of the Tarsier and to try to estimate the probable factors that have been in play in primate evolution, the difficulties and contradictions become apparent.

"*Tarsius*," according to G. Elliot Smith (1919), "represents the phylum whose progress was brought to a sudden stop in Eocene times by an over-development of, and an exaggerated reliance upon, those specialisations of vision and its cerebral instruments which were responsible for the differentiation of the Tarsioidea from the Lemuroidea, and gave impetus to those developments which produced the Anthropoidea from one of the Tarsioid families. But *Tarsius* was able to escape extinction only by adopting the safe nocturnal habits which also played a part in sparing the Lemuroidea." In other words, the Tarsier is the result of a scotopic specialization of sight beyond the level reached by the Lemurs, which, in turn, had precluded any further progress, although by this specialization it saved itself from extermination. Other members of the Tarsioid suborder were more fortunate in remaining diurnal. By doing so, they became modern Monkeys, Apes, and Men.

13. Adverse effect of nocturnal adaptation on further evolution of the Tarsier.—The thesis of an adverse effect of nocturnality upon the evolutionary progress intended eventually to lead toward the anthropoid stage is quite plausible. Unquestionably, the wealth of information about the external world gained under scotopic conditions in all respects—acuity, color, stereopsis, and range or distance—is much poorer, being partly or entirely abolished, compared with daylight vision. What remains doubtful is the course of the phylogenesis. The incompleteness of our information about the visual apparatus of the Lemurs does not permit us to speculate logically about this, however.

To judge from G. Elliot Smith's statement, both the Lemurs and the Tarsiers were originally diurnal and became nocturnal when competition by the diurnal animals of prey exceeded the limits of their tolerance. Whether or not this was so there is no way of judging. If, however, a well-developed central area and fovea are instruments of diurnality, both the Asiatic Tarsier and *Aotes* of South America would have to be considered forms of originally diurnal animals, since both possess a well-developed fovea, which secondarily became adapted to the nocturnal way of living.

This view is supported by the pronounced diurnality of all Tree Shrews (with the exception of the Pen-tailed Shrew), which preceded all these suborders of the Primates, the Lemurs, Tarsiers, and Monkeys. The presence in *Urogale* of an orimental or incipient central area agrees with this.

Important as the inherent phylogenetical tendency is, however, functional requirements and adaptations are also to be considered. In many cases the functional demand may have exerted pressure upon the plastic potentialities of bodily organization greater than the long-range factors inherited from the past. The visual apparatus of the Owls and Swifts may serve as an example. Here a new posterior or temporal fovea was created in response to the emphasis on high acuity and binocular vision. This structure is functionally motivated exactly in the same way as is the similar posterior or temporal fovea of the diurnal Hawks, Eagles, and Swallows, whereas an anterior or central fovea, important in all diurnal species, was abolished as useless in the Owls. Again, in the Domestic

Cat—an animal of pronounced nocturnal habit, but with both eyes almost facing anteriorly and obviously used stereoscopically—a well-formed central area is found, even though no certain fovea is present.

To conclude, the nocturnality of the Tarsier appears as a secondary adaptation, a "flight into the night," of an originally diurnal form. In its striving to adapt itself to the new mode of life, the Tarsier has gone as far as circumstances permitted by preserving its original diurnal central area and fovea and by adapting it and itself to the nocturnal habit.

14. PROBABLE FACTORS RESPONSIBLE FOR THE TARSIER'S NOCTURNAL ADAPTATION AND ITS EVOLUTIONARY STAGNATION.—What the actual biological factors were which exerted the phylogenetical pressure that brought about a change in the mode of the Tarsier's life during the Paleocene (60 million years ago) and Eocene (40 million years ago) can only be guessed. The Pterosauria or Flying Reptiles of the Jurassic and Cretaceous Periods, lasting from 60 to 150 million years in the past, and the Dinosaurs had died out by that time. But the large-toothed Birds of those times, some of formidable size, as, for example, *Hesperornis*, armed with a beak 10 inches long, and the smaller *Archaeornis*, and *Archaeopteryx*, and their kin, may still have lingered during the early part of the Tertiary Period to make life miserable for the small and largely helpless Early Primates.

There were, in addition, numerous predaceous terrestrial Reptiles in the Late Cretaceous Period, contributing to the complex scene. From what can be judged from the size and position of the orbits and scleral rings of the Early Birds, it appears that they were diurnal predators. When, during the Cretaceous and early part of the Tertiary Period, more modern birds began to appear, many of them retained the predatory habits of their predecessors. They, too, seem to have been largely diurnal in their habits. Most conspicuous among them were the giant flightless *Phororhacos* of the Miocene Epoch of South America (from 10 to 25 million years ago) and the *Diatryma* of the Eocene Epoch of North America and Europe (from *ca.* 25 to 40 million years ago).

The Falconiform Order, which includes well-flying diurnal Birds of Prey such as the Falcons, Hawks, Eagles, Ospreys, Buzzards, and Vultures, appeared later on the phylogenetical scene. This order may therefore have exerted a powerful influence upon the nascent Primates and may have been partly responsible for their complete disappearance from North America by the end of the Oligocene Epoch (*ca.* 30 million years ago).

Even more important may have been the early terrestrial carnivorous Mammals, such as the Creodonts, some of giant size, which lived during the Paleocene and Eocene Epochs (from 30 to 60 million years ago) and the more modern Miacids of the Late Eocene and Oligocene Epochs (from 25 to 35 million years ago). These subsequently became transformed into extinct and living Fissipedes: Civets, Weasels, Dogs, and Cats. Themselves partly arboreal, these ancient Carnivores may have been a potent inducement to some of the Insectivores to take refuge in the trees.

In the further course of evolution these arboreal Insectivores either became Primates or, in the Paleocene (from 50 to 60 million years ago), took an additional and final step in their striving to emancipate themselves from the burdens and deprivations of terrestrial existence and found safety and abundance in the air as Flying Foxes (Megachiroptera) and Bats (Microchiroptera). The Strigiform Order of Birds, the Owls, present during the entire Tertiary Epoch (since 60 million years ago), may have been another important factor in the ecological pressure that resulted in primate evolution.

15. TERRESTRIAL INCEPTION OF THE INSECTIVOROUS PHASE OF PRIMATE EVOLUTION.—The picture that one may draw of the probable beginnings and course of evolution of the Primates is necessarily tentative. The initial stage was represented by the terrestrial Insectivorous Mammals of the Upper Cretaceous Period, which lived from approximately 60 to 90 million years or more ago. They may have resembled in size and appearance some Soricide Shrews (Figs. 475, 476) or even more the Malayan Gymnurinae (*see* Brehm's *Tierleben*, v. 10, p. 347). Living almost exclusively on the ground, in shady undergrowth and in dense vegetation, they sub-

sisted on low forms of life, such as worms, insects, slugs, and the like which they were able to master. In their obscure habitat they found not only an abundance of food but also shelter from the big carnivorous beasts that ruled the world during that epoch.

Their most important distance receptor in such circumstances was the sense of smell, closely collaborating with the senses of touch and gustation. Sight, in general well developed in the Reptiles, of small use in a life close to the ground, where the view is obstructed by a mass of vegetation, receded to a poorly differentiated, though not meaningless, photophobic "warning sense." The other distance receptor, hearing, was retained and further developed. The reason was that hearing reacted to sound waves, which, unlike the rays of light propagated in straight lines, are capable of "turning around the corner."

Thus adapted for a life in obscurity, the Early Insectivores were admirably equipped for the "struggle for survival." Of this their little-changed modern descendants are a living testimony (*see* section on Common Shrew, this chapter). They and their kin, without glory or glamour, have existed these past hundred million years or so, while the mighty Dinosaurs of the Cretaceous Period have vanished. (One may pertinently ask whether the Early Insectivores were, perhaps, a prime agent in bringing about the downfall of the big beasts upon whose unprotected eggs and young, led by their efficient sense of smell, they may have preyed.)

Thus the Insectivores would have gone on without change for untold ages. Following the tendency of all living beings to expand, however, the various strains of the Insectivores embarked upon a conquest of other realms. Of these, several possibilities offered themselves: an underground, an aquatic, an arboreal, and an aerial existence. Each of these habitats was successfully invaded. The Talpidae or Moles and to a lesser degree some Soricidae went underground, with the resulting further reduction of sight and the overdevelopment of senses which work at close range. The Potamogalidae, or African Otter Shrews, and some of the Soricidae, such as the American Water or Marsh Shrew (*Neosorex palustris*) and its Old World counterpart (*Neomys fodiens*), and the curious Desman or Výchuchol (*Myogale* or *Desmana moschata*) of southeastern Europe and Central Asia have become aquatic.

16. Arboreal life and the origin of Primates.—The adaptation to the arboreal life of those Insectivores later to become either Primates or Chiropterans must have occurred prior to the earliest Tertiary Epoch, the Paleocene, that is, sometime during the later part of the Cretaceous Period of the Mesozoic Era (about 60–80 million years ago or earlier). The reason for thinking so is the paleontological discovery, according to Romer (1945), of skeletons of Insect-eating Bats with well-developed wings in the Middle Eocene deposits both in Europe and in North America whose approximate age is 40 million years. The ability to fly, accordingly, must have developed sometime during the Paleocene Epoch, 50–60 million years ago, and must have been preceded by an adaptation to arboreal life. This again agrees well with the appearance of both Lemurs and Tarsiers as early as the Paleocene (from 50 to 60 million years ago) and certainly during the Eocene Period (estimated to have lasted from 40 to 50 million years ago).

The arboreal habit developed by the Late Cretaceous Tree Shrews was one of the two possible ways to leave the obscurity and semi-nocturnality of the underbrush and to acquire a freer view of the surrounding habitat. The other way was to increase in size and strength, to develop offensive and defensive weapons, to perfect terrestrial locomotion, to widen the range and improve the quality of distance receptors—sight and hearing—and to add all other possible anatomical equipment for eluding or fighting aggressors or to overcome the resistance of prey, as the case may be. This road was taken by the majority of the Orders of Mammals. A classical example is the Horse, which evolved from a diminutive ancestor not larger than a fox terrier, the *Eohippus* of the American Lower Eocene (roughly 40 million years ago), gradually increasing in size to a giant *Megahippus*, approximating a Rhinoceros, a species which lived during the Pliocene Epoch, which lasted from 1 to 10 million years ago.

17. Changes in bodily equipment of the Primates caused by arboreal life.—Arboreal life, except for flying, was the only way to rise above the ground and thus to increase the range of view, to survey the surrounding territory better, to escape powerful enemies, and to reach the source of more abundant food. It required the adaptation of the limbs to climbing, the reorientation of the senses to new conditions, and a corresponding change in the integrating central organ—the brain.

Efficient claws were already present and were used first. This mode of progression has been retained until the present by the modern Tree Shrews and was developed to perfection by another group of arboreal Mammals, the Squirrels, which appeared during the Miocene Epoch (from 12 to 25 million years ago; *see* preceding section).

During this process of adaptation and apparently within a relatively short space of time, some of the arboreal Insect-Eaters developed the habit of grasping boughs or twigs with their digits, instead of digging with their claws into the bark (such incipient use of fingers to grasp objects is already observable in the Squirrels). The fingers and toes lengthened, they became more flexible, and their neuromuscular use more supple and varied, especially by the development of opposability of the thumb and the big toe. In this way, one must assume, efficient prehensile digital instruments developed. At the same time the original claws gradually flattened into shields protecting the terminal phalanges, thus giving better support to their pads when an object was being held.

Of all these changes, the opposability of the thumb to the remaining digits of the hand was of first importance. It not only increased and diversified the grasping ability of the hand but emancipated one hand from the assistance of the other. The thumbless Squirrels, for example, can use their hands very well to hold and efficiently manipulate a walnut or an acorn, but they are not able to do so except by the use of both hands. With an opposable thumb, however, a Primate has acquired a pincer- or tong-like hand which can hold objects unassisted by the other hand, thus increasing many times the usefulness of the hands. The Tarsier in this respect has advanced little beyond the Squirrel, while many Monkeys have again reduced the usefulness of the thumb or have lost it altogether.

The foregoing basic changes in the anatomy and function of the limbs must have occurred quite early in primate evolution, apparently not later than during the Paleocene Epoch (from 50 to 60 million years in the past). It was at that time that the true Lemurs and Tarsioids appeared, followed later by the Monkeys during the Oligocene Epoch (from 25 to 45 million years ago).

Simultaneously with these changes in the limbs, a veritable revolution must have taken place in the senses during the early phase of adaptation to arboreal life. Whereas the insectivorous Soricide Shrews are largely scotopic, the omnivorous tupaiide Tree Shrews have developed a pronounced diurnal habit, of paramount importance in an arboreal existence which requires the sense of sight to be fully developed and utilized. A diurnal habit was the prime factor, then, in enabling one branch of the early Insectivores to assume an arboreal existence, and as such it remained important until the present.

Evidence of this is found in the fact that most Primates, extinct and modern, except Humans, live in the trees. In the past, as now, trees meant safety, relative, if not absolute. This must have been true in spite of the many Birds of Prey, which included such forms as the modern Monkey-eating Eagle of the Philippines (*Pithecophaga jefferyi*), and in spite of the fact that the Strigidae, or Owls, have been making the nights unsafe at least since the beginning of the Tertiary Epoch. But, more important, trees were the source of food, especially in the tropics, which appear to be the real homeland of the Primates.

18. Diurnality, the prime factor in progressive primate evolution.—The fact that all Primates, from the earliest of which there is a paleontological record to the modern ones, show either a pronounced adaptation to arboreal life or derive from arboreal forms is evidence that the arboreal habit was a prime factor in their origin. Diurnality also was of equal importance in progressive primate evolution. Of the now living Primates, the advanced Pithe-

coidea, or true Monkeys, with few exceptions are expressly diurnal, whereas nocturnality has been retained—or rather redeveloped—only by the backward Lemurs and the conservative Tarsiers.

The flight of the Lemurs into night's darkness, evidently as a means of preventing their extinction, even in their principal home, the Island of Madagascar, where they are confronted with relatively inefficient competition, is rather remarkable (*cf.* J. Sibree 1915). In other parts of the world, as in Africa and on the mainland of southeastern Asia, where the competition is stiff, the few remaining forms, such as the Galagos, Pottos, and Lorises, exist only by sufferance.

The same may be said of the Tarsiers: they, too, have survived only on the secluded islands of the East Indies and in the Malayan Peninsula, which may well be compared zoögeographically with an island. Both the existing Lemurs and the Tarsiers appear as evolutionary flotsam left along the outskirts of the great regions where a dynamic, progressive primate evolution took place and where in the past the Lemurs and the Tarsiers had lived: almost the entire great Eurasian continent, most of Africa except Madagascar, and both Americas. (Australia, never in prehistory invaded by the terrestrial Placental Mammals, remained outside the sphere of primate evolution.)

The nocturnal habit assumed by the Tarsier merely indicates an attempt to postpone the complete elimination of this "debris" of a formerly much more abundant life. It is therefore improbable that, beyond the insectivorous stage, the main stream of primate evolution ever again passed through a nocturnal phase. Neither the nocturnal Lemurs nor the nocturnal Tarsiers of the Paleocene and Eocene Epochs, therefore, could have been the links in the evolutionary chain that led to the overwhelmingly diurnal Pithecoids. Otherwise, it would be necessary to assume, first, a transformation of the diurnal Tree Shrews into nocturnal Lemurs and Tarsiers and their dedifferentiation again into diurnal Pithecoids.

It is more probable that the inception of the Primates was in fair-sized terrestrial Insectivores of a preponderantly diurnal habit, somewhat resembling modern Malayan Gymnurines. The further phylogenetical stages may have been represented by the ancient, but less strictly photopic, Tree Shrews, followed by diurnal forms of the Lemurs and Tarsiers, and continued by the almost exclusively diurnal Monkeys, Apes, and Man.

The nocturnal genera, such as the Pen-tailed Tree Shrew (*Ptilocercus*), Lemurs, Tarsiers, Night Monkey (*Aotes* or *Nyctipithecus*), are all side lines, biologically motivated by their incapacity to compete successfully with their diurnal rivals, especially animals of prey. They took an easier, defensive way of self-preservation, paying for it by renouncing a further progress precluded by nocturnal conditions. Most of their diurnal cousins of past epochs, the Lemurs, Tarsiers, and Monkeys, with the exception of modern Tree Shrews, have left the scene not so much because they have been exterminated as because they have been transformed into more advanced diurnal Monkeys, Apes, and Humans.

The same idea is equally applicable to the Lower Insectivores, e.g., the Shrews and other Soricoids, such as the Moles (Talpidae), Solenodontids, Chrysochlorids, Erinaceoids, and possibly also the present Gymnurines and Macroscelidids. Most of them are remnants from past ages. They were able to preserve themselves only by the adoption of secretive habits, either by going underground, by becoming aquatic, or, if remaining above the ground, by strictly observing nocturnal habits (Bats, Soricide Shrews), by growing a more or less effective coat of sharp spines (Hedgehog, Tenrec), or in some other way. All these surviving members of the Orders of Insectivora and Chiroptera, as well as the nocturnal Primates, have followed the principle that "discretion is the better part of valor" and got out of the way of the well-armed, mighty, and bold aggressors which took possession of the earth.

Briefly, diurnality and arboreal habit appear to have been the main instruments of early Primate evolution during the Mesozoic Period of the earth's prehistory.

19. The problem of intellectual preeminence in primate evolution.—In the preceding subsection the thesis that arboreal habit and diurnality are the principal factors respon-

sible for the progressive evolution of Primates was discussed. The remaining and even more difficult subject is concerned with the inordinate development of the brain and mental faculties in which the Order of Primates surpasses all other animals.

The theme of Man's intellectual superiority has been a favorite topic of philosophers and students of nature since ancient times. With the increased knowledge of Man's bodily organization and his kinship to other Mammals, especially his near relatives, the Monkeys and the Apes, the answer was sought in the comparative study of the brain, sense organs, and behavior.

Among modern students G. Elliot Smith, in the words of Woollard (1927), has brought forward the concept of "the acquirement of skilled movements and the correlation of these with vision" as a causal factor in primate evolution. "The Tarsioidea," in the opinion of Smith (1919), "seem to have become differentiated from the Lemuroidea by a reduction of the face, which permitted the much fuller development of stereoscopic vision." But how exactly these and other relevant factors have co-operated in stimulating the growth of the brain and, with this, the development of mental faculties—properties to which, in the final analysis, Man owes his pre-eminence in nature—still remains one of the greatest problems of science. (*See* chap. XV for continuation of this topic.)

20. UNCERTAINTIES CONCERNING THE TRUE CAUSES OF THE PRIMATE EVOLUTION.—It is amazing how many details are known about primate evolution without the core of the problem, the true causes of the whole process, being found. It is necessary to recognize the fact that we do not know either the exact phylogenetical origin of Man or the precise phylogenetical process which led to it. We are not able to point to some specific and exclusive external and internal factors responsible for the phylogenetical appearance of the Primate Order in general and for the coming of Man in particular. The available explanations all are descriptive, logical, roundabout constructions instead of clear demonstrations of evidence.

First, the exact causes of the development of the subsequent higher primate suborders from the lower ones are not clear: the Lemurs from the Tree Shrews, the Tarsiers from the Lemurs, the Monkeys from the Tarsiers, the Apes from the Monkeys, Men from the apelike ancestors—if this was the phylogenetical sequence. We know, or rather are convinced, on the strength of a very obvious anatomical, physiological, and biological kinship, that some such chain of events must have taken place in the past. But just what the stimulating factors were and how the individual links in this long process were causally interconnected still remain largely guesswork.

A few critical questions are: Why, above all, was the adoption of an arboreal mode of life necessary in order to make Primates from the generalized ground-dwelling insectivorous ancestors, whereas, obviously, to make Man out of the apelike ancestor, the creature had again to come down from the trees and rely entirely upon bipedal gait, thus freeing its hands and arms from the duty of locomotion (since otherwise Man would have reverted to the largely quadrupedal habit exemplified by the Baboons)?

And how was the sense of vision responsible for this "anthropogeny," if at all, since, obviously, the Monkeys have developed this faculty practically to perfection, even though (or, should we say, because?) they went up into the trees and stayed there?

And, if vision was the only, or the principal, responsible factor, why did it not work in the preponderantly ground-dwelling Monkeys, such as the Baboons, where certainly there were enough compelling reasons for this: few trees to be used as a source of food and refuge, lots of "social life," and plenty of game animals to prey on?

And while it is plausible that the arboreal phase in primatogenesis may have been necessary for the rise of that order, is it not just as apparent that staying in the trees would have prevented further progress and that it is therefore likely that Man's direct ancestors were among the early simian-like Primates to come back to the ground, or that they never were as completely adapted to the life in the trees as are most other Primates?

But just what was the impelling cause that made Man's ancestors rise on their hind legs,

leaving their arms and hands completely free for use as manipulators, thus making possible the development of the brainiest creature of the globe, Man?

These and similar questions have been advanced by a great number of naturalists and thinkers ever since Charles R. Darwin made the principle of evolution a recognized factor in modern scientific thinking. In the final chapter of this book an attempt is made, on the basis of facts and logic, to understand the origin of Man in his physical and mental characters from the infrahuman forms that preceded him.

SEC. 13. MISCELLANEOUS NOTES ON THE VISUAL BEHAVIOR OF THE ANIMALS IN NATURE

1. Tree Frogs and their visual behavior.—The Tree Frogs, by definition, are anuran or tailless Amphibians of arboreal habits, inhabiting in numerous species many parts of the world. With other Frogs and Toads they form the Order of Anura, which, with the tailed Newts and Salamanders or Urodela and the limbless or wormlike Apoda, forms the Class of Amphibia. The Amphibians are phylogenetically the oldest land vertebrates which developed from fishlike ancestors. In external and internal makeup they are closely related to the latter, and their early development takes place in the water.

Since the Tree Frogs are well adapted to arboreal living, it was of considerable interest to observe them in their natural habitat, in order to determine, if possible, why and how these water-dwelling creatures took to the trees, and how they and their visual organs became adapted to the arboreal habit.

These observations of the behavior of Tree

Frogs were made in the woods of northern Wisconsin in late August. In some years Tree Frogs are quite numerous here, and the trees and bushes team with them. In other years, however, few of them are seen.

During the night there were long periods without any sounds that could be attributed to Tree Frogs, in spite of fairly good illumination, for the quartermoon was shining brightly and parts of the forest were full of light (1:00 A.M. in late August, 1948, and 1949). Only occasionally a brief sound, shorter than during the day, was heard, but there was no "chorus." During the early morning hours the Tree Frogs were still quiet. Even as late as 8:00 A.M. hardly a sound was heard from the trees. Thereafter, the Tree Frogs were heard more frequently, until, toward late afternoon, their voices multiplied and finally increased to a "chorus." This observation would indicate that the indigenous Tree Frogs are largely diurnal in habit.

There were two kinds of sounds: a peeping, high-pitched note and another soft, smooth, sonorous rattle. The latter especially was heard more frequently in something like a "chorus" started by one individual and kept up alternatively by the others on the neighboring trees. Unfortunately, in spite of all efforts, it was not possible to locate and identify the species with the character of the sound. According to A. H. Morgan's *Field Book of Ponds and Streams*, however, the first sound was to be attributed to the Spring Peeper (*Hyla crucifer*), the other to the Common Tree Frog (*Hyla versicolor*). (*See also* Brehm, v. 4, 1912; K. P. Schmidt 1929; Wright & Wright 1949; for figures in color *see* A. A. Allen in Nat. Geog. Mag., v. 97, 1950.)

The Common Tree Frog is an alert, vivacious animal, with a physiognomy indicating a flicker of batrachian intelligence. Its eyes are relatively large and bulging, as they are in all its congeners, and are mounted in such a way that almost the whole cornea and pupil are visible when observed directly from the front. The pupils are oblong horizontally, with pointed angles. The binocular overlapping of the two fields of view, roughly estimated from the position of the corneae, may be as much as 60°.

When the Frog is held quietly, small, jerky, horizontal movements of the eyeballs are seen from time to time, as well as inward-pulling movements. The horizontal movements are executed in the horizontal plane, in short jerks, as if the Frog were trying to hold in view an object of interest. Similar slight jerks of the head may also be seen, as if the animal were trying to fixate a visual object. The compensatory movements of the eyes in the horizontal plane are automatic. Whether these are labyrinthine or optical it was not possible to determine. The vertical movements of the eyes induced by the rotation of the animal around its axis may, with more certainty, be considered labyrinthine.

The pupil of the side exposed to light was smaller, the one kept in the shade larger. Sometimes the reverse was true, with the shaded pupil smaller, which, however, was opened wide when the animal was excited or when the eye was mechanically stimulated. The pupil exposed to light became smaller only after a considerable time, a half-minute or longer. A prompt, direct pupillary light reflex, comparable to that found in the higher Vertebrates, was absent. The nictitating membrane sweeps from below over the entire cornea at rare intervals. After decapitation the pupils were at once reduced to minute horizontal slits, while the protective reflexes of the nictitating membranes and the pulling-in of the eyeballs still persisted for some time.

The preceding sketch of the Tree Frog, with the exception of the sounds, indicates rather general organization of the visual system with few signs of specific diurnal adaptation. Other equipment, such as suction pads on the terminal phalanges, shows the advanced adaptation of this genus to arboreal habit and habitat. Whether there are any other detailed characteristics indicative of arboreal habit and diurnal adaptation, especially of the visual system, such as the preponderance of cones and the presence of a central area or fovea of the retina, must remain a problem for future investigation. (*Cf. also* Fig. 461).

2. PAINTED TURTLE.—The Genus of Painted Turtle (*Chrysemys picta*) is representative of several of the beautifully decorated Turtles of eastern North America. These Turtles have a more elaborately organized visual apparatus than do the Amphibians. Observation showed that their visual behavior was comparable with

that of the Anole Lizard and the Swallow, described earlier in this chapter. The feature common to all three species is an elaborate organization of the oculomotor apparatus, permitting the use of each eye individually or of both together as a binocular stereoscopic team (*cf.* Fig. 466).

The appearance of the Painted Turtle fully justifies its name. While most of the upper surface of its carapace or shield is more or less uniformly dark green and brown, its margins and those of the lower plastron are elaborately decorated with orange patches shading into yellow, and with dark-green and yellow stripes on the head, neck, tail, and limbs. (*See* for figures, partly in color, Brehm, v. 4, p. 403, 1912; K. P. Schmidt 1938; R. L. Ditmars 1946; C. H. Pope 1946.)

Observation in captivity showed the Turtle to be an alert visual animal. Its eyes are mounted at a slant, so that the two optical axes are directed forward and downward. The angle that each axis incloses with the mid-sagittal plane is approximately 60°, with the horizontal plane about 70°. The iris membrane, in turn, incloses an angle of 45° with the sagittal plane, the two iris membranes together making an angle of about 90° to the rear. The pupil is almost a perfect circle and is set a bit anteriorly from the exact center of the iris. There is a slight dent in the posterior pupillary margin. Occasionally a minute, but quick, spontaneous movement of the pupillary margin is noticed, which is probably an indication of the action of accommodation.

From the position of the eyes, one may conclude that the locality of principal interest to the Turtle is in the anterior direction and downward. This would agree with the habitual attitude, in which the head is held at an angle of 45° to the horizontal plane. In this attitude the two visual axes are directed to some extent forward, instead of only downward, as they would be if the head were held horizontally.

When the animal was alerted, its head was raised so that its axis formed an angle of at least 75°, and possibly more, with the horizontal plane. In this position, when the Turtle is in water, with its head above the surface, the dark pigmented streaks passing across the head and eyes, including iris and pupil, become perfectly parallel with the surface of the water. This again may indicate the probable role of these streaks as arrangements for absorbing the rays of light reflected from the surface of the water which would otherwise interfere with visual acuity (*cf.* "sighting grooves" of the Pike).

In the normal swimming position of the Turtle, both eyes deviate from the strictly lateral position for about 45°, as indicated by the position of the iris membranes. This is an indication of the deviation of the theoretical optical axes of the eyes toward the chin, with the lines of vision probably directed straight ahead and parallel to the surface of the water. The two lines of vision may well be used in binocular stereoscopic vision, as discussed in the sections on the Anole Lizard and the Swallow. To a Turtle swimming with its body just submerged, this attitude would afford a sweeping view over the entire expanse of the water of a lake or pond, so that it could see at once any object that might be of particular interest to it, such as a floating dead fish or other potential food.

The eyes of the Turtle, when the animal was quiet, gave an impression of alert watchfulness. They continuously scanned the field of view, being directed from one object to another. When both eyes moved, they frequently did not act as a perfect team, one occasionally lagging or standing still. The movements were short, quick jerks in a more or less horizontal plane only, or associated with up-and-down movements. The scanning movements were accompanied by those of the head and neck, especially lively when the animal tried to free itself from the grip of the examiner's hand. Hence the great mobility of the head and neck further assisted the movements of the eyes. Spontaneous movements of an individual eye in the horizontal plane may amount to at least 40°. If the eyeball was suddenly illuminated, it very promptly turned toward the stimulus.

When making scanning movements, the eyes moved easily in their sockets. When an object moved so that it fell within the Turtle's field of view, the head and eyes promptly turned toward it. Even a slight move of the examiner's hand at some distance elicited an immediate turning reflex of one or both eyes. However, when the hand was moved quickly or suddenly

toward the Turtle, the head and neck were promptly drawn into the shell.

The convergence of both eyes was more difficult to determine. Binocular convergence was easily obtained by moving fingers toward the eyes directly from the front. Repeated testing, however, definitely showed a converging downward, toward the mouth, when the Turtle had its head upraised—its usual attitude. Similar converging movements were also made anteriorly, toward the muzzle, when the animal wished to look upward. In this case, movements of the eyes were accompanied by those of the head and neck.

Occasionally one eye made a similar movement alone, sometimes followed by the other. Again, after fixing an object for a while binocularly, both eyes would relax and return to the initial resting position, clearly showing the presence of a divergent movement.

When an object was brought near one side, that eye alone quickly turned toward it, to fix it for a while, whereas the other eye sometimes remained shut. The stimulated eye was "cocked" at the visual object in the manner of a Robin looking for an earthworm. Occasionally both eyes moved together when an object was approached from only one side. Whether one eye or both as a team were used to fix an object, they again returned to the initial position after the object had disappeared or the stimulus ceased to attract.

The lids and the nictitating membrane may be shut either individually or both simultaneously. The corneal reflex, consisting of moving the lower lid upward and pulling the eyeball inward, was very promptly elicited from the corneal center and less promptly from the corneal periphery. It has not been possible to determine the presence of a pupillary reflex to direct illumination, however.

Compensatory movements of the eyeballs to a changed position in the sagittal plane may amount to about 35° or 40°.

When placed in a basin filled with water, the Turtle promptly sank to the bottom, pulling in its head and neck. However, the eyes made scanning movements all the time. After a while there was a general scramble of all four limbs, as if trying to escape, followed by a period of complete quiescence, with only scanning eye movements persisting.

While the Turtle was being held quietly for some time in a horizontal position, it became rather adjusted to this situation, showing more enterprise by its greater activity. When turned so that it saw the lake before it, it scrambled as if trying to regain its freedom. A buzzing bee aroused quite an interest and caused it to stretch its head and neck and follow the flying insect with its eyes.

When a visual object appeared on one side, so that its image fell on a point in the periphery of the retina– for example, in the horizontal plane —that eye promptly turned to a position where its center faced it. This visual reflex may be termed a fixing movement of the eye, indicating the presence of a differentiated locality of the retina—a central area found by Detwiler (1940) —and a corresponding organization of the entire visual apparatus, including the neuromuscular parts serving the purpose of fixation. The "fixing movement" could be elicited several times in succession, provided that sufficiently long intervals intervened between the tests.

The preceding observation, sketchy though it is, shows the Turtle to be in possession of a visual apparatus more advanced in its functional elaboration, and hence in its efficiency, than that of the native Batrachians. However, a more detailed study, together with correlation of various structures with their functions, would undoubtedly give a fuller picture of the role that visual and other sensory and motor systems perform in the life of the Turtle.

3. PURPLE MARTIN.—The Purple Martin (*Progne subis*) is the largest of the North American Swallows. In its bodily organization and its habits it resembles its smaller, more delicately built, and more nimble relative, the Barn Swallow, described elsewhere in this chapter. (*See* illustrations in Pearson & Burroughs 1936; Pough 1946; Peterson 1947; A. A. Allen 1951, p. 31.)

The objects of the observation recorded on the following pages were young birds fairly advanced in development, even though not yet fully grown, and adults. The young birds were

convenient subjects for the study of their eye movements when squatting on the perch of their birdhouse in a neighbor's garden. This they unwillingly shared with several families of House Sparrows, which insolently managed to take possession of part of it.

The young Martins, while waiting for their parents to bring them, alternatively and at frequent intervals, food which they caught on the wing, had to be constantly on guard against the Sparrows. When one of the Sparrows came uncomfortably close, the young Martin faced it suspiciously, and on some occasions it opened its beak, indicating its willingness to fight rather than to yield any further ground to the intruders.

The belligerent intention of the young was unmistakable: their feet were firmly planted on the ground to preserve balance, their grim countenances resembled the determined expression of large Birds of Prey such as Hawks and Eagles, with "brows" lowered, and eyes "hurling darts" against their potential foes. In this situation, on several occasions, it was possible to see, with the help of powerful binoculars, both eyes executing converging movements toward the object of their hatred, the Sparrows, with the convergence relaxing when their foes moved away. The movements of convergence were similar to those observed in the young Barn Swallow when binocularly focusing on an insect or some other object to which it paid attention (*see* section on the Swallow, this chapter).

The observation of the adult Purple Martins with 7× binoculars at a distance of 15 feet showed their eyes to be remarkably mobile. The birds, when on the perch of their house where they rested between flights, were constantly examining the world around them with either one eye or the other. The eye movements in their sockets were clearly visible and were often combined with short movements of the head and neck. The converging eye movements, however, could only rarely be seen, owing to the extreme alertness of the birds, the quickness of their movements, which only rarely offered the chance of a good frontal view of the head, and their dusky coloring. The black stripes around and in front of their eyes, especially visible in the female bird because of its lighter coloring and resembling the "sighting grooves" described in the Pike (sec. 4, this chapter), may be useful here, as in the fish, in reducing the stray light entering the eye and thus increasing acuity in binocular vision.

In flight, especially when soaring, the Purple Martin resembles the larger predaceous birds, such as Eagles and Hawks. Its distinguishing feature is long stretches of gentle gliding without much change of direction. Only occasionally may the soaring be interrupted by the flapping of wings, which is followed by a change of direction in the form of a turn or loop. If the flapping periods and change of direction are indications of a successful hunt, it is a puzzle how the bird is able to catch enough insects to sustain itself, even though it may cover a large area in order to satisfy its needs.

This may explain why Martins must fly such long distances, which is also to some extent true of the other Swallows and the Night Hawks. The Swifts, smaller birds, apparently subsist upon smaller insects, which are more abundant, and so they must make more frequent turns.

In any case, the hunting method of all these birds is an active pursuit, guided and controlled by sight, and is in no way the hit-or-miss affair suggested by Rochon-Duvigneaud (1943). The same is to be said of the small insectivorous Flying Bats or Microchiropterans, except that these are directed in their hunting by their superior ultrasonic hearing and possibly also to some extent by touch.

An observation of a Purple Martin, without leaving its perch, occasionally catching an insect that accidentally flies close to it may be mentioned as a curiosity and exhibition of constant visual vigilance.

By comparison with the Swallows and Swifts, the larger Birds of Prey, living upon larger animals harder to locate, with the chances of making a catch much less frequent, are forced to cover even more extensive hunting grounds than those of the Swallows. Hence their flight is almost entirely of the soaring type, which requires the smallest expenditure of energy during their prolonged hunting periods.

4. Dragonflies, Damselflies, and Insectivorous Bats.—It is interesting to com-

pare the hunting habits of the Dragonflies (Odonata) with the habits of the Swallows, Swifts, and Bats.

The Damselflies and Dragonflies, just like their avian and mammalian counterparts, catch their prey on the wing. They are rated as perhaps the best fliers in the insect world, and, of the two, the Dragonflies are superior. In their life, which is mostly spent in catching flying insects such as Mosquitoes, they are guided exclusively by their sight.

They are visually extremely alert animals. Their eyes are enormously developed, especially in the Dragonflies, where they make up most of the head. Each eye is made of a great number of ommatidia or individually stimulable units. The smallest ommatidia face forward, in the direction of flight, where they are most useful in binocular focusing on the prey (Fig. 444).

The entire head, when the Dragonfly rests, is frequently moved in various directions from the neutral position, which is mostly in the horizontal plane (to right or left), up or down, or in any one of the oblique meridians. The movements are very minutely adjusted in their speed and excursions, altogether indicating superior visual performance. The single moves may amount to more than 30° or 40°, with many very small moves possible. Whether the eyes are firmly fixed in their relative position or may also be moved individually must be further investigated.

The Odonates are preponderantly daylight hunters, some being crepuscular. Their flight, as could be expected, has much in common with the flight of the Swallows and Swifts. Its particular feature is a zigzagging course, as they dart here and there after their diminutive prey. This flight, as easily observed in the early hours during warm, quiet August and September evenings, is much more zigzag than that of any flying Vertebrate, a Swallow, Swift, or Bat. It greatly resembles the fluttering of the small Bats, reduced to much smaller proportions. Long straight stretches do occur, but they alternate with series of short darts, each measuring from 2 to 3 feet, more or less.

As in the Swallows, Swifts, and Bats, the hunting method of the Dragonflies is active pursuit, under the guidance of a superior sense of sight, where the element of chance, Rochon-Duvigneaud's "arabesques of flight," is practically eliminated. In this pursuit the excellence of their vision is their principal instrument.

Their photoreceptors are highly differentiated, with the smallest elemental ommatidia in the frontal parts of their huge composite eyes, and the larger ones in the peripheral parts. This affords them both high acuity and tridimensional stereopsis.

Their very flexible legs are adjusted not only for locomotion but even more to catch and "manipulate" the prey in the process of feeding.

5. Birds with preponderantly panoramic vision.—In hunting for prey, different species of Birds use their visual apparatus in different ways, as has been well described by their lifelong student, Rochon-Duvigneaud (1943, and earlier). One way is to use one eye at a time, individually; the other is binocular. The two may alternate, according to the situation; or they may be variously combined. (*Cf.* also section on the Swallow, this chapter.)

According to my observation, the House Sparrow (*Passer domesticus*) and the Domestic Pigeon (*Columba livia*), with their laterally placed eyeballs, ordinarily use their eyes monocularly for observation, as do the American Robin (*Turdus migratorius*) and numerous other birds. In pecking grain or aiming at an angleworm just prior to seizing it, the final act that follows the critical examination, however, these birds use both eyes simultaneously in a binocular stereoscopic way.

In the Pigeon, for example, there is nothing one would call a "frozen eye," as one would be inclined to judge on the basis of a superficial observation. When I observed the Pigeon as it squatted on the sill just in front of my window, about 40–50 feet above ground, the eye facing me moved all the time, as probably also did the eye looking in the other direction toward the buildings opposite and the court below where people were moving about.

Observation with powerful binoculars revealed surprisingly extensive movements of the visible parts of the eye in a more or less horizontal meridian, as well as up and down and in any other intermediate way. The impression gained was that of a sharp and constant vigilance, the animal using and mentally digesting

all the available cues, ever ready to fly away, if need be.

The bird, as I observed it, was somewhat suspicious of me, even though I was inside, behind windowpanes, and in relative shade. Every once in a while it would stop as it slowly paced the sill and focus its gaze for a second or two in order to examine me intently, although I kept quiet and although it had seen me in a similar position on many previous occasions.

The Pigeon would sometimes make a quick, short movement with its head backward and forward, along a line vertical to its line of gaze, in order to utilize the visual parallax to view me from another point. (Monkeys do the same when watching a suspicious object or person, except that they use both eyes and move the head sidewise; similar action is observed in many other animals.) The entire behavior of the Pigeon betrayed a high degree of visual alertness short of manifest alarm, the visual apparatus being used continuously to gain useful information which the curious bird was eager to obtain.

One had here a good demonstration of the tremendous advantage of a wide field of view, as the Pigeon has. The same is true of other Vertebrates which have panoramic, or rather largely panoramic, vision, practically amounting to a complete circle. It permits them to see simultaneously most of the horizon and to see it with about the same high acuity as that possessed by Man, as other observations of the Pigeons and Sparrows indicate. (*See* Fig. 457.)

This leaves the old and deeply absorbing question still unanswered: how to explain the superb tridimensional quality of the Pigeon's vision which, beyond doubt, this and many other birds have, in spite of their almost completely decussated optic tracts, as shown by experiment (*cf.* chap. VI, 5 [3]).

6. MONOCULAR AND BINOCULAR-STEREOSCOPIC USE OF VISION IN BIRDS.—The diurnal species of large Birds of Prey, such as Hawks and Eagles, have very excellent vision in both stereoscopy and acuity. This is confirmed by the fact that they possess two foveae in each eye, one lateral and one central (*see* Figs. 171, 172).

A Harlan's or a Red-shouldered Hawk or an Eagle, for example, when cruising over forests and glades and scanning for hidden prey, moves its head frequently from side to side. It is probable that they do so in order to bring the landscape into the range of their central foveae for a detailed examination, even though, because of the great distance, it was not possible to ascertain whether the head was actually inclined laterally and downward in the way the Robin does when "cocking" one of its eyes in looking for an earthworm in the lawn.

The behavior of a Flycatcher, Kingbird, and other Tyrannidae is a duplicate of the Robin's when examining details. The utilization of only one eye when intently fixing an object is also especially characteristic of Domestic Chickens when they notice a predator in the skies, which they follow with one eye, keeping their heads tilted at a slant. Yet all these birds when picking up their food—for example, a Robin in the moment when it tries to seize an earthworm; a Chicken and a Sparrow when picking grain from the floor—use both eyes simultaneously, that is, binocularly and apparently stereoscopically.

Stereoscopic use of vision in all those species that on other occasions are inclined to use each eye separately is especially in evidence during flight. When the Sparrows, for example, chase one another through the branches of a tree and most expertly dodge the twigs without touching a leaf, they use both their eyes simultaneously. The same may easily be observed in other small, alert birds, such as the Finches, Flycatchers, Titmice, or Chickadees. In this respect they perform a highly complex visuosensory-motor act. They almost equal the performance of the Swallows, skimming over the lake without ever touching the surface of the water with the tips of their wings, when hunting at evening for minute insects that congregate for their nuptial dance. In both locomotor functions the guidance is entirely intrusted to the stereoscopic sense of vision. In the Swallow the major share is apparently contributed by the two lateral or posterior foveae, in the Sparrow and Pigeon by the central foveae; in other birds the responsible structures are yet to be found.

Unilateral use of the visual apparatus, with a quick shifting to binocular stereoscopic use, when the need arises, is seen in numerous other

birds. A Redstart (*Setophaga ruticilla*), for example, systematically examines branches and leaves of a tree for insects, using exclusively one eye or the other, but probably both when aiming with its beak to pick the prey. A similar technique may be observed in various Warblers (Parulidae), House Wren (*Troglodytes aëdon*), and Nuthatch (*Sitta carolinensis*).

The Hairy Woodpecker (*Dendrocopus villosus*) exhibits interesting and somewhat different behavior. It fixes both eyes firmly on the point at which it aims the blows of its beak. Possibly it uses one eye or the other individually when quickly running up or down a branch or when hopping from twig to twig and looking for peeled bark or a dead branch, localities in which its prey may hide. It is duplicated in this behavior by the Chickadees (Paridae), which, in fact, appear to be miniature Woodpeckers.

Binocular use of the eyes may definitely be seen in the Downy Woodpecker (*Dendrocopus pubescens*). In this bird both eyes may converge toward a single fixation point a short distance in front of its beak when examining a dead branch for a bug, and not only when pulling it out of a crevice of the bark. During this occupation the gaze of both eyes is directed straight ahead, each line of vision passing along a black streak running toward the beak, the streaks resembling the "sighting grooves" described in the Northern Pike (sec. 4, this chapter).

In the female Mallard (*Anas platyrhynchos*), in the male of the same after a summer molting or the "eclipse," and in the young, the "sighting grooves" or rather pigmented "sighting streaks" meet in imaginary prolongations at a point situated some distance in front of the beak. The plane of these streaks is parallel to the surface of the water when the duck assumes its normal swimming position, during which its beak is inclined toward the horizontal at an angle of approximately 30°. This position appears favorable for binocular vision in the normal habitat of the bird, the marshes and swamps. It may also be advantageous to it during flight. When pursuing its peaceful occupation, the Duck seems, however, to rely principally on its panoramic vision.

7. Visual behavior of Lower Mammals.—A Woodchuck or Ground Hog (*Marmota monax*), one of the largest native American Ground Squirrels (Sciurinae), observed on a shady forest road during daylight, sees a man at 50 feet quite well, but, when one is still, it does not recognize a person at that distance as a potential enemy.

The road, where this observation was made, was frequented but little by humans (Iowa State Park at McGregor, overlooking the Mississippi River). Even though the observer, the author, was motionless during the entire time the animal was in sight, the Woodchuck remained suspicious, rising on its haunches from time to time and lifting its head as high as possible above the vegetation to have a better look, first with one eye, then with the other. Only after quietly and intently observing the object of its suspicion for some time did it feel assured, and proceeded, lumbering on all four legs, about the business of eating. However, again and again it would rise to look over the strange object until it finally decided to disappear in the tall weeds and shrubs.

In its exclusive use of monocular vision for a gnosic or "psychic" appreciation of visual impressions, the Woodchuck behaves in exactly the same way as do the smaller Rodents, such as Ground Squirrels or Gophers, Chipmunks, Rats, and Guinea Pigs. The Arboreal Squirrels deviate in this respect: while ordinarily they use their eyes panoramically, in circumstances which require greater attention they use them as a binocular stereoscopic team (*see* section on Squirrel, this chapter).

The preceding observation of the Woodchuck may indicate rather moderate acuity and visual resolution, which undoubtedly would have been greater in better light. The degree of caution exhibited by the animal shows a fair amount of mental capacity, considering the small previous experience the animal could have acquired in its secluded habitat.

8. Visual behavior of the Vertebrates during twenty-four-hour activity in summertime.—The activity and visual behavior of numerous species and larger groups of Vertebrates show great variation, depending upon the particular period of the twenty-four-hour day. That some animals are mainly or exclusively active during the day and rest during the

night, while others manifest the opposite behavior, is common knowledge. Obviously, such variation is caused and regulated chiefly by the intensity, and to some extent also by the quality, of the light, which also varies during the twenty-four-hour cycle.

More attentive observation discloses subtler gradings of daily activity, indicating a finer adjustment of the senses according to the specific period of the day. In brief, just as the animals are in various ways adapted to a great number of habitats spread over the globe and to the larger cyclic changes of each particular habitat, called seasons of the year, so they are also, in a more subtle way, attuned to the twenty-four-hour cycle of a solar day.

By observing the animals during their daily activity and rest, the impression is gained that the twenty-four-hour period of time is comparably subdivided, in the economy of living beings, as is the space in which they live and the two principal elements within which they live, water and air. This daily temporal diversification of behavior, in turn, points toward a similar diverse structural organization of various animal forms. Hence the anatomical basis of diverse animal behavior is a reflection of the daily cycle caused by the molding forces of nature.

In the following are described the habits of a few representative Vertebrates gained through rather casual observation in the American Middle West, during late summer.

The first riser in the morning, in cities and in smaller towns, is the Robin (*Turdus migratorius*, also *Planesticus migratorius*). This bird is, in fact, a Thrush, much larger than its original namesake of the Old World (*Erithacus rubecula*), with which it was mistakenly identified by the early settlers of America. Its merry morning song resounds first in the early dawn before any of the other diurnal birds begin their daily work. In this respect it resembles its black relative of the Old World (*Turdus merula*).

From the moment the first Robin's fluting calls are heard until the earliest timid chirpings of the House Sparrow (*Passer domesticus*) begin to be perceived from under the eaves of the town's dwellings, it takes fully thirty minutes. During the following quarter of an hour, Sparrows' voices gradually increase in intensity, sometimes to a very babble, frequently degenerating into lively disputes and formal quarrels. In another thirty minutes or so the Sparrows' voices have considerably subsided, as the birds settle down to the serious business of gathering food.

The Robin not only rises early, it also retires late. In the evening when the Sparrows have long since been still, the Robins continue for a while to hunt for the earthworms on the shady lawns. This is the more remarkable, since single blades of grass have at that time become largely indistinguishable to the less sensitive human eye.

The conclusion must be drawn that the Robins' eyes, while not as capable of perfect nocturnal vision as those of the truly scotopic Owls and probably also less than those of the Nighthawks and other Caprimulgidae, are superior in their adaptability to scotopic conditions to those of the Sparrow and Man. Undoubtedly, such graded visual behavior must be related to a somewhat different organization of basically similar visual apparatus in each of these species.

In small communities, in isolated groves around farms, and in the forests, the first to announce the day are the Blue Jay (*Cyanocitta cristata*) and the Mourning Dove (*Zenaidura macroura*). The first usually appear all of a sudden, in small, noisy flocks, raucously calling from the treetops and excitedly flying about, making a great commotion and fuss. The timid Doves, on the contrary, seem to make every effort to render their presence as inconspicuous and unobtrusive as possible. The very character of their cooing, which sounds as if it came from a distance, camouflages the true whereabouts of the birds, which, in fact, may be very near.

In the more extensive woods the conspicuous early risers are the Crows (*Corvus brachyrhynchos*). Their loud cawing sounds over great distances, as the birds excitedly fly from place to place in search of food, which may be the carcass of a rabbit or the nest of some smaller and helpless bird which they plunder, or when in great numbers they mob a luckless Owl which selected a wrong hideout for the day. In their behavior they greatly resemble their smaller congeners, the Blue Jays. Their keen-sighted eyes are good enough to detect anything suit-

able for consumption on the forest floor or in the tops of the trees, whether a heap of garbage or a Squirrel on a branch, which is lucky if it can slip into a hole in a tree.

Nor is this a matter of simple perception, since all objects are quickly scrutinized whether useful, neutral, or a source of potential danger. Of this the best example is the appearance of a man. To the Crows, Man is most acceptable when kept at a safe distance. The closest tolerated approach may be guessed at no less than one hundred yards, provided that there is sufficient cover in between, e.g., the bushes in a forest. Silent and invisible to a human intruder, the Crows may continue their plundering for some time, all the while keeping a sharp eye on the suspect newcomer. When the latter, unknowingly, comes too uncomfortably close, one of the lookout guards gives a signal, and the entire flock flies away. Or, as frequent experience shows, a few stragglers may continue their doings behind the camouflage, trusting that the dangerous visitor was fooled by the flight of some of them. However, if a hunter appears with a gun or a person with a stick held like a gun, no chance whatever is taken, and all the Crows fly away as soon as the limit of safety is reached, which in this case is a much greater distance.

The appearance and behavior of the diurnal Birds of Prey is always a fascinating sight. The little Sparrow Hawk (*Falco sparverius*), as it perches on a telephone wire, seems to rely chiefly on its patience and on its keen, bifoveal eyes to help it discover a grasshopper or a mouse hiding in the weeds. Its larger congener, the Red-tailed Hawk (*Buteo jamaicensis*), pursues the same policy of watchful waiting, as it sits on a high limb of a tree, overlooking the farm lands, hoping that chance may bring it a gopher or some other acceptable meal.

A flock of Bald Eagles (*Haliaeetus leucocephalus*), numbering on occasion as many as a dozen birds, is a magnificent sight. As the birds sail above the hills and marshes along the swinging shore line of the great lake, with more experienced older ones in the lead and on the far flanks, every wooded slope and grassy dale and every turn of the sandy beaches of the dunes are scanned for potential food. This "food," if still alive, takes pains to stay under cover of large trees and bushes, as the ominous shadows glide by, as do the various smaller birds, or, better yet, slips into the hole of a tree or a burrow in the ground, as the Squirrels and Gophers prefer. It is the competition and matching of the keenness of sight of the pursuer against that of the prey and of wits against wits that decide the biological outcome.

An easier way for the Eagles, then, to procure sustenance is to be on the lookout for dead fish which the water of the lake may have washed up on the beach. But again, it is more likely that the Gulls, always busy along the beach, will have been there first. It is this difficulty of procuring food that appears to be the principal reason for the long, sustained flights that the Eagles and other large Birds of Prey make, in order to cover huge areas with relatively small expenditure of energy.

During daylight hours enormous numbers of smaller Birds, amounting to many billions on the North American continent alone, are busy performing their daily duties, procuring food, building nests, and rearing their young. The bulk of these is represented by the Warblers (Parulidae), Vireos (Vireonidae), Titmice (Paridae), and Flycatchers (Tyrannidae), mostly migratory.

The remarkable feature of the small bird life is that, unlike most other Vertebrates, Birds have developed several subtle talents which to the human mind appear rather an expression of pleasure than a utilitarian necessity. These are complex auditory harmonics and refined color sense, manifested by singing and body coloring. These two talents indicate a correspondingly refined differentiation of their auditory and visual organs, including cerebral centers. A long and systematic investigation of this phase of Bird life is required to give account of it and to make it useful for the understanding of the same faculties found in the Primates, including Man. (*See* Charles R. Darwin's *The Descent of Man; cf. also* A. E. Brehm's *Tierleben* 1911–18; F. S. Mathews 1921; Pearson & Burroughs 1936; J. J. Audubon 1941; A. A. Allen 1951; E. T. Gilliard 1953.)

In their daily occupation, the small diurnal Birds show two rather distinct periods of increased activity. One is during the somewhat advanced morning hours, the other during the

late afternoon. The time in between, corresponding to the noon hours, the period of greatest heat during the summer, is a recess, or at least the birds are less active then.

As the day declines, the behavior of the Birds also changes in a way characteristic of each species. At a certain moment of reduced intensity of illumination prior to nightfall, objects still remain as bright as during the noon hours to human vision. It is then that the Sparrows, after a brief period of heightened activity, manifested by an excited fussing for better roosting places, gradually settle down for the night in some cover where they are tolerably safe from the sharp scotopic eyes of the Screech Owl (*Otus asio*). If they are disturbed and fly away, the Sparrows again try to locate their hideouts, but obviously, owing to their poor adjustability to scotopic conditions, have difficulty in finding them. And when the dusk thickens, they all become silent. At night, even when closely approached, the Sparrows remain perfectly still, as if in a trance, apparently not able to see anything in the darkness, when to human vision larger objects are still discernible.

Even more striking is the behavior exhibited by Domestic Chickens (*Gallus domesticus*) at a time when objects still remain tolerably distinguishable to human vision. This happens during late afternoon, when to subjective human appreciation the "photosphere" appears just as intensively illuminated as during high noon, although the composition of the light has definitely shifted toward the red, or long, end of the spectrum. At that period of the day one sees some of the Chickens already beginning to flock slowly toward the henhouse, illustrating the well-known proverb.

During the following half-hour or so, most of the chickens are gathered on their roosts. Thereafter, when the dusk thickens further, even though the human eye still sees most of the objects as clearly as before, there are still a few stragglers that strayed too far into distant fields. These, being less familiar with the details of the chicken yard and because of the increasing darkness, have difficulty in recognizing objects and finding their way home. One sees such late-comers slowly plodding through the tall weeds and over the lawn, often hesitating and making false turns, before finding their roosts. The behavior of these Chickens is reminiscent of amblyopics or persons suffering from hemeralopia or night blindness, who, because of their organically or functionally reduced acuity, have difficulty in finding their way about at night.

The behavior of Sparrows and Chickens at nightfall is in sharp contrast with that of other Birds, which, even though they are not nocturnal, continue their activity late into the dusk. The Robin, the early riser, is an example. Long after all Sparrows and Chickens have retired and the human eye has difficulty in distinguishing single blades of grass on the lawn, one occasionally sees the Robin cocking one eye to search for an angleworm or nightcrawler, which, fooled by decreased light, imprudently sticks its "head" out of the ground. The feat is perhaps somewhat less remarkable when one considers the short distance at which the Robin hunts, not exceeding 6 or 8 inches, in this way compensating somewhat for the decreased intensity of illumination. In any case, the Robin's day is considerably longer than that of the more strictly diurnal Sparrows and Chickens and partly overlaps the nocturnal activity of the Owls (Strigidae) and Nighthawks (*Chordeiles minor*) and also the Domestic Cat (*Felis domestica*).

Among the late hunters, the Purple Martin (*Progne subis*), Chimney Swift (*Chaetura pelagica*), and Barn Swallow (*Hirundo rustica erythrogastra*) are conspicuous. The last-mentioned bird, one of the best flyers, may frequently be seen sailing over the treetops late in the evening. In lake regions it may skim at high speed close to the surface of the water, rarely touching it, considerably after the sun has set and there is just enough light left to make objects fairly distinguishable to the human eye.

The Swallows apparently are attracted not only by the night moths which perform their nuptial dance just above the water but also by little fish, evidently Northern Brook Silversides and other fry, which, in turn, attracted by the moths, leap out of the water to hunt for the insects. These fish evidently represent richer food which the Swallows eagerly catch by diving, resembling diminutive Sea Gulls. (*See* sections on the Northern Brook Silverside and on the Swallow, this chapter.)

However, a moment comes in the gathering

dusk beyond which the insufficiently developed scotopic apparatus of the Swallow does not serve. It is at this moment, when the darkness of night is almost complete, that one hears the twittering of the last departing flock of Swallows as the first insectivorous Flying Bats (Microchiroptera) appear to fill the gap left by the Swallows. The fact that the Swallows continue hunting until late into evening dusk may to some extent be explained by the physical conditions, viz., sufficient remaining light reflected from the surface of the water, as frequently happens on calm nights. During this phase of the day, or a little earlier, there also appear the Nighthawks (*Chordeiles minor*) and other Goatsuckers or Caprimulgidae, to fill the transition from the daylight to the night.

As night deepens, the pronounced diurnal animals, in particular the Birds, disappear, and the nocturnal prowlers become supreme. The transformation in the life of a high northern forest, for example, is amazing. For long minutes there is not a twitter to break the silence, and a still, impenetrable darkness alone fills the space between the shrubs and trees. Only occasionally will the high-pitched or soft rattle of a Tree Frog interrupt the stillness. Then, all of a sudden, a single, deep, powerful, booming hoot spreads through the dark timber, the voice of a Great Gray Owl (*Strix nebulosa*).

After a while, other, different hoots sound through the darkness. They are in groups, strictly measured, and in orderly sequence, according to a definite pattern, characteristic of a Barred Owl (*Strix varia*). Some individuals, apparently the younger ones, repeat the same pattern but in a higher key, and others of the same species vary the same basic rhythm in minor ways.

Again, if the Great Horned Owls (*Bubo virginianus*) congregate in a particular locality and begin a dispute among themselves, a strange nightly serenade may take place in one or another corner of the dark woods. At another time, in late dusk, there may be a sudden violent swish along the shore trees, as a giant nocturnal robber shoots upon one of the Mallards browsing in the reeds, followed by a desperate squawk indicating either the end of a victim or a lucky escape with a bad fright.

And all this drama of the forest and lake enveloped in night, filled with primeval cunning, remains in the darkness, beyond the power of Man's visual apparatus to discern, even though some participants in it are obviously fully equipped by nature for it and now feel in their own element. It is the "struggle for existence," for life and against annihilation, as cruel as the one whose brightly colored battleground is illuminated by the shining rays of the sun. It is a contest between one set of the senses against the other set, against the cerebral performance of one and the other, and the many large and small details that differentiate one animal machine from another.

Difficult though it is to follow the nightly doings of the nocturnal Birds, it is even more difficult to follow during the night the creatures that crawl over the ground and hide between the roots of the trees and bushes and among the vegetation. On the surface all may appear unruffled. Yet attentive observation discloses surprising, though silent, activity in the fields and gardens and in the meadows and forests. Where during the bright day there seems to be nothing but clumps of grass and dead leaves, every step now appears to stir some object to life. Here a clod of earth hops away as a Toad, there a dead leaf is transformed into a Frog, leaping into a pond, or a broken twig becomes alive as a Snake wriggles away into a patch of weeds.

The number of living creatures in some localities is truly astonishing, especially toward the close of the summer, when a new generation of tiny arboreal Batrachians is on the march. Then the ground and the trees and bushes fairly swarm with them. All these creatures, each in its own way, are regulated by the night's low intensity of illumination, during which they are active.

On quiet evenings the surface of the lake, reflecting the last traces of the sun's light long since gone, at first sight resembling a perfect mirror, appears to be slightly disturbed by little pinpricks which expand into circles. They are caused by little fish of many kinds, commonly called Minnows, especially the Northern Brook Silverside (*Labidesthes sicculus*), hunting for "gnats." In this activity vision is the only sense used. How their eyes are employed as a

binocular instrument has already been discussed.

In the early evening, while there is still some light to make objects fairly visible to the human eye, the Insectivorous Bats (Microchiroptera) come out from their diurnal hideouts. They are seen fluttering between the tall trees of the forest, being especially attracted to the little glades and clearings where the crepuscular and nocturnal insects abound. In the cities, especially in the South, and for the same reason, they fly around the street lamps which attract the night moths.

The Bats are unique among the Mammals, since they alone have developed a true ability to fly. The flight of the native midwestern Bats, e.g., the Little Brown Bat (*Myotis lucifugus*), Pipistrelle (*Pipistrellus subflavus*), Brown Bat (*Eptesicus fuscus*), Red Bat (*Nycteris borealis*), Hoary Bat (*Nycteris cinerea*), and others, markedly resembles that of the Chimney Swift among the Birds and of the Dragonflies among the Insects. (*See* for details A. E. Brehm, v. 10, 1912; H. E. Anthony's *Field Book of North American Mammals*, 1928; and G. M. Allen 1939.)

The characteristic feature of the flight of Bats is the frequent sudden turns, sometimes amounting to aerial somersaults. The component turns of the flight are quite short, the impression of the entire performance being that of a constantly changing zigzag line, hence called erratic. By comparison, the turns of a Barn Swallow and even more those of the Purple Martin are gentle. There is also some slight resemblance to the flight of a Nighthawk, which also makes occasional sudden turns.

The Bats depend largely on their hearing, which is extraordinarily developed. In fact, it is capable of responding not only to high-pitched tones audible to the human ear but also to the ultra- or supersonic stimuli to which the human ear does not respond (Galambos 1942, 1943; Galambos & Griffin 1942; Griffin 1944, 1946, 1950).

Whether hearing is the only long-range or distance sense in the Bats, as it undoubtedly is the leading one, is a problem to be dealt with in the future. The excrescences over the muzzle which many species possess, richly supplied by the terminals of the trigeminal nerve, may be structures of a refined vibratory or tactile sense co-ordinated with the auditory sense proper. (*Cf.* F. P. Möhres 1952.)

In any case, the Bats appear biologically to be a mammalian counterpart of other aerial insect hunters, the Swallows, Swifts, and Dragonflies, whose leading sense is vision. All of them have a similar mode of life and subsist upon a similar diet. The only difference is the form of physical energy used for orientation and the sense organs by which they detect their flying food: in Birds and Dragonflies light and the eyes, in the Bats sound vibrations and the ear, and possibly the trigeminal sense. Hence one group of animals is practically entirely adapted to diurnal conditions, the other to nocturnal. The period of activity also determines what their enemies are: diurnal Birds and Insects hunted largely by diurnal Birds of Prey; Bats, mostly by Owls. (*See* on ultrasonic perception of Porpoises, Kellogg & Kohler 1952.)

The Owls (Tytonidae and Strigidae) are of special interest as a comparison. Like the Bats, they, too, are practically entirely adapted to the nocturnal way of life. Their two principal problems—the procurement of food and the avoidance of annihilation—they have solved differently, by an overdevelopment and scotopic specialization of vision, although the auditory sense is not neglected.

While the Owls reign supreme over the smaller Vertebrates that populate the forests, fields, and barnyards, the Bats dominate the hosts of nocturnal insects in the fields and forests. Both take advantage of the numerous creatures that use the nocturnal reduction of light as a means of escaping from their pursuers. In the case of the Owls and Goatsuckers, this seems to be an adaptation of the original sauropsidan diurnality to the nocturnal adaptation of their prey, mostly small Mammals and Insects. In the case of the Insectivorous Bats, it is rather a continuation of a nocturnal habit inherited from their ancestors, the Early Mammals, as discussed in the section on the Common Shrew.

Another ecological relationship is between the Owls and Bats, which is that of predator and prey. Both are adjusted to nocturnal life, even though in different ways. The fact that,

although using different leading senses, both remain a thriving part of the faunal community indicates their complete and successful biological adjustment to each other.

(For a description of twenty-four-hour activity of animals in tropical Africa *see* Martin Johnson, *Camera Trails in Africa*, 1924, chap. XIII: "Seeing Africa from a Blind.")

9. Photopic and scotopic modes of vision and their antagonism as a molding factor in vertebrate evolution.—The two modes of vision, diurnal and nocturnal, may be considered two opposite, alternative habits used for the same biological purpose, which is the maintenance of life. If one does not work, the other still remains to be tried. When conditions become unbearable in full light, there is darkness to escape into; and when, after a period of trial and error, this does not work, a species, a family, or an order may try to save itself by switching back to habits long since abandoned. If this succeeds, fine; if it fails, the unsuccessful species perishes. It is a deadly game of biological hide-and-seek, where the forms and methods of making a living constantly change and the "formalities" are abandoned for the sake of saving the "substance," the life.

In this game, which Charles R. Darwin appropriately called the "struggle for existence," as in a complex duel, partners change positions, or they change partners; or they abandon the contest altogether, by retiring into quieter recesses of nature. They may do so either forever, or temporarily, for longer or shorter periods. When they are found again by their ever searching pursuers, they may be forced to join the battle, even though in different circumstances and with new weapons and new protective equipment.

The original conditions from which the Early Vertebrates emerged and how they began to use vision as an instrument of their phylogenetical advancement remain unknown. Even so, it is legitimate to speculate that at a certain stage of its phylogenetical perfection the Vertebrate Ancestor came into possession of a bodily organization which in the further course of evolution caused it to become a true Vertebrate. (*See* chap. XIII, 2.)

The Vertebrate Ancestor, we may assume, almost from its inception, must have been organized along a vertical-sagittal plane, with a leading cephalic extremity at one end and the formation of a principal locomotor apparatus at the other. The creature, furthermore, must have been photosensitive, a faculty that became gradually centered in the cephalic end of the body.

In fact, the photosensitiveness must have been the very factor that gave impetus to vertebrate origin, as already discussed. Also, the nature of the circumstances that shaped the Vertebrate Ancestor makes it probable that its photosensitiveness was at first negative. But it was just as imperative in the subsequent phase of its evolution that the same Ancestor became positively photosensitive, since only thus could it have evolved into a true Vertebrate. The result was an animal dominated by its photoreceptors.

When the Vertebrate Ancestor evolved into an early Fish, its photoreceptors assumed the form of eyes resembling those possessed by the modern Fishes. These eyes were capable of forming images of external objects, to which the brain and the locomotor apparatus responded in a purposeful way. This was the case, irrespective of whether the result was a phobic reaction, flight, as when avoiding a pursuer, or a positive reaction, as when attracted by a prey to be pursued. In both cases the sense of sight was a decisive factor.

It must, then, be assumed that the early Fishes were strongly diurnal, just as most modern Fishes still are (notable exceptions being elasmobranch Sharks and Rays, chondrostean Sturgeons, siluride and ameiuride Catfish, and some other forms). The reason for this assumption is the necessity of procuring food, which in most cases consisted of moving animals which had to be captured by active pursuit. The few species of Fishes that have rudimentary visual organs or have lost them altogether are those that became trapped by conditions where the sense of sight, because of the absence or extreme reduction of light, had lost its usefulness, as in the cave-dwelling species (*see*, e.g., Ramsay 1901).

The fact of the almost universal dependence of Fishes on vision is, in another way, demonstrated by the abyssal forms living at great

depth in the oceans, where little or no light penetrates (*see* Beebe 1930, 1931, 1932, 1934). These have developed various modes of artificial illumination as a substitute for the absent natural light which permit them to use their organs of sight in a more or less normal manner. (*See also* La Gorce & Marden 1952.)

When the first Amphibians evolved from their piscine ancestors, they were able to continue their customary way of life in full light. This was natural for them because daylight vision is superior to vision in reduced illumination. And this was possible because no important terrestrial animals, including Arthropoda, of which the Winged Insects, for example, were just beginning to emerge, had as yet appeared. The paleontological record of the Carboniferous Period of the prehistory of the earth, dating approximately 205 to 255 million years in the past, indicates this.

It was just during this period that the Amphibian Class reached its climax. But soon, owing to the very fact that some Amphibians developed in such a way that they were able to prey upon their weaker congeners, the remainder were forced to adapt themselves secondarily to a secretive or nocturnal way of life as a means of survival.

When subsequently more highly organized Vertebrates evolved, first, the Reptiles, and from these the Birds and the Mammals, the situation became even less favorable, pushing the surviving Amphibians even deeper into a nocturnal way of life. As a reminiscence of their phylogenetical transformation from diurnal aquatic animals into nocturnal or seminocturnal terrestrial dwellers, even now most modern Amphibians, after passing through the initial aquatic phase, remain for the rest of their life dependent on water as a permanent refuge.

In their adulthood, according to competent authorities, most Amphibians are rather attracted to poorly illuminated, damp localities and, in general, shun strong light. The reasons for this amphibian nocturnalism and scotopia are not difficult to find: their small size, inefficient organization, and general helplessness, which make it difficult for them to compete with more highly organized and more efficient rivals. These circumstances, then, must be considered the principal factor which imposed upon the Amphibians the largely scotopic way of life.

The result of the adaptation of the aquatic Vertebrates to terrestrial conditions, in so far as vision is concerned, was a change from the overwhelmingly photopic vision of the Fishes to the preponderantly scotopic vision found in the Amphibians. The impetus for the change from the aquatic to the terrestrial environment, it seems, was not only a search for food but also the necessity of escaping predators among the fish. Yet the Amphibians, since their development takes place in the water, had to continue their close attachment to it, even though they could return to it safely only when the photopic vision of most of their finny pursuers was put out of action during the night. It was the first major period of stress, the "amphibian bottleneck," which the evolving Vertebrates had to pass through in their conquest of a new environment.

When during subsequent periods predaceous Reptiles evolved, and from these predaceous Birds, both largely diurnal in habit, the nocturnal habit of the Amphibians continued not only to serve them well but also to keep them perpetually under its influence.

The luxuriant development of the Vertebrates at the reptilian stage became possible through a complete emancipation from their former aquatic habitat and through continuation of their ancestral piscine diurnality, which is especially pronounced in the Lizards.

When the first Mammals developed during the age of Dinosaurs or Dominant Reptiles, they were again pushed into nocturnality as the only means of avoiding extinction. This second depression, the "mammalian bottleneck," may have been more severe and exacting than the first, the amphibian, since the Mammals were entirely emancipated from their ancestral refuge, the water, and there were now many more diurnal predators, both the Reptiles and the Birds. This bottleneck left a deep imprint upon the entire mammalian class which has lasted until the present (*see* section on Common Shrew, this chapter).

Only relatively few of the mammalian orders have been able to emancipate themselves from nocturnality and return to their habit of good, clear daylight vision possessed by their aquatic ancestors, the overwhelmingly diurnal Fishes.

The most successful in this reorganization of visual apparatus were the Higher Primates, the Monkeys, Apes, and Humans. But among the Primates also there are some notable exceptions. The Lemurs, as a rule, are overwhelmingly nocturnal (Hooton 1942), apparently a secondary adaptation of the originally diurnal Tree Shrews and the Early Primates which succeeded them.

The climax of nocturnality, finally, was attained by the Tarsiers, which among the Higher Mammals are the most completely adjusted to nocturnal life (*see* section on Tarsier, this chapter). The Bats went even further in their adjustment to life in darkness, in that they, to a great extent, eliminated vision as an active epicritic sense, relying entirely on hearing as their leading distance receptor.

The widespread adaptation to the nocturnal way of life among the now living Mammals is worthy of note. Most Dogs, Bears, and especially Cats are more or less nocturnal, and, if duplex or arrhythmic, the emphasis is on night habit. Whether this is a continuation of the primitive mammalian nocturnality exhibited by the Soricide Shrews and most other Insectivorans or a secondary adaptation to the nocturnality of the animals upon which they prey is difficult to decide.

The nocturnalism of the Mammals appears to be a "vicious circle," in which the prey tries to escape into darkness, where it is again followed by the predator, which also becomes nocturnal or arrhythmic. The pursued prey may again try to find salvation in readapting itself to daylight conditions, with a concomitant increase of visual acuity and color perception, improved audition, better locomotion, and increased intelligence. It is a perpetual process, whose success is measured by survival.

A number of vertebrate species and larger taxonomic subdivisions have adopted a mode of life where vision is of little or no use. Such are fossorial, or burrowing, speleal, or cave-dwelling, some aquatic, and many nocturnal animals, e.g., *Proteus*, *Amphiuma*, *Necturus*, Caecilians or Gymnophiona, *Sphenodon*, *Notoryctes*, *Chrysochloris*, *Urotrichus*, *Myogale* or Desman, the Moles, Soricide Shrews, Insectivorous Bats, *Spalax*, Opossum, Sirenians, and many others. Here again several reasons may have worked together to bring about the result: an inherent habit, the search for food, avoidance of extinction, small use of vision in poor illumination, and so on. The fact that most of these animals have persisted for long geological periods is an evidence of their life's success. (*See* for an able presentation of this subject G. L. Walls's book, *The Vertebrate Eye*, 1942; *see also* Platc 1922–24; Hesse & Doflein 1935–43.)

Chapter XV

Vision and Its Role in the Origin of Man

SEC. 1. THE ROLE OF VISION IN THE EVOLUTION OF VERTEBRATES

1. Phylogenetical role of vertebrate visual system.—The most advanced of the animals, the Vertebrates, rely more than other living creatures upon the information they receive from their environment through their organs of sight to satisfy their principal needs, viz., the acquisition of food, self-preservation, and reproduction. This dependence is so complete that we can say that without the visual organs and the visual system there would be no Vertebrates. In this sense vision and the Vertebrates are one. Without the sense of vision, the vertebrate forms of animal life would never have developed (*see* chap. XIII, 2). Nor would the Vertebrates have differentiated into countless forms during the preceding geologic periods.

The few exceptions, such as the cave-dwelling species, all of whom derive from ancestors with well-developed visual organs, are aberrations which merely underline the rule. The same statement is equally applicable to the nocturnal forms, such as the Bats and other Insectivores and some Rodents, where vision became unimportant or was abolished altogether.

2. Vision and the visual organs in the economy of Vertebrates.—In appraising the relative importance of vision in the life of Vertebrates in comparison with the other senses and faculties, it is necessary to avoid both exaggeration and oversimplification, faults which the obvious importance of the sense of sight might induce. A balanced view is obtained only through the study of all pertinent factors: the visual organs and centers themselves, their minute organization, physiological performance in normal and pathological conditions and in experiment, and not least through observation of the behavior of living animals and of the biological conditions under which each larger group or individual species lives.

Such investigations may reveal many of the numerous factors that make up the "external world" of each particular group or species, to which it is adjusted in internal organization, habits, temperament, and all other respects. This may show unsuspected adaptations undergone by one species or another and many deviations from the original plan. As a result, such study may reveal each animal species to be a true reflection of all those numerous factors which are summed up in the concept of habitat or environment.

The exact role played by vision in the phylogenetical advancement of the Vertebrates, in particular of the Mammals, and in the rise of the Primates is exceedingly difficult to determine. Superficial examination gives the impression that vision was the major, and probably the decisive, factor in primate evolution, culminating in the advent of Man and in the development of human intelligence. However, other important factors unquestionably contributed their share to this outcome. The difficulties in the way of an objective appraisal are formidable, because of the long course and fluctuations of the evolutionary process, with the shifting of emphasis from one factor to another and with some factors working at cross-purposes. The major difficulty remains the insufficient record of life during past ages.

It is obvious that a study of the role of vision in the various Vertebrates, to remain within the bounds of the practicable, must be limited to a few representative cases. Hence vast material must remain untouched. In the preceding chapter, therefore, we described and analyzed a few representative Vertebrates, beginning with the Fishes and terminating with the Mammals. These phylogenetically graded portraits, even though few, may nevertheless give a glimpse of the forces and factors, including vision, that

have molded the Vertebrates into their various shapes and given them their many diverse roles.

In this chapter the probable factors responsible for the advancement of the Primates and the probable role of vision in this advancement are discussed. In particular, an attempt is made, by a careful analysis of known and some hypothetical factors, to identify the circumstances responsible for the rise of Man to his present pre-eminent status in the world.

3. Classification of the Vertebrates according to their dependence on vision.— The earliest Vertebrates were the Fishes, living in the aquatic habitat in which they originated. They were followed by the transitional Amphibians, from which arose the terrestrial Reptiles, which, in turn, gave rise to the Birds and the Mammals.

Together with other animals, such as the unicellular Protozoa, the multicellular Coelenterates, the various more or less wormlike animals, the Arthropods, Mollusks, and others, the Vertebrates are assembled in numerous diverse communities whose members depend upon one another to a greater or lesser degree. This is equally true of plant life, without which animal life would not be possible. All these factors contributed in one way or another to the rise of Vertebrates and their multifarious differentiation and are indispensable to their maintenance.

The phylogenetical perfection of the visual function of the Vertebrates, as far as the available evidence permits us to judge, was not a straight line ascending from the lowest to the highest levels. Among the fishlike classes, especially among the many Teleosteans, there are some with structurally highly organized eyes, including a differentiated fovea, and sight which is among the keenest of all Vertebrates. Contrasting with these are Fishes, with small, poorly developed eyes and vision which biologically plays a subsidiary role at best. The extreme is the cave-dwelling species, where the organs of sight have become atrophic or have disappeared altogether. Except for these qualifications, the Fishes, even though phylogenetically the most primitive Vertebrates, are among the most advanced visually.

The Amphibians, even though as a class they have progressed further, are, on the whole, inferior to the Fishes in visual equipment and performance. In comparison, the level of the visual attainment of the Reptiles is above that of the Amphibians, many being equipped with a highly differentiated retina and fovea, an efficient oculomotor apparatus, and elaborate centers. In functional accomplishment and versatility some Lizards—for example, the Chameleon and Anole—equal and in some respects exceed most other Vertebrates (*see* preceding chapter). Many other Lizards—for example, the large *Anolis equestris* of Cuba and the Rhinoceros Iguana (*Cyclura cornuta*) of Haiti and Puerto Rico—judging from their extensive eye movements, may also have an efficient visual apparatus.

The Birds, with their relatively enormous eyes and minutely differentiated retina, which has one and sometimes two or more differentiated foveae or areae, are the visual animals par excellence, in which this faculty by far predominates. Many Birds also excel in ocular movements and are certainly in this respect superior to all Mammals, including Man and other Primates, contrary to the opposite statements on this subject by the foremost authorities. This is well illustrated by the Swallow and the Eagle, as described in the preceding chapter. The observations on other species, as, for example, the Rhinoceros Hornbill (*Buceros rhinoceros*) of Java, which can easily perform extensive eye movements, also indicate the presence of a highly differentiated visual apparatus. (For details on the eye of Fishes, Amphibians, Reptiles, and Birds *see* chap. V, 11; for the visual pathway *see* chap. VI, 5.)

The Mammalian Class is quite diversified in the structural development of its visual organs and their function. It contains orders, families, and species, such as the Primates, including Man, which, in the organization of their visual apparatus, are fairly close to the top of all Vertebrates, while the Orders of Insectivora and Chiroptera are characterized by a pronounced microphthalmia and poor sight. In a few extreme cases vision is abolished altogether. The remaining orders, with respect to vision, range themselves between these two extremes. Each order, family, and often each particular species of Mammal, in the adaptation of sight, is an exact reflection of its particular mode of life and

FIG. 518-A—Samples of fruit native of the Middle West of North America, or introduced from abroad. Center: Hawthorn apples of Red-Fruited Thorn (*Crataegus mollis*), of somewhat angular spherical shape, the largest measuring one-half inch diameter, crimson red in color, the smallest immature fruit orange colored. Right and left: clusters of Pimbina or Highbush Cranberry (*Viburnum opulus amer.*), fruit broadly ovoidal, one-third inch long, translucent bright scarlet or cardinal red. Upper center: Lance-leaved Buckthorn (*Rhamnus lanceolata*), fruit globular in shape, one-fourth inch in diameter, and purple-black in color. Below: a twig of Matrimony Vine (*Lycium halimifolium* or *L. barbarum*), native of Central Asia, with several ripe berries, ovoidal in shape, one-third inch long, red in color, with a few unripe smaller berries green in color, and a blossom with violet petals and yellow stamens. The ripe, brilliantly colored fruit vividly contrasts with the green foliage, while the unripe green fruit blends with it, hence it is difficult to see by the shape alone. The same is also true of the ripe dark-colored Buckthorn berries which can easily be seen against the clear sky between the leaves. The biological rôle of the red, orange, yellow, purple, blue, violet, black and white fruit is two-fold: one, to attract animals, principally Birds, capable of responding visually to it, and to use it as food; the other, to disperse fruit seeds through the agency of animals. In this way the evolution of the colored fruits and of the color sense became biologically beneficial in two ways: by furnishing food to animals, and by dispersing plants into new regions of the world.

the requirements of that life. Each Mammal, in other words, is the product of a particular combination of evolutionary factors. However, whereas each particular smaller or larger taxonomic group of Mammals reacted in the manner and degree of development of its vision to its particular mode of life, other and more basic factors have put a general imprint upon its visual behavior.

4. Vision and the origin of Mammals.—The most primitive of living Mammals, the Insectivores or Bug-Eaters, are of special interest in the phylogeny of primate vision. In their bodily organization they are at the bottom of the mammalian scale. Phylogenetically they are closest to their reptilian ancestors. This contention is further corroborated by paleontology, which shows the most ancient Mammals to have been insectivorous in character (*see* Fig. 477).

This poses the following alternatives: first, since the Early Mammals may have evolved from large-eyed and keen-sighted Reptiles, they probably had inherited good vision. In this case the reduced sight of the Insectivores would be a secondary phenomenon imposed by their special mode of living. The other alternative would be a reduction of vision in the earliest Mammals, or possibly such reduction had already occurred in their reptilian ancestors during the evolutionary process of becoming Mammals. In either case, differing only in time, the Mammalian Ancestors or the Early Mammals must have reduced their dependence on vision and compensated for it by increasing their reliance on other senses, especially those of smell and hearing, as the only means of survival.

An enforced adaptation to optically unfavorable circumstances may be described as an "evolutionary bottleneck." Those Reptiles that were to become Mammals had to squeeze through it. While undergoing this long and painful process of severe reorganization, the vision of the Early Mammals was lost, in some largely, in others entirely. When, at the end, a Reptile was transformed into a Mammal, it is plausible that little remained of the original good reptilian vision, barely enough to form a nucleus from which a fresh start could be made. Such a nucleus was preserved in those forms that did not undergo an extreme degree of adaptive specialization. Such may have been some tropical Shrews and possibly forms similar to the Gymnurinae of India. Others, exemplified by burrowing forms like the Moles, in which the eyes became reduced to insignificance, apparently had no role in the further evolution of Vertebrates.

5. Impediments to a progressive evolution of Mammals.—The factors which constituted the "evolutionary bottleneck" mentioned earlier can be identified only by circumstantial evidence. One factor may have been the Dinosaurs or Dominant Saurians, who at that time were at the zenith of their development, preying on weaker inhabitants of the dry lands. Another may have been the Pterosaurs or Flying Reptiles, which infested the air. However, these may have been merely the most palpable "enforcers" of an emerging new order, while there were probably many other more subtle and elusive factors which are now impossible for us to determine or appraise. Whatever these factors were, their discipline was extremely severe, and their influence lasted many millions of years.

The result was that for many weak animals there were but few avenues of escape from certain annihilation. One was flight into the twilight of dense vegetation; the other was subterranean retirement; and the third was to take to the trees and thence, for some, to the air. The ancient Mammals followed all three evolutionary avenues. In all cases they had to adjust themselves to different living conditions. The common feature of the first two was to decrease or abandon vision, while in the arboreal and aerial way of life, on the contrary, the sense of vision became dominant.

The nascent Class of Mammals, in order to squeeze through the "biological bottleneck," had to undergo numerous adaptations in habits, functions, and anatomical organization. The Early Mammals had to follow specific rules of life. Their body size had to remain small. As compensation for their reduced or lost sight, they had to overdevelop their senses of smell, touch, hearing, and gustation and, in general, remodel their characters and temperaments to a high degree of alertness, boldness, persistence,

and endurance. They had, in addition, to reorganize their entire bodily machine, which required an increase of fuel for a greatly stepped-up metabolism to cope with the increased expenditure of energy imposed by their small size and greater activity. In most essential changes the terrestrial and subterranean Insectivores were emulated by their winged relatives, the Insectivorous Bats or Microchiroptera, with the important qualification that the latter became entirely dependent upon hearing and possibly upon touch and vibration, as the guiding senses in the procurement of their insect food, which they caught exclusively in flight.

6. POSSIBLE EXCEPTIONS IN THE EVOLUTIONARY MAMMALIAN BOTTLENECK. – The evolutionary process sketched here, which resulted in a transformation of some Reptiles into Early Mammals or Protomammals, still remains

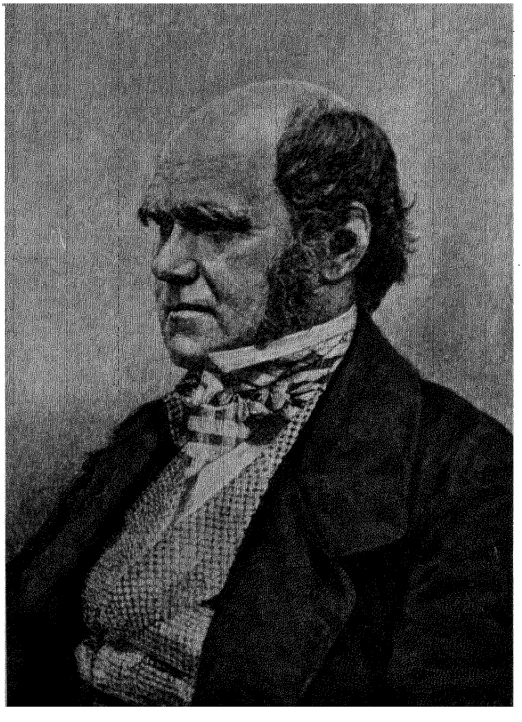

FIG. 519.—Charles Robert Darwin (1809–82) at the approximate age of forty-five. One of the most influential naturalists of all time. In Haeckel's opinion, "a Newton of the organic world." Author of the book *On the Origin of Species by Means of Natural Selection, or the Preservation of Favoured Races in the Struggle for Life*, 1859; *The Descent of Man, and Selection in Relation to Sex*, 1871; etc. Elaborated the idea of "evolution" of animals and plants, by proposing the theory of the origin of species from lower forms under the influence of "natural selection" and of "sexual selection," as the molding factors which in the continuous "struggle for existence" have produced all forms of life which have existed during the past ages and presently populate our globe. Darwin's ideas, as few in the history of mankind, profoundly influenced biological thinking and have affected the entire concept of nature, of life in general, and of Man's relation to nature and the world in particular. An engraving made in 1881 for *Harper's Magazine* from a photograph taken by Messrs. Maull & Fox, 1854, and published as a Frontispiece to v. 1 of *The Life and Letters of Charles Darwin, Including an Autobiographical Chapter, Edited by His Son, Francis Darwin*, by John Murray, 3 vols. London, 1888. (For additional biographies *see* O. Hertwig 1909; W. Waldeyer 1909; Bradford 1926; M. C. Lloyd 1928; J. Rostand 1947; and an autobiography edited by Sir Francis Darwin, 1950.) *See* following figure.

largely obscure. We must very inadequately substitute hypothesis for knowledge of most of the factors which were involved and their interplay.

It is certain that those species which had adapted themselves to subterranean and aerial modes of life did not contribute to the rise of the

It is not at all improbable that some strains of the Early Mammals now extinct did not sink to the point of visual dissolution found in most of the modern Shrews and Moles. Their "biological bottleneck" may have been a little less narrow than that through which the ancestors of the Soricidae and Talpidae went.

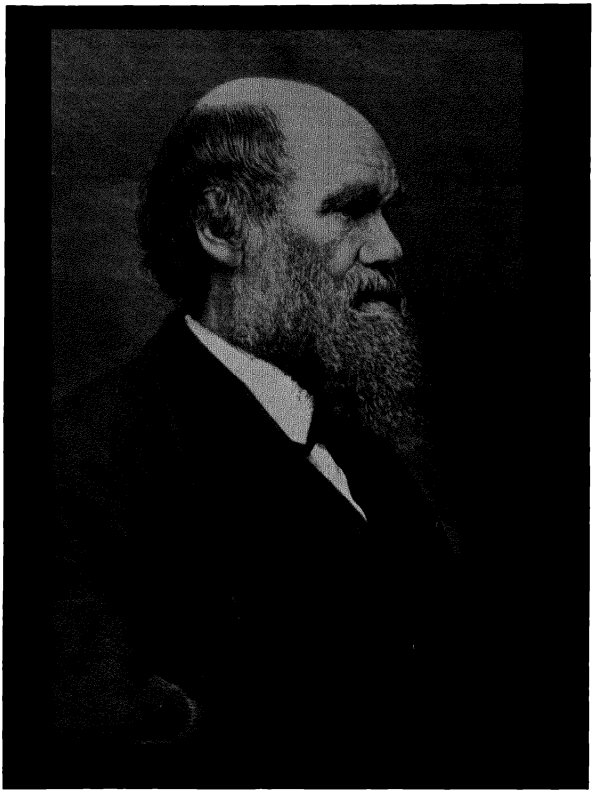

FIG. 520.—Charles Robert Darwin (1809–82) in advanced age. Courtesy British Information Service. *See* preceding figure.

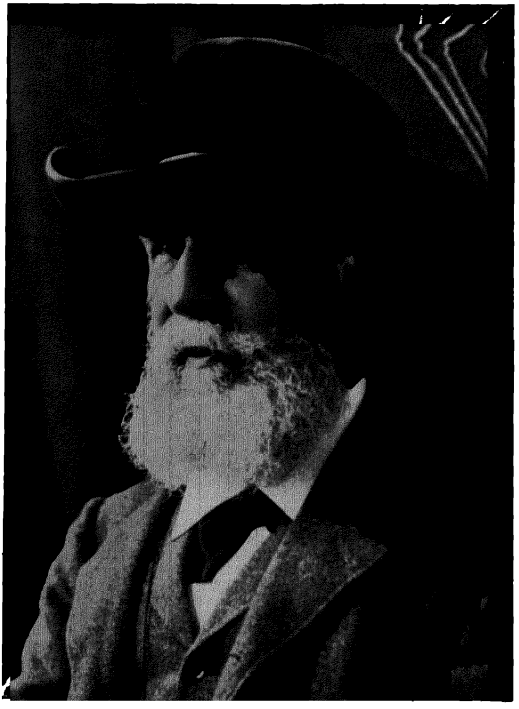
Primates. It must have been different with those Early Insectivores or Protoinsectivora which remained on the ground. They were able to retain their general features, such as dentition, proportionate limbs, some omnivorous taste, and, most important, a modicum of the original good vision inherited from their reptilian ancestors.



The living testimony of this contention possibly is found in some modern Insectivora such as the Hedgehogs, whose vision, even though not excellent, is better than that found in most of the terrestrial Shrews (as Herter & Sgonina 1933 found in their experiments). Other examples may also be cited: the Water Shrews, the African *Potamogale*, and perhaps most of all

the Indian Gymnurinae and the African Elephant Shrews or Macroscelidae (*see* Figs. 478, 479). All these, according to the scanty information available, have fair vision, even though some are nocturnal (Brehm). Enough similar well-seeing forms of the Early Mammals may have persisted during the "dark ages" of early mammalian evolution, to form a start from which more advanced Mammals have subsequently developed.

7. PROBABLE FACTORS RESPONSIBLE FOR THE EVOLUTIONARY PROGRESS OF EARLY MAMMALS.

What were the probable biological factors that initiated and continued transformation of the Early Insectivores into more advanced Mammals?

If living Insectivora are at all representative, some of their Triassic ancestors may not have been exclusively "insect-eaters," that is, depending solely upon Arthropods, Snails,

Ernst Haeckel

FIG. 521.—Ernst Heinrich Haeckel (1834–1919), biologist and philosopher, at the age of eighty. Professor of zoology at Jena, Germany. Protagonist of the idea of organic evolution. Formulated the "first law of biogenesis" or an abridged embryonic recapitulation of the historic evolution through which the particular animal species passed during its phylogenetical past. One of the chief defenders of Darwinism. Author of *Allgemeine Anatomie (generelle Morphologie) der Organismen* (1866), *Natürliche Schöpfungsgeschichte* (1868), *Anthropogenie oder Entwicklungsgeschichte des Menschen* (1874), *Studien zur Gastraeatheorie* (1877), *Die Welträtsel* (1899), *Die Lebenswunder* (1904), etc. Portrait from Haeckel's *Die Natur als Künstlerin*, Vita Deutsches Verlagshaus, Berlin-Charlottenburg, 1914. Biography *ibid.*; another by Bölsche 1906.

Slugs, Centipedes, Earthworms, and other small creatures easily procured through olfaction, audition, and gustation. Their diet must also have included some of the fruits, such as various berries and nuts and also buds. Small Rodents, such as Mice, Rats, Chipmunks, and Squirrels, are a good illustration of this. Fruits, to be sure, may also have been procured principally through smell. But the fact that much of this plant food grew above the ground and had to be noticed at a distance and reached by climbing implies the necessity of at least some adaptation to an arboreal mode of life. Moderately fair vision was a necessary requisite for this. The desire to gather fruits which grew on bushes and trees may have been the inducement to take the first step away from a strictly terrestrial manner of life and to embark upon a more venturesome career above the ground.

An additional inducement may have been the appearance of winged insects and their larvae and pupae during the late phase of the Carboniferous Period, long before the first Nonplacental Mammals of the late Triassic Period emerged. A subsequent inducement may have been fruits growing on angiosperm plants during the Jurassic and Cretaceous Periods of earth's prehistory (from 152 to 58 million years ago, according to Zeuner 1952).

All these factors and probably others may have provided sufficient stimulus for some of the Early Insectivores to take to the trees, to embark upon an arboreal mode of life, eventually terminating in the development of Primates—the Lemurs, Tarsiers, Monkeys, Apes, and Humans, and, as a side line, the Flying Bats.

Other and more numerous Early Mammals pursued their divergent evolution, forming numerous extinct and living modern orders: Carnivores, Cetaceans, Ungulates, Rodents, and others. Each of these followed its own evolutionary line, including its own mode of vision, whose past history, specific biological motivation, structural equipment, and physiological performance are at most sketchily known, or are not known at all. (*See* G. G. Simpson 1949, 1953; W. K. Gregory 1951.)

SEC. 2. THE ROLE OF VISION IN THE ORIGIN OF PRIMATES

1. The foundations of primate vision.—The foundations upon which primate vision, including Man's, are built are at least as old as the entire Chordate or Vertebrate Phylum. (This theme is dealt with in chap. XIII, 2.)

This still leaves the question: What were the particular factors, and how did they work together, which shaped the specific character of primate and human vision, whose salient features are diurnalism associated with high visual acuity; well-differentiated color sense; strictly binocular stereopsis; and richly developed mental attributes?

The first requisite in finding the answer to this question would be to know the various ways in which other Vertebrates have solved their particular problems of vision. Unfortunately, we do not have this knowledge. There is, therefore, little with which primate vision can be compared. The few samples given in the preceding chapter, especially the Anole and the Swallow, at best merely indicate the solution of this problem, emphasizing at the same time its great complexity.

2. Character of primate vision and the origin of the Primates.—The first important feature of primate vision is the obligatory or permanent binocular stereopsis in which both eyes work in unison, with the larger parts of the two monocular fields in common. In this way each eye receives a slightly different image from the same object. In the visual centers of the brain the two slightly discrepant images are fused into a single subjective experience, of which the tridimensional character, or perception of depth, is the distinguishing feature.

Two other essential features are diurnalism and high central acuity, made possible by the formation of a specially differentiated central fovea. The fourth feature, also associated with the diurnal habit, is color vision, best developed in and around the fixation points. To these four, a fifth essential feature, more highly developed in Man than in any other species, must be added—the faculty to discriminate, that is, to see intelligently, to memorize, to reproduce subjectively, and to utilize past visual experiences in many practical ways, alone and in combina-

tion with experiences received through other senses and memorized, all of which forms the specific "human mind." This is a subject which from Aristotle to our own times has inspired a profuse literature (*see* Part I, in this book, especially chaps. II, III, and IV; on physiological optics *see* especially H. von Helmholtz' *Treatise*, 1924, and others; and Bethe *et al.*, Handb. d. norm. u. path. Physiol., 1929–31).

3. ELLIOT SMITH'S HYPOTHESIS OF VISION AS THE CAUSE RESPONSIBLE FOR THE RISE OF PRIMATES.—The problem of the origins of primate vision has been in the focus of scientific interest for the past few decades. G. Elliot Smith and his associates and followers did most to keep it alive. In his essays on *The Evolution of Man* (1927), in which he plotted the probable course that led to the rise of Man and the factors that contributed to it, he wrote (p. 44):

> Increased reliance upon the guidance of the sense of sight awakened in the creature [Tarsier] the curiosity to examine the objects around it with closer minuteness and supplied guidance to the hands in executing more precise and more skilled movements than the Tree Shrew attempts. Such habits not only promoted the development of the motor cortex itself, and cultivated the discriminative powers of the tactile and kinaesthetic senses, but they linked up their cortical areas in bonds of more intimate associations with the visual cortex.

In the process of the rise of the Primates from the Infraprimate Ancestors, the increase in size and functional elaboration of the great prefrontal areae, "concerned with attention and the general orderly co-ordination of psychic processes," and the further evolution of cortical centers of conjugate eye movements were the prerequisite milestones, a goal not yet attained by the Tarsiers but only by the true Monkeys. In Elliot Smith's words:

> The Primates at first were a small and humble folk, who led a quiet life, unobtrusive and safe in the branches of trees, taking small part in the fierce competition for size and supremacy that was being waged upon the earth beneath them by their carnivorous, ungulate, and other brethren. But all the time they were cultivating the equable development of all their senses and limbs, and the special development of the more intellectually useful faculties of the mind that, in the long run, were to make them the progenitors of the dominant mammal—the mammal destined to obtain the supremacy over all others, while still retaining much of the primitive structure of limb that his competitors had sacrificed.

The foregoing paradisaical picture of the conditions in which the Primates were reared during their infancy may be essentially true, even though our information is too scanty to pass an objective judgment on it. The point that raises our doubts is the aggressive character of the shrewlike ancestors of the Primates, so much emphasized by most observers (as described in chap. XIV, 9), and a similar trait characterizing practically all terrestrial Monkeys of the Old World and likewise the Apes and Man (*see* secs. 4 and 5, this chapter). As presented by one of the competent observers, S. Zuckerman (1932), incidentally verified on many occasions by the writer of these lines, the character of many Simians is far from peaceful innocence; in fact, it often verges on demoniacal sadism and cruel despotism. The possible importance of this trait in human evolution is further discussed in subsequent sections of this chapter. (*Cf. also* Hooton 1942.)

4. THE PHYLOGENY OF VERTEBRATE STEREOSCOPIC VISION.—The development of stereoscopic vision appears to have been one of the essential factors in the evolution of the human intellect. Just how primate stereopsis evolved and just how it, in turn, became instrumental in the rise of Man's intellect—the core of the problem of anthropogenesis—is not as yet clear. The views expressed on this subject are not precise and not well documented. The following remarks are intended to help solve this problem at some future time when more positive information becomes available.

Let us begin with the definition of stereoscopy, which simply means single, tridimensional vision with two eyes. However, before analyzing its conditions and possible causes, it is important to point out the magnitude and complexity of this problem, the solution of which will require concerted action along many lines of approach: physical-optical, anatomical, physiological, and psychological. Also it must be borne in mind that human stereopsis is only a special case, one of the many ways in which the problem of tridimensional single vision was solved by the various Vertebrates and Inverte-

brates. (*See* interesting comparative study of vertebrate stereopsis by J. Orione 1950.)

Binocular stereoscopic vision is already clearly expressed in the lowest Vertebrates, the Fishes. According to Rochon-Duvigneaud (1922, 1925, 1933, 1934, 1943), Verrier (1927, 1938, 1945), and my own studies, in almost all Fishes so far examined the frontal portions of the monocular fields of view overlap, producing a common binocular field comparable with that of Man (*see* sections on Sunfish, Trout, Pike, and Bullhead, in chap. XIV).

In Man, it is assumed, single stereoscopic vision is accomplished through the fusion of two homonymous sets of fibers above the chiasma, carrying similar or identical impulses from both retinae (*cf.* chap. VI, 4, 5, 6; *also* Fig. 361). In the Inframammalian Vertebrates, in which chiasmal decussation is believed to be complete, Rochon-Duvigneaud assumed a different arrangement within the cerebrum to compensate for such total crossing. In my own experiment with the Pigeon the optic fibers were found to be completely crossed in the chiasma (chap. VI, 5 [3]). However, two small bundles were found to recross above the chiasma, to terminate in the ipsilateral half of the diencephalon (*see* Fig. 190). That this arrangement must have some function, even though we remain ignorant of it, is obvious. On the other hand, this ipsilateral connection is too scanty to serve as the basis of stereopsis. Additional anatomical and physiological experimental investigations upon keen-sighted Birds, such as the Eagle, Hawk, Swallow, Swift, and others, are required to clarify this and related points (*see* sections on Anole Lizard and Swallow, chap. XIV, 7, 8).

Whereas there is the possibility of an arrangement in the visual system of Birds and Reptiles which would effectively duplicate the partial decussation in the chiasma of Mammals, even though this is unlikely because of the absence of commissural connections of both neopallia by way of the corpus callosum, such compensatory partial recrossing of the optic fibers above the chiasma in the brain of Fishes is even less likely. Hence the problem of vertebrate stereopsis must be sought in a different direction.

In the Inframammalian Vertebrates, according to Rochon-Duvigneaud, a lifelong investigator of vision in all classes, the two eyes are mostly used independently. On special occasions both eyes are used simultaneously, as a conjugate team, aiming at a single object. The binocular association, then, in all Vertebrates below the Mammals is a facultative arrangement. In the Mammals, definitely so in the Primates, on the contrary, the two eyes have lost their independence, becoming permanently coupled into a team always working in unison.

5. This author's view on the probable origin of primate vision from that of Infraprimate Vertebrates.—A tentative view that I formed gradually on this subject may be stated as follows: The vertebrate visual system, including its sensory and motor components, gradually evolved from the Prevertebrate Ancestors, through the Fishes, to the Mammals, according to essentially the same bilateral plan (even though the earliest optic primordia may, or may not, have originated from a single *Anlage* or orimental nucleus). This bilateral plan is the same that is manifested in all bilaterally organized animals. It is visible in the early vertebrate embryo as soon as the optic primordia are recognizable and is present without exception in the entire Vertebrate Phylum (*see* Fig. 434).

A principle of so universal an occurrence indicates an original and basic functional interdependence of the two peripheral photoreceptors, the eyes. The binocular association may undergo change, and the bond tying the two eyes may weaken, sometimes to a point of complete dissolution, but in most Vertebrates it is clearly indicated. The two eyes exert a reciprocal influence, mostly positive, occasionally negative.

In all Vertebrates, including Inframammals, the two eyes, when at rest or in their initial position, are firmly related to each other. This arrangement must be considered both anatomical and functional. It is maintained by the size, shape, and position of the two eyeballs in the orbits, by the organs and tissues filling the orbits, by the tension in these tissues sustained by circulation, by the fasciae and the common integument, and especially by the extrinsic eye muscles when at rest. This may be considered the neutral position, the position of balance. In it the two monocular fields of view have a defini-

tive position in relation to the head and are definitely related to each other.

In the majority of Vertebrates, Rochon-Duvigneaud and others and especially J. Orione found that the two fields partly overlap in front. This neutral, inactive, balanced arrangement may be changed by a number of factors, most obviously by the action of extrinsic eye muscles and their nerve centers. Consequently, the two monocular fields of view may vary in relation to each other and relative to the head.

In the Primates, owing to the coupling of both eyes into a conjugate team, the two lines of view are always focused on a single point, a common fixation point, whose distance alone may vary.

In the Inframammals there are several possibilities: both eyes may remain permanently in the neutral position; or one eye only may maintain a neutral position, while the other eye may go on exploring its own visual space as far as the anatomical limits set by the orbit, etc., which may be further increased by the movement of the head and neck, of the body, or of both; or both eyes may temporarily team up in pursuing a single, commonly viewed object, which again may be carried out with the eyes alone, with the assistance of the movements of the head and neck and/or also of the body, or of the body alone. The various movements, or combinations of movements, are specific for the animal to which they are biologically appropriate.

Only that act of vision in which both eyes are directed toward a single object should be considered a binocular visual act. In Man and in all other Primates, according to this definition, all vision is perforce binocular and stereoptic. In many other Mammals a similar situation obtains, even though it is apparent that further detailed investigation, especially in various Carnivores and other sharp-sighted orders, is necessary.

In the low-ranking Mammals, according to Rochon-Duvigneaud, the two eyes are also coupled into a functional team. This problem, however, requires further study. According to our own observations, most Rodents, such as the Mouse, Rat, Rabbit, Guinea Pig, Gopher, and Woodchuck, focus with only one eye, alternately first with one and then with the other. The Red and the Gray Squirrels also use a unilateral fixation by preference. However, on occasion, when especially aroused, they squarely face the object of their attention, focusing it with both eyes. Similar behavior was noticed in the Philippine Tree Shrew (*see* sec. 10, in the preceding chapter).

In the Guinea Pig there are no ipsilateral, noncrossed optic nerve fibers above the chiasma, and very few in the Rat, according to our own experiments (*see* chap. VI, 5 [4, 5]). Stereopsis in the sense of human vision, accordingly, must be denied to the Guinea Pig, and almost entirely to the Rat.

An incipient stereopsis, however, must be admitted both in the Squirrel and in the Tree Shrew. In both species binocularity, that is, simultaneous use of both eyes, is apparently present. Automatic stereopsis on all occasions is quite evident in some Dog varieties, in the Cat, Leopard, Lion, Bear, Monkey, Ape, and Man whose eyes face forward and whose lines of vision are directed toward the common point of fixation. In all these species, as far as investigated, almost half the optic nerve fibers remain uncrossed in the chiasma. This again harmonizes with the generally current view, according to which a partial crossing in the chiasma is an indicator of the anatomical arrangements serving stereoscopic vision. (*See* chap. VI, 4, 5 [6, 7], 6.)

6. Problem of inframammalian stereoscopic vision.—The vision of many Inframammalian Vertebrates, measured by human standards, is unquestionably far superior to that found in most Rodents, definitely so in comparison with the Guinea Pig, Rat, and Rabbit.

The binocular convergence observed in the Golden Eagle, Barn Swallow, and Anole Lizard resembles exactly that which is standard in the Primates. There is no justification for denying these species binocular stereopsis, which in some cases is possibly superior to that of the Primates. The fact that they do not have partial decussation in the chiasma, as do the Primates, is no evidence against this, since their visual apparatus has not yet been adequately investigated. Hence the possibility must be left open that in the Birds of Prey, Owls, Swallows, Swifts, the Anole Lizard, the Chameleon, and probably many other Vertebrates, including

some Fishes such as the Trout and Pike, central arrangements are present which make possible a facultative use of their visual apparatus in stereoscopic binocular vision. In fact, in some, as, for example, in the Swallow and the Anole, a central visual mechanism more pliable than the human must be postulated which permits them an easy change from purely panoramic, or largely panoramic, vision to binocular stereoscopic vision, and back again, as the functional situation demands from time to time. Such rapid switching from one visuomotor mechanism to another may be compared with a quick accommodation of dioptrical apparatus from an aerial to an aquatic condition observed in those Birds that gain their livelihood by diving.

7. THE ROLE OF ACUITY IN THE PHYLOGENY OF PRIMATE VISION.—Visual acuity is the ability to distinguish fine details of the viewed object. It is the faculty which, in addition to the ability of the visual organs to react to the photic impulses in general, may be considered basic, that is, the very essence of vision.

Visual acuity may be defined as the responsiveness of the visual organs to light stimulation, or its absence, limited in space. Its anatomical prerequisites are a photoreceptor mosaic made up of a sufficient number of individually stimulable elements, and a system of conductor units to the central organ which permits separate transmission of impulses generated from small groups or even from individual photoreceptors. Such "spatial organization" appears indispensable, indicating an inability of a diffusely organized visual system to respond spatially.

The degree of acuity of vision is a function as varied as the biological tasks it serves in the diverse animal species. It ranges from a condition that is only a little above complete lack of response to light stimuli arranged in space, through the various intermediate stages to the highest possible degrees permissible by the fineness of the organic structures and the analytical properties of the physical mediator, light. The first is exemplified among the Fishes by the Bullhead, and among the placental, eutherian animals by the terrestrial Shrews, Moles, and Bats (*cf.* preceding chapter). It is characteristic of the Order of Insectivora, typified by the terrestrial or Soricide Shrews, all animals of pronounced nocturnal habit. At the other end of the scale are types active in full daylight and possessing rapid locomotion, such as the Birds and the higher Primates, including Man, whose behavior is largely regulated by sight.

The habit of an animal, whether photopic or scotopic, is obviously decisive in determining the minimum of visual acuity each given species requires. The particular factors determining visual acuity may be imperfectly described as the "way of life," mode of locomotion, food habits, and habitat.

In the case of the Swallow, for example, a very high degree of visual acuity, associated with quick binocular convergence and instantaneous accommodation, alone satisfies the biological task of vision, which is to catch small insects on the wing at high speeds (*see* section on Swallow in the preceding chapter). Yet an equally high degree of acuity and binocular convergence and stereopsis is required by a Chickadee or Titmouse, a bird that flutters from twig to twig, instead of crossing long distances at high speeds, as the Swallow does. Even though the conditions in which these two species hunt for their prey appear on the surface quite dissimilar, in both cases they put a high premium upon sharp discrimination of fine details: the Swallow must notice and locate a minute flying insect at a great distance against the usually uniform background of the sky; the Chickadee must discover small bugs and their eggs among the leaves and in the crevices of the bark of the trees, which offer as a background a confusing variety of minute details. In such conditions only a visual apparatus capable of quick testing of minute shades of illumination and quick appraisal of shapes and sizes, transformed into a tridimensional judgment of minute distances, is good enough. A similar rapid appraisal of a bewildering number of minute details, differing little in size, shape, and color, must be made by the visual apparatus of a flying Eagle when scanning the landscape at high speeds in search of prey.

The high performance of primate vision with respect to acuity is based on numerous observations and experiments with monkeys and on innumerable tests of normal human individuals and pathological cases, as well as on practical

experience. This high degree of acuity in human vision is apparently the most important single faculty upon which Man's intelligence is based. So refined a tool is undoubtedly the product of a long evolutionary process.

By reversing our argument, it is probable that at some time in the distant past Man's Ancestors did not possess a high degree of visual acuity. The probable phylogenetical stages and the probable factors which, starting from insignificant beginnings, have produced the visual apparatus with the help of which Man rose to his present pre-eminent status, may have been as follows.

8. PROBABLE LIVING HABITS, AND THE VISUAL ACUITY OF EARLY MAMMALS.—The early shrew-like Mammals, ancestors of all subsequent Mammals, were probably humble creatures, spending their lives in subdued light in places thickly overgrown with vegetation, as do the present Shrews and many small Rodents (*see* section on Shrew in the preceding chapter; *cf.* Weinstein & Grether 1940). When some of them embarked upon a more definitely arboreal life, becoming early Prosimians, they continued their nocturnal habit, as do their descendants even now. Why many modern Lemurs persist in their nocturnalism and arboreal habit is quite difficult to explain, notably so for the bulk of the Prosimians inhabiting Madagascar, the remnant of the hypothetical ancient Lemuria, or Gondwana. There are no palpable factors in Madagascar, such as powerful carnivores, acting as "enforcers" of nocturnality. (*Cf.* J. Sibree, *A Naturalist in Madagascar*, 1915.) The explanation of the prevalent prosimian nocturnalism as being caused by an atavistic inertia is even less appealing. More easily explained is the nocturnalism of the African Galagos and Pottos and the Asiatic Lorises and Tarsiers as imposed by fierce competition from the more advanced members of the local fauna, in particular by animals of prey, such as Snakes, Birds, and Mammals, including the more advanced Primates, the Monkeys (*cf.* F. Barth 1950).

Whether or not the almost universal nocturnalism of modern Prosimians, the pure rod retina, and the color blindness which accompany it are inherited or enforced by some special factors, future investigation should be able to reveal. Contrasting with the prosimian nocturnalism is the pronounced diurnalism of most living Tree Shrews, or Tupaiidae (*cf.* section on Tree Shrew in the preceding chapter). Unquestionably, they are phylogenetically older than the Prosimians. They successfully managed to survive, in spite of their diurnalism—and, in fact, because of it—in ecologically similar conditions, while the Prosimians had to escape into darkness. What complex interplay of the various factors is responsible for this difference in habit, only a thorough study of conditions on the spot may explain. But the very fact of the presence of strongly diurnal Tree Shrews permits one to hypothesize that the evolutionary stream of Early Vertebrates which evolved into true Monkeys or Anthropoidea, almost entirely diurnal, must have by-passed the forms which became differentiated into largely nocturnal Prosimians.

In summary, just as some Insectivores may have passed through a less narrow "evolutionary bottleneck" and saved much of the diurnality inherited from their sharp-sighted reptilian ancestors, subsequently to become diurnal Tree Shrews, so the latter, or some of them, may have embarked upon an arboreal way of life, to become primitive Primates and subsequently true Monkeys, without sacrificing much, if any, of their original diurnality. The evolutionary road along which moved those Vertebrates eventually to become Higher Primates, that is, the Monkeys, Apes, and Humans, may have been less devious than is commonly assumed. The diurnality of the piscine and reptilian ancestors of the Mammals may have continued uninterruptedly, without too profound modifications, through the Early Mammals into Tree Shrews and finally into higher stages of Primates and Humans. (*Cf.* Le Gros Clark, *History of the Primates*, 1953.)

9. DIURNAL HABIT AND VISUAL ACUITY OF ADVANCED VERTEBRATES.—The diurnal habit of the majority of modern Monkeys, as of the other diurnal Mammals and Vertebrates, if not an absolute yardstick by which to measure acuity of vision, is at any rate a fairly good indicator of it. In subdued light, all other factors remaining equal, details must be larger to be no-

ticeable than is necessary in good light. In other words, finer details may be seen in good light than are seen in poor illumination. High acuity demands good illumination, such as full daylight usually provides. Hence only the diurnal habit could have furnished the necessary phylogenetical basis upon which the vision of the Monkeys, Apes, and Humans could have evolved. For this reason the Prosimians must be excluded from the course of anthropogenesis or the process culminating in the emergence of Man. Almost the same applies to the Tarsiers, except for the very early, nonspecialized forms of the suborder of Tarsioidea, which, judging from their smaller orbits, were very likely diurnal.

In short, a more or less pronounced diurnalism, associated with a fair to high degree of visual acuity, must be considered the essential condition obtaining during the entire long course of evolutionary changes and intervening stages, beginning with the Fishes, Amphibians, Reptiles, and through the Early Mammals, which eventually terminated in the rise of Higher Primates and the advent of Man.

10. DIURNALITY, ARBOREAL HABIT, AND THE HIGH ACUITY OF PRIMATE VISION.—The high degree of visual acuity possessed by most Monkeys, all Apes, and Man, in comparison with most other Mammals, is well attested by numerous observations, experiments, and tests. In fact, as far as investigated, only the keen-sighted Birds and some Lizards may possess acuity equal or superior to some Monkeys and to Man. (*See especially* Weinstein & Grether 1940; Grether 1941.)

The need for a type of vision capable of analyzing the minute details and objects that constitute the natural habitat is obvious in the Monkeys. They must, because of their arboreal and semiarboreal mode of life, be able to see clearly the branches on which they climb or onto which they leap. They must, further, recognize by sight at considerable distances the fruits upon which they subsist and must notice the enemies which threaten them both from the air and on the ground, to which most of them occasionally descend. But, above all, they require good acuity for the location and recognition of their food at a distance, like the Birds and unlike most other Mammals, which they finally test by taste and smell only after they have picked it with their hands.

Careful, detailed examination of objects by sight is a characteristic of the Monkeys. Small concealed objects, such as fruit, grain, or insects, they find by pushing aside the vegetation, grass, straw, foliage, shavings, or fur either with one hand or with both. A good illustration of such use of both hands under the guidance of eyes is the so-called "grooming," or "fur-picking," a frequent mutual favor the Monkeys give and receive. In this visuo-manipulation both hands are used to search systematically over the fur for possible parasites, the eyes being used entirely binocularly, the stereoptic quality of vision, as well as acuity, being basically utilized (Fig. 526, sketch *16*).

Most Monkeys and Apes are agile, mobile, alert animals. They are constantly on the move, ever doing something, except during periods of rest, which in most species is during the night. Such activity puts a premium on the visual apparatus, which for them is by far the most important sense. The highly perfected primate vision is, then, the matrix out of which developed human vision.

11. THE ROLE OF COLOR VISION IN THE EVOLUTION OF PRIMATES.—The specific subjective reaction to the hues of the visible color spectrum of light is a further perfection or refinement of the basic function of vision, which is responsiveness to light in general. It may be looked on as a subsidiary quality secondary to the original or primary function of responding to light and to the visual acuity or discrimination of details of the viewed objects arranged in space or dimensionally.

How general color vision is in the Vertebrates is even now not well known. Opinions vary from those who would admit it in most species to those denying all or most color vision in by far the majority of the Vertebrates, including most Mammals.

Observation of the animals and their behavior in experiments suggests that many Vertebrates, beginning with the Fishes, especially the Teleosts, on through the Amphibians, Reptiles, Birds, and including the Mammals, possess some degree of specific hue discrimination, with

numerous species having a highly developed ability to discriminate hues. In a respectable number of species of all vertebrate classes, color vision must be rather well developed and may not differ substantially from that in Man. In some of them, particularly in Birds, color vision may be superior to Man's. The Prosimians appear to be color blind, according to experiments of Bierens de Haan & Frima (1930), which agrees with their mostly pure rod retina (Kolmer & Lauber 1936; Detwiler 1939, 1940, 1943; Rochon-Duvigneaud 1943). Good color vision, on the contrary, is practically certain in most Higher Primates, the Monkeys, Apes, and Man. In some, e.g., the Cebus Monkey, however, color vision is comparable to that of a protanopic dichromate with defective red vision (Grether 1940).

The ability to perceive hues specifically, next to superior acuity and binocular stereopsis, may have been one of the principal factors contributing to Man's rise to his pre-eminent status. The need to utilize all potential visual cues present in nature, including chromatic cues, in addition to the bi- and tridimensional, may have been the basic condition for the perfection of primate vision. The increase in quality and quantity of information conveyed by chromatic vision compared with achromatic plainly provided the stimulus to develop it, as was well presented by G. L. Walls in chapter XII of his book *The Vertebrate Eye* (1942). Once developed, it greatly increased the usefulness of the sense of sight to the ancestors of Man in their "struggle for survival."

It is true that color vision may be defective under the conditions of civilized life, without interfering with most normal pursuits. This may, however, be quite different under natural conditions, where an appreciation of hues, or lack of it, may mean success or failure in the severe struggle for survival and in the sexual competition for mates, that is, for posterity. Color vision must have been especially important in the female progenitors of mankind, to whom the principal task of procuring vegetable food was intrusted (as indicated by a tenfold frequency of the major red-green color defect in men, according to R. W. Pickford 1947). Color vision in the phylogenetical sense must, therefore, be considered as one of the principal pillars upon which Man's vision was built.

(*See* for physical, physiological, and pathological aspects of color vision: A. Bethe *et al.* 1929–31, *Photoreceptoren;* P. J. Bouma 1947; *The Science of Color*, published by the Optical Society of America, 1953; H. von Helmholtz' *Treatise*, 1924–25; J. B. Judd 1952; J. H. Parsons 1924; R. W. Pickford; T. Preston 1928; J. P. C. Southall 1937; R. W. Wood 1934; G. W. Walls 1942; W. D. Wright 1947; Symposium on Color Vision in *Documenta ophthalmologica*, v. 3, 1949; for the commercial aspects of colors *see* D. H. Taylor *et al.* 1950; for psychological aspects *see* F. Birren 1950.)

12. THE ROLE OF COLOR VISION IN THE STRUGGLE OF ANIMALS FOR SURVIVAL.—Under illumination of less than a certain minimum of intensity, all visible objects appear to be different shades of gray, ranging from a lighter gray to a saturated gray which appears black. Above a certain intensity of illumination and increasingly so toward full daylight conditions, in addition to the quality of "whiteness," other qualities emerge which are called "hues." This addition of many varieties of color shades or hues greatly increases the number of potential cues, of which many animals avail themselves. It is the difference between the so-called "achromatic vision" obtaining in Man in scotopic conditions when the visual apparatus is adjusted for night life, and the so-called "chromatic vision" characteristic of adjustment for daylight activity.

The addition of numerous spectral or chromatic qualities to the intensities, localities, shapes, sizes, tridimensional character or depth perception, and the temporal sequence of sensations greatly improves the sense of sight as a tool with which to test the viewed objects. Biologically, this must be of small or no importance for many animals, whereas for others it appears to be essential.

In many species, for example, those of nocturnal habits, hence in most Mammals, color vision is of small value or none. Here the various shades of gray or of brightness and forms suffice to distinguish one object from another; the lowering of the threshold or the increased sensitiveness to weak stimuli is more important here. This is realized under the scotopic conditions under which Cats and other members of the Feline Family, for example, hunt. Almost

the same seems to be true of the Canines. To the totally color-blind Cat, therefore, the far more essential quality is a summation of stimuli in the visual apparatus through which the slightest movement of a Mouse, for example, is detected.

Co-operation of the auditory sense in locating the source whence the rustling caused by a Mouse comes is yet another help to the hunting Cat. In the largely amblyopic Soricide Shrew or a Bullhead, living in obscurity, discrimination of the spectral hues would be an unnecessary luxury, capable as these species are of locating their food by their superior olfactory sense, assisted, in the Shrews, by a fine auditory sense and touch, mediated by the vibrissae or "whiskers," and in the Bullhead by the gustatory sense. A situation similar to that in the Cats obtains in the Tarsiers and Owls and probably also in most Prosimians, where, in contrast to the macrosmatic and micropic Shrews, the principal role is assigned to the greatly increased achromatic sense of sight, assisted by the auditory sense. In the Insectivorous Bats, finally, the ultrasonic auditory sense became supreme.

In the case of the Tarsier, a strictly carnivorous Primate, the dependence for its livelihood is divided between the senses of sight and hearing, with an even greater emphasis upon nocturnal vision; the Tarsier resembles the Owl in this respect as in others, for example, the dull-mottled grayish and brownish coloration and the fluffy, noise-deadening texture of its fur. It is, then, no surprise to find, as in the Cat and Night Monkey, no photoreceptors in the Tarsier's retina which could with certainty be called cones, the rodlike structures being found here, as in the Night Monkey, also in the very center of its small fovea. It must be assumed, then, that, as in the Cat and Night Monkey, color vision plays no role in the Tarsier's life, even though this species and the Night Monkey did their utmost to preserve their central acuity in scotopic conditions, as the presence of a fovea shows. (*Cf.* section on Tarsier in the preceding chapter.)

Whereas color vision plays no important role or none at all in the life of nocturnal animals, particularly Mammals such as the Cat, Dog, Raccoon, Mink, Marten, Polecat, Rat, Mouse, Civet, and questionably also the Squirrel, a quite different situation obtains in most animals active during daylight. These are found in all vertebrate classes, with only the Amphibians and many Nonprimate Mammals in addition to most Prosimians on a doubtful list (e.g., *Lemur mongoz*).

Of the Fishes described in the preceding chapter, three are of a pronounced diurnal habit (Trout, Sunfish, and Pike), one is pronouncedly nocturnal (Bullhead), and one diurnal, with an extension of activity into crepuscular and nocturnal conditions (Northern Brook Silverside). These habits for each particular Fish agree with the kind, quality, and quantity of photoreceptors that each of them possesses. This close agreement between the behavior and the structure is fully borne out by other species described in the preceding chapter: the Anole Lizard, Swallow, Tree Shrew, and probably also the Squirrel, which are diurnal, and the Soricide Shrew and the Tarsier, which are scotopic or nocturnal. This, in connection with other modern investigations and observations, permits one to conclude that the presence of structural cones, whenever found, is fair evidence of at least some degree of color vision. On the basis of this criterion, widespread discrimination of hues among most Vertebrates must be claimed. Such a deduction harmonizes with physiological experiments on Monkeys and with human physiology.

13. COLOR PERCEPTION A BASIC QUALITY OF VERTEBRATE VISION.—The preceding evidence points to color perception as one of the basic qualities of vision in most Vertebrates. The varied colors found adorning the bodies of many Fishes may not be an idle decoration, even though in many instances we are not able to explain their biological usefulness. Almost the same is to be said about the many varied colors found in the numerous Amphibians and Reptiles, although the evidence for color vision in the first is mostly negative so far. We are on safer ground in trying to appraise the frequently brilliant coloring of many male Birds whose behavior often indicates appreciation of their colors by their mates. From our own observation, such are the Parrots, including Lories, Parakeets, Macaws, Cockatoos, Pheasants, Rhinoceros Hornbill, Peruvian Cock, Quetzal, Motmot, Scarlet Ibis, Weaverbirds, Tanagers,

Finches, Peacocks, Birds of Paradise, and Hummingbirds. The significance of the brightly colored plumage of these and other Birds in "sexual selection" has been discussed in detail by Charles R. Darwin in his book *The Descent of Man* and has been touched upon again by F. Kipp (1939) and others (*cf.* A. A. Allen, A. Brehm, Chute, Gilliard, Ripley & Weber, W. J. Schmidt, and Zahl). In comparison, the coloring of most Mammals is dull. But even here there is reason to suspect more appreciation of color than is commonly assumed.

And should good hue discrimination be denied to the Primates (except the nocturnal Prosimians, Tarsier, and Night Monkey), which in many species show gaudy coloring no less brilliant than the multicolored adornment of many Fishes, Frogs, Toads, Salamanders, Lizards, Snakes, Turtles, and Birds? Examples are the male Mandrill, whose scarlet-colored nose, blue cheeks, yellow goatee and sideburns, and equally vividly colored posterior may not appeal to civilized aesthetic feeling but may be a potent stimulus to the opposite sex of its own species. Other bizarre color compositions are the vivid blue and green of the penis and scrotum in some Cercopithecs, which contrasts with the red color of the hind part of the body. Many other Monkeys, as for instance the Mangabeys, Rhesus Macaques, and certain Baboons during the ovulation period, may also be mentioned. What the true biological significance of such odd decoration is we do not know, but we must assume that it is essential. (*Cf.* Darwin, *The Descent of Man*, 1871, chaps. IX–XVIII.)

If hue discrimination is not to be denied to numerous Vertebrates as a means of recognizing their mates and also their enemies, color vision must also be admitted to be an important means in their acquisition of food and, in general, in their orientation in the environment.

14. Color of fruits, and its relation to the color sense of animals.—The role of color, especially of red and of black, as a means of attracting frugivorous birds to the many kinds of fruits, is well known, just as is the power of attraction of the flowers for certain birds and many insects; the fondness of the Ruby-throated Hummingbird for the red-flowering Scarlet Sage or Salvia, *Salvia splendens*, for example, is notorious (F. Knoll, 1921–22, 1924, 1925; A. Kühn & Dora Ilse 1925; Porsch 1924, 1931; K. Guenther 1931; and especially H. N. Ridley 1930). The same must be true of those Mammals which subsist on fruits and other produce of plants. Especially is this likely in the case of the microsmatic Monkeys, whose acquisition of food under natural conditions depends primarily on colors, less on shape and size, and only slightly on the senses of smell and taste.

In most instances fruit would not be easily noticed by animals if it were not for its color. The green, unripe fruits, for example, blend with the green foliage and remain unnoticed until they become ripe and change color. The many various red, scarlet, purple, orange, yellow, brownish-yellow, bluish-yellow, and green-yellow berries, grapes, and pods, especially the brightly colored fruit of numerous members of the Rosaceae or Rose Family, when ripe, contrast vividly with the surrounding green foliage. Without such hue contrast, for example, the small red-colored Hawthorn apples would be difficult to notice at biologically effective distances by size, shape, and brightness alone, concealed as they are in a dense foliage (*see* Fig. 518-*A*).

Among the numerous fruits common in the North American Middle West and distinguished by bright colors may be mentioned such well-known species as the wild red cherry, pimbina or highbush cranberry (*see* same figure), shadbush (juneberry or serviceberry), chokecherry, barberry, many varieties of hawthorn (*see* same figure), fever bush, checkerberry, cranberry, raspberry, strawberry, bunchberry, dogwood, currant, hips of the wild rose bush, berries of the American holly, bittersweet, and, among the cultivated fruits, the sweet and sour cherry, pear, apple, and grape. The great attraction these fruits have for the Robins, Thrushes, and Blackbirds is shown by the latter's persistent interest and the quick consumption of berries during the time of ripening.

That other less vivid colors, mostly purple, blue, or black, have a similar effect upon some fruit-eating birds, even though for us their coloring is subdued, is shown by their speedy disappearance after they become ripe. Such somber-colored fruits are those of the blackberry,

mulberry, elderberry, various huckleberries and blueberries, gooseberry, wild black cherry, wild plum, black cherry, arrow-wood, porter's plum, fruit of the sour gum tree, sassafras, buckthorn, wild grapes, and many other similar products of our orchards, gardens, fields, meadows, bogs, hedges, and forests (*cf.* Fig. 518-*A;* and R. S. Lemmon 1947).

In summary, the coloring of all these fruits seems to have the definitely utilitarian purpose of attracting birds, for which they supply food and by which their seeds are propagated and dispersed. However, this interesting problem still remains to be investigated by modern scientific methods.

15. EVOLUTIONARY INTERDEPENDENCE OF COLORED FRUITS AND PRIMATE COLOR SENSE.—Since it is probable that the evolution of the Primates took place in the tropical regions of the world, it would be of great importance to learn something about the coloring of the fruits of those regions and of its biological effect. Of this, unfortunately, little is known. H. N. Ridley (1930) describes them as "dull-coloured and not very showy." From other scanty information recently published on this subject, for example, from the beautifully colored illustrations in the article by J. R. Magness (Nat. Geog. Mag., v. 100, p. 325, 1951), however, the many fruits of the citrus family, mango, banana, persimmons, papaya, and possibly also of durian indicate the coloring of the tropical fruits, if anything, is even more varied and vivid than that of the fruits of the temperate regions of the world. We are therefore entitled to hypothesize that fruit coloring, wherever present, was evolved for the direct purpose of attracting, by its specific hues, the attention of the animals, including Primates, which feed upon it.

The evolution of colored fruits, of course, was a process parallel to the evolution of the color sense in the animals to be attracted. It indicates a close biological interdependence of the fruit-eating animals and the fruit-bearing plants. This relationship became beneficial to both partners, which profited from it: the animals in getting food, the plants in perpetuating themselves and spreading into new regions. It is a relationship similar to that found in the flowering plants depending for pollination upon Insects, except that in the latter the sense of smell and taste, besides vision, is an essential factor. (*See* detailed presentation of this subject in H. N. Ridley, *The Dispersal of Plants throughout the World*, 1930.)

16. EVOLUTION OF COLORED FRUITS AND THE ARBOREAL HABIT.—In the evolution of colored fruits, still another factor is worthy of consideration. It does not appear to be mere coincidence that the fruit-bearing plants are the trees and shrubs and not the low-growing herbs, weeds, and gramineous or grasslike plants (Graminaceae), certainly so in the tropical regions (*see* K. Guenther 1931). This fact harmonizes with the arboreal habits both of the Primates and of the Birds. Naïvely expressed, colored fruits began to grow on shrubs and trees when there were animals capable of noticing them by sight and able to get to them by climbing and flying. Inversely, the Primates began to evolve from the terrestrial Shrews through the semi-arboreal Tree Shrews, and likewise the Birds began to become formed out of the terrestrial Dinosaurs when the fruits began to grow above the ground. But the origin both of the fruit-bearing trees and of the fruit-eating Birds and arboreal Mammals must have started "from the ground," beginning with the low-growing plants and the terrestrial animals.

Still another factor was the urge of many plants to decrease competition for solar energy —light—by growing tall and hence forming lofty treetops. In this way the elevation above the ground of the leafy and fruiting parts of the trees may have been the prime incentive for the ancestors of Birds and Primates to embark upon their arboreal way of life, rather than to take to the arboreal "refuge area," as believed by some (Barth 1950). The lofty canopy of the primeval Brazilian forests described by A. von Humboldt (1805–23, etc.), A. R. Wallace (1853), H. W. Bates (1863), and others, full of light and fruit-bearing trees, according to K. Guenther (1931), illustrates this condition well (*see also* R. Spruce 1908; R. R. Gates 1927; M. L. Jobe Akeley 1950; and W. R. Philipson 1952, esp. p. 38).

One may develop this idea further in various directions. One is the growing of the fruits on shrubs and trees above the ground, out of reach of the strictly terrestrial animals, such as the

Soricide Shrews and most of the Rodents and likewise most terrestrial Insects. In this way, useless destruction during the optimum period of ripening, the time most useful for attracting the arboreal Mammals and flying Birds, and the competition which would largely interfere with the prime purpose of the colored fruits—the distribution of seeds at some distance from the parent-tree—are reduced.

The picture of a functional interdependence of the colored fruits and the color sense, as sketched, is obviously too simple to do justice to the immensely complex and in many ways overlapping spheres of life of many animal and plant species living in the same natural community, and the many factors involved. A more detailed investigation may disclose similar relationships of other species, in particular of the various Mammals, occasionally, periodically, or regularly subsisting on fruits, of which just a few may be mentioned here: Bears, Raccoons and Squirrels, and in the tropical countries Coatis, Viverrines, fruit-eating Bats or Flying Foxes, but especially Monkeys, Apes, and Lemurs. Many of these, as much as their habits are known, contribute to the very purpose for which the colored fruits were evolved rather than interfere with it, fostering the spreading of the fruit-growing plants and in this way further augmenting the source of their own food supply. (*Cf.* Dice 1952.)

In summary, there is sufficient evidence in favor of the hypothesis of the origin of colored fruits and of color vision as mutually interdependent phenomena, caused by the general urge of the plants and animals alike for a more abundant life.

The color sense of animals when it is well developed may not be very different from, and in many cases may be superior to, the human color sense. An example of this is the gorgeously colored plumage of the Hummingbirds (Trochilidae) and of the Birds of Paradise (Paradiseidae) developed through sexual selection. The delicate shadings of their various colors and the many patterns are exquisite, pointing not only to an excellent color vision by itself but also to a highly developed aesthetic color sense, or appreciation of color harmonies and contrasts. How much superior this sense of the Birds may be to the color sense and color aesthetics of primitive, untrained humans is shown by the use the natives of New Guinea and of other parts of the world make of the gaudy feathers of the same birds for their own adornment, which, together with their garishly painted faces and bodies, rather recalls the bizarre coloring of the lesser Primates, for example, Mandrill and Rhesus Macaque, already mentioned. (*Cf.* E. T. Gilliard, "New Guinea's Rare Birds and Stone Age Men," Nat. Geog. Mag., v. 103, p. 421, 1953; and Ripley & Weber, "Strange Courtship of Birds of Paradise," Nat. Geog. Mag., v. 97, p. 247, 1950; for the biological role of color vision *see* C. R. Darwin, *The Descent of Man*, 1871 or later editions; and E. A. Armstrong, *Bird Display and Behaviour*, 1947; for the fruits eaten by the Tree Shrews *see* chap. XIV, 10; for the food of the Monkeys and Apes in their native habitat and in captivity *see* secs. 4 and 5, this chapter.)

SEC. 3. THE ORIGIN OF MAN

1. INTRODUCTION.—The principal features of Man's bodily and mental organization are similar to the features characterizing other Primates, of which the most obvious are manipulative ability, visual acuity, and stereoscopic vision. Other human peculiarities, such as erect posture, with the characteristic poise of the head, and bipedal gait, are in vivid contrast to the quadrumanous posture and locomotion of all Monkeys and Apes. This similarity and contrast have been, since Darwin's and Wallace's inauguration of the concept of evolution, the object of much speculation on the origin of Man from some infrahuman species, as well as why and how such a change could have been accomplished. In these speculations special attention was paid to the locomotor apparatus, viz., the foot, leg, pelvis, spine, and poise of the head, the arrangement of the muscles of the extremities, as well as to the skull and the brain, including the visual apparatus, and their uses.

In appraising these changes, opinions have fluctuated from the assumption of a close phylogenetical relationship of Man with the large Anthropomorphous Apes to that of an early separation of Man's linear ancestors from the

common primate stock and their abandonment of an arboreal habit, if, indeed, they ever were as completely adapted to it as are the majority of the now living Monkeys and Apes.

An attempt is now made to appraise the bipedal gait of the various classes and orders of the Vertebrates, beginning with the Birds, on through the lower orders of Mammals, and terminating with the Infrahuman Primates, to find out what effect this mode of locomotion may have had upon manipulation, posture, gait, development of the brain, and vision. In this way it may be possible to determine, perhaps, what stages in vertebrate organization preceded, and which functional factors were responsible for, the reorganization of the body characteristic of Man.

2. Bipedal gait of the Birds and its effect.—The most universally bipedal Vertebrates, aside from Humans and certain extinct Lizards, are the Birds. Avian bipedalism most certainly evolved from that of their ancestors, the Dinosaurs. By intrusting the task of terrestrial locomotion exclusively to the hind limbs, it enabled the Birds to concentrate completely upon the use of the upper or anterior extremities for aerial locomotion, or flight.

This was an immense advantage, since it opened a new frontier to this class. For this mode of life a parallel perfection of the sense of sight was a necessary prerequisite and a consequence. But avian bipedalism, associated with flight, had a drawback in completely adapting the arms and hands for the use of locomotion, albeit of a nonterrestrial kind. Hence it in itself precluded the development of extremities which could be used for manipulation, capable of close co-operation with visual control. And it was the visual control of detailed motor acts which was the key to a further elaboration of the so-called "mental faculties," eventually terminating in the rise of Man.

Even so, the "handling" abilities of many Birds, for example, Parrots and Weaverbirds, are nothing short of astonishing, especially since for the making of their artfully constructed nests, for example, they are forced to use their feet and beak, at best clumsy instruments, compared with primate hands. (The gorgeously colored Leadbeater's Cockatoo, for example, uses one foot to carry a morsel of food to his beak, exactly as do Man and Monkeys in the same situation, except that they use hands.)

The superior power of vision possessed by the Birds, absolutely necessary for their life, because of the lack of adequate "handling extremities," remained therefore largely unused for the development of mental faculties specific for the Primates.

3. Bipedal gait of Mammals an exception.—The bipedal posture and progression in Mammals is rather an exception, and, when present, it is used facultatively, on special occasions only.

There is, however, one group of Mammals in which bipedalism is firmly intrenched, viz., the marsupial Kangaroos. Here the powerful hind legs, assisted by an equally stout tail, are the exclusive supporting and propelling limbs, the progression being by leaping. The diminutive front limbs have practically no part in locomotion in these Mammals. They are used to some degree in "handling" objects, even though this handling is of a rather simple, summary kind. The weak, short fingers are here provided with long, hooklike claws, which, because of their poorly diversified movements, precludes their use as primate fingers. This, in turn, harmonizes with the herbivorous habit, relying upon taking food by means of a long muzzle, long neck, and flexible body. The situation in this respect in Kangaroos is essentially the same as in other herbivorous animals, as exemplified by Horses, Antelopes, Deer, Giraffes, and others, hence making the need for detailed visual control of manipulations unnecessary.

4. The use of the forelimbs for manipulation in Infraprimate Mammals.—More use of the forelimbs in "handling" objects is found in small Rodents, for example, in Mice, Rats, Chipmunks, and Squirrels. These habitually take and hold the kernels of grain with their front paws when eating. At other times, when running around, they use all four extremities.

The use of the front paws and toes as "hands" and "fingers" in the Mice is rather well diversified. This is even more manifest in the Squirrels, including the Chipmunks, as described in one of the sections of the preceding

chapter (Figs. 493–96). The manipulation of objects—for example, nuts and acorns, when gnawing the outer, hard shell, or pine cones, when extracting the kernels—is quite a dexterous act, even though it remains relatively below the performance of primate fingers. The Squirrel's hands and fingers are used only to hold the nut or a cone and to turn it, always bimanually, as in a flexible vise, whereas the extracting of the kernels is done with the teeth, unlike the method of most Simians, which always pick up the morsels with the fingers, together with the opposable thumb (Figs. 526, 531, 532, 534, 537, 539).

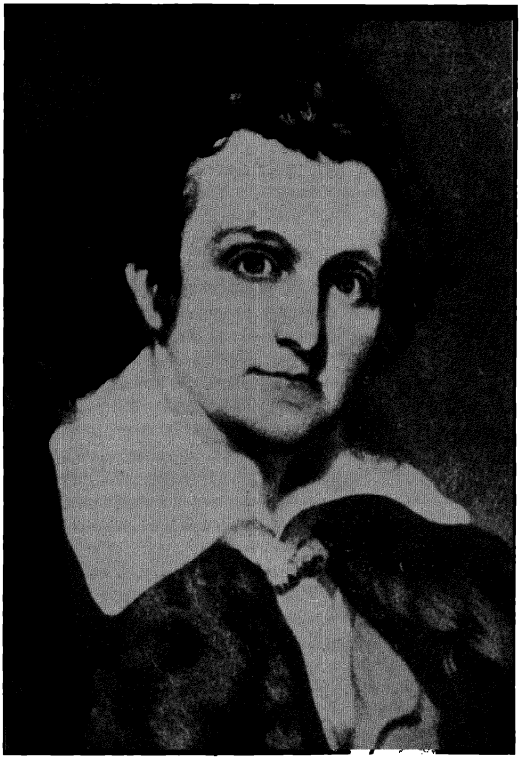


FIG. 522. John James Audubon (1785–1851), French-American naturalist and painter of wildlife. An acute observer of nature, in particular that of early North America. Author of a monumental book, *The Birds of America*. From a painting by F. Cruickshank. Courtesy National Audubon Society, 1006 Fifth Avenue, New York. For biography *see* F. H. Herrick, *Audubon the Naturalist*, 1938.

The Tree Shrews use their hands and fingers in a way which is only a little more elaborate, as described in the preceding chapter. Here, too, the fingers are employed in a wholesale manner, no diversified use being apparent. The relatively long, curved claws would, in any case, be a hindrance to an individualized use of fingers and are, instead, cleverly used as a hooked "poker" or a grabbing tool. However, the hands are more frequently used individually in taking and holding morsels of food and carrying them to the mouth.

5. BIPEDALISM AND MANIPULATIVE ABILITY OF THE TARSIER.—In the Tarsier the specialization of its hind limbs for locomotion and of the

front limbs for handling, as in Man, is complete (*see* section on Tarsier in the preceding chapter, and Figs. 513, 514). In spite of this, there are so many qualifications here that a comparison suffers a great deal. The long, relatively powerful legs of the Tarsier are used not for walking but for leaping across long distances. The hands, provided, as originally in all Primates, with five fingers, are used as quick prehensile graspers and in a wholesale way, with all fingers, including the thumb, lumped more or less together. Also, while the hands are not exactly the propelling organs, they do assist in the process of locomotion in their role as organs of attachment which hold the body in position just before leaping, and to arrest the shock at the end of the jump. In certain situations, as in "chinning," the hands and the arms are actively used in assisting the legs or are used alone (Fig. 506).

The Tarsier's hands are used in a special way in seizing food and in eating. The character again is wholesale rather than diversified, as described in detail in the section on the Tarsier. The seizing of food, in particular a live animal, is a formal attack in which the entire body is employed, after locating and sizing up the prey by means of sight and hearing. In this assault both hands are used simultaneously, and the prey is seized almost simultaneously with the mouth.

FIG. 522*A*.—Heinrich Klüver (1897), professor of experimental psychology at the University of Chicago, at the approximate age of forty-two. A lifelong investigator of the mental capacities and behavior of the Infrahuman Primates. Author of *Behavior Mechanisms in Monkeys* and of many other publications, including those on the pathology of vision. Courtesy Professor H. Klüver, Chicago.

More variation in the use of the hands and fingers is seen when the Tarsier chews his morsel, but even here the hand is merely assisting the chewing apparatus (Fig. 511). On rare occasions the thumb is seen opposed to the other fingers, perhaps by accident, as shown by another illustration (Fig. 513). The use of the thumb and fingers in the human way and in that of most Simians, especially by opposing the tip of the thumb to the tips of other fingers, was

never noticed during our observations. (*Cf.* Figs. 526, 531, 532, 534, 539, 540.)

The verdict about the Tarsier must be rather negative. This Primate strayed far from the course along which Man's Ancestors must have traveled in its nocturnalism, its special type of bipedalism, and its poorly diversified use of hands and fingers. The nucleus from which Man took origin, on the preceding evidence, must be sought in some primitive primate forms of long ago, before the present Tarsiers began to differentiate along their special evolutionary lines.

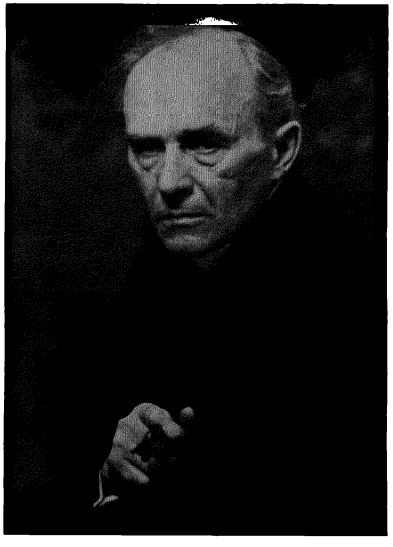

FIG. 523. Carl Ethan Akeley (1864–1926), naturalist and sculptor, originator of the modern art and science of taxidermy, which, as exemplified in the American Museum of Natural History in New York and in the Chicago Natural History Museum, has preserved and re-created true animal life as much as any textual description and illustrations have done. In the words of Henry Fairfield Osborn, in the Preface to Akeley's book on Africa (1923), Akeley was a sculptor and biographer of the vanishing life of that continent, who used taxidermy in recording the vanishing greatness of the natural world, which he immortalized in the museums. Akeley's greatest achievement was, perhaps, the stimulus he gave for the establishment of Gorillas' sanctuaries in the Belgian Congo, around Mount Karisimby, in his "Gorilla Country," where his body rests. Portrait from C. Fisher, "Carl Akeley and His Work," Scient. Month., v. 24, p. 97, 1927. *See* Akeley's book *In Brightest Africa*, 1923. For additional biographical information *see* Mary L. J. Akeley, *Congo Eden*, 1950.

6. SIMIAN BIPEDALISM AND MANIPULATIVE ABILITIES, AND THEIR ROLE IN HUMAN EVOLUTION. The change from the quadrumanous, that is, modified quadrupedal, way of locomotion to complete separation of the locomotor function of the hind limbs from the manipulative, exploratory role of the forelimbs must have been a very gradual process of adaptation and reorganization extending over a vast stretch of time, difficult now to estimate. To trace this momentous process, it is necessary to begin with the condition which may be considered generally simian, gradually coming to a critical point where the two ways separated, one continuing along the customary way characteristic of all Infrahuman Primates, the other taken by Man.

The initial condition may be considered that found in many Marsupials and in the majority of Mammals, in which all four limbs are used for locomotion. In these a more definite tendency to use the forelimbs as manipulative instruments is noticeable in all those species which habitually climb trees and bushes for food. Such are the Opossum, Raccoon, Mustelids, Cats, and most small Rodents, for example, Mice, Chipmunks, and Squirrels. Good manipulative use of the forepaws is seen in the Cat when it "washes" its face or catches a mouse.

The Tree Shrew also occasionally uses one of its forepaws to pull a morsel of food, instead of both hands simultaneously in the way the Squirrels, Chipmunks, and Mice do. Beginning from this, perhaps, as a starting point, it is possible that, with increased adaptation to the arboreal mode of life, some ancient Tree Shrews developed an opposable thumb and long fingers, in this way initiating a transformation of their forepaws into typical prosimian and simian forehands (Figs. 524–40).

In the Monkeys, with complete adaptation to the arboreal way of life, the hind limbs became also transformed into supplementary grasping hands (Fig. 540); hence the designation of this order as Quadrumana or "four-handers." But the forehands and hindhands of the Monkeys are never exactly equivalent in anatomical structure and performance, the manipulative ability of the forehands always being superior to that of the hindhands. The first are able to perform more delicate motor acts, while the latter, more robustly built, give better sup-

port to body weight and function as the propelling limbs, assisted by the grasping pull of the forehands. In the brachiating Apes the locomotor function of the arms and hands more or less prevailed (Figs. 528, 535, 536).

The division of labor between the forehands and hindhands of the Primates is, in fact, merely a modified continuation of the same physiological division between the front and hind extremities found in practically all quadrupedal animals, which, in turn, is a reflection of the orientation of their bodies, with one pair of limbs leading, the other propelling, in protions, some of the Primates, later to develop into Human Ancestors, began to spend more time on the ground, they already had more robustly built hind limbs, which could gradually be converted into typical human "legs" and "feet." This change to a more emphatic use of the hind limbs for standing and walking may have taken place more easily in those Primates which were originally not so completely adapted to the arboreal way of life, or in those which, because of their habits and the character of their habitat, with few trees and more open country, had less incentive to keep to the trees

FIG. 524.—Slender Loris (*Loris* or *Stenops gracilis*), a small nocturnal Lemur of South Asia. From A. Brehm' *Tierleben*, 2d ed., v. 1, p. 258, 1876, with special permission of the Bibliographisches Institut A.G. (Dr. E. List) Mannheim, Germany. (*Cf.* Fig. 500.)

gressive locomotion. The leading extremities naturally need to be more delicately organized than those whose task is more a passive support. This is the consequence of the bisymmetric organization of the body along the midsagittal vertical plane, with concentration of the principal sensory organs and the brain in the leading segments of the body, which form the head during ontogenesis and phylogenesis.

A different anatomical organization and functional specialization of the forehands and hindhands persisted throughout the entire course of primate history. When, for reasons discussed in the following subsections and sec-

The initiation into human erect posture and bipedalism is well illustrated by the terrestrial Macaques and Baboons and other Simians, which spend much or most of their time on the ground (Figs. 526, 527; *see also* secs. 4, 5, this chapter). Their use of the forehands in locomotion resembles that of other quadrupeds although it has its peculiarities, such as the shambling or shuffling gait of the Baboons. However, when resting or feeding, their habitual posture is sitting on the buttocks, with the body and head more or less upraised. This leaves their arms and hands temporarily entirely free for "handling" objects in many ways and for vari-

ous purposes, such as the close visual scrutiny of objects, and bringing them close to the organs of taste and smell. In this complex control, it must be assumed, the superficial sense of touch, very highly developed precisely in the hands and fingers and very elaborately represented in the cerebral cortex, and the deep proprioceptive muscle sense are constantly used, together producing complex ideational and sensomotor formulas in the brain (*cf.* P. Bard 1938; Woolsey, Marshall & Bard 1942; Critchley 1953).

all Infrahuman Primates. The other was the development of obligatory bipedalism, with the emancipation of forehands from locomotion, now entirely taken care of by the hind "legs" and "feet," with the concomitant erect posture of the body as the result.

The first possibility is exemplified by the largely ground-dwelling Baboons and Hamadryads, or Dog-faced Monkeys (Cynocephali, or Cynomorphous or Cynocephalous Monkeys), which greatly resemble dogs not only in their elongated snout but also in their quad-

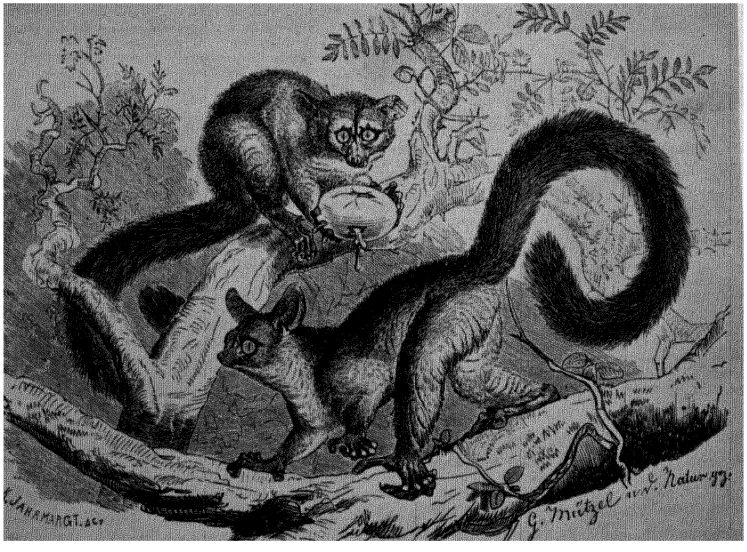

FIG. 525.—Large nocturnal Galagos or Lemurs of the island of Madagascar. From A. Brehm's *Tierleben*, 2d ed., v. 1, p. 272, 1876, with special permission of the Bibliographisches Institut A.G. (Dr. E. List), Mannheim, Germany.

7. ABANDONMENT OF ARBOREAL HABIT BY TERRESTRIAL PRIMATES AND MAN'S ANCESTORS, AND THE PARTING OF THEIR EVOLUTIONARY WAYS. - When the phase of primate evolution in which differentiation between the use of fore and hind extremities became more accentuated, two possibilities opened. One was conservative, that is, to continue, despite prehensile hands and feet, the ancestral mode of progression on all four limbs, which is essentially modified quadrupedal. This is the case with practically rupedal posture and habit (Figs. 526, 527). This solution of the problem of readaptation to the terrestrial mode of life may have been the easier way out. In it not a great deal of reorganization of the body and limbs was necessary. The limbs, especially since in the original moderate arboreal adaptation they did not become greatly different in length and structure, could have remained little changed. The length and arrangement of the fingers and toes may have remained almost the same. The delicate prehensile power

of all four extremities, especially of the forehands as instruments of the well-developed simian intellect, representing a definite advantage, was largely retained. Obviously for this reason, the Dog-faced Primates never developed the speed of locomotion possessed by the Canines, Horses, Antelopes, and some Cats, which would have made a radical reorganization of their limbs mandatory (as exemplified by the Patas Monkey). Viewed from another angle, the retaining of all four prehensile hands by the Cynocephalous Monkeys from the viewpoint of human phylogeny had its evil consequences, in that it had precluded obligatory bipedalism and erect posture, the two conditions absolutely indispensable for the use of arms and hands as delicate instruments of mind and, in turn, necessary for the rise of higher intelligence.

The other road open to the semiterrestrial Primates, for the reasons discussed earlier, was a radical change to a bipedal terrestrial life. This change could not have occurred abruptly, but only over a long stretch of time. There may have been many trials and failures, some prehominid Primates again retreating to the arboreal conditions they were accustomed to, the others readopting a quadrumanous terrestrial locomotion.

It is, in fact, difficult to visualize conditions for which one of the two modes of locomotion would not have been satisfactory, and certainly they seem to have been an easier way out, as illustrated by the modern Monkeys and Apes (Figs. 526–40).

At this point along the evolutionary road, which terminated in the coming of Hominidae, the veritable crossroads of humanity, the Primates had three choices: one, to turn back into the primeval jungle; another, to become terrestrial Cynocephali; and the third and most difficult, to become human.

8. Physiological and biological motivation of the bipedal gait and of erect posture in Man's Ancestors.—The probable factors which may have been especially responsible for the adoption of bipedal gait and erect posture in Man's Ancestors are lost in the impenetrable evolutionary past. There are as yet few concrete facts in available paleontological information which would shed light on this crucial problem. There certainly are no particular anatomical or physiological factors which alone could be held responsible for human bipedalism. The senses of the living Primates, the Monkeys and the Apes, with few exceptions, are fairly close to those possessed by Man. Acuity, color vision, and stereopsis appear to be about equal in many, in some slightly superior, in others not greatly inferior, to that of Man. Manual organization and dexterity, even though not equal to the human in many Monkeys, approaches it; in some it may surpass it. Hence the best hypothesis at present is to put the emphasis on the *specific manner* and *degree of collaboration* of the original primate senses and motility, particularly manual dexterity and vision, which eventually resulted in the coming of Man. (*Cf.* following subsection.)

The types of Primates from which the development of the specific human organization started may be imagined as rather small in size, possessing acute senses, of an alert, inquisitive disposition, and of largely terrestrial habits. They may have resembled somewhat the smaller and medium-sized monkeys, such as the Macaques, and less so the more specialized Cynocephali (Figs. 526, 527). The proportions of limbs were more harmonious in both than in the large Apes. Their hands had an opposable and not too drastically reduced thumb (Fig. 540, sketches *16*, *19*). Their feet, even though typically prehensile, were straight plantigrade, with the sole and heel resting flat on the ground (Fig. 540, sketches *15*, *17*, *18*, *20*). Hence they were favorable material from which, after further perfection, more efficient human hands could have evolved and from which, by elimination of unnecessary detailed movements, more compact arrangement of tarsal and metatarsal bones, and strengthening of the musculature, the human leg and foot could have been formed.

Whether or not the now living large Anthropomorphous Apes and those of the past that resembled them could have furnished material sufficiently pliable to lend itself to such a radical reorganization, is doubtful (*cf.* secs. 4, 5, this chapter). The least suitable would be the types resembling the Orangutan, whose legs and feet are completely adjusted to the arboreal habit. The next would be the Chimpanzee, whereas the Gorilla and the Gibbon appear to be more

advanced toward pronounced bipedalism. But all now living Apes appear in a greater or lesser degree to be highly specialized for arboreal life. Admirably adapted for it as they are, if they were forced to undergo such radical reorganizations as would be required for life exclusively on the ground, they would be doomed to certain failure. Only a primate type, nimble, elastic, and not too far removed from the original quadrupedal mode of progression of its shrewlike ancestors, could have been the stock from which Man emerged. This form may, perhaps, be typified by one or several extinct Simians discovered in India and in East Africa (*see* Leakey; Le Gros Clark & Leakey; and Le Gros Clark 1953; *cf.* sec. 8, this chapter).

Whichever the simian-like ancestors of Man were, they must be visualized as having attained the stage through their previous history, inclination, and circumstances where they began to use their hind extremities for locomotion by preference. In the course of time, their hind limbs became powerful, better attached to the pelvis, itself changed in shape, and straightened so they could carry their bodies swiftly and without undue effort for long distances. In this way the arms and hands were largely emancipated from locomotor duties and were employed for the exploration of the immediate surroundings and for the manipulation of objects under visual control.

The other consequence of emancipation of the arms and hands was the freedom of the senses, first that of vision, which was now able to concentrate upon problems other than the immediate control of locomotion. The sight was now free to roam over the territory between the immediate surroundings and the distant horizon and mentally to digest countless impressions from objects and events, and to adjust conduct in the best possible way.

With this, the terminal phase of human evolution was initiated. The outcome was the formation of a strong, powerfully built, bipedal animal, swift of pace, equipped with efficient exploratory limbs, under balanced control of the senses and motility, the most important being vision. The Human Ancestors finally embarked upon a strictly terrestrial career, to become, in Homer's expression, the true *epigeoi* or "earthly dwellers."

Bipedal gait and upright body posture appear to have been the principal factors which molded Man. Yet they were not the initiators, but only the potent levers applied to human evolution. The prime factor, as in all animal motivation, was the need to acquire food by means of the arms and hands, to ward off danger, and to secure progeny, or, in other words, "the struggle for existence."

9. THE "STRUGGLE FOR EXISTENCE" THE PRIME FACTOR RESPONSIBLE FOR THE RISE OF MAN. —The motivating stimulus for the reorganization of a quadrumanous into the bimanous-bipedal body of Man's Ancestors, in the final analysis, must have been purely functional. At one particular phylogenetical stage, it must be presupposed, these ancestors developed a tendency to rise and stand on their hind limbs more often and for longer periods of time than do any now living Simians. A special stimulus may have been peculiar dietetic habits and a peculiar habitat.

In a largely open, grassy, savanna-like prairie much vegetation consists of gramineous grasses. The average height of these grasses when mature is from 4 to 6 feet. At this level the hands must be used for long stretches of time in gathering the kernel-bearing ears. The most favorable and least fatiguing posture for this occupation is bipedal standing and walking. The same is true also of a habitat containing low-growing, fruit-bearing shrubs and bushes, where the position of the gathering arms and hands is most comfortable and efficient in an upright position.

In contrast, in the high forest the fruit-bearing treetops are easy of access only to the arboreal Primates and to Birds. Here Man's Ancestors would have been greatly handicapped, forced as they would have been to gather fruit by time- and energy-consuming climbing. Another extreme would have been a diet of low-growing herbs, roots, and tubers, requiring a stooping attitude comparable to that of the Gorilla (*see* secs. 4 and 5, this chapter). The dependence upon either tall fruiting trees or low-growing herbs would have worked against a strictly bipedal gait and upright posture.

The obvious reason would have been the small chance that an incipient biped would have

had to survive during phylogenetically available time. Hence the more profitable way would have been a reversion either to an outright arboreal or to a quadrumanous terrestrial habit, whichever would best fit the circumstances.

Another and perhaps equally decisive reason for the cultivation of prehominid bipedalism and upright posture was the deficiency of the tree-grown fruits in proteins and fats, in contrast to carbohydrates, salts, and vitamins. The need for proteins especially may have been caused by the active, roaming habit. During the incipient stage this need may have been satisfied by the gathering of small animals, such as snails, slugs, some insects, shells, frogs, lizards, birds' eggs, and their young, and the like. With an increase in body size and an active, roaming habit, this omnivorous inclination, present, even though little exercised, in many of the Primates (e.g., the Chimpanzee and Baboons), may have been the prelude to more pronounced hunting for game animals, more plentiful in a diverse habitat and open savanna than in a dense forest. (*Cf.* sec. 8, this chapter.)

Additional factors may have contributed to the tendency toward exclusive bipedalism. The basic one may have been the scarcity of food, both plant and animal, in most regions at any given time. This made it necessary to cover wide spaces of territory, many repeatedly, as the seasons of differently ripening fruits, supply of eggs, or abundance of game demanded. This migratory struggle of nascent humanity for survival could have become more successful with the developing upright posture and bipedal walk, requiring a modified pelvis, elastically acting vertebral column, and long muscular legs able to be fully extended and thus to support the body weight with a minimum of expenditure of muscular energy. All these changes developed for the express purpose of transporting the body swiftly and without much fatigue over long distances and many varieties of ground and obstacles.

10. PROBABLE PHYSICAL CHARACTER, HABITS, AND THE HABITAT OF PRIMEVAL MAN.— Many more factors besides those enumerated must be imagined to have worked together in the complex process through which one or more types of Simians became gradually transformed into primitive Humans. In speculations along this line it is necessary to take into consideration every scrap of evidence from paleontology, paleobotany, and geographic and geological conditions of past ages, as well as climatic changes. In this way, perhaps, it will be possible to determine roughly the likely regions and the probable conditions in which primeval humanity was finally molded. In this process the flora and fauna of the likely homelands of Man and other external circumstances contributed a substantial share, in addition to the inherent potentialities of Man's Ancestors carried over from the past.

From what is at present known, especially from the paleontological researches of Leakey and of Le Gros Clark (1950, 1951, 1954), it now appears that a separation of the human line from the other Primates took place farther back in the past than had formerly been assumed. Man's upright posture and bipedal gait, even though evolved from the common primate organization, represent a substantial deviation from the locomotion of the Monkeys and Apes, which is quadrumanous, that is, essentially modified quadrupedal. This substantial bodily reorganization, assuming all other factors reasonably equal, must have required a very long stretch of time, its roots possibly reaching as far back as the early period of primate phylogenesis. During all that time other subdivisions of the Primate Order continued to cultivate quadrumanous locomotion and to perfect it in various special directions, usually with emphasis either upon the hind or the fore limbs. One notable exception in this respect, among all nonhuman Primates, is the Tarsier, where, as in Man, the hind limbs are used practically alone for the leaping gait, with the almost complete emancipation of the arms and hands from locomotion (*cf.* chap. XIV, 12). The other is the Gibbon, with his frequent bipedal walk but brachiating arms (sec. 5 [3], this chapter).

The upright posture and bipedal gait of primeval Man almost certainly indicate that his home was neither an impenetrable jungle nor a pronounced mountainous country nor swamps nor deserts. It must have been instead a flat or gently rolling savanna and prairie or low hills, mostly overgrown with grass and interspersed with shrubs and wooded patches. The climate

was warm or subtropical, with sufficient and well-distributed rainfall.

Primeval humanity, accordingly, must have shunned extreme conditions and preferred milder parts of the world with a variety of natural conditions and products. Its habit was rather mobile, strolling over the wooded hills and grassy plains. As the long, muscular legs carried the body, the hands were busy examining objects, gathering fruits and carrying them to the mouth, collecting various small animals and birds' eggs or catching larger prey. During the long ages since the first definite use of the legs as the principal carriers and the hands as the exclusive manipulators of objects under visual guidance, this division of two physiological tasks gradually became firmly intrenched in human nature. Locomotion became the sole duty of the legs and feet, perfectly adjusted to balance the weight either at a slow, measured walk or at physiologically high speeds. The arms and hands, in turn, became the most versatile grasping organs that nature had devised. The entire bodily machine became reorganized, including the senses and the regulating and directing mechanisms of the brain. From an originally largely quadrumanous, that is, essentially quadrupedal creature, capable of a short leaping gait, with limited intellectual capacities, Man became, in the course of a long evolutionary process, a high-speed biped and an enduring walker, with hands which serve his intellect and a mind which encompasses the universe.

11. Contribution of vision to Man's rise to his pre-eminent status in the world.— On the argument of the preceding subsections the following thesis concerning the rise of Man from obscure origins to his dominant place in nature may be advanced.

Human vision developed from more simple conditions found in Man's Ancestors. It is the dominant sense upon which, phylogenetically and ontogenetically, human intellect principally rests. Not vision alone, however, but a concurrence of several fortunate circumstances is responsible for the growth of Man's superior intellect. The principal factors were the erect posture of the body and the bipedal gait, initiated by the terrestrial habits of Infrahuman Primates and developed to perfection by Man's Ancestors. The long-range influence was the omnivorous diet working under the impetus of the "struggle for existence."

The arms and hands, emancipated from the task of locomotion taken over entirely by the legs and feet, became transformed into delicate tentacles capable of handling objects in the most varied ways. Manipulation, or the use of hands, is mostly under the control of vision, with the assistance of the somesthetic senses of touch, muscular sense, temperature, pain, and the sense of balance. These sensory qualities help regulate the actions of the muscles of the hands and arms and other co-ordinated groups of muscles to perform purposeful acts of the will.

The arms and hands, chiefly under the close guidance of vision, are Man's principal organs of exploration of his immediate environment. They are his anatomical instruments by means of which he acquires food, feeds himself, takes care of himself and his kin, and in many other ways adjusts himself to his immediate environment. With his hands, too, he defends himself and commits acts of aggression. By means of his hands, mostly guided by vision, Man fashions and uses various tools and instruments through which his capacities and physical powers are magnified many times. In this way Man sets himself in relation to his distant environment, seemingly as far as the limits of the universe and the confines of time. (*Cf.* H. Petersen 1924.)

The possession of such versatile organs of mechanical accomplishment has tremendously enlarged the influx of knowledge, which in turn necessitated a many-sided development of the brain as a repository of past experiences and an integrator or inventor of new combinations of numerous complex skills. The most important of these is speech or language, the instrument of crystallized thinking, and human intellectual intercourse.

Without the kind of vision possessed by Man, he would not be the supreme intellectual being on this globe. But without the locomotor and handling extremities he has, he would never have developed the kind of vision he has, nor would he have been able to make practical use of it, as he did and does. Many other peculiarities of human organization, such as the upright

position of the head and the flexible neck on which the head pivots, contributed their share in making Man what he is.

It is doubtful whether a similar statement could be made concerning any other part of the human organism, not excluding the brain itself. Marvelously organized as the human brain is and working as a superefficient integrator and arbiter, it never would have become that without the quasi-mechanical tools, the arms and hands, and the legs and feet. No other organ can compare with them in importance in the rise of human intellect. The task of the heart and the vascular system, of the organs of digestion, respiration, generation, and the rest, as in other animals, is to maintain the physical integrity of the body and of the human race, irrespective of the intellectual level and accomplishment of its possessor, whether it be an Aristotle or an *Australopithecus*.

The three principal factors upon which Man's physical character and intellect rest are vision, manipulative ability of the arms and hands, and the locomotor ability of the legs and feet and other adaptations that make the upright gait possible. The sense of hearing, closest in its "spiritual" or "intellectual" quality to the sense of sight and the basis of human speech, must itself take second rank in comparison with the superb performance of vision in the kind and variety of information that it supplies to Man's intellect. Much lower in the scale must be ranked all other senses, such as taste and smell, whose roles in the building of the human mind are relatively modest. Of greater importance are the various modalities of the somesthetic sense, of equilibrium, of motility in particular as the indispensable components of the manipulative and locomotor functions of the extremities, and of speech. Each, according to its particular role, contributes to the harmonious working of the perfect human machine.

Human vision, that is, the organs that perform it, like vision in other animals, developed to serve the particular purposes of human life. Human vision had to be good to notice in a rough, summary way large and medium objects at long and medium distances, still or in motion, colored or without color, in good light or in the semidarkness of twilight. But it also had to be good enough to analyze the minutest objects within the manipulative range of the arms and hands, as well as to discern moving Humans and larger animals several miles away.

The arms and hands, working under the close binocular guidance of the eyes, became Man's universal instruments, easily and quickly carried by sturdy legs anywhere over the accessible parts of the globe. Largely with their co-operation, vision became the funnel through which an immense wealth of impressions poured into the brain, which expanded into a huge repository of past experiences of the most varied kinds which could be integrated with other senses and motility, recombined, and put to new uses. In this way the foundations of the superior human intelligence were created.

In summary, the adaptations of the legs and feet for locomotion and of the arms and hands for manipulation in Man's Ancestors and the subsequent development of human intelligence may be, in a larger sense, viewed as a special case of adaptation to a new, terrestrial habit and habitat. Just as a Fish had to undergo fundamental reorganization in order to become an Amphibian, the latter to be transformed into a Reptile, thereafter to become a Mammal or a Bird, so the originally arboreal Primate had to pass through very many changes in order to become a Human. In each case the cerebral development did not precede but apparently followed the reorganization of the body for the new way of life. In the origin of Man, too, the primary stimulus was the change of habit and habitat, which, under the general urge of life, was followed by the transformation of the anatomical mechanisms, including the brain, resulting in the intellectualization of Mankind. (*Cf.* secs. 7, 8, 9, this chapter.)

SEC. 4. INFRAHUMAN PRIMATES AS AN ILLUSTRATION OF MAN'S ANCESTORS BEFORE THEY ASSUMED AN ERECT POSTURE AND BIPEDAL GAIT

1. Introductory remarks.—In the preceding chapter various representative Vertebrates were portrayed, in an attempt to discover just what role vision played, and in what way, in the formation of their characters. For this, we had necessarily to delve into their environment,

habits, and anatomical organization. These sketches, of necessity, had to be brief. Even so, they showed each animal species to be quite well adapted in habits and organization to the particular conditions in which it lives. Expressed differently, each particular set of environmental factors and their particular use, given the opportunity, produced their own particular type of animal. In all species investigated, vision was found to play its own special role.

The evidence so far adduced in the present chapter indicates that the process by which Man was formed was no exception. Unfortunately, however, our knowledge of the early stages of human evolution is quite meager. One is therefore forced to resort to speculation, inference, and deduction to re-create the picture of Man's infrahuman ancestors, their physical and physiological character, sensory and mental faculties, probable behavior in their natural habitat, and, finally, the principal environmental factors which probably initiated and influenced the course of human evolution. (*Cf.* secs. 8 and 9, this chapter.)

2. MAN'S DERIVATION FROM INFRAHUMAN ANCESTORS.—From what was said in the preceding section, it is apparent that at some time in the distant past Man's Ancestors probably resembled more or less one or another of the present species of Infrahuman Primates. The first association in this connection is the large, so-called Anthropomorphous, or Manlike, Apes. An idea of close kinship between Apes and Man seems to have been entertained by many. However, in spite of the obvious similarities, objection may be raised to this view on several points mentioned below. Hence all that may be accepted as certain is the derivation of Man from some early infrahuman primate ancestor, whether an early Tarsioid, an early Cercopithecoid, or even an early Prosimian.

The question of whether the linear ancestors of Man resembled one of the now living forms or some extinct and perhaps not yet discovered species, what the intervening stages of human evolution were, what the probable living habits of Man's Ancestors and the physical and climatic conditions of their successive habitats were cannot be answered except on the basis of well-documented evidence. Here we shall merely call attention to a few bodily and psychic features which make the thesis of a close phylogenetical relationship with the Great Apes difficult to accept. These are (*cf.* Figs. 528–40): disproportionately long arms and short legs in Apes, the reverse of those found in Man and in the terrestrial Monkeys; disfigured feet in some, unfit for a straight plantigrade gait on flat ground (Orangutan, Chimpanzee); excessively short neck, restricting the mobility of the head, especially in the adults; excessive shortness and relative weakness of the thumb, making it and the fingers less fit for delicate "picking" prehensions; all-around crudity, robustness, and clumsiness of the entire body build; the peculiar curvature of the spine, different from the S-like shape of the human spine, and the large canine teeth, all of which, without considering further details, make the so-called Manlike Apes difficult to bring into close ancestral relationship with Man. In contrast, the even proportions of the limbs of the smaller Monkeys and their use and the structure and use of the feet compare rather favorably with those of Man (Figs. 526, 527).

Other features of the Apes, such as their practically exclusive vegetarianism, their relative unsociability or solitary, hermit-like way of living in their primeval arboreal home, tend to underline their isolation from the main primate stream, to which direct ancestors of Man appear to have been much closer. For these reasons some of the smaller Monkeys seem more fit, at any rate, to illustrate the physical appearance, the character, and the habits of that phase of nascent humanity in which its basic mental and bodily organization and its social instincts, which represent one of Man's most prominent features, were formed. (*Cf.* W. L. Straus, Jr. 1949.) Such are some of the Macaques and the so-called Dog-faced Monkeys or Baboons, in spite of the beastlike appearance of the last-mentioned species, which seems to be an adaptation to the conditions of their quadrumanous terrestrial mode of life. (*See* A. Brehm's *Tierleben*, 4th ed., v. 13, 1916: *Die Säugetiere*, v. 4; also Zuckerman, Carpenter, Klüver, Hooton, Malbrant & Maclatchy, C. Akeley, and Mrs. Mary L. Jobe Akeley; *see also* following section.)

3. Character, habitat, and behavior of the Rhesus Macaque.—The Java Macaque (*Macacus cynomolgus, Macaca cynomolga*), and the Indian Rhesus or Red Macaque (*Macacus rhesus, Macaca mulatta*), the *bandar* or *markat* of the Hindus, may be taken as typical of the Macaques. These and other kindred species inhabit all of southern and southeastern Asia and North Africa, including the Rock of Gibraltar in Europe.

The Rhesus, in a number of local species, inhabits central and northern India, Kashmir, Nepal, Sikkim, much of China, part of Tibet, and most of Japan, here being the northernmost living subhuman Primate in the world.

Physically the Macaques are well built, being huskier than the African Cercopithecs but lighter than the Baboons. Climatically, they are quite hardy. In the Himalayan Mountains they prosper at an altitude of 9,000 feet, where they prance about in winter under snow-covered pine trees. Others live in the dry and hot Gujarat, while still others find it comfortable in the hot, steamy bamboo thickets of flat Bengal.

The habitat of the Macaques is almost anywhere: in forests and orchards, in jungles and next to cultivated fields, and also in rough, rocky country. Water is a necessity for them, and they swim and dive excellently, especially when pursued. Even though they are arboreal and capable climbers, easily making leaps of from 12 to 15 feet, they spend much of their time on the ground in search of food. Ridley (1895) frequently observed in the jungle large Macaques walking erect for short distances.

The male Macaques are formidable fighters, well armed with powerful canine teeth, strong enough to ward off a Leopard, their chief enemy.

They are not especially choosy about food, even though they have a "sweet tooth," eating many kinds of fruits, seeds, kernels, leaves, buds, insects, and eggs. Some observers saw them eating crabs and shells. In my own long experience the Rhesus Macaques hardly ever touch any meat, either raw or cooked. In captivity, with this exception, most other human food is readily taken by them, especially bread and milk and sweet fruits, such as bananas, apples, pears, and grapes.

The senses of the Macaques are acute. They seem to love colored objects. Their vision and visual attention are of superior quality, brightness discrimination and color vision, visual acuity and form vision being little inferior to, or as good as, that of Man (*see* experiments by Shepherd, Klüver, Brecher, Bierens de Haan, Révész, and Grether).

The Macaque's brain and other parts of the nervous system, like the remainder of the body, are organized according to the same general primate plan as in Man (*cf.* Fig. 280). The visual system in particular has all the elements of Man's: eyes, optic nerves, chiasma, subcortical centers, visual radiations, cortical visual centers or striate areae, albeit they are simplified and of sketchy configuration, as could be expected from a phylogenetically less advanced Primate (Fig. 186). Even in its minute histological structure, as, for example, that of the retinal nerve cells, their arrangement, and synaptic relationships, in the minute structure of the lateral geniculate nucleus and of the striate cortex, all details are very similar to the human, even though they are not exactly the same (*cf.* Polyak, *The Main Afferent Fiber Systems*, 1932; *The Retina*, 1941 or 1948; and chaps. V–IX in this book; for other data *see* Hartman & Straus 1933).

The Macaques are pronouncedly social animals. They are found in bands of from 10 to 50. They are very active, much of the time being busy with the gathering of food or playing and squabbling with their companions. Occasionally such squabbles degenerate into more serious fights. Much of the time the whole company is on the move, examining every bush or clump of grass for something to eat, always on the alert for a possible enemy.

In character the Macaques may be described as highly intelligent, alert, bold, clever, tricky, saucy, inquisitive, tough guys, capable and ready to defend themselves and their own, when need be, to the utmost; occasionally wicked, treacherous, unreliable, and again, when treated well or when not molested, tolerant but moody; in youth gentle and full of "monkeyshines," in advanced age irritable and of morose disposition.

In their family affairs they are full of tender love for their young, exhibiting a high degree of social unity (principle of "all for one, one for

all"), sometimes to the point of utter disregard of personal danger. They are capable of heroic self-sacrifice but are also extremely greedy, avaricious, and jealous in matters of food. On still other occasions, for example, in the presence of a snake, true or artificial, they show themselves to be abject cowards.

The mental abilities of the Macaques, much investigated during the past few decades, are of a high order, on that score alone fully justifying their rank of primate mammals. Their powers of observation of whole situations and minute details are very good. Their memory is excellent and long lasting. They can easily be trained to perform complex acts in the laboratory and in the circus, where they can be great "showmen."

In laboratory experiments the ability to acquire visuo-mental ideas of a practical kind, a degree of abstraction and some reasoning power, the presence of "practical memory," and a good degree of mental retention were found. Even though only the rudiments of the highest mental powers are present, the Macaques have been found, on the whole, far superior mentally to most other experimental animals, such as the Dog, Cat, and Elephant. Whether Macaques ever use objects as tools, as do the Cebus Monkeys, has not been found out and is questionable (W. T. Shepherd 1910; H. Klüver 1933). In intelligence the Rhesus Macaques have been found, however, to be outranked by both the Cebus Monkey and the Gibbon (W. E. Galt 1939).

Contrasting with the many creditable features of the Macaque's character are those of an adverse kind. In accord with their moody, irritable, and unpredictable disposition, they are easily provoked and offended, their reaction quickly becoming stormy rage, an eruption of violent emotions expressed by loud, angry voices and other signs of ill will. On a few occasions they have been observed throwing stones, sand, or water at their molesters. The outburst of anger may be accompanied by a reddening of the face and of the hind part of the body. When thoroughly aroused, they are little devils, ready to attack anyone, including humans. (For similar behavior of the Spider Monkey observed in nature *see* W. R. Philipson 1952, p. 35.)

Toward the weaker members of their community they sometimes become malicious, sadistic tyrants. They bite, pummel, and otherwise torment their unfortunate victims with pleasure, even preventing them from getting food, drink, and rest. Briefly, the Macaques, especially the old males, are unstable, inscrutable, evil fellows, ready to commit every malicious trick that springs to their minds and is within the limits of their physical power. As a counterpart, the female Macaques, when in sexual heat, are described as veritable nymphomaniacs.

The Macaques have a definite sense of the "rights" due them, and of "injustice" done to them, as the following episode convincingly shows. Among the half-dozen or more of these monkeys held in several large cages for experimental purposes, there was "Peter," a large male with long canines, and a gruff character. He was accepted by the younger males and the females as a recognized overlord. One morning the experimenter wished to examine the pupils of the eyes of one of his females to compare their size after an experiment made some time earlier. In order to have a good look at the eyes the experimenter had to entice the female to come quite close to the wire wall of the cage, and himself had to approach it closely. This was difficult with the timid female, who had the big "boss" at her side always ready to snatch away the morsel of food offered her. Several times the experimenter almost succeeded, but each time Peter almost got the food. Little by little, by occasionally threatening Peter with a dirty look, and in between intently peering at the pupils of the female slowly approaching, the experimenter thought he had almost achieved his object when suddenly he was given a severe blow on the head by the cunning Peter, who in no time had retreated to the opposite corner of the cage.

Translated into human psychology, Peter's act was a punishment of the experimenter for having fooled him repeatedly on that occasion. It is difficult to deny that the big male had "understanding" or "insight" into the situation, and deliberately intended to revenge himself for "unjust" treatment. It was clearly a demand for at least equal, if not preferential, treatment, commensurate with his superior rank, maintained through his greater strength and cunning. Unpleasant as this interpretation may be to civilized human feelings, Peter's action, in

the light of phylogeny, appears as an early spark of an emerging "morality," upon which the social order of the primate world, including Man's, is based. It gives us a glimpse of the primitive primate mind from which the immensely increased and complicated human mind itself developed! (*Cf.* Epilogue.)

The following observations may further round out the portrayal of the Macaque's character. They are, above all, greedy, incorrigible egotists. Their greed, to be sure, exhibits all the gradations from the highest to the lowest. This greed is especially manifested in relation to food. The crassest greed is, naturally, exhibited by the hungry animals, for example, during the morning feeding if they were poorly fed during the preceding day or two and no food was left overnight. On this occasion one sees the Monkeys not only avidly gulping the morsels and stuffing their cheek pouches, but also holding as many pieces of food in each hand and foot as they possibly can. The limit of what appears to be legitimate greed, finally, is attained when a Macaque drops one or more pieces of food in order to rob another Monkey, even though that morsel may be smaller and of poorer quality.

But the greed of the Macaques has a transient quality. They have never been seen by this observer to hoard food or to accumulate a cache. The other extreme—the offering of food by one individual to another, not excepting parents and their children—has never been seen by this observer either. The greatest unselfishness they demonstrated, which by a long stretch of the imagination could be interpreted as an expression of altruism, was a benevolent abstention from interfering with other, usually weaker and meeker, members of the group, which happened only when there was an abundance of food and physiological hunger was completely satisfied.

Another feature of the Macaque's character, in particular of the weaker individuals, such as the females and the young, is a frantic effort to escape from some terrifying experience, at the expense of other members of the same group. In this situation, as soon as the keeper approaches, e.g., with the net the monkeys learned to know from previous experience (one such experience is quite enough!), they all move to the opposite corner of the cage. As the dreaded net comes closer, all the monkeys crowd together, and each tries as hard as he can to squeeze into the mass of bodies, heads, and limbs, in order to hide behind this living shield.

This act and its purpose are exactly the same as the tactics employed by human criminals when they grab an innocent bystander and use him as a living shield. There is, however, a significant difference between the wicked humans and the frightened monkeys: the former intently watch both victim and adversary during the fracas, while the monkeys, in contrast, hide their faces as much as possible from their pursuer, and seem to be afraid even of his appearance, and try to avoid their fate by closing their eyes to it. The proverbial "ostrich diplomacy," much practiced by modern nations, may have had an early start in primate evolution.

Only occasionally do the monkeys throw furtive glances at the dreaded figure, just enough to determine his whereabouts and his intentions. In this situation, all the manifestations of fear that the primate organism is capable of are seen, evacuation of the bladder and rectum being prominent. On other occasions, when a little monkey finds himself in an entirely helpless situation, the reaction is a silent stupor accompanied by an intermittent clonic shiver, such as may be experienced by unfortunate humans in a condition of paralyzing fear.

Still another feature of the Macaque's character occasionally observed may be worthy of recording: a ganging-up on one or another of the group, constantly harassing him, until he is in an extremely nervous state. What the occasion eliciting this attitude is, it is not possible to determine except, perhaps, by prolonged observation. On the surface, the cause is, as in human life, unaccountable "dislike" or "incompatibility of character."

A positive feature of the Macaques' character is their gregarious instinct to stick together. Even after a squabble, sometimes resulting in the injury of one or several members of the group, they peacefully huddle together, friend and foe alike, nursing their wounds as best they can.

4. Character, habitat, and behavior of the Dog-faced Monkeys or Baboons.—The physical, mental, and social features so char-

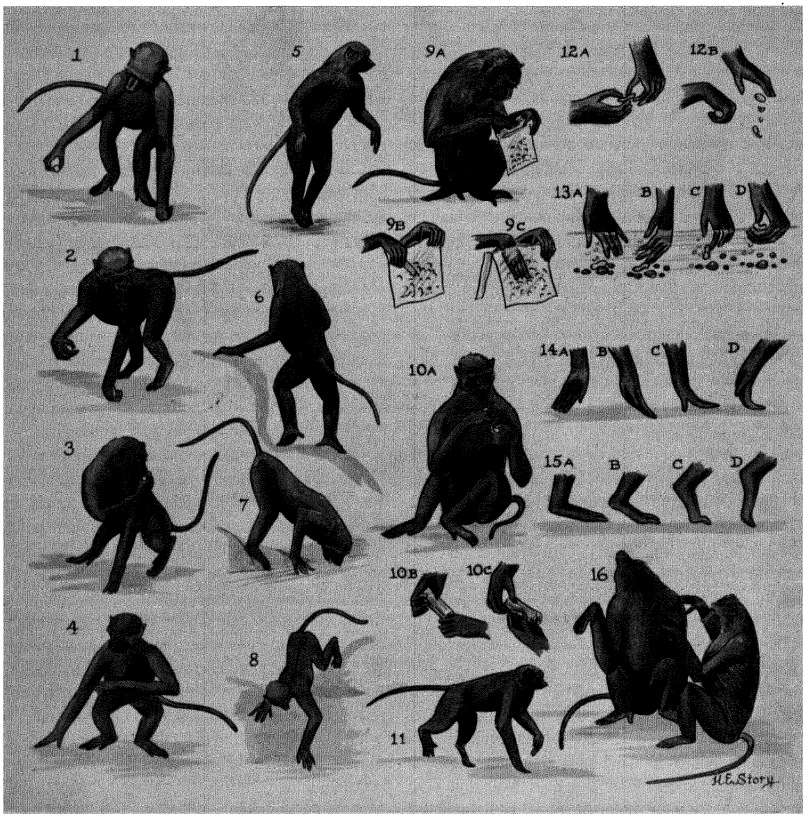

FIG. 526.—Baboons of the species Guinea Baboon (*Cynocephalus sphinx*) observed on "Monkey Island" in the Zoölogical Park at Brookfield, Illinois, in conditions similar to those in which they normally live in their natural habitat. *1*, picking up candy with right hand; *2*, turning to left, facing a possible competitor; *3*, testing candy by smell before eating it; *4*, scratching right arm with index finger of left hand, guided by sight; *5*, walking on slightly flexed hind limbs, while balancing with forelimbs; *6*, rear view in an upright walking posture, beginning of the next step with the left foot, with additional support afforded by resting the left arm on a rock; *7*, leaning over to drink; *8*, young, fishing for peanuts; *9A*, sitting and using hands to open a sack of popcorn by holding one upper corner with the thumb of left hand opposed to other fingers and tearing off the top with the thumb of right hand opposed to other fingers; *9B*, similar manipulation, continuing to tear off the top; *9C*, left corner held by left hand, in a fashion typical of Higher Primates, with the extended fingers of right hand reaching for popcorn; *10A*, right hand, with thumb and third digit opposed, carrying half of the candy bar to the mouth, the other half held by the thumb opposed to other fingers of the left hand; *10B*, first act of unwrapping of candy bar—both hands holding opposite ends of bar, with thumbs opposed by other fingers; *10C*, second act—right index finger and left thumb sliding under the wrapper in order to remove it; *11*, adult walking on all four limbs, with fingers and toes, when resting on ground, extended flat or overextended when progressing (unlike the Apes, especially Orangutan); *12A*, thumbs of both hands opposed to index fingers holding a peanut, just before breaking its husk; *12B*, fingers of right hand holding a part of peanut, fingers of left hand extended to drop broken shell; *13A*, *B*, *C*, *D*, left hand fishing for peanuts, fingers and thumb first extended, then locating one peanut by touching it with extended fourth and fifth fingers, then moving it with the tip of index finger, and finally seizing peanut by the opposed index finger and thumb; *14*, position of left hand in walking: *A* and *B*, back and side views, tips of overextended fingers alone touching ground; *C*, further extension of fingers, with two terminal phalanges resting on ground; *D*, overextended terminal phalanges still resting flat on the ground in forward progression, with thumb clearly off the ground, with palm in no phase touching the ground; *15*, movements of the foot in walking: *A*, foot squarely placed on the ground, including ex

acteristic of the Macaques are further accentuated in the more powerful and fiercer Cynocephali, Cynopithecidae, or Dog-faced Monkeys (Figs. 526, 527). Of these, several species have been studied either in their native habitat or in captivity. The older but still quite useful observations have been collected by Alfred Brehm in his encyclopedic *Tierleben* or *The Life of the Animals*. Especially worthy are his presentations of the Gelada Baboon (*Theropithecus gelada*) and of the Hamadryas (*Papio hamadryas*), both natives of the middle parts of Africa and the latter also of a part of Arabia, and of the Chacma Baboon (*Papio porcarius*) of South Africa. Other observers, such as L. Heck and S. Zuckerman, have further enriched our knowledge of these and other related species. (*See* S. Zuckerman 1932 and 1933.) Other large allied species, Drill (*Papio* or *Mandrillus leucophaeus*), and Mandrill (*Papio mormon*, *Papio* or *Mandrillus sphinx*), live in low tropical forests of African Guinea.

The Baboons, even more than the Macaques, give the impression of being tough, determined animals, supplied with powerful dentition, including long canine teeth for defense, always ready to take care of themselves in any conceivable situation.

They inhabit the entire wide territory of Africa south of the Sahara Desert and, in Asia, a part of the Arabian Peninsula. The country they live in is mostly mountainous and rocky, Hamadryads preferring medium altitudes, from 3,000 to 6,000 feet, while Chacmas are found in a higher zone, from 9,000 to 12,000 feet. They shun dry desert, preferring regions with good plant growth. The vicinity of water is an absolute necessity for them, to which they cling tenaciously, and they know how to find it, if need be, by digging.

The diet of the Baboons is quite mixed. It consists of various roots, tubers, bulbs, herbs, leaves and buds, grasses and grain. Native fruits such as wild figs, tamarind, *Cissus* grapes, and berries of the *Khetam* shrub are eagerly eaten. In many regions their favorite food is the "prickly pear" or fruit of the *Opuntia* cactus, which, incidentally, they have helped to spread over a wide territory. Their staple food is *Ixia*, a variety of iris, whose roots they dig from the soil with their hands.

Whenever opportunity offers itself, the Baboons are quick to plunder fruit orchards, vineyards, and fields of Indian corn and millet. They are said to be especially partial to Durra or Dhurah, a cultivated variety of *Sorghum vulgare*, a tropical cereal widely grown in Africa and southern Asia.

The Baboons also eagerly hunt for every kind of small life, such as insects, especially grasshoppers, centipedes and millipedes, scorpions, worms, snails, lizards, mice, shells, crabs, young of birds and their eggs. In order to find insects and other small animals, they turn over loose stones, several of the Baboons applying their concerted effort to the larger boulders. They are bold and tricky enough to take an earth bee's comb filled with honey, a delicacy to them, from its burrow.

Whenever they can, the Baboons satisfy their craving for protein-rich food by attacking game animals, also hunting larger animals like antelopes and the young of sheep and goats, and in this way occasionally becoming partly carnivorous. This report, based on native belief, was questioned by Zuckerman (1932). However, that there may be more than a kernel of truth in it was shown by Klüver's Baboons, which eagerly caught stray rats in his laboratory and devoured them.

Baboons congregate in troops whose size varies according to the species, being usually larger than the bands of Macaques. The average size may be from 150 or 250, to 300; but much larger congregations numbering several thousands are mentioned by some observers. Only one-tenth of the bands are fully grown males, whereas the fully grown females are

---

tended phalanges of toes, but with the heel slightly off; *B*, heel further raised, toes slightly flexed; *C*, entire sole lifted clear off the ground, with flexed toes alone supporting the weight; *D*, entire foot off the ground, except the tips of toes, the foot at right angles with the ground ("ballerina stance"); *16*, adult sitting with his head thrown back in a typical posture, allowing inspection of his fur by a companion using both hands, the left holding the hair aside, the right picking dandruff and "lice" with index finger and thumb, all minute objects closely scrutinized, and all delicate movements carefully guided by vision. (*Cf.* following figure.)

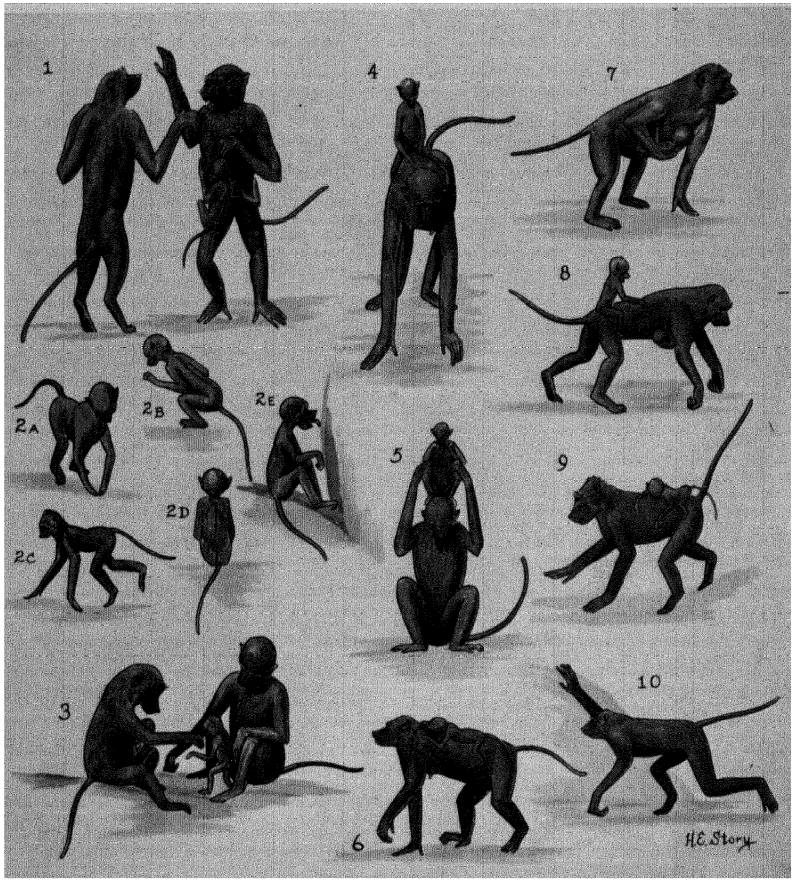

FIG. 527.—Guinea Baboons observed in their daily activity on "Monkey Island" of the Zoölogical Park at Brookfield, Illinois, in conditions resembling their natural habitat. *1*, two females apparently in an argument about a baby belonging to one, to whose abdomen it firmly clings, both females standing on their hind extremities in human fashion, probably either for greater emphasis or in preparation for a fight (note left female standing on tiptoes slightly flexed, affording a firmer grip on the ground, right female with feet flat and toes, including big toe, extended to increase supporting surface, the hind limbs of both females slightly flexed); *2*, young in *A* walking on all fours, half-profile; *B*, hind limbs flexed before jumping; *C*, walking on all fours in lateral view; *D*, rear view of a sitting posture, human fashion; *E*, licking surface of the rock while sitting in side view; *3*, two mothers with young babies, in a friendly chat, watching one of the babies attempting an upright walk; *4*, baby taking a ride on the back of its mother walking on all fours, front view; *5*, baby having fun sitting on the top of the head of its mother which holds it by its knees, front view; *6*, side view of a mother walking on all fours, with a baby napping on her back, firmly gripping her fur; *7*, mother limping on three limbs while holding a baby to her chest with the right hand, in side view; *8*, mother in side view walking on all fours with fingers of both hands flexed to form "knuckles," the newborn infant hanging to her chest, with the older youngster riding upright on her far back; *9*, side view of a mother walking on all fours, with an infant clinging almost crosswise to her lower back; *10*, side view of an adult walking on a ledge, holding to the rock with his right hand, with left fingers flexed. (*Cf.* preceding figure.)

about twice that number. Hence the number of individuals of reproductive age amounts to approximately one-third of the total, the remaining two-thirds being young and adolescents. Each troop is said to inhabit its own territory, approximately 1½–2 miles in diameter, even though they are much on the move about the country to find better feeding grounds.

Much of the time during the day hours the animals are on the move, particularly in the morning and afternoon, gathering food or going to or from the watering places or night shelters. When on a plundering expedition, they exercise the greatest caution. Most Baboons rarely climb trees, usually only when hard pressed. There are, however, exceptions, such as the Babuin (*Papio cynocephalus*) of Sudan and adjoining regions, which customarily spends nights in the trees high above the ground.

In rocky country, the true home of the Baboons, they scale the most difficult cliffs with unsurpassed skill, ease, and speed. For the night, each band selects a protected, favorably located shelter difficult of access by a marauder, usually in cracks and caves along the steep walls or under overhanging cliffs. Here they are protected from inclement weather and are relatively safe from the depredations of Hyenas and, in particular, Leopards, their principal enemies.

In posture and movement the Baboons betray their true quadrumanous terrestrial nature (Figs. 526, 527). Even when they rise on hind legs, they often support their body on one of their hands. Their gait, when slow, appears clumsy. When pursued, they fall into a shunting gallop unlike that of any other animal. It is said that they can easily be overtaken by a dog. But in the broken country where they live, with their climbing ability, formidable weapons, numbers, and habit of acting as a team, and their courage, they are more than a match for almost any of their natural enemies. Their great numbers in their home countries testify to their success and to their adaptability to various conditions of life, including resistance to the encroachment of human civilization.

The disposition and mental character of the Baboons form a kaleidoscopic picture. These qualities depend largely on age, sex, and species and to some extent on individuality, as well as on the various accidents of life. Age is an essential factor. The youngsters are generally playful, amiable, and full of spirit. The females usually treat their babies with great love and concern during the first few weeks or months of life. Thereafter their affection gradually cools to a state of indifference or outright animosity. Toward the males whose sexual mates they are, the females practice a tricky submissiveness or trade their charms for the favors of their overlords in true courtesan fashion.

The fully grown males are powerful, well armed, hard-boiled, and tough, usually suspicious, ill disposed, and difficult to please. They are always ready to pick a quarrel with other grown males, usually on the basis of sex rivalry. The older they get, the more ugly their dispositions become. On small provocation, for a "cross look" for instance, they may take offense, their fury erupting with an elemental force. They have a long memory for wrongs done to them, real or imaginary, and do not forget to take revenge at an opportune time. Physically, too, they are tough animals, difficult to kill with buckshot. When hit, unless in the head or chest, they just rub the spot and run away as if nothing had happened.

The males, especially in confinement, are very jealous of one another, and fight for the females, sometimes to the point of the females' and their own destruction. Toward the females they are exacting, sadistic tyrants.

There is, however, another side to this offensive character of the Baboons. They are described as highly intelligent, quick-witted, resourceful, sure of themselves, never embarrassed to find a way out of a situation, no matter how difficult. They are pronounced "herd animals," sticking together, in their family and their band, and most unselfishly protecting them against enemies.

Their instinct of self-sacrifice becomes especially evident on the approach of a dangerous enemy, such as a Leopard or a party of hunters. In such a situation the entire troop becomes "mobilized" for common defense, expressed by the assumption of a defensive position, by a loud growling, barking, and howling, and by a general uproar and hubbub. In an actual attack against an enemy, the entire band works as a concerted team, the powerful males being in the

forefront of the battle line and in the rear guard.

In their natural habitat the Baboons are described as being ordinarily tolerant of other animals and of native humans, for example, at the watering places where they often wait patiently until the others have satisfied their thirst. Toward humans, if not molested, they exhibit a high degree of indifference. On a few occasions, possibly when hunted, they are said to have attacked people, sometimes using stones for that purpose.

On one occasion an old Baboon, hit by a hunter's bullet, was helped by two young ones to get away, and even in that desperate situation he found opportunity to castigate his helpers for not having performed their samaritan job quite to his liking.

A remarkable episode, showing a high degree of cool determination and astuteness, is described by Brehm. In a hunting drive in Abyssinia in which two experienced greyhounds were also used, a troop of the Hamadryas Baboons crossed a ravine, leaving a young animal behind, which, in order to escape its pursuers, leaped upon a rock. "We were already congratulating ourselves," says Brehm, "that we would get hold of that one; yet it happened otherwise. There appeared from the other bank one of the largest males. Gravely and with great dignity, without the least hurry, and without paying attention to us, he fearlessly marched toward the dogs, throwing at them dagger-like glances, and in this way keeping them in perfect check; then he climbed the rock slowly, comforted the little one, and retreated with it close to the dogs, which were so nonplussed that they let him and his protégé quietly pass by." A somewhat similar episode was observed among the Chacma Baboons by Zuckerman.

On another occasion a troop of Baboons tried to prevent people from coming to a watering place, by throwing stones, pieces of wood, and mud at them. In order to shoo them away, a shot was fired, severely wounding a young Baboon. Quickly it was picked up by its mother and carried away. On the next slope the entire troop stopped and gathered around the luckless animal, which continued to wail. With anxious eyes it looked at its wound and tried to stop the blood with its hands. Its mother plucked leaves from the next shrub and tried to plug the wound. But the horrible wailing continued for another quarter of an hour until, after a last sigh, the stillness of death set in. Thereafter the entire band disappeared into a thorny thicket carrying away the body of the victim. Similar experiences, where Baboons carried away their dead and wounded, have been reported by other observers, according to Brehm. No such experiences or the use of stones as weapons have been reported during recent times. (*See also* Charles R. Darwin's *Descent of Man.*)

The intellectual abilities of the Baboons are rated quite high by those who have observed them in nature and their tricks in captivity, in the circus, or in experiments. The Babuin especially is reported as being intelligent and docile. However, most of the observers emphasize their unpredictable emotionalism, the sudden flaring-up of their anger, its quick rise to a climactic rage, and its long duration.

In their natural condition the Baboons have only a few serious enemies, such as the Lion, Hyena, and Leopard, of which the latter appears to be the principal. Snakes, Lizards, and Frogs are highly respected by them, as by the other Monkeys and Apes. Yet in spite of the terror these animals hold for them, their curiosity may get the upper hand of them and force them, for example, to open the boxes in which snakes are kept to have a good look at the dreaded things.

The interesting observation made by De Beaux, reported by Brehm, on the way the Gelada Baboons communicate among themselves by voice, may be of importance in understanding the origin of human speech. According to this:

> The voice of the Gelada is extraordinarily flexible, and unusually mellow; even his loud call does not sound as harsh as the barking of a Hamadryas. And Martin talks directly of a speech. During the noon siesta, when the menagerie had few visitors, the family used apparently to entertain themselves by chatting, in the most lively way, when it sensed itself alone. The modulation and accentuation of the tones was so varied that one was forced to think oneself to be in the presence of creatures endowed with the power of speech: The sounds recalled somewhat the inarticulate voices made by people hampered in their speech by an organic defect.

In the following, as a comparison, are a few notes from my own observation on the vocal and bodily expressions of the Rhesus Macaques. These are of several kinds, each sound having a distinct semantic value, and each is promptly understood by all members of the community. The sound "Oh!" brief and sharp, given once or several times in succession, is an expression of astonishment or surprise, its meaning being exactly the same as that of the same sound pronounced in a like situation by Man, Baboons, and other Monkeys. Other sounds and actions have also specific meanings: the call for food and during lonely hours, sounding like a prolonged, somewhat high-pitched, plaintive *oooo!* pronounced as in the word *true;* a high-pitched squealing, when molested or threatened, for example, by a more powerful monkey; a quiet chattering accompanied by a quick succession of smacking of the lips and tongue, sometimes without smacking, with baring of the teeth, and grimacing, as an expression of friendliness or subservience or as an invitation to be nice; a turning of the back part of the body toward a monkey or a person, with or without a few short grunts, used as a friendly gesture or a sign of subservience; a quick motion of the head down and up, somewhat resembling a Chinese nod, with or without a short grunt and with or without an opening of the mouth, while intently fixing the eyes on a person or another monkey, meaning an interrogation complex, as if saying "What is the matter?" "What do you have up your sleeve?" Many other sounds and signs, variously combined and modulated, may be distinguished; altogether, this is a subject worthy of a thorough study. (*See* the vocal expressions of *Macacus cynomolgus* observed in the Malayan jungle by Ridley 1895; *see also* C. Darwin, *The Expressions of the Emotions in Man and Animals,* 1873; and K. Lorenz 1951.)

In conclusion, even though the above-mentioned simian expressions of thoughts and feelings are few and primitive, they may well have served as a nucleus from which human speech, the pride of mankind, originated.

5. Comparison of human character and that of the lesser Primates.—Both the Macaques and the Baboons, in physical equipment, in sensory, mental, and emotional faculties, and in habits, may roughly illustrate the early Infrahuman Primates directly ancestral to the present human race or races, before they assumed a bipedal gait and erect posture and before their hands became entirely emancipated from the task of locomotion. In their basic characteristics they represent the germ from which Man developed. If the comparison is not in all respects flattering to Man's self-esteem, this is not the fault of the Monkeys or of Man, but is due to the common catarrhine inheritance.

In comparison, Man's superiority in intellect, emotions, and morals appears to be only in degree and not in kind. Universal human selfishness, ruthless cruelty in internecine struggles of the human races, creeds, nations, and classes, sexual promiscuity, and individual and collective greed are, in fact, only feebly emulated by Man's infrahuman relatives. (*Cf.* chap. XII on primate sociology in Hooton's book, *Man's Poor Relations,* 1942; and subsequent sections, this chapter.)

This adverse picture, on the other hand, is equally balanced, if not overcompensated, by the tremendous powers of human intellect, Man's ever searching, inventive genius for technical accomplishment, his merciful compassion for the sufferings of his own kind and even for those of his lesser brethren, by his artistic abilities, and by his superior ability to organize his life, which has, by and large, incomparably improved his own lot since the prehistoric dark ages and through historic times.

It may be of interest to mention here diseases similar to human diseases from which the lesser members of the Primate Order suffer. These are apparently many, including cancer, observed in several cases by Klüver, but they are naturally less well known than human pathology (*see* A. H. Schultz 1936; and H. J. Scherer 1944). It stands to reason that, under natural conditions, as an illness attains a degree which interferes with the essential activities, the animal is eliminated by death, usually through beasts of prey. This is also true of advancing age. Nature, cruel in its ways, does not tolerate a biological ballast, a factor which has become of increasing importance in advanced human society.

In artificial conditions such as in confinement, where a defective individual remains pro-

tected, conditions develop not unlike those found in Man. An illness may develop in an aged Macaque, resembling, for example, a primary optic atrophy, with a substantial impairment of vision, interfering with feeding and other normal activities, as observed by myself. (On a similar effect of old age in Mountain Sheep *cf.* A. Murie's book, *The Wolves of Mt. McKinley*, 1944.)

6. Behavior of the Monkeys under natural conditions.—The following story related to W. Horst by a native of Nepal, and published by F. W. Champion in his book *The Jungle in Sunlight and Shadow* (1934), describing a Leopard catching an Indian Bandar or Rhesus Macaque, illustrates vividly not only the extreme curiosity by which the Monkeys are dominated but also the cunning of their principal enemies, the Leopard and the Tiger.

The native's story, translated into English, was as follows:

"Yes, Sahib, panthers [i.e., Leopards] are very bold and very cunning. Have you ever seen one catch a monkey? No. Well, I will tell you what four or five men of my village and I saw in the patch of jungle you beat through yesterday. We had been ploughing since dawn and sat down to rest under the big mango tree. There were some brown monkeys feeding quietly in the trees near by, and suddenly one of them gave the usual sharp alarm call. We then heard the grunt of a charging panther, and saw a big one rush half-way up one of the smaller trees and then down again as the monkeys left it for the safety of the large *jamun*. He then charged over to the foot of the *jamun* and scratched up the grass and leaves round its roots. The excitement among the monkeys was now tremendous and they leapt about the branches in an agitated way, which was just what the panther expected and wanted. Had a monkey missed his hold or had a branch broken under one of them, the panther would have had his meal. But his luck was out and in a short time we saw him stretch himself out on the ground a few feet away from the tree and apparently go to sleep. The monkeys soon quieted down and we could see them looking down at the panther with the greatest interest. After a little while one of the bigger ones climbed right over him and began to drop leaves and twigs onto him; but still there was no sign of movement. The other monkeys then began collecting closer and closer above him, and it was obvious that they couldn't understand what had happened. One then climbed down a tree a short distance away and took a few steps towards the panther, but his nerve failed him and he dashed back to safety. There was still no movement from the panther, however, and soon three or four monkeys were on the ground, taking good care to keep well out of reach of claws and teeth. This continued for nearly half-an-hour, the monkeys drawing nearer and nearer, until at last one, bolder than the rest, actually touched the panther with his hand. This was what the patient hunter had been waiting for; he struck immediately and, seizing the inquisitive monkey, he quietly carried his victim away to the patch of thick thorn out of which the pig broke yesterday. That, Sahib, shows the cunning and the patience of a panther when he is hungry, and how the inquisitiveness of monkeys can lead them to their destruction."

This story also illustrates well the extreme importance of the arboreal habit, the excellent sense of vision, and the high intelligence of the Rhesus Monkeys, even though in this particular instance the mental powers of the too inquisitive leader of the band were outwitted by those of the tricky feline. The related episode also shows the phylogenetical pressure that the big beasts of prey exert as the enforcers of the jungle's "law of tooth and claw," matched only by the Primates' combination of quadrumanous arboreal adjustment, keen vision, and superior intelligence. The use of leaves and twigs as "tools" by the Monkeys in testing the Leopard's reactions also agrees with a similar use of objects by the Baboons (*see* preceding section).

Other useful hints on jungle life may be quoted from the rich experience of Champion, in particular on the alertness and acuity of senses of various animals under natural conditions, especially of the Monkeys, and the way they react to the presence of the "law enforcers," the Tiger and the Leopard:

Some creatures will stand perfectly motionless when frightened, others will rush away without a sound, birds will frequently hurl themselves into the air with a scream, and many animals have special cries that denote anger or terror. The tiger and the leopard are the two animals above all others that cause alarm among other creatures of the wilds, and on sighting or scenting either of these great felines the many and varied inhabitants of the jungle will behave in a number of different ways. The elephant will probably stand perfectly motionless and watch, possibly occasionally striking the ground with his trunk; the sloth-bear, who is in the jungle but not of

it, fearing nobody, will pay not the slightest attention; the wild-pig will bolt as fast as he can go; the deer will generally stand and stamp their fore-legs, frequently uttering their calls of alarm; the jackal will fill the jungle with his cries of "pheaou"; the peacock will fly rapidly away with raucous shrieks of fear; and the monkeys, comparatively safe in the branches of the trees, will hurl abuse at these great disturbers of the peace of the jungle.

It is the alarm cries made by the two common species of monkeys of India—the langoor and the common *bandar*—that are generally considered to be the most useful sign to the sportsman of the presence of a tiger or a leopard. In my previous book I expressed the opinion that the harsh guttural alarm cry of the black-faced langoor was the most valuable of all jungle signs. . . . I know that langoors are individuals and all do not behave in quite the same manner. In some places langoors are much more jumpy than others, and . . . may occasionally be caught napping. . . . langoors rely upon eyesight only for detecting enemies. . . .

The continued and agitated alarm cries of langoors in a jungle in most cases is the most valuable sign available that indicates the presence of a tiger or a leopard. Some langoors in some places will call, although not to the same extent, for other animals and very occasionally langoors will not call when a tiger or a leopard is close to them—because they haven't seen it, or just possibly, because they recognise that it is not in a hunting mood.

Brown monkeys [that is, Rhesus Macaques] are also very useful indicators in the same way, but, in the jungles with which I am acquainted, they are possibly not so alert or quick-sighted as langoors—or at least so it seems to me. I have several times heard them call for a dead leopard or a leopard-skin and for crocodiles, but I have not yet heard langoors do this.

Similar observation of the behavior of the Rhesus and Java Macaque and Langur Monkey is found in the book by J. Corbett (1953) and in the paper by H. N. Ridley (1895).

7. Character, habitat, and behavior of the Mandrill, Drill, Chimpanzee, and Gorilla.—The natural conditions under which live the large Manlike Apes and the larger Cynocephalous Monkeys, which in many respects resemble them, and their behavior in free nature are but little known. The present scanty knowledge was mostly deduced from circumstantial evidence and is largely obtained from biologically untrained observers, such as hunters and natives. This is apparently due to the small effort made by experienced naturalists to investigate these animals in their natural habitat, despite the importance they represent for the phylogeny of Man. This is the more unfortunate since the great problem of Man's origin could obviously be better understood if the conditions in which these animals live were thoroughly known. The following description chiefly summarizes the report by R. Malbrant & A. Maclatchy (1949), based on prolonged personal observation in French Equatorial Africa, with additions taken from a few other sources.

The Mandrill (*Papio* or *Mandrillus sphinx*) seems to be mostly of a terrestrial habit and inhabits forests which have little developed underbrush. It rarely climbs small trees, either for food or to sleep. It congregates in bands numbering sometimes as many as 100 individuals. Its food consists of grain, insects, and fruits, including bunches of *Elaeis*, terminal twigs and seeds of the sunflowers, and the various mushrooms. During the rainy season it lives in brushwood, where it finds an abundance of fruit. Later it invades the natives' *manioc* cultures, to which it is very destructive. In character it is considered inoffensive.

The smaller Drill (*Papio* or *Mandrillus leucophaeus*), like his larger congener, lives in the forests and is also exclusively terrestrial. It climbs the low limbs of the trees, but only for the night. It congregates in large bands, vagabonding everywhere. There is nothing said about food, nor is any other information given.

The Chimpanzee (*Pan troglodytes*, of which two varieties are mentioned—*P. t. troglodytes*, and *P. t. paniscus*)—lives in thick secondary forests, never in the open savanna. It forms small groups or families, which occasionally may include as many as 60–80 individuals. In comparison with the more powerful, taciturn, and reserved Gorilla, it is boisterous and expansive in character. The bands are always on the move, covering large territories very rapidly. The loquacity of the Chimpanzee is expressed in frequent loud shouts and may be heard whether the band is on the move or at rest. Even during the night the Chimpanzees are sometimes active, as indicated by their "nightly concerts," which may be interpreted as a partial nocturnalism. In habit they may be considered partly

arboreal and partly terrestrial. They spend their nights in the trees, where the females make large nests, whereas the large males sleep next to the tree trunks. When pursued, they escape to the ground.

The food of the Chimpanzee varies: fruits growing on the trees, red fruit of *mayombo*, palm nuts, peanuts, bananas, sugar cane from the plantations, and the like. The following plants are mentioned specifically: *Staudtia gabonensis*, *Poga oleosa*, *Pachypodanthium confine*, and *Irvingia gabonensis*. Chimpanzees, like all other Primates, have a "sweet tooth" and cleverly pillage hives of wild bees to get honey. They are also fond of large white grubs found in the stems of certain trees.

The Lowland Gorilla (*Gorilla gorilla*), by far the largest of the Manlike Apes, is a denizen of dense, primeval jungle. Along the middle Congo River and the Gaboon River it is found only occasionally in the so-called "gallery forests" and in the open savanna. In the Oka region and near to Aboundji it is, however, found in wooded patches dotting the sandy savanna. Even though it has an affinity for the thick forest, it apparently is easily adapted to the thick, brushy growth along the margins of human cultivations. As a rare exception, perhaps, single individuals may penetrate through the gallery forests into plain savanna.

The Gorilla's retiring character makes him a subject difficult to observe in nature. As soon as he notices danger, he becomes silent.

The band is a family consisting of a male, a female, and the young. In some localities bands made up of 15, 20, and 25 are assembled around a single old and a young male, with several females and their young. It is not certain whether the Gorilla is monogamous or polygamous, although the latter seems to be probable. (In one instance Akeley observed three, possibly four adult males, and perhaps a dozen females and youngsters; in another band there was but one male and several females; *see also* Reichenow 1921; Bingham 1932.)

The Gorillas do not move about as much as do the Chimpanzees. But, like the latter, they appear to incline to a partially nocturnal habit, making mysterious nightly visits to plantations in search of food. Some of them, more courageous, dare in plain daylight to invade gardens of the native villages, where they pillage bananas, and are bold enough even to attack the natives.

The families spend the night in low trees, the female with the young ones on the limbs, the husky male at the base of the tree trunk. According to Bingham, the nesting habit varies according to circumstances, the nests being built either all on the ground, part on the ground, or part in the trees, some as high as 40, 50, and 60 feet; Reichenow (1921) found Gorillas' nests in some regions always on the ground or close to it; in other regions, where there are many Leopards, the nests are partly in the trees, like those of Chimpanzees.

The Gorilla habitually walks on all four extremities, the hands resting on the ground upon "knuckles." Sometimes only the impression of the thumb, index, and middle finger is found in the track, indicating the major part of the body weight is carried by the hind extremities, while the arms and hands are used merely as an auxiliary support. (This harmonizes with C. Akeley's observation of an imprint in mud of a Gorilla's foot with a heel, "which no other living thing in the world but the gorilla and man has.")

In its movements the Gorilla is clumsy, and it does not get aroused except when on the ground. The male becomes especially aggressive when the female is to give birth to young, attacking everyone approaching his domain. (*See* description of an unprovoked attack by C. Akeley 1923, and by H. C. Bingham 1932.)

Because of his weight, the Gorilla shuns acrobatics such as are practiced by the lighter Chimpanzee. When climbing, it exercises caution and climbs only trees of small diameter. Large, bulky males dislike climbing and dare to ascend only lower limbs. Even so, accidents occur, such as one where a Gorilla fell from a tree and broke his spine. Hence a Gorilla ventures into higher branches only when hard pressed.

In choosing his food the Gorilla is an eclectic. He eats terminal shoots of young *parasoliers*, a variety of forest fruits, especially *atanga* and wild *mango*, wild sorrel, banana, the red fruit of *mayombo*, sweet *manioc* or *cassava*, peanuts, palm nuts, a kind of *kola* nut, and the like. The mentioned plants are apparently representative of only the investigated regions, while the prod-

ucts of many more regions remain unexplored (*cf.* sec. 5, this chapter).

Both Chimpanzee and Gorilla, according to Reichenow, are exclusively vegetarians, subsisting mostly on leaves, buds, and the soft pith of stems, while fruits are merely an accessory food. Much preferred by them is *Musanga smithi*, whose large leaf, buds, and sweet fruit are especially attractive to them.

8. Observations of the habitat and habits of the Mountain Gorilla.—The natural conditions in which the Mountain Gorilla (*Gorilla beringei*) lives and how he is adapted to them are equally little known. Nobody qualified by scientific training and experience in the field, except Bingham (1932), has studied them. This is the more deplorable, since in the opinion of C. E. Akeley and R. M. Yerkes this Ape appears to be on the verge of extinction (Yerkes 1951). This gap may be filled in only inadequately by the following information from C. Akeley's and M. J. Akeley's books (*see* for the original report on the Gorilla, and for the first description, by T. S. Savage 1847, and by P. Du Chaillu 1855, respectively, C. E. Akeley's book 1923, pp. 191, 193, 237; *see also* A. Brehm's *Tierleben;* for the illustrations of brain, hands, and feet *see* F. Tilney, *The Brain from Apes to Man*, 1928; and Figs. 286, 536–40 in this book).

Carl E. Akeley, the originator of modern scientific taxidermy, imbued with true scientific zeal, made the first and almost the only attempt to study the Mountain Gorilla and to photograph him in his native habitat on the high slopes of the mountains Mikeno and Karisimbi, around Lake Kivu in the Belgian Congo.

The Gorilla, according to Akeley, appears to be a silent creature. Only when aroused does he emit a terrific roar, and the powerful male may rush against the invader of his sanctuary in defense of his band.

The Gorilla does not travel either far or fast, and an average man probably could outrun him. The country he lives in is mountainous, intersected by deep chasms with steep slopes. The vegetation consists of a thick growth of trees and bushes.

In Akeley's opinion "the gorilla is not a ferocious beast, although I was gaining the utmost respect for his size and power." And again: "When I came up with the old male that I had killed first, he had run back and forth on the hillside barking in protest or surprise at my intrusion just as I have seen little monkeys run back and forth on a limb and bark; but of his having savage intentions against me I saw no sign. Of the two I was the savage and the aggressor. In the case of the female I had just shot, the same was true, even though she was accompanied by her baby. She evidently preferred to get away if possible. Cornered, I think and hope she would fight for her young." This young Gorilla, about four years old, Akeley met: "a half hour later when we were trying to find a way down we came across him and, as he ran about, one of the guides speared him. I came up before he was dead. There was a heartbreaking expression of piteous pleading on his face. He would have come to my arms for comfort."

Another interesting scene, which Akeley caught with his movie camera, practically the first and only one taken in the natural habitat, he described as follows:

> Ten minutes later the guides ducked, and crouching, came back and fell in behind me. I took the gun from the bearer, and looking over the tops of the greenery of a little rise in front of us I saw a spot of black fur perhaps fifty yards ahead. As I crouched, waiting for a better view, the animal I was watching climbed up on a nearly horizontal branch of a tree looking back in my direction. In the meantime, the motion-picture camera had been brought to my side. I raised it carefully, put it in position, and all this time another larger gorilla was making the ascent of the horizontal branch of the tree. It was apparently an old mother and her two-year-old baby. Almost before I knew it I was turning the crank of the camera on two gorillas in full view with a beautiful setting behind them. I do not think at the time that I appreciated the fact that I was doing a thing that had never been done before. As I ground away, a second baby came scrambling up a near-by tree. The baby seemed very much interested in the operation. The mother professed indifference and a certain amount of boredom and after a bit pretended to lie down on one arm and go to sleep. The babies, one of them at least, seemed to be amused. He would stand up, fold his arms and slap them against his breast, which suggested uproarious laughter on his part. . . .
>
> There were probably ten or twelve in the band; but never again [after the band bolted away when Akeley, in order to change the scene and make a close-up view, showed himself in full view] did I get

the opportunity to photograph them—just little glimpses of black fur dodging about through the greenery. At one time with my glasses I watched them across a ravine for a considerable time. The old female was lying down on her back yawning and stretching, but she was too far away for a photograph. So finally, feeling that I had about all I could expect from that band, I picked out one that I thought to be an immature male. I shot and killed it and found, much to my regret, that it was a female. As it turned out, however, she was such a splendid large specimen that the feeling of regret was considerably lessened. This female had a baby which was hustled off by the rest of the band. The baby was crying piteously as it went.

This was the first film taken with a movie camera perfected by Akeley, and first of any photographs, still or moving, taken of the Gorilla in his native habitat.

Up to a certain time Akeley had not seen more than one male Gorilla in a band. Later, however, he changed his opinion, as the following experience shows:

We were near the edge of a ravine the opposite slope of which was cleared of bamboo and bush. I suggested to him [Akeley's gun-bearer] that if we could possibly see them in a place like that, it would enable us to do the things that we wanted to do. Not that I actually hoped for any such luck; but as a matter of fact, fifteen minutes later we heard the bark of a gorilla. Peeping through the bush we saw the entire band on that opposite slope, all of them in full view. There were at least three old males, I think four, and perhaps a dozen females and youngsters. They, of course, had seen us. They were making off toward the crest of the opposite slope as fast as possible. [A similar scene was described by Bingham 1932.]

My first thought was along these lines: "Here is a perfectly peaceful family group including three or four males. I could use my two males [previously collected for the museum] without apologies. There is really no necessity for killing another animal." So the guns were put behind and the camera pushed forward and we had the extreme satisfaction of seeing that band of gorillas disappear over the crest of the opposite ridge none the worse for having met with white men that morning. It was a wonderful finish to a wonderful gorilla hunt.

Such was Akeley's work and its scientific motivation, which finally resulted in the creation of the "Gorilla sanctuaries" around Lake Kivu and elsewhere.

Even though the Gorilla is partial to deep woods, he is not arboreal. Akeley believed that the Gorilla "has nearly passed out of the arboreal phase of life and is perhaps entering the upright phase and that he is the only animal except man that has achieved this distinction." To stand erect and balance, an animal needs heels. The plaster cast of the Gorilla's foot shows that the gorilla has "developed a heel." (My own observation in zoölogical parks shows, however, that the Chimpanzee also has a "heel," and uses it and steps on the sole in a way similar to, but slightly differing from, that of the Gorilla and Man; *see* sec. 5, this chapter.)

The gorillas I saw in Africa always touched both their feet and hands to the ground in running but most of the weight was on their feet. Their legs are short, their arms long, and they carry the body at an angle of 45 degrees forward. They do not, however, put their hands down flat and rest their full weight on them. They seem to be evolving toward a two-legged animal. And if they spent most of their time in trees they would not have developed heels and leg muscles for walking upright on the ground.

Not only has the gorilla developed a heel, but his big toe is much nearer like man's than that of any other animal. This may seem a small matter, but a big toe that turns out from the foot as a thumb . . . is useful in climbing. A big toe that is parallel with the other toes is useful for walking but not for climbing.

But the gorilla has not lost all his arboreal characteristics by any means. The length, size, and strength of his arms are evidence of the tree-climbing habits of his ancestors. I know that a gorilla can now climb with more ease than the average man. But I only once saw gorillas in trees and that was when I was taking the moving picture of a mother and two youngsters, and an active man could have walked up the inclined trees these gorillas were on about as easily as they did. Nor did I see any evidence of their having been in trees.

In this observation Akeley concurs with E. Reichenow that "the gorilla is much more a stranger to tree living than the chimpanzee."

The hand of the gorilla is as interesting to me as his foot. If you look at the illustration of the plaster cast you will see that it looks much like a man's, finger-nails and all. You will see that the fingers are bent over. When running he puts his knuckles on the ground. It is a peculiarity of the gorilla that when his arms are extended his fingers are always bent over. He can't straighten them out except when his wrist is

bent. [*Cf.* Fig. 536, sketch *4;* Fig. 538, sketch *2; cf. also* Fig. 540, *1, 2.*]

This peculiar feature Akeley believed to be a legacy of the Gorilla's arboreal habit, "which has not left him even in all the years he has been developing heels, muscles, and toes which are good for ground work only." Hence Akeley was certain that the Central African Gorillas have practically abandoned the arboreal habit.

That the Gorilla makes a hammock-like nest in the trees to sleep in Akeley denies. In this Akeley agrees with Reichenow, who found them also mostly, if not always, on the ground. Bingham's observation, however, provides evidence for such tree nests.

I cannot help believing that this report arises from a confusion with the chimpanzee habits [continues Akeley]. The chimpanzee is not strong enough to fight a leopard. Consequently, he has to sleep out of reach of this foe. The gorilla, on the other hand, has no foe but man. No flesh-eating animal in his territory is large enough to harm him. The gorilla is a vegetarian, so he kills no animals for food. . . .

Altogether, then, as the gorilla has no enemies, he has no need to fashion himself a bed out of harm's way. All the gorilla beds I saw were on the ground. They consisted of a pile of leaves, about what the long arms of a gorilla could pull together without moving. I saw no signs of their occupying these hastily constructed sleeping places more than once.

As to whether the Gorilla is monogamous or polygamous, Akeley honestly confessed his limitations: "The truth is that people know little about the habits of the gorilla." In spite of much work, little is known about the Gorilla's bodily organization.

And even less of study has been given the gorilla's living habits than has been devoted to his dead body and bones. Most of the information which man can get of and from this nearest relative in the animal kingdom is still to be had . . .

As I travelled down from Mikeno toward the White Friars' Mission the fascinating possibilities of the study of the gorilla and its immense scientific importance filled my mind along with the fear that his extinction would come before adequate study was made. These considerations materially led my mind to the idea of a gorilla sanctuary; and I realized that a better place than the one I had just left could hardly be hoped for.

Meanwhile, Akeley's dream materialized when the Belgians, beginning in 1925, established a system of wildlife refuges in Central Africa for the preservation and study of the Gorilla.

Since the publication of C. Akeley's book, knowledge of the Gorilla's habits and habitat has increased somewhat through the efforts of Yerkes (1927–29), Bingham (1932), and Gregory & Raven (1937). The most useful observations of the food habits, manipulation, and locomotion, nest-building, and social behavior are by Bingham (1932) and by Malbrant & Maclatchy (1949; *see* preceding subsection). The attempts by Mrs. M. L. Jobe Akeley (1950), partly summarized in the following, were unfortunately largely frustrated because of insurmountable difficulties.

The Gorilla country along Lake Kivu, in the experience of Mrs. Jobe Akeley, is not free of Lions, as Carl Akeley believed, since these have been seen on one occasion on the slopes of Mount Karisimbi at an altitude of 12,000 feet and higher. The powerful arms and long canine teeth of the Gorilla seem, therefore, quite indispensable for the survival of this Ape.

But the omnipresent menace, especially to the babies and young Gorillas, are the numerous Leopards infesting the jungle, the more so as they are the largest and most formidable of all African Leopards. Other Carnivores, such as the Hunting or Wild Dog, Jackal, Civet Cat, Genet, Mongoose, and Ratel or Honey Badger could normally represent hardly any danger for the powerful Ape.

The Mountain Gorilla inhabits mostly the dense forests of the slopes of the extinct volcanoes of the Albert National Park and a few scattered sanctuaries outside the park in the Tshabirimu and Tshabinda Mountains, at Walikale, Baraka, and other places where he is protected.

His range is from 8,500 feet altitude and up, as far as his favorite food is obtainable (12,000 feet and more). In this mountainous climate he is well protected from the heavy rainfall and icy winds by his thick coat of hair.

When excited, the Gorilla assumes a human-like bipedal attitude; his normal mode of locomotion, however, is quadrumanous, with feet placed flat on the ground and hands supported

by the knuckles. The span of the outstretched arms may be more than 8 feet, the length of the arms contrasting with the short legs. In the quadrupedal posture the head and shoulders necessarily are higher, the back sloping down toward the pelvic region.

The footprints of the Gorilla resemble those of the natives to a surprising extent. The distinguishing mark is the imprint of the abducted big toe, this feature not differing greatly in every case, since many native toes are very short, partially webbed, and somewhat prehensile.

The procurement of food by the Gorilla is not a great problem, since there is plenty of it in his native habitat. He is almost exclusively a vegetarian and a heavy eater. His ordinary fare in the lower altitudes is succulent shoots of young bamboo, and in the higher regions sorrel, blackberries and wild celery, including its large, knobby roots. The occasional additions to the herbaceous diet are large white larvae, which he, as does the Chimpanzee, gets by breaking up decaying logs.

The only serious enemy of the Gorilla seems to be the Leopard, by which not a few young ones apparently are destroyed. The evidence is the small number of immature animals in the Gorilla family and their remains found in the Leopard's excrements. The protection against the wily cat is parental care, the mother holding the baby in her arms during the night and carrying it on her back during the daytime when feeding on the ground. The adolescent Gorillas make their beds high up in the trees, where some of them may yet perish, since the Leopard is an excellent climber.

The beds of the young are close to those of the grownups, who spend their night on the ground, next to some protecting tree trunk and under a canopy of vines. But the most potent defense is the grown-up male:

> With one grip of his powerful hands, the gorilla can break the leopard's back or twist his head from the torso. It is only when the young gorillas stray beyond their parents' watchful eyes or fail to make their beds far enough above the ground that the silent sneaking leopard can seize and destroy them. Otherwise there is peace in the great woodlands. Elephant, buffalo and gorilla—all herbivorous animals—have plenty of food to spare, hence there is no conflict between them, no struggle for survival.

Of special interest was the "bedroom" of a band of twenty-two Gorillas, in which two pairs of "beds" consisted of a big bed and a little one beside it, on each side of a large *Hagenia* tree. The beds were used each night for about a week, during which time the band was feasting in a large celery field. The two pairs of nests apparently were used by two females and their babies, indicating their friendly relationships. Most of the beds were clean, although some were used more than once, in which case they usually had a fresh "sheet" of vines over the old, soiled "bedding." The Gorillas seem to have no external parasites.

The Gorillas, except when in danger, are very silent in their behavior. During many nights of observation of their camping grounds not a sound was heard from them by Mrs. Akeley. During feeding time, if they were unaware of the presence of Man, Derscheid heard mothers cooing to their little ones in a succession of highly pitched and pleasant, sweet, and melodious tones, "not unlike some silvery though monotonous bird song."

The Gorilla seems to be rather peacefully inclined, except when attacked, or in any way interfered with.

> But harmless as a gorilla may be when undisturbed, yet few men, unless armed or else expert in tree climbing, would care to meet a gorilla unexpectedly and face to face in the midst of the dark jungle. . . . When a gorilla's family is threatened he will charge with a terrific speed. A lion or a leopard with its "nine lives," as has been said, would have only small likelihood to survive the attack of an infuriated gorilla. Never might he achieve victory. A man would have no chance at all. [*Cf.* Bingham 1932 on the suddenness of the Gorilla's attack.]

The Gorilla is the most elusive of wild creatures living in the deepest jungle. In the "Gorilla sanctuary," after the period of indiscriminate pursuit, it is now fairly safe from destruction. But it seems that this most manlike Ape is now so well protected as to become a sealed enigma even to science. It seems unwise, therefore, to put such a complete prohibition upon any legitimate scientific study of the Gorilla. Time seems to be running low, and the present favorable opportunity may not last forever.

SEC. 5. OBSERVATION OF THE MONKEYS AND APES IN CAPTIVITY

1. INTRODUCTION.—The best way to learn about the habits of Infrahuman Primates is to observe them in their native habitat (*cf.* preceding section). The next best way is observation in large, well-organized zoölogical parks, where the animals are kept under conditions approximating those in nature. Here the Monkeys and Apes are little hampered in satisfying their natural instincts and in exercising their native talents. It is here, then, that one may get an answer to many a question concerning the behavior of the individuals, groups, or sexes toward each other, to learn about their postures and movements, the use of their hands and fingers in various manipulations, the employment of their limbs in progression and in climbing, the reaction and acuity of their senses, the varied expressions of their physiognomy and its meaning, their vocal utterances and their significance, the associations they form with their kind and possibly with other animals and humans, and other numerous acts so abundantly developed in this highest category of Mammals.

These observations and impressions may go a long way to help form an opinion about the probable course of human evolution. Especially they may show the role that vision played in the rise of the Primate Order from its ancestral origins and the way the coming of Man was probably prepared for and accomplished.

In the following are a few observations which I made during the past few years at Brookfield Zoo and at Lincoln Park Zoo in Chicago, partly undertaken under the stimulus of the ideas expounded by W. L. Straus, Jr., on the origin of Man.

2. MACAQUES AND BABOONS.—In the Indian Rhesus Macaque (*Macaca mulatta*), in the African Chacma Baboon (*Papio porcarius*), Hamadryas Baboon (*Papio hamadryas*), Guinea Baboon (*Cynocephalus sphinx; see* Figs. 526, 527), Drill (*Papio* or *Mandrillus leucophaeus*), and Mandrill (*Papio* or *Mandrillus sphinx*) the four extremities do not differ greatly, the legs being only a little longer and the toes being relatively short. The fingers (Fig. 540, sketches *16* and *19*) are somewhat stubby, their length not so disproportionate in comparison with the thumb as in the Anthropomorphous Apes, especially in the Orangutan (sketch *9*) and in the Gibbon (sketch *11*). The opposition of the thumb to the fingers is therefore relatively more effective than in the Apes, where the thumb is much shorter and weaker than the fingers (sketches *1*, *3*, *6*, *7*, *9* in same figure). In the proportion of their fingers and thumb the Baboons resemble the Macaques and Man. Hence in all of them the hands form more efficient grasping instruments, better fit for delicate manipulations such as picking seeds, small fruits, and insects, and "grooming." The picking of small objects, made exclusively under the guidance of vision, is excellent and is frequently practiced (Fig. 526, sketches *1*, *4*, *9A*, *9B*, *9C*, *10A*, *10B*, *10C*, *12A*, *12B*, *13A–D*, *16*; *cf.* Figs. 531, 532, 534, 539).

The feet of the Macaques and of many other Monkeys, especially of the various Baboons, Drill, and Mandrill are long and narrow (Fig. 540, sketches *15*, *17*, *18*). In this respect they approach human conditions more than those of the large Apes (*2*, *4*, *5*), even though they still are essentially prehensile, with abducted big toes. The feet of the Hamadryas or Chacma Baboons, for example, are narrow and long, with flat soles, the entire surface of which is placed on the ground. The toes are provided with nails somewhat resembling claws, useful for digging.

The fingers and toes, including the thumb and the big toe, can easily be stretched out, or dorsoflexed, as in Man, or better (Fig. 526, especially sketches *14* and *15;* Fig. 540, sketches *15*, *18*). In the Drill the fingers can be easily dorsoflexed or overstretched, to make an angle of 90° relative to the plane of the palm. The fingers and hands in the macaque-like and Dog-faced Monkeys are delicate and flexible, easily used for all kinds of fine manipulations.

In walking, the Macaques, Baboons, Drill, and Mandrill habitually use all four extremities. They place their feet with the entire sole, or almost so, flat on the ground, in the way Man does (Fig. 526, sketches *4*, *6*, *7*, *9A*, *10A;* Fig. 527, sketches *5*, *7*). In progression the heel end of the foot is lifted first, while the distal end,

together with the toes, remains last on the ground, exactly as in the human walk (Fig. 526, sketches *11*, *15A–D;* Fig. 527, sketches *2C*, *6*, *8*, *10*). In this movement the toes are overextended, or dorsoflexed, forming not only a support for the body weight but also a propelling fulcrum for forward progression. In the quadrupedal, or rather quadrumanous, walk mostly practiced, the palms of the hands, together with the outstretched fingers, are placed flat on the ground, the fingers remaining last on the ground in the forward movement. Both the fingers and the toes are nicely lifted off the ground in preparation for the next step. (*Cf. also* F. W. Jones 1942, chap. XXV; and W. L. Straus, Jr.)

Frequently, especially in the Baboons, only the fingers touch the ground, with the palm off (Fig. 526, sketch *11*). Sometimes only their extremities, approximately the two terminal phalanges, are put down lightly, sharing the support of the body weight but little. In this way the principal portion of the body weight in the Baboons and Macaques, in progression, rests on the hind extremities, in contrast to the thoroughly arboreal Orangutan, for example, in which much of the body weight in quadrupedal progression rests on the arms (Fig. 532, *6*, *7;* Fig. 535, *10*). The condition present in the Gorilla may, perhaps, be considered intermediary (Fig. 536, *2*, *4;* Fig. 538, *2*).

When not walking, both the Macaques and the Baboons sit on their buttocks, where they have developed callosities. The body is maintained and secured in an upright position by the legs and feet sprawling on the ground. In this way the arms and hands are temporarily freed from locomotion and are employed for manipulations, such as examination of objects under visual control. The locomotion, then, is composed usually of short quadrumanous walks or leaps from one to the next sitting posture. No stretching of the imagination is required to visualize this habit further increased by the human ancestors by lengthening the walking periods until true bipedalism developed.

The Macaques, Baboons, Drill, Mandrill, and similar Monkeys are alert, quick-witted, vigorous, and intelligent animals, which show all essential human traits in appearance and behavior. Even in such grotesque and gaudily colored species as the Drill and Mandrill, this similarity is no less apparent. The behavior and mannerisms of the Monkeys impress one even more with their "human"—or shall we say their fundamental "primate"?—quality. Not only do the Drill's fingers resemble human fingers, but the manner in which he casually wipes his mouth with the back of his right hand is identical with that of an unsophisticated country lad. And the way he deftly catches a fly is a virtuosity itself, which could be duplicated by a human artist only after long training. It gives evidence not only of acute sight and alert attention but also of exceedingly quick co-ordination of binocular movements of the eyes with the muscles of the neck, shoulder, arm, hand, and fingers. (*See* similar action observed in the Tree Shrew, chap. XIV, 10 [7].)

Finally, in their emotions, their excitability, and their tender love, the Monkeys have been recognized since time immemorial as the reflection, sometimes advantageous, of Man. The sight of the family of Bonnet Monkeys, with a very young baby lovingly huddled to his mother while she "grooms" an adolescent, with the father contentedly watching them, or that of a Hamadryas mother holding her baby in her arms and observing it with eyes full of love, could hardly be better duplicated in human life.

3. GIBBONS.—The smallest of the so-called Apes, the Gibbon Lar (*Hylobates lar*), has a thumb only half the length of his fingers (Figs. 528–31, and Fig. 540, sketches *11*, *13*). In spite of its shortness in comparison with the extraordinarily long fingers, the thumb is well used in opposition with the index finger when picking small morsels of food. However, the impression is that the long fingers are more fit to grasp the limbs in brachiation than to be employed for continuous, delicate manipulations as they are by the Macaques, Baboons, and Man. (*See* C. R. Carpenter in *Psychol. Monog.*, No. 84, 1940, for an excellent presentation of the Gibbon's behavior in nature.)

The Gibbons, both Lar and Siamang (*Symphalangus syndactylus*), probably practice a bipedal gait more often than any other Ape or Monkey (Fig. 528, *5;* Fig. 530, *2*, *4*). When walking, they do so exclusively on their legs and feet, resembling Man in this respect. Never

during our observations have we seen a Gibbon resorting to the quadrupedal gait intermittently or preponderantly practiced by all other Infrahuman Primates, the Monkeys and the Apes. This is true in spite of the arboreal adaptation of feet which makes it impossible to place the toes flat on the ground, but always slightly bent (the toes with the well-opposable big toe are made good use of for grasping).

Nor does the Gibbon use his arms and hands to support himself when walking, as, for example, the Gorilla, Chimpanzee, and Orangutan do when attempting a bipedal gait. The only use the Gibbon makes of his arms and hands is

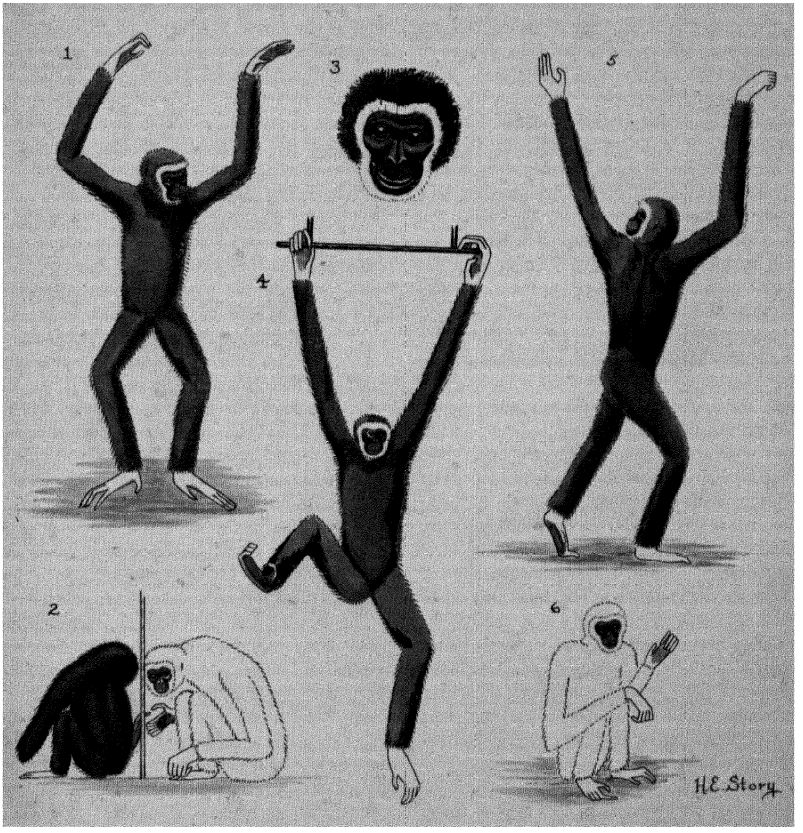

FIG. 528.—Gibbons of the species Lar (*Hylobates lar*), dark and white phases, observed in Lincoln Park Zoo, Chicago. *1*, walking erect, with slightly flexed lower limbs or legs, toes of right foot slightly flexed, toes of left foot extended and resting flat on the ground, arms semiflexed and used for balancing; *2*, two friends separated by a partition, listening to each other and watching through the cracks, feet resting flat; *3*, portrait of a Gibbon, with protruding and compressed lips uttering call "woot-wootoooo . . ."; *4*, Gibbon hanging from a horizontal bar, left leg slightly flexed, with left foot in midair, right foot grasping a vertical bar of the cage; *5*, side view of the Gibbon walking in bipedal fashion, right sole and toes resting flat on the ground; of the left foot, the toes alone resting on the ground, with the sole lifted up as in human progression, and the arms and hands balancing; *6*, sitting posture of a light color phase, human fashion.

The impression gained from observation in captivity is the same as from other high-quality musical displays, e.g., the Nightingale, Brown Thrasher, and Mocking Bird: enjoyment of the senses, the exuberance of life, and, in the Gibbons, an apparent entertainment. In this, perhaps, the Gibbon is an example of the human ancestors whose vocal propensities finally culminated in singing and in human speech. Whether some utilitarian purpose, such as the sex life, is involved in this, as Darwin assumed, remains to be investigated. (*Cf.* C. R. Darwin, *The Descent of Man*, chap. XIX.)

The Gibbons are at times very active for long periods, performing acrobatics on ropes and swings, or rolling or playing together on the ground, then again resting. In this respect there are marked individual differences. Visually they are very alert, all their locomotion and manipulations being carried out under strict visual guidance.

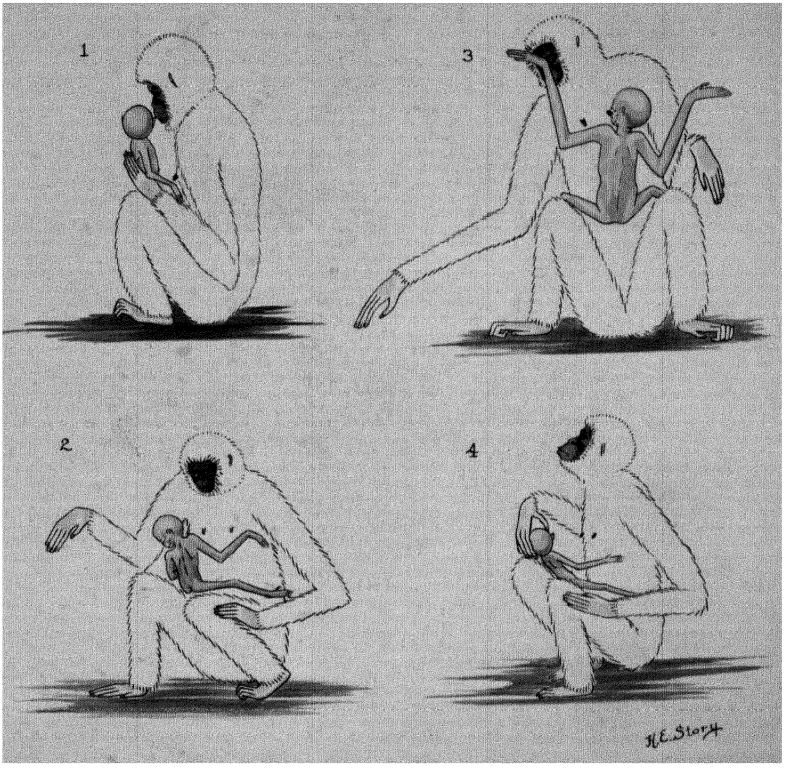

FIG. 529.—A female Gibbon Lar (white phase), nursing her newborn infant, observed in the Zoological Park at Brookfield, Illinois. $1\frac{5}{12}$female holding her two-day-old infant, lateral view; *2*, infant holding the fur of its mother with lower extremities, its long arms free; *3*, infant in nursing position, holding to its mother with lower limbs, while waving its arms in the air; *4*, mother picking up her infant with right hand, its head held by the thumb of the right hand opposed to other slightly flexed fingers.

4. CHIMPANZEE.—The smaller of the two Anthropomorphous Apes inhabiting Africa, the Chimpanzee, is lighter, more agile, and more definitely arboreal than the Gorilla (Figs. 532, 533). However, in limbs and their use it is simi-

The impression gained from observation in captivity is the same as from other high-quality musical displays, e.g., the Nightingale, Brown Thrasher, and Mocking Bird: enjoyment of the senses, the exuberance of life, and, in the Gibbons, an apparent entertainment. In this, perhaps, the Gibbon is an example of the human ancestors whose vocal propensities finally culminated in singing and in human speech. Whether some utilitarian purpose, such as the sex life, is involved in this, as Darwin assumed, remains to be investigated. (*Cf.* C. R. Darwin, *The Descent of Man*, chap. XIX.)

The Gibbons are at times very active for long periods, performing acrobatics on ropes and swings, or rolling or playing together on the ground, then again resting. In this respect there are marked individual differences. Visually they are very alert, all their locomotion and manipulations being carried out under strict visual guidance.

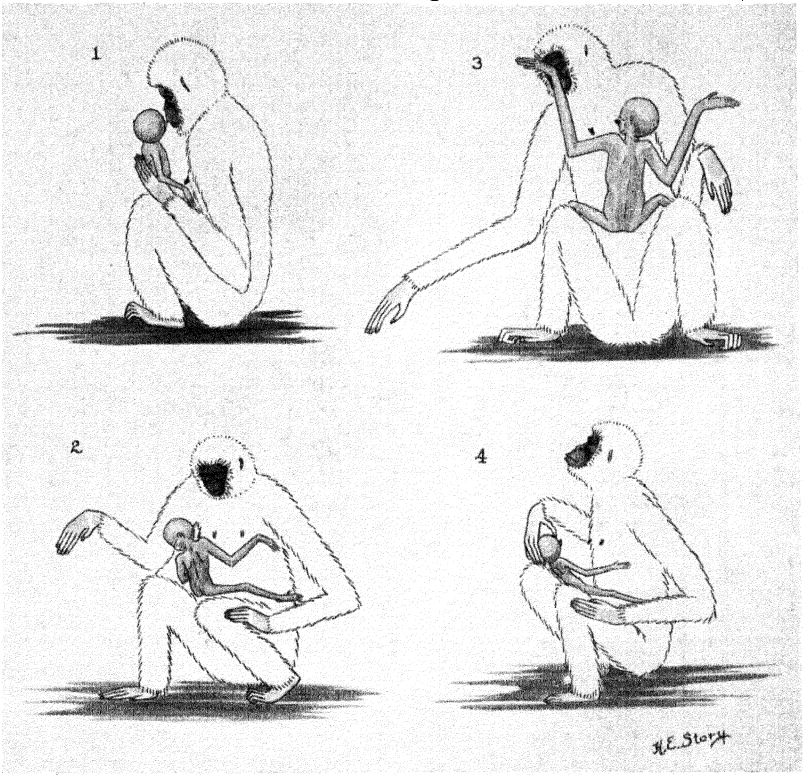

FIG. 529.—A female Gibbon Lar (white phase), nursing her newborn infant, observed in the Zoölogical Park at Brookfield, Illinois. *1*, ♀female holding her two-day-old infant, lateral view; *2*, infant holding the fur of its mother with lower extremities, its long arms free; *3*, infant in nursing position, holding to its mother with lower limbs, while waving its arms in the air; *4*, mother picking up her infant with right hand, its head held by the thumb of the right hand opposed to other slightly flexed fingers.

4. CHIMPANZEE.—The smaller of the two Anthropomorphous Apes inhabiting Africa, the Chimpanzee, is lighter, more agile, and more definitely arboreal than the Gorilla (Figs. 532, 533). However, in limbs and their use it is simi-

larly equipped, but with added characteristics of its own (*see* following subsection on Gorilla).

The walk of the Chimpanzee on even ground resembles that of the Gorilla, in that almost the entire sole is placed flat on the ground. There is, perhaps, a slight emphasis on the outer edge, and the toes are not entirely straightened, but are slightly bent at their joints (Fig. 532, sketches *2* and *4*).

Unlike the Macaques, Baboons, and Man, the Chimpanzee is not able to place the palm of his hands and fingers flat on the ground, resembling the Gorilla in this respect (Fig. 532, sketches *6* and *7*). In spite of this handicap, he is able to peel the skin of a banana with the index finger and thumb of one hand or of both, sometimes assisted by the teeth. He is not able to pick up a peanut from a flat floor in the way of the Macaques, Baboons, and Man, however, and uses for this purpose the middle and index fingers of a hand placed with its back downward.

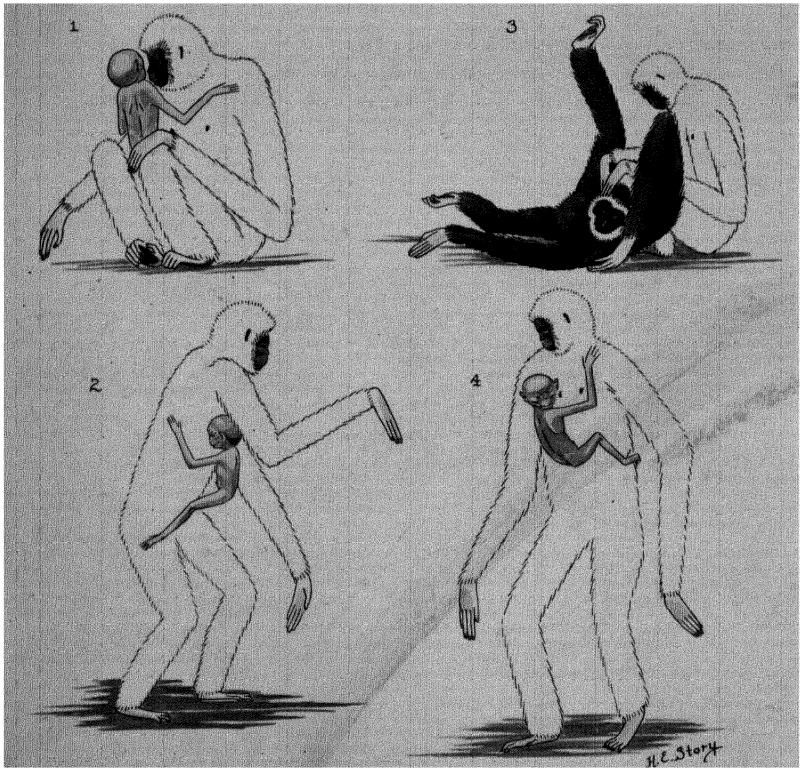

FIG. 530. Female Gibbon Lar nursing a newborn infant, and a pair of the same species grooming, observed in Zoölogical Park at Brookfield, Illinois. *1*, female in a sitting position, with the infant clinging to her fur in an elevated position; *2*, female walking in human fashion, with her legs, however, slightly flexed, infant clinging with all its four extremities to her in a nursing position; *3*, two Gibbons enjoying siesta, the white female grooming the fur of her relaxed black mate, under control of vision; *4*, female walking human fashion, with slightly bent legs and loosely hanging arms, infant clinging in a nursing position.

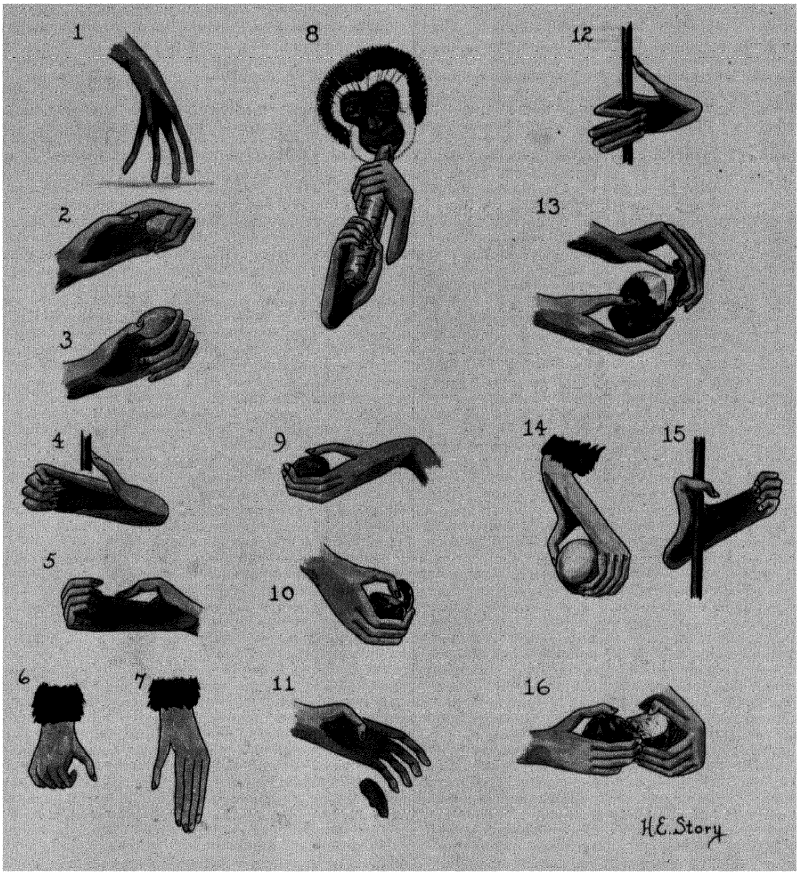

FIG. 531.—Use of the hands and feet by Gibbon Lar, observed in the Zoölogical Park at Brookfield, Illinois. *1*, left hand with fingers extended and spread out, touching an object, the thumb weaker and shorter than in the human hand; *2*, volar view of left hand clutching a sweet potato with fingers alone, without the assistance of the thumb; *3*, volar view of left hand holding a sweet potato between the thumb opposed to index finger; *4*, plantar view of right foot, with long toes flexed and short thumb pushing against a bar; *5*, plantar view of right foot with all toes flexed, showing disproportionately short "big" toe; *6*, dorsal view of right foot with all toes more or less flexed in standing pose; *7*, dorsal view of left foot with all toes extended and body swinging in midair; *8*, nibbling a raw carrot while holding it with left hand at the root end and with right foot at the top end; *9*, left hand holding a sweet potato between opposed index finger and thumb; *10*, right hand, with the thumb pushing against the peeling of a sweet potato to remove it; *11*, volar view of left hand opened in order to drop the sweet potato; *12*, volar view of right hand, with fingers clutching an upright bar and thumb pressing against it in the opposite direction; *13*, use of both hands in removing the skin of a white potato by holding it in the right hand and peeling off the skin by taking it between the opposed thumb and principally the index finger of the left hand; *14*, right foot holding a ball between the flexed toes and the big toe, hand-fashion; *15*, palmar view of left foot, with big toe hooked around an upright bar and other toes flexed in midair; *16*, both hands used in human fashion to break a white potato into halves, with fingers flexed around outer surface and opposing thumbs pressing against inner surface of each half.

Nor does the Chimpanzee easily notice small objects quickly detected by the Macaques and Baboons, but he notices larger objects, especially if they are brightly colored. This reduced visual alertness and acuity are probably caused by the less refined organization of the retina, where many more bi- and polysynaptic midget bipolars are present in the central area than in the Macaque.

The intellectual abilities and the habits of the Chimpanzee, more than of any other Ape, have been repeatedly studied by numerous investigators (Köhler, Bingham, Klüver, Benchley, Nissen, Yerkes, Kohts).

5. Orangutan.—This largest of the Infrahuman Primates inhabiting Asia, the "Man of the Jungle" of the Europeans, the "Mias" or

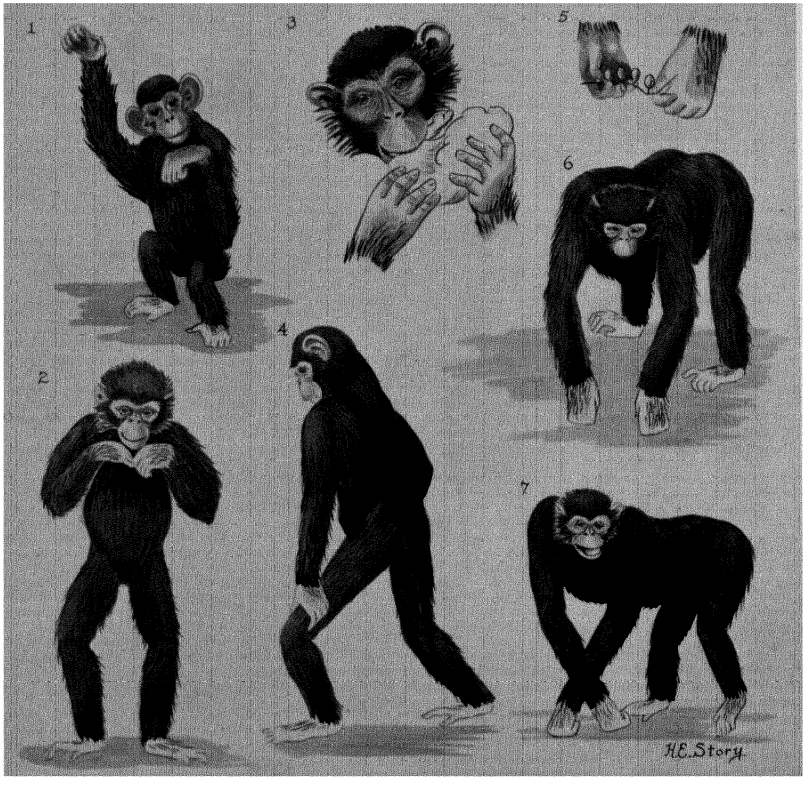

Fig. 532.—Chimpanzee (*Anthropopithecus troglodytes*), observed in his daily activities, in the Zoölogical Parks at Chicago, and at Brookfield, Illinois. *1*, an adolescent in half-erect posture, holding with his right hand a bar of the cage; *2*, an adult walking erect, with arms held against chest, legs slightly bent, soles planted flat on the ground, but with toes flexed; *3*, adult eating lettuce by holding it between fingers and thumbs (not seen in the picture); *4*, an adult walking erect, with legs bent, his body supported by arms, and hands holding his thighs above the knees, impersonating an old man, or actually suffering from rheumatism; *5*, gobbling grapes from a strand held rigid by the stem, between index fingers and thumbs of both hands, picking each grape separately with his lips; *6*, walking on all four limbs, using "knuckles" of his hands and with his toes bent (front view); *7*, lateral view of the same in quadrupedal walk, showing incapacity of Chimpanzee to extend his fingers and toes fully and place them flat on the ground, in the way usually done by the Macaques, Baboons, and Man. (*See* preceding figures.)

"Mayas" of the Malays, is noteworthy for his advanced adaptation to life in the trees, which, conversely, makes him least fit for terrestrial existence (Figs. 534, 535). His arms are proportionately very long, touching the ground when the much shorter legs are fully extended (Fig. 535, sketch *10*). The legs and feet, however, are entirely unfit for walking on even ground. Neither the foot nor the toes can be stretched out, hence the sole cannot be placed flat on the ground.

When standing or walking, the toes are bent under the sole, which in turn is not parallel with the ground, but incloses with it an angle facing inward (Fig. 535, sketches *1*, *2*, *6*, *7*, *8*). The toes are bent toward the sole, filling the angle,

FIG. 533.—Chimpanzees observed in the Zoölogical Park at Brookfield, Illinois. *1*, adult Chimpanzee walking on a horizontal bar and keeping balance by holding another bar with the terminal phalanges of the fingers of his left hand, the left foot and flexed leg supporting most of his weight; *2*, elderly Chimp in a sitting posture, amusing himself by clapping his hands in response to the audience, with his right fingers fully extended, his left fingers partly flexed, his right toes extended, his left toes flexed in their terminal joints, except the big toe, which is fully extended; *3*, *5*, and *6*, an adolescent having fun by making himself into a ball, then rolling over and over again, but taking care to protect his face and eyes with his hands; *4*, apparently a mated pair of older Chimps sitting together, the female examining the fur of the male and picking "lice" or dandruff with the index finger opposed to the thumb, assisted with the fingers of the other hand, every act controlled by vision.

the outer side of the bent toes being also used as additional support. This arrangement forces the Orangutan to step on the outer margin of his foot. Altogether, the Orangutan's feet in terrestrial locomotion resemble human fists, which give to the body only unstable support.

Since the structure of the foot forms merely an insecure base for the entire body weight in walking, the arms are used as additional support. But the arms also represent only an awkward buttress, since the hands and fingers cannot be stretched out and the palms and fingers cannot be placed flat on the ground, in the way the Macaques, the Baboons, and Man can do. This is evidently caused by the shortness of the tendons of the muscles of the forearm and fingers, which do not permit stretching, even less overextension, of the fingers of the Orangutan so clearly demonstrated by the mentioned species (*cf.* Figs. 526, 527). Consequently, when the hand is placed with the palm down, the fingers are bent under, or the back surface of the hand is placed down.

An Orangutan hobbling on all fours, conse-

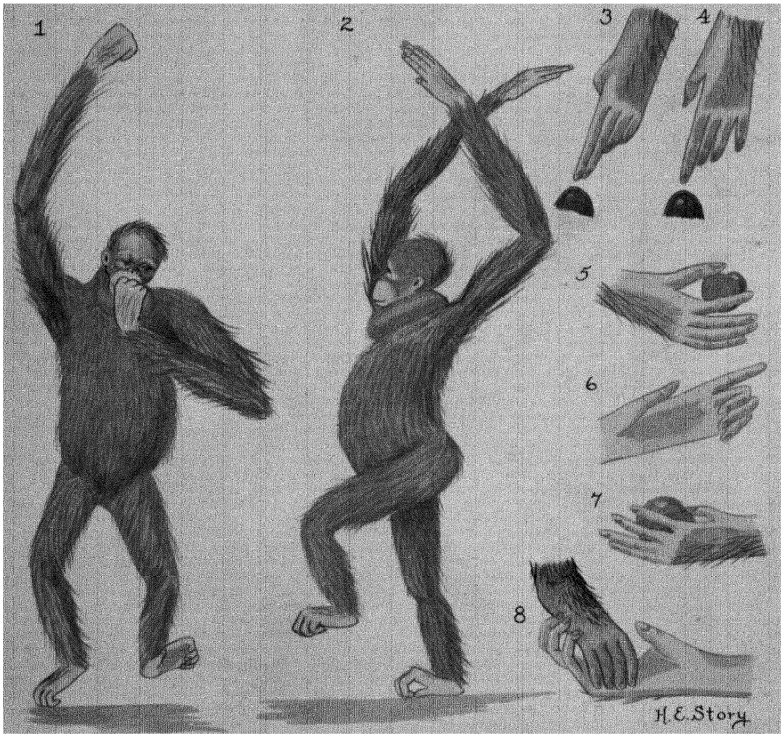

FIG. 534.—Orangutan or Orang-Utan (*Pongo pigmaeus*) observed in Lincoln Park Zoo, Chicago. *1* and *2*, front and side views in erect bipedal walk, demonstrating the inability to put toes and soles flat on the ground, which necessitates the maintenance of a precarious balance with the help of the upper extremities; *3*, first and second fingers of the left hand touching the toe end of the artist's shoe; *4*, index finger alone exploring artist's shoe; *5*, holding an apple between the thumb and index finger of the right hand, the arm extended and fruit generously offered to the observer; *6*, index finger of the left hand extended in an attempt to touch artist's hand; *7*, left hand holding lightly an apple between extended fingers opposed by the thumb; *8*, hand shaking of two friends in adjoining cages, the dark, shaggy hand being that of the Chimpanzee, the lower, lightly shaded hand that of the Orangutan.

quently, is a sorry sight. Its walk is remarkable for its clumsiness, and the way it differs from the human walk (Fig. 535, *10*). It consists of a hopping shuffle, in which the much longer arms are used as crutches to support the body, while the shriveled legs and feet are pushed forward between the arms to make the next step. This mode of progression markedly resembles the limping of a person with crippled legs walking on crutches. The short, deformed legs are never used alone as a support either in standing or in walking.

The hand of the Orangutan is noteworthy for its diminutive thumb (Fig. 540, sketch *9*). The thumb, however, is opposable, but the remaining long and solid fingers, especially the third and the fourth, are evidently more fit for grasping thick branches of the trees as a solid "hook" in brachiation than for performing delicate "epicritic" movements, as do the fingers of Man, Macaques, and Baboons when examining small objects under visual guidance.

The principal role of the Orangutan's fingers, then, is to function as strong, safe "hooks" for the powerful muscles of the arms and shoulders on which the heavy body of this large Ape swings much of the time during its brachiating progression in the tops of the trees. In this function, as in the Gibbon, the thumbs receded to an auxiliary instrument useful only for manipulation in feeding, as in the opening of the tough shells of the fruits grown on the trees (e.g., *Durian*). The use of the big toes of the feet, which are also relatively shorter and weaker than in the Gorilla and Chimpanzee, is not much different (Fig. 540, sketch *10*).

The preceding description and interpretation of the Orangutan's limbs is based on observation of two 2½-year-old youngsters seen by the author in Lincoln Park Zoo, in Chicago, during 1953. In spite of their tender age and rather delicate build, they proved to be good, though rather deliberate, climbers on the bars of the cage and on the rope. Their walk, with the feet gathered into fistlike balls, however, was awkward, the outer edges alone being used for support. Both were alert, intelligent creatures, either playing together and occasionally teasing each other or intently observing the visitors and stretching their little hands to beg for food.

The characteristics described clearly indicate the organization of the limbs and, in fact, of the entire bodily machine of the Orangutan for exclusive existence in the tops of the trees, the Orangutan's natural home, where he finds food and shelter and from which he but rarely descends to the ground. The scanty observations by the travelers in the Orangutan's native countries Sumatra and Borneo agree with this interpretation. On this basis it is safe to conclude that the Orangutan is only remotely related to Man's ancestral line. The arboreal adaptation of his bodily equipment is so profound that it could not have permitted the readaptation necessary for a strictly terrestrial bipedal life. This must be said in spite of the many human-like traits this big Ape exhibits.

Not the least of these traits is the Orangutan's mental and emotional makeup, as the observation of another pair of somewhat older adolescents at present in the Brookfield Zoo showed (1953). Their age might be guessed as five or six years. They were lively and playful fellows. They were apparently quite happy with each other and had lots of fun. They played all day long with an old gunnysack, which they pulled over their heads again and again in an endless variety of ways. Or they rolled over in a pile of straw, scattering it over the floor of the cage. The climax of this performance appeared to be the piling of the straw over their heads so that it cascaded down their necks and bodies. Or they shoved the straw here and there or tried to heap it on the door frame of the cage. Then again they made themselves into balls, with arms and legs pulled to the body, and rolled over the floor, taking care to protect vital parts, especially the face and the eyes, with their hands. They resembled two happy human youngsters rolling about the floor as if their bodies were made of rubber and had no bones. Their behavior contrasted markedly with the dull, reserved, almost morose disposition of the adult Orangutans, who sometimes remained for hours in the same pose with hardly a motion noticeable. These four adolescent Orangutans illustrated well the highly developed, almost human, intellectual faculties of the advanced Primates. (*See* description of the Orangutan's behavior in captivity by W. H. Furness 1916 and by B. J. Benchley 1942, and in his native habitat by A. R. Wallace, in *Malay Archipelago*, 1869, and in A. Brehm's *Tierleben*.)

6. Gorilla.—The largest, rarest, and least known of the Anthropomorphous Apes, the Gorilla, lives in two, possibly more, species-scattered localities of Central Africa, from the lowlands of French Congo in the west to the dense forests on the slopes of Mounts Mikeno and Karisimbi around Lake Kivu, in the Belgian Congo. Because of his great scientific importance, the Gorilla is now protected in many regions. (*Cf.* sec. 4 [7, 8], this chapter.)

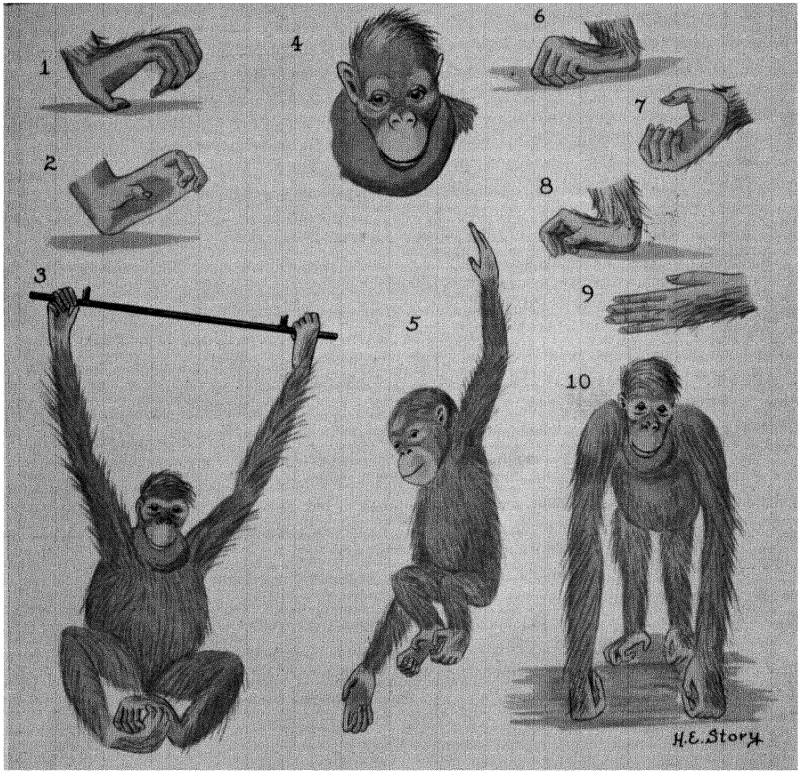

Fig. 535.—**Orangutan or Orang-Utan observed at Lincoln Park Zoo, Chicago.** *1*, medial, *2*, somewhat plantar, **views of the left foot seen in walking, with heel and outer margin touching the ground, the remainder of the hollow sole off the ground, with long toes bent under, because of inability to extend the toes and foot straight and to place them squarely on the ground in the human manner;** *3*, **swinging on a trapeze, with shorter and weaker hind feet drawn up as useless appendages, illustrating the prevalent importance of the forelimbs in the arboreal, brachiating mode of locomotion;** *4*, **Orang's physiognomy expressing the placid disposition of this great frugivorous ape living in his secluded arboreal habitat;** *5*, **young specimen from the habitat group at the Chicago Natural History Museum, illustrating the intensive specialization of this Primate for arboreal life;** *6*, **lateral view of left foot in walking, with the long toes bent under, owing to the inability to stretch them in the way Man, Baboons, and Macaques can do;** *7*, **plantar view of right foot flexed in preparation for grasping a bar, showing remarkable similarity to human hand;** *8*, **inner view of right foot, with toes flexed, the outer margin of the sole and flexed toes alone resting on the ground, showing the inability of this arboreal Primate to extend the toes and the rest of the foot and to put them flat on the ground, as Man and Monkeys do;** *9*, **dorsal view of left hand with fingers fully extended, showing diminutive thumb not reaching to the metacarpo-phalangeal joint;** *10*, **front view in walking on all fours, with fully extended forelimbs but with all fingers and toes flexed.**

As far as is known, this Ape is partial to a thick, primeval jungle. A few of them occasionally stray into transitional savanna, as mentioned in section 4, this chapter. The larger species native to the Mikeno-Karisimbi area is a pronounced mountain dweller, ranging above 8,500 and up to more than 12,000 feet.

Observed in a zoo, the Lowland Gorilla gives the impression of being a heavy-set and rather dull, but treacherous, animal (Figs. 536–39). When young, however, it is remarkably flexible in body, alert in senses, and surprisingly agile in bodily movements and behavior. It is almost as accomplished an acrobat on a trapeze and in climbing a rope as the Chimpanzee, being in this respect inferior only to the Gibbon. His climbing antics and acrobatics, which include frequent brachiations or climbing and swinging by the arms, are endless and are executed with great vigor and agility under continuous visual guidance. The shortness of the neck, characteristic of all large Apes, especially of the Gorilla, during his youth does not in the least interfere with the quick movements of his head in the assistance of the ocular movements indispensable for the visual control of the upper extremities.

The young and adolescent Gorilla is remarkably intelligent and resourceful, as exemplified by one about four to five years old, observed by the author in 1924 in the London Zoo, and again by five mostly adolescent Gorillas observed at Brookfield Zoo and Lincoln Park Zoo, in Chicago, during 1953. There was no end to the tricks these so human-like animals played on their keepers. Their inventive genius in devising various methods of use or games with simple objects such as an automobile tire was remarkable. Their intellect seemed to be continuously working, finding new tricks such as acrobatics on the trapeze or whirling on the floor, and the like. And all this busy activity was for the purpose of impressing the admiring audience whose reaction was attentively observed and appreciated. The behavior of the young Gorillas was true stage-acting, accompanied by all kinds of mannerism, although there was little change in facial expression, and the acting was mostly performed silently. (*See* for the behavior of John Daniel in F. Tilney, *The Brain from Ape to Man*, 1928; *see* for scientific observation and testing R. M. Yerkes 1927–28, and Bingham's experiments reported by Benchley 1942.)

The sensory and mental alertness, bodily agility, the flexibility of the limbs, and the generally amiable and humorous emotional disposition gradually change with advancing age, the large, powerful males becoming passive, immobile, morose, not to be lightly trusted. In the experience of Yerkes, in his psychophysical processes the Gorilla is slow, Man and Chimpanzee relatively quick, and the Orangutan perhaps intermediate—"Slow but sure, seems not to have carried her genus to preëminence in the grim struggle of organisms for survival and supremacy."

In walking, whether slow, running, hopping, or galloping, the Gorilla habitually uses all four extremities. It resorts to a bipedal walk only for a few steps (*cf.* Mrs. Benchley, and personal observation). The four longer fingers of the hands are held bent at the first phalangeal joints, and the second and third phalanges are placed with their backs more or less flat on the ground. In this way the hand is used as a "hoof." From the description of Malbrant & Maclatchy, summarized in the preceding section 4, it appears that sometimes the thumb, index, and middle fingers alone are used as a support in quadrupedal progression, the last two fingers being held bent at their joints in order to approximate them in length with the length of the outstretched thumb. This probably occurs in leisurely progression over soft ground. In captivity, according to our observation, the thumb hardly ever touches the ground.

The use of the Gorilla's foot, in both bipedal and quadrupedal standing and walking, is surprisingly similar to that of the human foot (due consideration being given to the essentially prehensile character of the Gorilla's foot, and the abduction of the big toe from the sagittal axis of the foot).

When the foot is put flat on the ground, it rests on it with its entire undersurface, from the heel to the tips of the toes. The toes likewise rest with their undersurfaces on the ground, with no indication of the bending-under of the toes at their joints, as is the rule in the Chimpanzee and even more so in the Orangutan. Nor is there the slightest indication of the emphasis

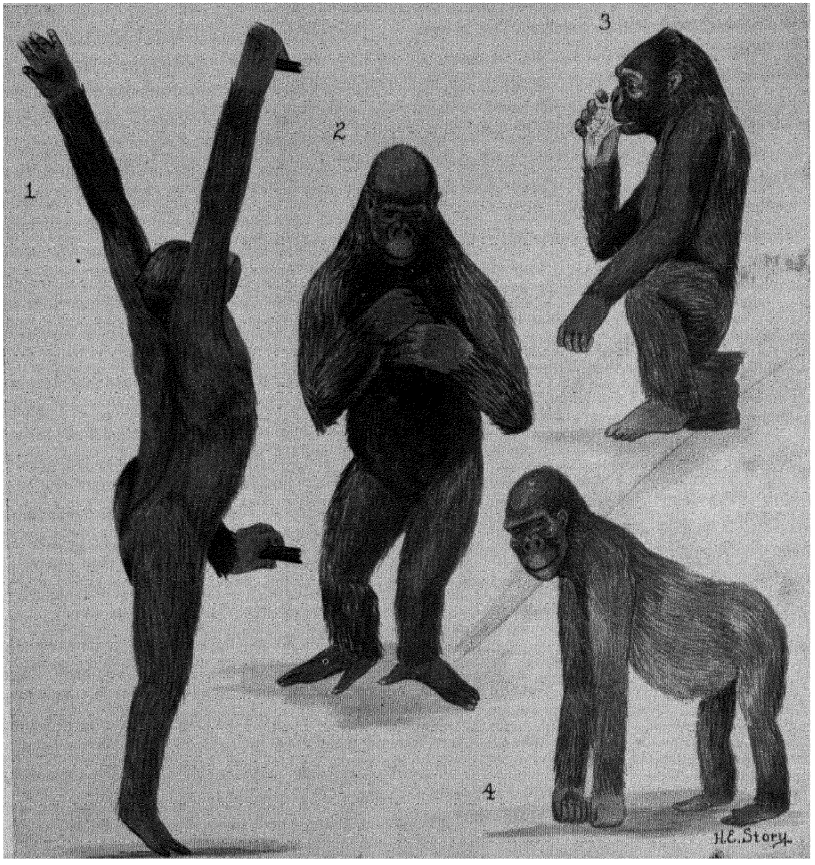

FIG. 536. – Young and adolescent Gorillas of the lowland variety (*Gorilla gorilla*), native of the French Cameroons of central West Africa, in a climbing, bipedal standing, sitting, and quadrupedal position, observed in Lincoln Park Zoo, Chicago. *1*, a young male, approximate age seven years, approximate weight 225 lbs., climbing side wall of his cage, left foot grasping hand-fashion a narrow shelf, with toes of right foot lightly resting on ground and supporting but little weight, left hand reaching behind, toward a trapeze just above, right hand securely grasping a narrow shelf, right arm pulling most of body weight, with all movements controlled by vision; *2*, same in upright posture, feet and toes placed flat on the ground, legs slightly flexed, with fists pounding his chest, a supposed expression of well-being, the bipedal gait being resorted to off and on for short periods of time; *3*, same sitting on the edge of a rubber tire and eating lettuce, which he holds in his right hand; *4*, a female, possibly from seven to eight years of age, her approximate weight 200 lbs., standing on all four limbs, ready to stroll about. Young Gorillas, as observed in zoölogical parks, are playful and full of tricks which they are ready to pull on their attendants. When grown, especially the huge and powerful males, attaining and exceeding 500 lbs. in weight, they become morose and unpredictable, making their management difficult. In nature their habits and behavior, of which little is as yet known, show them to be rather shy, retiring dwellers of deep jungles, living mostly on the ground and retiring to low limbs of trees for the night only. For other details *see* A. Brehm 1911-18, *Säugetiere;* C. E. Akeley 1923; Gregory & Raven 1937; and chap. XV, 4, 5, in this book.

on the outer edge of the sole regularly observed in the Orangutan.

The mechanics of the Gorilla's foot in walking is also practically identical with that of the human foot. When the foot is carried forward, as when taking a step, it and the extended toes are lifted clear off the ground, before being placed down again. In this, the toes are maximally extended, or rather overextended, the big toe abducted, and all toes held a little above the level of the sole. In this way the obstacles of the rough ground are easily cleared.

When the next step is initiated, the foot and the toes are set in motion in a nicely co-ordinated way. First the heel and the sole are lifted, the toes still remaining for a while on the ground. There is no dragging of the toes on the ground, and the extended toes and the foot are finally lifted and carried forward in making the next step. There is no indication whatsoever of

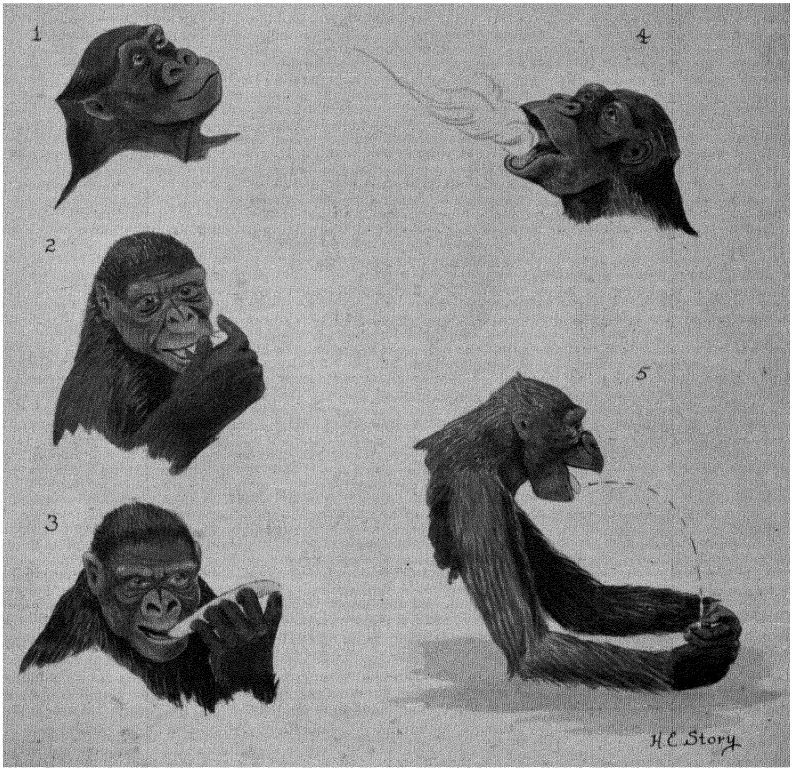

FIG. 537. Attitudes, acts, and reactions of an adolescent Gorilla, observed at Lincoln Park Zoölogical Gardens, in Chicago. *1*, attentively listening to artist's voice humming a song, and trying to locate the source of the voice; *2*, eating an apple, holding it in his right hand, with the thumb opposed to other fingers, in human fashion; *3*, eating a banana, holding it with the fingers of his left hand, after having previously removed the skin; *4*, avidly inhaling cigarette smoke blown by the artist into his mouth, intentionally held open; *5*, cleverly directing the stream of water into his mouth by pressing a bubbling fountain with his left thumb. This plate shows the immensely complex performances in which the entire bodily machine co-operates with the cerebral integrator, co-ordinating its many parts, sensory and motor. The total impression is that of remarkable similarity to human behavior in comparable situations of sensory stimulation or volitional impulse.

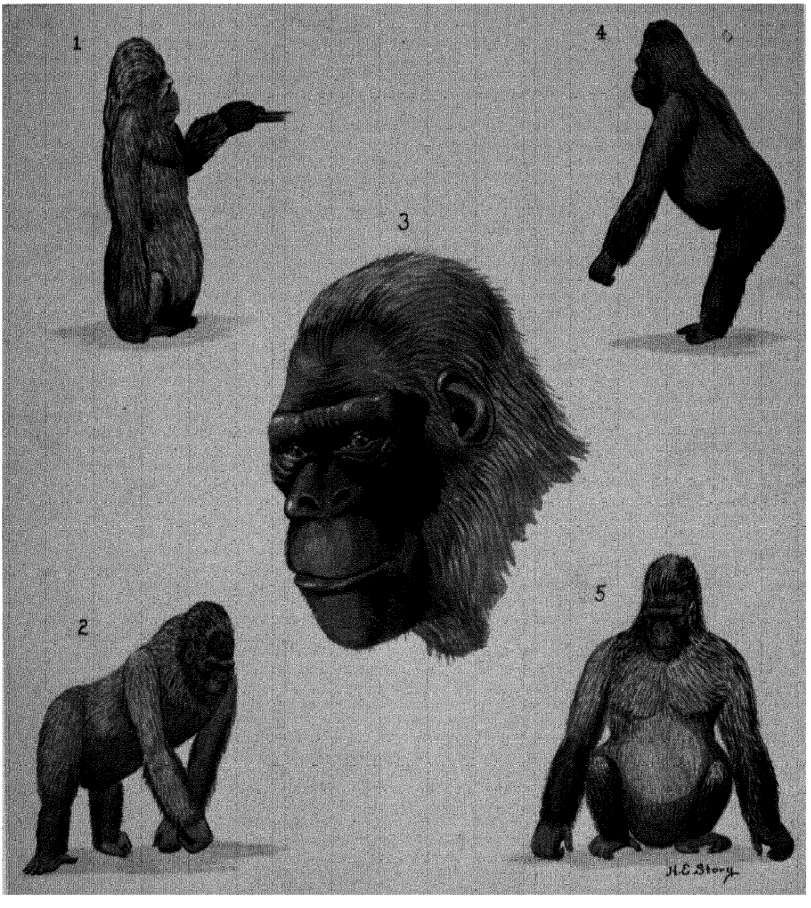

FIG. 538.—Portrait and attitudes of "Bushman," an adult male Gorilla of the lowland variety (*Gorilla gorilla*), sketched from life at Lincoln Park Zoo in Chicago, 1947. *1*, sitting posture in right-side view, with left hand grasping a horizontal shelf and right hand reaching to the ground; *2*, walking on all fours, both hands resting on "knuckles," the toes of the right foot and the big toe extended, the sole resting flat on the ground, the toes of the left foot bent under; *3*, physiognomy characteristic of a fully grown male Gorilla, with a flat, furrowed forehead surmounted by a high crest decorated with erectile hair, with prominent brow ridges, relatively small eyes, broad and flat nose, large prognathous or projecting muzzle, with thick, prehensile lips, small chin, and diminutive, shriveled-up auricles, altogether not unlike a crude rendition of the human physiognomy; *4*, side view of the body slowly raised from a quadrupedal posture to an erect bipedal stature; *5*, front view in a sitting posture, the principal weight of the body resting on the haunches, supported both with flexed legs and with outstretched arms, with all fingers and toes flexed. The physical and sensory-mental resemblance of the Gorilla and of other great Apes to Man cannot be denied, except on preconception. The question of how this and other Primates could be fitted into the ancestral tree of Man has not been answered satisfactorily. The available evidence indicates that none of the Great Apes is directly ancestral to Man and that the human races may have originated from smaller Primates, more or less resembling modern Macaques and Baboons. (*See* text.)

walking on bent toes, as the Orangutan does, or of stepping on the outer edge of the foot, as is the Chimpanzee's habit. It all markedly resembles the walking mechanics of the human leg and foot, with all detailed movements executed nimbly (taking into account the Gorilla's much broader foot and the abducted big toe; *see* Fig. 540, *2*).

The resemblance of the use of the Gorilla's foot to that of the human foot is shown in the similarity of its tracks to human tracks, especially of the African natives, observed in nature. The enormous human-looking Gorilla tracks show the mark of a heel, which no other footprint, except the human, shows, according to Carl E. Akeley (1923).

The intermittent short attempts of the Gorilla at upright bipedal standing and walking are only passing intervals between the much longer periods of quadrupedal or rather quadrumanous standing or progression. Even in an upright bipedal stance, which is done well and firmly, the legs are rarely fully extended in human fashion, but habitually remain slightly bent at the knees. Hence the body weight never completely rests upon the skeleton and ligaments, as it does in Man, but must be partly assisted by muscular force.

The Gorilla's bipedalism and upright posture, according to this, in spite of his essentially terrestrial habit, must be considered as incipient. They may be compared with the early stages through which Man's Ancestors passed long ago. The Gorilla's bipedalism is probably far less advanced than was that of the *Australopithecus*, but it is of a somewhat higher degree than the bipedalism of the Chimpanzee and is definitely higher than that of the Orangutan. (*Cf.* D. J. Morton, *Evolution of the Human Foot*, 1924, and *Human Origin*, 1927.)

The hand of the Gorilla is broad and heavy, the fingers rather short and thick, the thumb relatively small (Fig. 540, *1*). The detailed proportions resemble those of the Macaque (*16*) rather than those of the Gibbon (*11*), Chimpanzee (*3*, *6*, *7*), and Orangutan (*9*, in same figure). More than in any of the Apes, the hands of the Gorilla resemble those of a heavy-set Man. This is especially true of the four fingers. The thumb, however, is relatively much smaller and weaker, in agreement with the reduced or absent thumb in the rest of the higher Primates, except Man. In spite of this, the thumb is well opposed to other fingers, as is occasionally the big toe to other toes when the foot is used for grasping.

Rope climbing is done in human fashion, with great vigor and expertness. The bars of the cage are frequently held with the fingers, without the use of the thumb. Judging from the structure of his hands and their use, however, the Gorilla appears to be less capable of performing delicate manipulations than are the Macaques and Baboons but is probably more capable than the Orangutan, and possibly also than the Chimpanzee and the Gibbon. (*See* on this point, however, Benchley 1942, p. 253.)

The feet of the Gorilla conform in principle to the prehensile type of other Monkeys and Apes, closely resembling those of the Chimpanzee (Fig. 540, sketch *2*). In spite of their prehensile construction and broad, massive shape, they are well adapted for walking on flat ground, and especially on large limbs of the trees, where their broad soles, strong, abducted big toes, and the V-shaped position of both feet are very advantageous. Their adaptation for walking on flat ground, however, is less complete than that of the Baboons. They are definitely less fit for bipedal progression than the much narrower and relatively longer human feet, but more so than the feet of the Chimpanzee, and far more so than the feet of the Orangutan. The Gorilla's feet may be compared with the Gibbon's feet, which, in spite of the latter's narrow shape, are well adapted for walking on flat ground.

In appraising the bodily and functional equipment of the Gorilla, it appears that this largest and heaviest of the living Apes is more of a terrestrial dweller, even though he has not abandoned the arboreal habit to the extent that the Baboons have. His fingers cannot be straightened out, and even less overextended, as can those of the Macaques, Baboons, and Man; hence he is forced to walk on knuckles, resembling the Chimpanzee in this respect, but not to the degree found in the Orangutan. (Akeley found that when the Gorilla's arms are extended, his fingers are flexed, and can be straightened only when his wrist is bent.) Even so, the Gorilla has emancipated himself far more from the arboreal habit and has adapted

himself better than the Chimpanzee, and far more so than the Orangutan, to a bipedal and semi-erect life on flat ground in a way and degree somewhat approaching Man.

In the Gorilla's "descent from the trees" several factors may have acted concurrently. One is the great bulk of the Gorilla, especially the physical strength of the males. (The famous "Bushman" of the Lincoln Park Zoo in Chicago, when in his prime, weighed 548 pounds on an empty stomach, and measured 6 feet and 2 inches in height; *cf. also* the accompanying figures.) The other is the formidable offensive and defensive weapons, such as the strong arms

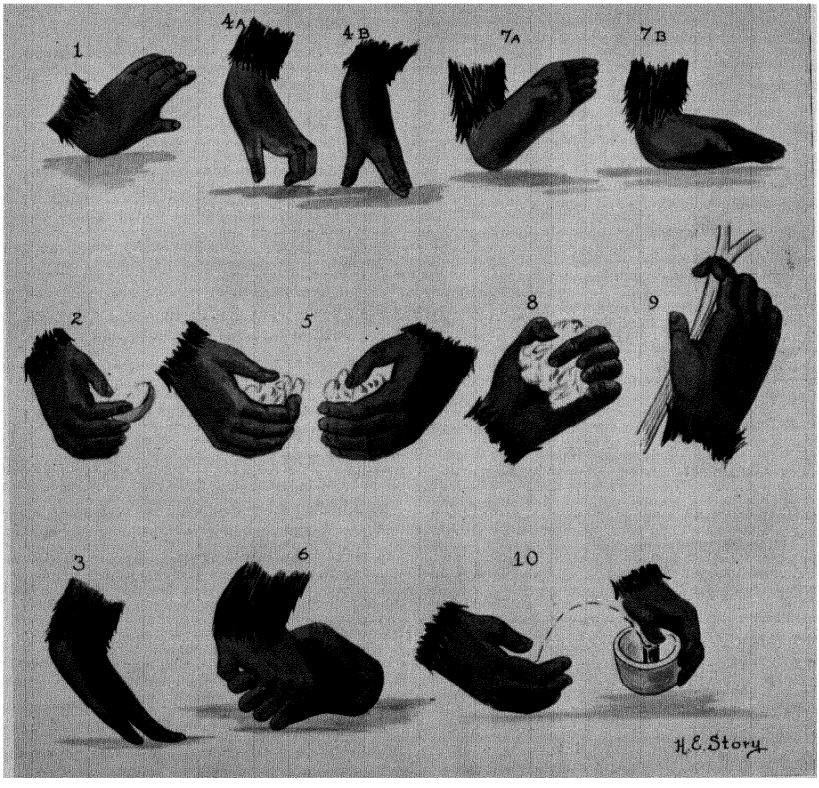

FIG. 539.—Gorilla's hands and feet and their use in manipulation and locomotion. *1*, left hind foot in walking, heel placed first on the ground; *2*, right hand holding an apple between thumb, index, and middle fingers; *3*, left foot running on tiptoes, with the heel kept off the ground; *4*, left hand in locomotion: *4A*, first phase in a forward step, with fingers flexed; *4B*, second phase in a forward step, with fingers extended and touching the ground with their tips; *5*, breaking of a head of lettuce in halves with both hands, using pressure of thumbs to break the halves into smaller pieces; *6*, right foot in grasp of the left hand; *7A*, first act in walking, with the heel of left foot first placed on the ground; *7B*, second act in walking, with the outer margin of foot resting on the ground, with the remainder of the sole not quite on the ground; *8*, left hand holding a piece of lettuce; *9*, right hand holding a celery stalk between index and middle fingers; *10*, pressing with the left thumb a stream of water from a drinking fountain and directing it into his cupped right hand, which is raised to his lips. The illustrated postures and manipulations of the Gorilla are comparable to those of human hands and feet, commensurate with the more delicate build of the latter.

and hands and powerful dentition, including long canine teeth, set in massive jaws, moved by proportionately strong masticating muscles, all carried by the powerful muscles of the head and neck, set upon a massive trunk.

It is likely that in the normal conditions of the Gorilla's habitat, this equipment would be more than sufficient to ward off potential enemies like the Lion, Leopard, and Hyena (*cf.* C. Akeley, and M. Jobe Akeley). Relative safety, then, permitted the Gorilla to spend most of his time on the ground, where in turn more food to nourish his bulky body was to be found than would be the case in the trees ("Bushman's" fare, consisting entirely of fruits and vegetables, with the addition of vitamins, according to Mr. L. S. Carpenter of the Lincoln Park Zoo in Chicago, often was more than 20 pounds at one meal). Thus, the quantity and quality of food appear to have been the prime "moving agents" which induced the Gorilla to come down from the treetops and which permitted him to lead a largely terrestrial existence. In the descent of the Gorilla to the semiterrestrial mode of life, the importance and usefulness of vision, the common heritage of all Primates, remained as essential for the maintenance and preservation of this species as it was in the life in the treetops.

7. Observation of the Monkeys and Apes, and the problem of Man's origin.— The Monkeys and Apes, like the members of other mammalian orders, are adapted to a great many ways of life, with the arboreal habit preponderating. A few may be exclusively terrestrial, as, for example, the Patas Monkey (*Erythrocebus patas*) of western Africa, who with his high legs, narrow feet, and digitigrade gait emulates the Cheetah, the fleet Hunting Leopard of Asia and Africa, equally adapted to desert conditions and to swift running.

Most of the Primates, however, are strictly or largely arboreal. This, especially in the larger species, has enforced a great deal of anatomical reorganization of the original conditions inherited from the insectivorous ancestors. Close arboreal adaptation is accentuated in all Anthropomorphous Apes, most in the Orangutan, and least in the Gorilla. This fact militates against a close phylogenetical relationship of the Apes to Man, in spite of the numerous anatomical, biological, and psychic resemblances.

At one time, before they attained a state recognizable as human, the ancestors of Man may have resembled the smaller Monkeys like the Macaques and Baboons in many ways. It is probable that, like them, they were largely quadrupedal, or quadrumanous, with a strong tendency to sit on their buttocks in order to use their hands freely for manipulation under visual control. This tendency toward an upright sitting posture further developed into a frequent rising on the hind extremities, with occasional short bipedal runs.

The most powerful stimulus to increase this tendency to preponderantly and ultimately exclusively bipedal locomotion and upright attitude must have been the acquisition of food. Whether this was entirely carnivorous, as assumed by Professor Dart, or of a more diversified kind, with the products of plants representing a large or principal source, is further discussed in section 8. (*Cf.* observation of Macaques in their native habitat by Ridley 1895.)

Whatever the stimulus, the observation of the various Primates indicates that the ancestors of Man never could have become so completely adapted to arboreal life as are the present Apes, Gibbons, and all American and most Old World Monkeys. They probably never passed through a brachiating adaptation, with the enormous development of the upper extremities and shoulders and the reduction and deformation of lower extremities, but have continued the emphasis upon the lower limbs so clearly shown by the Macaques and Baboons.

The tendency to rise on the hind limbs may have begun very early in human evolution, probably long before the Anthropomorphous Apes became clearly outlined (*cf.* Ridley 1895). The great length of time required for this is indicated by the complete anatomical adjustment of prehistoric and modern humanity to an upright bipedal gait.

The transition from a quadrumanous to a bipedal posture must have been a long, slow process. There may have been many attempts in the past to accomplish this. Some have failed entirely. Other waves, arising in different parts of the world from different stock, possibly gave rise to different branches of the present human-

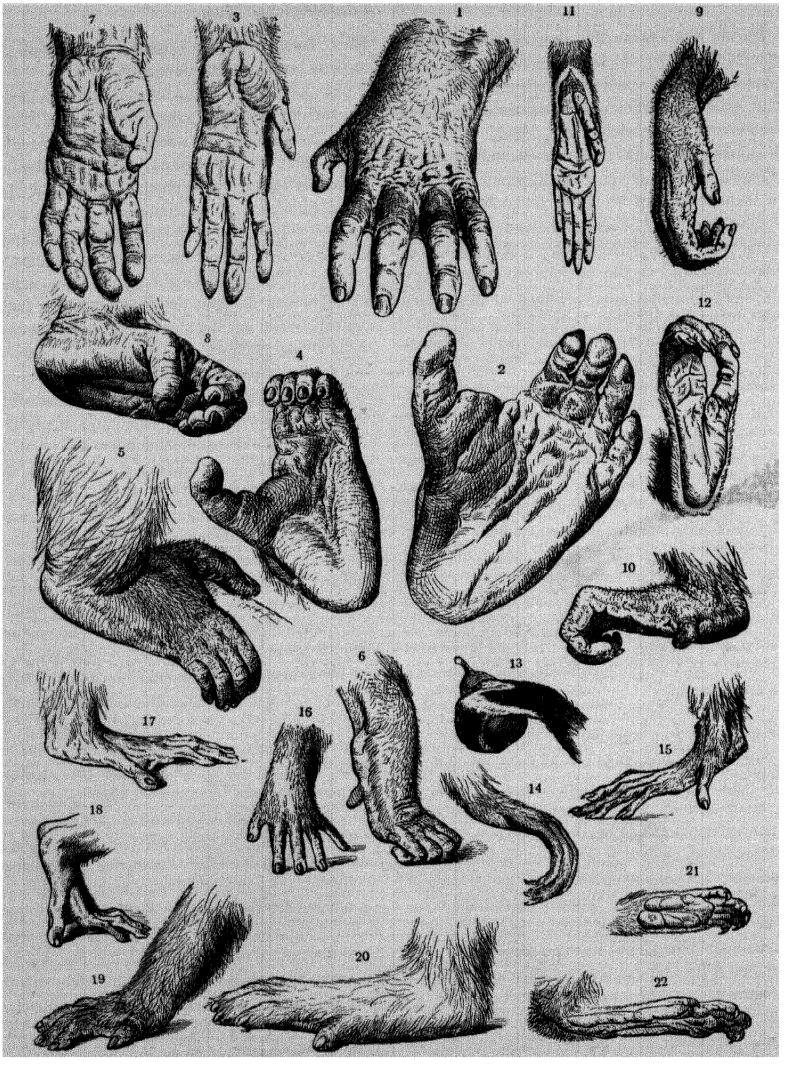

FIG. 540.—Hands and feet of the Monkeys and Apes, the parts of the body which, next to the organs of vision, are most intimately related to the habits of Primates and hence most responsible for their emergence from a general mammalian stock and for the origin of Man: *1*, back view of left hand of the Gorilla; *2*, plantar view of the left foot of the Gorilla; *3*, *7*, palmar views of left hands of Chimpanzee; *4*, plantar view of left foot of Chimpanzee; *5*, dorsal view of right foot of Chimpanzee resting on a tree limb; *6*, right hand of Chimpanzee supported on knuckles; *8*, left foot of Chimpanzee with toes bent, showing opposable big toe, an act not possible for the human foot; *9*, right hand of Orangutan; *10*, right foot of Orangutan in a grasping attitude as in clinching a branch, showing a diminutive big toe; *11*, volar aspect of left hand of the Gibbon Lar; *12*, plantar view of right foot of the Gibbon Lar, showing opposable big toe; *13*, left hand of the Gibbon Lar, holding fruit with all five fingers apposited; *14*, hand of the

ity summarized in *Homo sapiens* and to the prehistoric Hominidae.

The marked physical characteristics of the various human races, differing so completely from one another in some respects, even though practically all possessed the same or very similar intellectual potentialities, may be the common result of similar factors working from different angles for the same purpose. To determine the starting points of the various branches of modern humanity, to trace their particular evolutionary courses, and to identify the responsible factors should be the goal of modern anthropology.

SEC. 6. DARWIN'S VIEW ON THE ORIGIN OF MAN, AND ON THE CAUSES OF MAN'S PRE-EMINENT PLACE IN NATURE

In the second revised edition of his classical book *The Descent of Man* (1899, p. 47) in the section on "Natural Selection," Charles Darwin discussed in some detail the causes of Man's erect posture and its consequences:

We have now seen that man is variable in body and mind; and that the variations are induced, either directly or indirectly, by the same general causes, and obey the same general laws, as with the lower animals. Man has spread widely over the face of the earth, and must have been exposed, during his incessant migration, to the most diversified conditions. The inhabitants of Tierra del Fuego, the Cape of Good Hope, and Tasmania in the one hemisphere, and of the Arctic regions in the other, must have passed through many climates, and changed their habits many times, before they reached their present homes. The early progenitors of man must also have tended, like all other animals, to have increased beyond their means of subsistence; they must, therefore, occasionally have been exposed to a struggle for existence, and consequently to the rigid law of natural selection. Beneficial variations of all kinds will thus, either occasionally or habitually, have been preserved and injurious ones eliminated. I do not refer to strongly-marked deviations of structure, which occur only at long intervals of time, but to mere individual differences. We know, for instance, that the muscles of our hands and feet, which determine our powers of movement, are liable, like those of the lower animals, to incessant variability. If then the progenitors of man inhabiting any district, especially one undergoing some change in its conditions, were divided into two equal bodies, the one half which included all the individuals best adapted by their powers of movement for gaining subsistence, or for defending themselves, would on an average survive in greater numbers, and procreate more offspring than the other and less well endowed half.

Man in the rudest state in which he now exists is the most dominant animal that has ever appeared on this earth. He has spread more widely than any other highly organized form: and all others have yielded before him. He manifestly owes this immense superiority to his intellectual faculties, to his social habits, which lead him to aid and defend his fellows, and to his corporeal structure. The supreme importance of these characters has been proved by the final arbitrament of the battle for life. Through his powers of intellect, articulate language has been evolved; and on this his wonderful advancement has mainly depended. As Mr. Chancey Wright remarks: "a psychological analysis of the faculty of language shews, that even the smallest proficiency in it might require more brain power than the greatest proficiency in any other direction." He has invented and is able to use various weapons, tools, traps, etc., with which he defends himself, kills or catches prey, and otherwise obtains food. He has made rafts or canoes for fishing or crossing over to neighbouring fertile islands. He has discovered the art of making fire, by which hard and stringy roots can be rendered digestible, and poisonous roots or herbs innocuous.

Colobus Monkey or Guereza without a thumb; *15*, right foot of the same with toes almost stretched; *16*, left hand of *Macacus sinicus* or *M. radiatus* with fingers extended; *17*, left foot of same with toes resting flat; *18*, same with toes dorsoflexed as in progression; *19*, right hand of the dog-faced Baboon with fingers almost stretched flat; *20*, right foot of Baboon with toes resting flat on ground; *21* and *22*, hand and foot of the Marmoset Monkey, showing undifferentiated toes provided with claws instead of nails. Note disproportionately short, weak, and poorly opposable thumb in Apes and fingers which cannot be put flat on the ground (sketches *1*, *3*, *6*, *7*, *9*, *11*), contrasting with long, strong, and easily opposable big toe in same (*2*, *4*, *5*, *8*, *10*, *12*); shorter fingers and an opposable thumb, which, together with the palm of the hand, can be stretched and put flat on the ground in Monkeys (*16*, *19*), and the ability of the foot and toes in the same to rest flat on the ground and support the weight of the body (*15*, *17*, *18*, *20*). From A. Brehm's *Tierleben*, 4th ed., v. 13, p. 424, 1916, with special permission of the Bibliographisches Institut A.G. (Dr. E. List), Mannheim, Germany. (*Cf. also* W. L. Straus, Jr., in Am. J. Phys. Anthropol., vols. 27, 28, and in Quart. Rev. Biol., vols. 17 and 24.)

This discovery of fire, probably the greatest ever made by man, excepting language, dates from before the dawn of history. These several inventions, by which man in the rudest state has become so pre-eminent, are the direct results of the development of his powers of observation, memory, curiosity, imagination, and reason. I cannot, therefore, understand how it is that Mr. Wallace maintains, that "natural selection could only have endowed the savage with a brain a little superior to that of an ape."

Although the intellectual powers and social habits of man are of paramount importance to him, we must not underrate the importance of his bodily structure, to which subject the remainder of this chapter will be devoted; the development of the intellectual and social or moral faculties being discussed in a later chapter.

Even to hammer with precision is no easy matter, as every one who has tried to learn carpentry will admit. To throw a stone with as true an aim as a Fuegian in defending himself, or in killing birds, requires the most consummate perfection in the correlated action of the muscles of the hand, arm, and shoulder, and, further, a fine sense of touch. In throwing a stone or spear, and in many other actions, a man must stand firmly on his feet; and this again demands the perfect co-adaptation of numerous muscles. To chip a flint into the rudest tool, or to form a barbed spear or hook from a bone, demands the use of a perfect hand; for, as a most capable judge, Mr. Schoolcraft, remarks, the shaping fragments of stone into knives, lances, or arrow-heads, shews "extraordinary ability and long practice." This is to a great extent proved by the fact that primeval men practiced a division of labour; each man did not manufacture his own flint tools or rude pottery, but certain individuals appear to have devoted themselves to such work, no doubt receiving in exchange the produce of the chase. Archaeologists are convinced that an enormous interval of time elapsed before our ancestors thought of grinding chipped flints into smooth tools. One can hardly doubt, that a man-like animal who possessed a hand and arm sufficiently perfect to throw a stone with precision, or to form a flint into a rude tool, could, with sufficient practice, as far as mechanical skill alone is concerned, make almost anything which a civilised man can make. The structure of the hand in this respect may be compared with that of the vocal organs, which in the apes are used for uttering various signal-cries, or, as in one genus, musical cadences; but in man the closely similar vocal organs have become adapted through the inherited effects of use for the utterance of articulate language.

Turning now to the nearest allies of men, and therefore to the best representatives of our early progenitors, we find that the hands of the Quadrumana are constructed on the same general pattern as our own, but are far less perfectly adapted for diversified uses. Their hands do not serve for locomotion so well as the feet of a dog; as may be seen in such monkeys as the chimpanzee and orang, which walk on the outer margins of the palms, or on the knuckles. Their hands, however, are admirably adapted for climbing trees. Monkeys seize thin branches or ropes, with the thumb on one side and the fingers and palm on the other, in the same manner as we do. They can thus also lift rather large objects, such as the neck of a bottle, to their mouths. Baboons turn over stones, and scratch up roots with their hands. They seize nuts, insects, or other small objects with the thumb in opposition to the fingers, and no doubt they thus extract eggs and the young from the nests of birds. American monkeys beat the wild oranges on the branches until the rind is cracked, and then tear it off with the fingers of the two hands. In a wild state they break open hard fruits with stones. Other monkeys open mussel-shells with the two thumbs. With their fingers they pull out thorns and burs, and hunt for each other's parasites. They roll down stones, or throw them at their enemies: nevertheless, they are clumsy in these various actions, and, as I have myself seen, are quite unable to throw a stone with precision.

It seems to me far from true that because "objects are grasped clumsily" by monkeys, "a much less specialized organ of prehension" would have served them equally well with their present hands. On the contrary, I see no reason to doubt that more perfectly constructed hands would have been an advantage to them, provided that they were not thus rendered less fitted for climbing trees. We may suspect that a hand as perfect as that of man would have been disadvantageous for climbing; for the most arboreal monkeys in the world, namely, Ateles in America, Colobus in Africa, and Hylobates in Asia, are either thumbless, or their toes partially cohere, so that their limbs are converted into mere grasping hooks.

As soon as some ancient member in the great series of the Primates came to be less arboreal, owing to a change in its manner of procuring subsistence, or to some change in the surrounding conditions, its habitual manner of progression would have been modified: and thus it would have been rendered more strictly quadrupedal or bipedal. Baboons frequent hilly and rocky districts, and only from necessity climb high trees; and they have acquired almost the gait of a dog. Man alone has become a biped; and we can, I think, partly see how he has come to assume his erect attitude, which forms one of his most conspicuous characters. Man could not have attained his

present dominant position in the world without the use of his hands, which are so admirably adapted to act in obedience to his will. Sir C. Bell insists that "the hand supplies all instruments, and by its correspondence with the intellect gives him universal dominion." But the hands and arms could hardly have become perfect enough to have manufactured weapons, or to have hurled stones and spears with a true aim, as long as they were habitually used for locomotion and for supporting the whole weight of the body, or, as before remarked, so long as they were especially fitted for climbing trees. Such rough treatment would also have blunted the sense of touch, on which their delicate use largely depends. From these causes alone it would have been an advantage to man to become a biped; but for many actions it is indispensable that the arms and whole upper part of the body should be free; and he must for this end stand firmly on his feet. To gain this great advantage, the feet have been rendered flat; and the great toe has been peculiarly modified, though this has entailed the almost complete loss of its power of prehension. It accords with the principle of the division of physiological labour, prevailing throughout the animal kingdom, that as the hands became perfected for prehension, the feet should have become perfected for support and locomotion. With some savages, however, the foot has not altogether lost its prehensile power, as shewn by their manner of climbing trees, and in using them in other ways.

If it be an advantage to man to stand firmly on his feet and to have his hands and arms free, of which, from his pre-eminent success in the battle of life, there can be no doubt, then I can see no reason why it should not have been advantageous to the progenitors of man to have become more and more erect or bipedal. They would thus have been better able to defend themselves with stones or clubs, to attack their prey, or otherwise to obtain food. The best built individuals would in the long run have succeeded best, and have survived in larger numbers. If the gorilla and a few allied forms had become extinct, it might have been argued, with great force and apparent truth, that an animal could not have been gradually converted from a quadruped into a biped, as all the individuals in an intermediate condition would have been miserably ill-fitted for progression. But we know (and this is well worthy of reflection) that the anthropomorphous apes are now actually in an intermediate condition; and no one doubts that they are on the whole well adapted for their conditions of life. Thus the gorilla runs with a sidelong shambling gait, but more commonly progresses by resting on its bent hands. The long-armed apes occasionally use their arms like crutches, swinging their bodies forward between them, and some kinds of Hylobates, without having been taught, can walk or run upright with tolerable quickness; yet they move awkwardly, and much less securely than man. We see, in short, in existing monkeys a manner of progression intermediate between that of a quadruped and a biped; but, as an unprejudiced judge [Broca in *Revue d'Anthropologie* 1872] insists, the anthropomorphous apes approach in structure more nearly to the bipedal than to the quadrupedal type.

As the progenitors of man became more and more erect, with their hands and arms more and more modified for prehension and other purposes, with their feet and legs at the same time transformed for firm support and progression, endless other changes of structure would have become necessary. The pelvis would have to be broadened, the spine peculiarly curved, and the head fixed in an altered position, all which changes have been attained by man. Prof. Schaaffhausen [transl. in Anthropolog. Rev., p. 428, year 1868, and in Owen's Anatomy of Vertebrates, v. 2, 1866, p. 551] maintains that "the powerful mastoid processes of the human skull are the result of his erect position;" and these processes are absent in the orang, chimpanzee, etc., and are smaller in the gorilla than in man. Various other structures, which appear connected with man's erect position, might here have been added. It is very difficult to decide how far these correlated modifications are the result of natural selection, and how far of the inherited effects of the increased use of certain parts, or of the action of one part on another. No doubt these means of change often co-operate: thus when certain muscles, and the crests of bone to which they are attached, become enlarged by habitual use, this shews that certain actions are habitually performed and must be serviceable. Hence the individuals which performed them best, would tend to survive in greater numbers.

The free use of the arms and hands, partly the cause and partly the result of man's erect position, appears to have led in an indirect manner to other modifications of structure. The early male forefathers of man were, as previously stated, probably furnished with great canine teeth; but as they gradually acquired the habit of using stones, clubs, or other weapons, for fighting with their enemies or rivals, they would use their jaws and teeth less and less. In this case, the jaws, together with the teeth, would become reduced in size, as we may feel almost sure from innumerable analogous cases. In a future chapter we shall meet with a closely parallel case, in the reduction or complete disappearance of the canine teeth in male ruminants, apparently in relation with the development of their horns; and in horses, in relation to their habit of fighting with their incisor teeth and hoofs.

In the quoted passage Darwin touched in an admirable way upon the principal factors responsible for the rise of Man and their interaction. In the following sections an attempt is made to analyze these factors further; their complex interplay and their respective value in molding, from one or from several higher Primates, the race or races of Mankind.

SEC. 7. ANALYSIS OF FACTORS RESPONSIBLE FOR THE ORIGIN OF MAN FROM AN INFRAHUMAN PRIMATE

1. INTRODUCTORY REMARK.—The subject of the origin of Man from some earlier and less perfectly organized form, ever since, by virtue of Darwin's publications, it was recognized as a legitimate object of scientific inquiry, has been dealt with in numerous books, papers, and lectures. But as G. Elliot Smith pointed out in his essays on *The Evolution of Man*, most of these, while vastly enriching our detailed knowledge of Man's past and his status in nature, have "brought us so few indications of any serious attempt to probe into the really vital issues regarding the way in which the brain has acquired its highest powers" (G. E. Smith 1927). This situation has not materially changed during the subsequent thirty years (up to 1955). Since Elliot Smith, more deeply perhaps than most other writers, was absorbed by the problem of human origins, the following analysis and commentary on it is based principally upon his writings.

2. PRIME FACTORS WHICH INITIATED HUMAN EVOLUTION.—Among the factors which have influenced the Lower Primates to assume human shape and character, time is essential. "Evolution needs vast periods of time for its operations." But time alone is not enough, other factors being absolutely necessary. Only when fortunate co-operation of all these various factors took place did there result the appearance of this most remarkable species of Mammals, Man.

What these other factors were has been a matter of much speculation. In the opinion of Elliot Smith, the prime factor was "the steady and uniform development of the brain along a well-defined course throughout the Primates right up to Man, which must give us the fundamental reason for 'Man's emergence and ascent', whatever other factors may contribute towards that consummation."

This raises an alternative question: Did the prehuman brain possess some autochthonous, innate property or impetus to increase in size and elaborateness and to follow a preordained course toward the human and impose itself upon the rest of the body and remodel it to make a Man, which would be quite incredible and contrary to all experience of observation? Or was the causal connection quite the reverse, and did the body of some particular Primate, because of its changed mode of living, become gradually reorganized into human shape, with the brain following and complementing this reorganization?

This latter contention is more likely, supported as it is by innumerable observations, including those described in the preceding chapter. In each of those instances it is obvious that the organisms as a whole and in all minute details are nicely adjusted to the particular tasks they fulfil.

The thesis to be tested here is whether the changed habits and other external circumstances of Human Ancestors have been the prime factor in bringing about an anatomical reorganization of the body, requiring also a more elaborate directing cerebral machine—or did the brain impose itself upon the rest of the body, which it shaped according to its liking, to make, from a lesser Primate, a Man?

The divergent human evolution, away from that of the Monkeys and Apes, with its emphasis on intellect, must have its particular causes. Even if reliable proof of a close anatomical kinship of Man is furnished, it still is possible that his line separated from the common ancestral stock at a time before the ancestors of the Apes became definitely specialized for arboreal life and Man's Ancestors, largely terrestrial, became entirely *epigeoi* or bipedal ground dwellers, with both corporeal and, secondarily, cerebral organization diverging very considerably from that of the Apes, with the cerebral change merely following.

3. ARBOREAL LIFE AND ITS CONSEQUENCES IN EARLY EVOLUTION.—The identical problem is presented by the increased learning capacity of the Tree Shrews and Monkeys: was it the result of the gradual perfection of the cerebral cortex, or was that perfection forced upon them because of the necessity imposed by the more demanding conditions of an arboreal habit?

The *neopallium* or "new cortex," so much increased in the Mammals, is, according to Elliot Smith, the instrument of "associative memory" most easily conforming to the *sensorium commune* of Aristotle. "In the forerunners of the Mammalia the cerebral hemisphere was predominantly olfactory in function." While this may be true, considering the hippocampal formation takes up much of the cortex, the entire cortex in the Lizards, for example, is small, and, whatever its role, it is of less weight in the total function of the brain, in comparison with the large and excellently organized optic lobes of the midbrain. Hence the Lizards and Birds must be considered predominantly "visual animals." The observations and tests, including those made on the Anole Lizard, Turtle, and Swallow, described in the preceding chapter, give ample support to this view.

On the basis of these facts it is easier to maintain the thesis that in the saurian ancestors of the Mammals the leading sense must have been sight, which, however, receded into the background as they had to squeeze through the "biological bottleneck." This greatly impaired their vision and in some species abolished it altogether. Hence in these the emphasis, largely or entirely, shifted to the senses of smell, touch, taste, and hearing. (*See* sections on Shrew, in the preceding chapter.)

In the readaptation to arboreal or aerial modes of life, olfactory dominance was again suppressed, and the sense of vision was restored to its former dominant role, as in the Tree Shrews, or audition became the leading sense, as in the Bats. In the first, visual dominance was accompanied by the expansion of the sensorimotor cortex, since, as Elliot Smith logically assumed, the agility of their movements required an efficient motor cortex and muscular sense. This, in turn, caused the sense of smell to recede, and the sense of vision, tactile sense, kinesthesis, and motility to increase, with a corresponding increase in the respective areae in the cerebral cortex. The actual anatomical findings in the brain of the Tree Shrew support this view, as our description and figures in the preceding chapter show.

But just how arboreal life has brought about these remarkable changes still remains a matter which merits further assiduous inquiry. It may be roughly granted that it is in Tupaia and the Primates "that these tendencies attain any really significant expression." But this statement needs to be qualified. Many other Mammals have a well-developed cerebral cortex. Such are the Carnivora, many Rodents, Elephants, Seals, and so on. Their behavior, their well-developed mentality, and their success in the "struggle for existence" are objective evidence of this.

The motivation of the early arboreal impetus, which in the long run resulted in the coming of the Primates, appears quite complex. It is difficult at this time to single out any particular factor which could be made responsible for their development. The agility of the arboreal Squirrels, for example, is at least as great as that of the Tree Shrews, as far as our own observations go (*see* preceding chapter).

"In the vast majority of living animals," according to Elliot Smith, "behaviour is dominated either by smell or vision." The olfactory dominance, with certain reserve, is true only in Lower Mammals. But even in the terrestrial Shrews audition and tactile senses must contribute a large share to their life's business. In many Fishes, Amphibians, Reptiles, Birds, and Mammals, while one or another sense more or less prevails, other senses nevertheless contribute an important share. In the Pike, for example, the sense of vision obviously is by far the most important; in the Bullhead the senses of smell and gustation. In the Sunfishes, in contrast, the senses of smell and taste are constantly used, even though vision predominates. In the Swallow the senses of vision and hearing lead, the first apparently being by far the most important. In the Tree Shrew vision is excellent, but olfaction is still important and is constantly resorted to. The Tarsier again has developed to an extraordinary degree both vision and audition, in this respect resembling its avian counterparts, the Owls.

Whether the sense of smell alone possesses "affective qualities," as Elliot Smith assumed, is more than questionable. Such qualities may also easily be found in the sense of hearing and in vision, and not only in the higher animals. When a hungry Pike sees a Sunfish, upon which it preys, the image on its retina evokes just as much of an "anticipatory" feeling of a good dinner as does the chemical stimulus from a decaying piece of meat in the olfactory and gustatory apparatus of the almost blind Bullhead. Each sense, therefore, is "affective" in Elliot Smith's sense, each having an "anticipatory memory" based upon phylogenetical and individual experience.

Also, to be useful, every sense, including smell and taste, must have more than "vaguest indications of spatial relations," else it would mislead. A Bullhead finds the bait very well and quickly by scent alone in the muddiest water.

Since vision must have begun practically simultaneously with the chemical senses, as discussed in chapter XIII, 2, it is not necessary to assume that animals which depend principally or entirely upon it get their sustenance in a roundabout way, via the transolfactory transmission of visual impulses, as Elliot Smith assumed, but more or less directly. This may be accepted as certain for such species as, for example, the Trout and the Northern Silverside, which catch insects flying above the water. Scent in this instance is entirely eliminated. Visual impulses in these species are directly transmitted to the co-ordinated motor nerve centers and other organs of execution, leaving the olfactory apparatus entirely or almost entirely aside.

If suppression or elimination of the olfactory receptors and centers is already found in the Fishes, visual organs must be provided on the higher levels of the animal scale, with an independent mechanism for spatial relations or attributes. There is, in fact, good reason to assume that in the Mammals, especially Primates, it is this apparatus upon which the sense of space is to a great extent based. But here we are touching upon an immensely complex problem which concerns the cerebral mechanism, largely still unknown, by which the various senses are capable of mutual influencing and integrating.

4. Erect posture, its origin and consequences for human evolution.—Ever since Charles Darwin published his book, *The Descent of Man* (1871), Man's erect posture has been one of the principal controversial topics in the discussions of Man's origin from some infrahuman form. In the passage quoted in section 6, Darwin discussed in some detail the probable causes, the manner of its development, and its consequences. "Man could not have attained his present dominant position in the world without the use of his hands, which are so admirably adapted to act in obedience to his will. . . . The free use of the arms and hands, partly the cause and partly the result of man's erect position, appears to have led in an indirect manner to other modifications of structure."

Elliot Smith, in the book mentioned, in support of his thesis of the leading role of the brain in the origin of Man, however, poses the following question: "If the erect attitude is to explain all [as according to Munro 1893], why did not the Gibbon become a man in Miocene times or earlier?"

The simple answer to this is the obvious advantage that life in the jungle had for the Gibbons. There was enough food there and plenty of shelter from powerful predators; hence, even now, in spite of the Tigers and Leopards, Gibbons remain plentiful in their present homeland, Siam, Burma, and Malaya. To abandon the jungle by entering the more or less treeless prairie would have meant starvation and death, unless the way of life was modified, principally by becoming swift bipeds, living in larger bands, with highly developed intelligence and the social habit of co-operation. And this is precisely what Man's Ancestors must have done. From this point of view, the Gibbon and the larger Apes (the Gorilla, Orangutan, and Chimpanzee) appear as the conservative remnants of a much more abundant population which remained in the shelter of the jungle, whereas the more venturesome strains, adaptable to more exacting conditions of prairie life, became humans. The Anthropomorphous Apes gave up the plains with their perils for the security of an arboreal asylum, but in giving up the struggle they also renounced progress.

The growth of the brain, in Elliot Smith's opinion, presumably driven by some innate

urge, is the principal, possibly the only, factor responsible for the origin of Man. He says:

> The whole of my argument has aimed at demonstrating that it is the steady growth and specialization of the brain that has been the fundamental factor in leading Man's ancestors step by step upward from the lowly Insectivore status, and through every earlier phase (Amphibian and Reptilian) in the evolution of Mammals—for Man's brain represents the consummation of precisely those factors that throughout the Vertebrata have brought their possessors to the crest of the wave of progress. But such advances as the assumption of the erect attitude are brought about because the brain has made a new posture and skilled movements of the hands possible and of definite use in the struggle for existence. Yet once such a stage has been attained, the very act of liberating the hands for the performance of more delicate movements opened the way for a farther advance in brain development to make the most of the more favourable conditions and the greater potentialities of the hands.

The growth and elaboration of the human brain, in Elliot Smith's opinion, briefly, is the primary factor; the erect posture and human character are its consequences. This reverses the logical argument which, to our way of thinking, should be, first, the functional requirement, then its consequent changes in bodily structures. (*See also* D. J. Morton 1927.)

What factors caused the growth and elaboration of the human brain, as interpreted by Smith, remains a mystery. It is much more logical and in accord with the ideas expressed and carefully documented in the preceding chapter to regard the growth and perfection of the human brain not as a cause, but as a consequence, of the changed mode of life, primarily of the terrestrial, upright gait and the emancipation of the arms and hands for exclusive use in manipulation, adopted by Man's Ancestors.

The brain, like any other bodily organ within the limits of its inherent capacities, had to increase in size and modify its internal structure in all its details under the influence of changed functional demands. The limits of the inherent capacities of the primate brain, fortunately, were wide (*see* for details L. Edinger 1911; Ariëns Kappers *et al.* 1936; N. Beccari 1943). If they had been as narrow as those of the brain of a Fish, a Lizard, or a Bird, no amount of functional stimulus would have availed. The ability to fly developed by some Fishes was limited by the initial primitive organization of their limbs, while the Bats and Birds, beginning with more plastic limbs, could develop this mode of locomotion to perfection. The simian ancestors of Man, once they had embarked upon a roaming career in the open country and specialized in gathering fruits and in hunting animals for their sustenance, were forced gradually to increase their cerebral machine in size and elaboration, perfecting their senses of vision, audition, vocal intercommunication or speech, and their social instincts in that order. These functional and habitual factors, together with the manipulative ability of their hands, then, appear to be the principal pillars upon which the survival and progress of the human race or races were based.

The steady growth of the human brain and the elaboration of Man's mental faculties were not the cause, but the consequence, of the specialization of the legs and feet for locomotion and of the arms and hands for manipulation of objects, which received its principal stimulus from the erect posture and bipedal gait. The corresponding adaptation of the remainder of the body, including the senses and the brain, followed.

This view agrees well with the anatomical organization of the Promethean *Australopithecus*, discovered by Dart, with human legs and feet for walking erect and arms and hands for manipulation, but in possession of a brain only a little larger than in the present Anthropomorphous Apes. (*See* Le Gros Clark, *History of the Primates*, 1953, and his paper, 1954.)

5. Secondary factors impeding or facilitating the effect of the upright gait.—In the estimate of the phylogenetical role of the upright posture and the emancipation of the upper extremities from locomotion, other factors, some positive, some negative, must be considered.

The liberation of the arms and hands from locomotion may be only relative. In the Tarsier, for example, the usual posture is sitting on the haunches, with the arms and hands usually perfectly free, which can be used as auxiliaries in feeding, as described and illustrated in the preceding chapter. In spite of this freedom, how-

ever, the Tarsier's hands are poor prehensile instruments, of small use in performing delicate movements. They are used almost entirely as crude grabbing tools, in a wholesale manner. They are also used in assisting locomotion, in which the long and powerful legs are the principal propelling limbs. The manipulative ability of the Tarsier seems never to have been much developed, because of his leaping mode of progression and his nocturnal habit, which prevented his vision and his brain from progressive elaboration toward human status.

While the erect posture of the Tarsier was sufficient to prolong the existence of this ancient suborder in its tropical habitat, it did not eliminate the inhibitory effect of the negative factor, which was the nocturnal mode of life. In contrast, in the rise of Man powerful positive factors were at work, which fostered such progress. The diurnal habit, with full development of visual potentialities, upright gait, use of the hands under visual guidance, and social co-operation, with the development of speech, were the principal stimuli for a harmonious development of Man's senses and mentality.

The thesis of the primacy of the brain in human origin must be substantially qualified. The greatest concession one could make to Elliot Smith's viewpoint would be that erect posture and cerebral perfection were two reciprocally interconnected processes, tied by other factors, the most important being the emancipation of the upper extremities from locomotion and their exclusive use as instruments of the mind.

The interaction of the emancipated hands and the progressive perfection of the senses and mind, Elliot Smith formulates in these words: "The ability to perform skilled movements is conducive to a marked enrichment of the mind's structure and the high development of the neopallium, which is the material expression of that enrichment." This in turn stimulated the growth and elaboration of the rest of the cortex, and thus gave a powerful impulse to the growth of "the faculty of shaping its conduct in anticipation of results" or, briefly, of the reasoning power.

The ability to shape one's conduct in anticipation of the results, as a definition of the substance of reasoning, is, however, a widespread phenomenon. In its elemental form it is possessed even by the lowliest animals, for example, by a Paramecium, a Bacterium, or a Caterpillar. The lowliest Vertebrates, the Fishes, may develop a visual memory of long duration, as Darwin reported from observations of Möbius. And doesn't the Pike shape its conduct according to the anticipation of a fat Sunfish? In this light, the mentality of the higher animals, particularly the Primates, is but an immensely expanded and elaborately organized potentiality also possessed by the less advanced forms of animal life. They all have a common root—living matter. In Darwin's words, "there is no fundamental difference between man and the higher mammals in their mental faculties."

6. THE DEVELOPMENT OF HUMAN INTELLIGENCE, AND THE ORIGIN OF SPEECH.—The outstanding features of Man, in addition to his upright bipedal gait and the exclusive use of his arms and hands as manipulative instruments of mind guided by vision, are the great scope of his intelligence and the ability to speak and to understand speech. How his intelligence increased beyond that of all other animals and how speech developed were and remain problems awaiting a satisfactory answer.

"The increasing ability to perform actions demanding skill and delicacy received a great impetus," according to Elliot Smith, "when the hands were liberated for the exclusive cultivation of such skill; this perfection of cerebral control over muscular actions made it possible for the Ape-Man to learn to imitate the sounds around him, for the art of learning is a training not only of the motor centres and the muscles concerned, but also of all muscles, because posture involves the whole body and it is more or less concerned in every act. The benefits that accrued from educating the hands added to the power of controlling other muscles, such as those concerned with articulate speech."

The preceding thesis of a direct relationship between the increased manipulative proficiency of the hands and the origin of speech, however, is more than questionable. There is no causal connection between the two. One can readily see, on the other hand, such a connection between the increasing mental capacities of rising

humanity and the more elaborate production and understanding of the sounds made by the organs of speech.

A sign language of gesticulation and physiognomic expressions may have developed simultaneously or at a slightly preceding phase, as predecessors and assistants to articulate vocal speech. In any case, they play a secondary role as a means of communication.

Articulate spoken language must have evolved from the early chaotic elements of gesticulation, grimacing, and inarticulate utterances. Its principal phylogenetical motivation, however, must have been the necessity for the invention of a means of communication, or transmission of thoughts, by organs not used either for locomotion or for manipulation—in other words, the vocal organs. Just as the legs and feet had to take over the entire burden of carrying the body in order to make the hands free for handling objects, so the vocal and associated organs had to take over practically the entire task of transmission of ideas, in order to free the hands. In this way the vocal organs, otherwise used only for physiological purposes, became employed for a very essential function. In vocal speech there is little or no need for gesticulating arms and hands or for the postural movements of other parts of the body, which all had to be kept free of such uses. This is especially true of the arms and hands, since they had to be employed as manipulative tools of the mind. The grimacing physiognomy, of no other use, was, on the other hand, useful in spoken language, employing, at least in part, the same apparatus.

Once articulate vocal language was sufficiently developed, it became a disseminator of thought and in turn a stimulator of the developing intellect, that is, of the intellectual mechanism of the brain.

Speech and the expanding intellectual powers were not the cause, however, but the consequence of an upright gait. Man's Ancestors did not begin to walk upright because they first developed a superior thinking machine, as Elliot Smith postulated, but were forced to grow a large and elaborate brain, with a complex structure, in order to provide centers for upright posture, manipulation of objects, and communication by spoken and auditory language. The development of the superior intelligence followed as a logical result.

The enormous expansion of the intellectual powers or of intellectual discrimination based upon acquired knowledge was rather secondary to the upright bipedal gait. It was the bipedal gait which made Man an enduring wanderer and a fast runner, and his hands efficient manipulators. And it was these two factors which immensely increased the scope of human experience, principally visual, in contrast to the modest mental scope of the largely sedentary jungle-dwelling Apes.

The evolution of speech necessarily followed the development of upright gait, roaming life, and the habit of hunting in packs and gathering fruits and tubers as a family team or group. In fact, as Elliot Smith thinks, "the acquisition of such fuller means of communication with his fellows by vocal symbols may have been one of the essential factors in converting Man's ultimate simian ancestor into a real man."

This view is in accord with Dart's discovery of *Australopithecus*, a Primate in possession of erect posture and human-like arms and hands, but a brain only half the size of the smallest modern human brain and but a little larger than that of a large Gorilla. It is likely, then, that a similar situation was present in Primates directly ancestral to Man, indicating the primacy of erect posture over that of the brain in human evolution.

The increase in intellectual powers and the gradual development of articulate speech must have been a very long and slow process. The initial condition may not have been radically different from the vocal utterances of the now living Monkeys and Apes. The duration of the formative phase of speech and its perfection, starting from this ill-defined moment, must have been quite long, extending over untold ages. How long this process of intellectual maturing lasted is only dimly indicated by modern languages, whose complexity becomes more apparent, the more ancient forms are studied (e.g., Sanskrit [Samskrta], Ancient Greek, Latin, etc.; on language *see* O. Jespersen 1922; Sapir 1939; *see also* C. Monakow 1914; H. Head 1920, 1923; and J. M. Nielsen 1946).

Such an extremely complex device of human intellectual intercourse presupposes that the

duration of Man's mental evolution must be figured in hundreds of thousands of years, and probably a good deal more. This is in accord with other signs of prehistoric human activity, notably with prehistoric pictorial symbolism. Such is seen, for example, in the mural drawings in the caves of northern Spain (Altamira) and of southern France (Lascaux Cave), whose estimated age is from 15,000 to 30,000 years and perhaps much more. This evidence shows Man's visual functions, including color sense and aesthetic appreciation of forms, to have been at that early date practically as good as it is now.

7. THE FACTORS RESPONSIBLE FOR THE RISE OF MAN, AND THEIR INTERPLAY.—The various factors, whose interplay had brought about the coming of Man, Elliot Smith summarized as follows:

> . . . the evolution of the Primates and the emergence of the distinctively human type of intelligence are to be explained primarily by a steady growth and specialization of certain parts of the brain; that such development could have occurred only in the Mammalia because they are the only plastic class of animals with a true organ of intelligence [i.e., the cerebral cortex]; that an arboreal mode of life started Man's ancestors on the way to pre-eminence, for it gave them the agility; and the specialization of the higher parts of the brain incidental to such a life gave them the seeing eye, and in course of time also the understanding ear; and that all the rest followed in the train of this high development of vision working on a brain which controlled ever-increasingly agile limbs.

This thesis of Elliot Smith may be accepted in a general way, with, however, certain qualifications: that all Vertebrates, certainly all Mammals, possess an organ of intelligence, even though in many it is small in size, of inferior structural complexity and functional efficiency; and that in the Lower Vertebrates it is not the cortex but other parts of the brain which phylogenetically preceded it and substitute for it; that the cortex proved to be the most successful in this sense; and that arboreal life by itself was not the cause, since the Birds are both arboreal and agile.

We may accept entirely the following words of Elliot Smith, that the solution of Man's origin "is not to be sought merely in comparisons of Man and the Anthropoid Apes. Man has emerged not by the sudden intrusion of some new element into the Ape's physical structure or the fabric of his mind, but by the culmination of those processes which have been operating in the same way in a long line of ancestors ever since the beginning of the Tertiary Period," and even much earlier.

8. VISION—THE LEADING SENSE IN THE DEVELOPMENT OF MAN FROM AN INFRAHUMAN PRIMATE.—The investigation of the eyes and visual centers of the brain in the various Vertebrates shows an advanced structure in those species of all classes largely or principally relying on sight. Among the Lizards, such are the Chameleon and Anole; among the Birds, the Eagle and the Swallow; among the Mammals, the Primates, as described in chapter XIV. The Primate Order depends so much upon the sense of sight as to deserve the designation "visual animals." Of all orders, in this order alone—from the lowest to the highest: the Monkeys, Apes, and Man, including the nocturnal Tarsier and Aotes—the central fovea and area of the retina, specialized for epicritic or refined vision, are universally found. This fact, together with the possession of hands and fingers fit to perform delicate manipulations under visual guidance, shows the overwhelming role that vision plays in the life of the Primates.

The specific question of what role vision played in the origin of Man has already been discussed on several occasions in this book. In his analysis of the possible causes, Elliot Smith found "a localized and precocious expansion of those areas of the brain which we associate with the power of articulate speech," and he thinks that "there are grounds for believing that the acquisition of true articulate speech was one of the essential factors in the emergence of Man's distinctive characters."

The examination of the endocranial casts of the primitive human races, for example, of Figure 33 in Elliot Smith's book, shows the occipital lobes of the Rhodesian Man, where visual centers are located, to be large and protruding far backward, whereas the temporal lobes, associated with hearing, are relatively small. This precocious phylogenetical development of the visual parts of the human brain, compared with other parts, especially with the poorly developed temporoparietal association area of Flechsig, indicates that vision was a step ahead

of hearing and speech during human evolution. This, of course, has its parallel in all Higher Primates in which the refined epicritic vision is superior to the auditory sense. This interpretation is also in accord with the concept expounded previously in this chapter.

These and other facts and observations suggest that vision was the dominant sense in Man's Ancestors, whatever other factors have contributed to the emergence of human intelligence.

The identity and sequence of the factors which culminated in the formation of Man from an Infrahuman Primate may be imagined as follows. The arboreal habit had, from the beginning, enhanced the dominance of vision in the Primates. The terrestrial habit and the erect attitude of Man's Ancestors continued and increased the same emphasis upon vision. In the savanna-like habitat, away from the sheltering jungle, acute vision was even more important for survival. The upright gait and the emancipation of arms and hands from locomotion and their transformation into delicate grasping organs, capable of being used either together or singly, had further removed the senses of smell and taste from the source of food, making vision and, in a lesser degree, hearing the leading senses. An additional factor was the roaming habit, made possible by the swift bipedal locomotion. The impulse toward increased development of hearing, imposed by Man's social habits, made of it the most important auxiliary sense, indispensable in his struggle for life. The development of speech as the easiest means of intercommunication between the members of the family or tribe belongs in the same category.

These factors appear to be the principal pillars upon which the human mind was built. The brain, because of them, was forced to follow suit. Like any other bodily organ, it had to organize itself according to the increased functional demand. This again was possible because of the essential organization of the vertebrate, especially the primate, brain and because of the plastic potentialities of its tissue inherited from the Prevertebrate Ancestors.

The importance of stereoscopic vision in the origin of Man is not quite obvious, and even now its essence is not fully understood. Its role in human development, in contrast with the Infrahuman Primates and other Vertebrates, probably was overemphasized. Since binocular stereoscopic vision, in view of a practically identical anatomical arrangement, must be assumed to be the same or similar in all Higher Primates, certainly so in all Monkeys and Apes and even in the nocturnal Tarsier, and as a facultative arrangement in at least some Lizards and Birds, it could have been neither a primary nor a decisive factor. Hence binocular stereopsis could not have been the principal factor which prepared "the way for the further cultivation of those high powers of discrimination and understanding that are distinctive of the Human Family," as Elliot Smith believed. But, together with the upright gait, manipulative ability of the hands, and the development of speech, binocular stereopsis, further improved and elaborated, was an additional factor in human origin, just as were visual acuity and color perception. It was an expression of the general improvement and further refinement of the human visual apparatus, all required as a basis for harmonious human development.

SEC. 8. MAN'S EARLIEST ANCESTORS PRECEDING AND DURING THE ASSUMPTION OF ERECT POSTURE AND BIPEDAL GAIT

1. PROBLEM OF LINKING MAN WITH HIS INFRAHUMAN ANCESTORS.—The probable evolutionary process by which the ancestors of Man became transformed from the so-called "Quadrumans" into strict "Bipeds-Bimans," that is, Primates possessing "legs" and "feet" exclusively assigned to carry the body, while the "arms" and "hands" became entirely organs of manipulation directed by the "mind" and largely guided by the sight, was described in detail in section 3, in this chapter. Also discussed were the probable factors which may have initiated and carried out this transformation.

In this picture of transformation, in the present state of our ignorance, much unfortunately remains hypothetical. The later successive stages toward the status of *Homo sapiens* may

have resembled one or another or several of the so far known prehistoric human or human-like races, beginning with *Australopithecus, Pithecanthropus-Sinanthropus,* Neanderthal Man, and the Aurignacian or Cro-Magnon race, and finally culminating with the arrival of Modern Man. (Whether this was or was not the actual phylogenetical series which led to *Homo sapiens* or whether, perhaps, most or all mentioned types merely represented various side lines off the main stem remains a problem for future investigation.)

The earlier and more primitive stages which, on general grounds, must undoubtedly have preceded, the very "missing links" connecting the simian-like forms with the incipient humans, the stages which have "approximated very closely to a simian level," are now being discovered and their significance appraised (Le Gros Clark & Leakey 1950). Future investigation may perhaps determine whether any one of these was ancestral to Man or perhaps others linking more directly with the prosimian stock.

The difficulties of finding such "missing links" are not only technical, nor are they all caused by scarcity, in view of the abundant new paleontological material recently uncovered in East Africa. It is reasonable to think that the transformation from a simian to a prehuman form was a very gradual, slow process, spreading over a long stretch of time, and that the early Hominoids and possibly also Hominids had separated from the early Tarsioids or Cercopithecoids at least as far back as the Oligocene Epoch, or from 25 to 35 million years ago.

During this long space of time there must have been stages in the human ascent differing little from the usual simian organization. Such forms, even though in the direct ancestral line of Man, would hardly be distinguishable from some extinct collateral branch. Yet it was in precisely this critical stage that, under some specific stimulus, a germ began to grow which in the long run caused the human line to part from the lines of all other Primates. Figuratively speaking, it is probable that, if it were possible to recreate such simians, they could hardly be recognised as Man's direct ancestors and would be lost among the other extinct or living Primates. In fact, it is probable that such identification could be made certain only if the entire chain of evidence were complete—a most unlikely event.

In spite of the probability that none of the now living Simians and most of those known to have lived in the past may have been the true "missing links," the gap between the Lower Primates, from which Man's line must have arisen, and the early prehistoric human races has been narrowed through recent discoveries. These may, at any rate, be used to plot in a general way the course of human evolution and to hypothesize about the appearance, habits, and environment of Man's simian-like and protohuman ancestors.

The first to be mentioned, but most recently made, are discoveries of the Miocene Hominoids or Apes, *Proconsul* and *Limnopithecus.* They flourished over wide parts of Africa, Asia, and Europe. Their geological age may be estimated at from 10 to 25 million years. The smallest of the *Proconsuls* were smaller than the Chimpanzee, the largest attaining the size of a large Gorilla. They were, however, more lightly built, embodying cercopithecoid features, indicating a terrestrial and not an arboreal habit. These Apes were definitely not arboreal brachiators but were terrestrial runners and leapers. Their bodily organization was generalized, allowing further specialization either along the pongid line or toward a "type of limb structure which might have permitted the gradual acquisition of an erect posture characteristic of the Hominidae" (Le Gros Clark 1950; Clark & Leakey 1950). Some of these Apes possibly served as the origin of the Hominidae (Le Gros Clark 1953), unless Man had an independent prosimian origin (Robinson 1952).

The other and even more spectacular discovery of *Australopithecus africanus,* formerly known as the "Taungs Ape" or "Taungs Ape-Man," made thirty years ago by R. A. Dart, in Johannesburg, South Africa, and amplified by further Australopithecines such as *Paranthropus* and *Plesianthropus* and others by R. Broom and his co-workers, definitely ties up the preceding and less advanced Primates with those which followed and were indisputably primitive Hominidae, as, for example, *Pithecanthropus* and *Sinanthropus.*

2. The African Australopithecinae or "Southern Apes."—This type, first discovered by Dart in 1924 at Taungs in Bechuanaland and subsequently amplified by additional specimens in the Transvaal, is remarkable in that it approached Man in the structure of the skull, limbs, pelvis, and dentition. The noteworthy exception was the brain. In its volume of 600 or 650 cc. it exceeded but little, according to Dart, the size of the brain of the Gorilla (500 gm., according to Obersteiner; 650 cc. in the largest Gorilla, according to Dart), and at the most it may have attained the volume of 700–800 or 850 cc., according to Broom. The australopithecine brain, then, was somewhat smaller than, or equal to, that of *Pithecanthropus* (775 gm.) and was considerably below the smallest modern human brain (1,000 gm. for man, 900 gm. for woman, according to Obersteiner).

The *Australopithecus* or "Southern Ape," as Dart called this primate type, was, accordingly, the earliest Primate to attain an erect posture and bipedal gait, even though his brain had advanced but little, if at all, beyond the best-developed brain of the large modern Apes.

The "Dartians," as the Australopithecines were named by Sir Arthur Keith, were the "ground-living anthropoids, human in posture, gait, and dentition, but still anthropoid in facial physiognomy and in size of brain" (Nature, 1947). (*See*, for illustrations, G. Elliot Smith, *The Evolution of Man*, 1927, Fig. 4; R. Broom & G. W. H. Schepers, *The South African Fossil Ape-Men, the Australopithecinae*, 1946, Pls. I and II; R. R. Gates, *Human Ancestry*, 1948, frontispiece and Pl. I; Le Gros Clark, Quart. J. Geol. Soc. London, v. 105, p. 13; Le Gros Clark, *History of the Primates*, 1953; and R. Moore, *Man, Time, and Fossils*, 1953, Pls. XXVI and XXVII.)

In his bodily organization, *Australopithecus* approached, or rather preceded, Man in several respects. In developing a real "forehead" and in his human dentition he "dared to emulate Man," as Dart expressed it. The brain of a juvenile was somewhat bigger than that of an adult Chimpanzee. His arms, hands, pelvis, feet, and legs were especially human-like. His head was also poised in a more nearly human fashion, pivoting closer to its center of gravity on the top of the spinal column than is the case in the modern Apes.

The Australopithecinae were, in the words of Le Gros Clark,

> hominoids of small stature (probably similar in this respect to the pygmy races of present-day mankind), with brains not much larger relatively than those of the gorilla and chimpanzee, massive jaws showing many human features, a dentition fundamentally of human type . . . and limbs approximating in their structure and proportions to those of the Hominidae. They were evidently capable of standing and walking with an almost erect posture, and the hands and feet were relatively small and delicately built. . . .
>
> So far as the *morphological* evidence at present available can be assessed, it seems a reasonable inference that they either represent a group which occupied a position quite close to the main line of later hominid evolution, or else they represent only slightly modified descendants of such a group.

The decision must depend partly on the geological age of the australopithecine deposits. (This age, according to the estimate of R. Broom 1950, would be from 1 to 5 million years or more, or approximately from the Middle Pliocene to the Early Pleistocene Epoch.)

The Australopithecinae, according to Dart, "are proto-human beings; and they are the most primitive hominids of whom we have knowledge."

The pertinent question, then, is how *Australopithecus* was able to develop human hands and bipedal gait without a human brain. Our logic demands that human hands could have evolved in no other way than as exclusive instruments of a mind which had attained at least the minimum characteristic human qualities. In Elliot Smith's thesis discussed in section 7, the primacy of the brain, secondarily followed by the reorganization of the rest of the body, was the principal argument.

This particular question was answered by Dart's further discoveries (1948, 1949). From the numerous remains of animals associated with those of *Australopithecus*, it is apparent that he was an intelligent, courageous, fleet-footed, terrestrial, meat-eating hunter. For his food supply he drew upon almost every kind of small and big game found in South Africa: Turtles, Birds, Insectivores, Rodents, small Bucks, Rock-Rabbits, Crabs, birds' eggs, two

or three species of Baboons, fourteen Bovidae, three carnivores, such as the Lion, Hyena, and Jackal, two extinct species of Pigs, a Rhinoceros, Hippopotamus, two kinds of Giraffes, and the Elephant. The fauna indicates the Early Pleistocene Epoch, which may be roughly estimater at 1 million years ago.

Other considerations indicate that, in spite of his smallish brain, the *Australopithecus* must have been a clever hunter. Judging from the age of the remnants of his game, which include mostly juveniles and the aged, he caught it more by tricks and cunning stratagem than by power. The aged individuals, weakened by general decrepitude and disease, he could easily have overcome. But many juveniles, constantly under the surveillance of the powerful adults, he could have enticed away only by a trick. This assumption is justified when one considers the rather high intelligence and cunning of the Apes, such as Chimpanzee, Orang, and Gorilla, well attested by experiment and observation. (*Cf.* Köhler, Yerkes, Klüver, Bingham, Benchley, and my own observations; *see* secs. 4, 5, this chapter.)

"The profusion of the bone breccia," to quote Dart, "shows that they were capable and successful in their hunting of very big game." It also shows that *Australopithecus* subsisted largely, possibly entirely, on a meat diet. This in turn presupposes efficient techniques and methods of capturing game which made such extensive leaning upon hunting possible.

Since the weapons of these hunters were, at best, primitive, consisting of stones, large animal bones, or branches used as clubs, bludgeons, or bone breakers, or sharp bone splinters and stag and antelope antlers used as daggers, this further presupposes considerable mental ability to make such a technique successful. Their wits, however, were not sharp enough to devise a way of deliberately fashioning the edged tools and cutting weapons, a feat achieved during the next succeeding human evolutionary stage (*cf.* Oakley 1950).

The majority of skulls of Baboons, which in some regions represented the principal game, were found by Dart, Broom, and Schepers to have been fractured by heavy bludgeon blows or split open or smashed in a way indicating that they had been slain by some such weapon as a piece of rock held in the hand or perhaps attached to a handle; or they showed round holes through which the brain had been extracted. Other skulls of Baboons showed double depressed fractures into which fit the hammer-shaped ends of long bones of large Ungulates which had been used as attacking bludgeons.

It is noteworthy that most australopithecine skulls also showed similar fractures, as Schepers found, indicating that these Protohuman Primates were not only assiduous hunters but also cruel cannibals. In attacking, the Australopithecinae favored a direct frontal approach to the quarry, which indicates that they were bold and courageous. Since the left side of the victim's skull was usually crushed, the right hand was used by preference to deliver the well-aimed *coup de grâce*. Dart writes:

> The deposits of Taungs, Sterkfontein, and Makapansgat tell us in this way a consistent, coherent story not of fruit-eating, forest-loving apes, but of the sanguinary pursuits and carnivorous habits of protomen. They were human not merely in being bipedal, in maintaining an upright posture, and in having the facial form and dental apparatus of humanity; they were also human in their cave life, in their love of flesh, in hunting wild game to secure meat, and in employing implements, whether wielded and propelled to kill during hunting, or systematically applied to the cracking of bones and the eating of food. There is only one physical feature—namely, brain quantity (not brain quality)—which separates these proto-men from early man. . . .
>
> Similarly, on the cultural side there is apparently no feature other than *the deliberate manufacture of stone tools* which separates these proto-men at the present time from early man.

Other findings of Dart indicate a systematic use of fire by *Australopithecus*, for example, the charred appearance of some bones accumulated in the "kitchen middens" which appear to have been deliberately fractured and split, in order to extract the marrow. This creature, then, is the first on record to master the making of fire, hence the epithet "Promethean" given to him by Dart as an allusion to Prometheus, the legendary hero of the ancient Greek saga.

The picture of this early protohuman creature, which subsisted principally, if perhaps not entirely, on big game, may be further sketched in from the information kindly furnished by Professor Dart (1952 and 1953):

One of the principal reasons for the early failure of European and American scientists to appreciate the significance of the Australopithecinae in the human evolutionary story was their quite natural lack of knowledge about South Africa.

Geographically and geologically South Africa is almost as much of a desert as North Africa. In one year five times as much water runs over the Niagara Falls as runs in all of the rivers in the whole of the Union of South Africa, taken together. An arid savannah country of this sort can maintain much game, but it has no forests or fruits to compare with the woodlands and the berries, apples, and nuts, etc., of Europe, Asia, and the Americas.

The earliest Primates arose from or are indistinguishable from the Insectivora, so their diet was doubtless insectivorous at the outset. The South African baboons are quadrupedal most of the time and turn over every stone for scorpions, raid birds' nests for their eggs and young, devour any small veld creature like grasshoppers, lizards, etc., with relish, and are reputed not only to attack lambs and ewes, but also to hunt buck. Their diet is essentially vegetarian tubers and bulbs, fresh shoots of plants and the raiding of the gardens and orchards of introduced plants, maize, melons, bananas etc., but as none of these is indigenous to South Africa, they would fare poorly if they were not omnivorous by nature.

The Australopithecinae, according to Professor Dart, leave no doubt that

there must have been an anthropoidal phase in human development and that the arboreal and terrestrial specialisations within the anthropoid group were fundamentally dietetic in origin, and expressions of herbivorous versus carnivorous specialisation respectively. . . .

Man's ancestors avoided extreme adaptation to the arboreal way of life because of their blood lust. The carnivorous propensities of the pronograde anthropoid stock, ancestral to mankind, weaned them away from the forest and its succulent leaves, roots, and fruits that attracted the living anthropoids and enticed man's ancestral stock into the savannah or prairie where there was enough wild game.

The terrestrialized baboons of Africa show us that savannah life is perfectly feasible for primitive anthropoidal creatures provided they have an omnivorous diet, *i.e.*, including insects, birds' eggs, and small game. There are those (like Straus of Johns Hopkins) who think that the human stock could have broken away from the primate stock at a cercopithecid stage and L. H. Wells showed that the foot of the baboon is in some ways closer to the foot of mankind than are the feet of living anthropoids. The Tarsier split-off would lie unnecessarily far back. There never would have been a theory of evolution if there were no monkeys and apes to fill in gaps between Tarsius and Man.

Whatever be the route of evolution we know both Tarsier and monkey have tails. Whatever the cause of the divergence between monkey and ape, it was fundamentally postural since it involved the loss of the tail. That means that in addition to a lot of sitting down and concurrent liberation of the hands (under the direction of the now reasonably stereoscopic eyes), the tail musculature instead of wagging a futile counterpoise behind could be concentrated on the cloacal evolution on the ventral aspect instead of being completely at the rear of the body.

One of the biggest factors in this increased sitting-down of anthropoids on their ischial tuberosities and thighs as compared with cercopithecids, to my mind, is the lengthening of the periods of gestation and especially of infancy, in creatures capable of manipulating their offspring and carrying them in or under their arms instead of their clinging instinctively to the maternal belly or back. What that entailed visually, manually, and posturally in the evolutionary story is more easily imaginable to you as a neurologist than it is to me to depict here.

When there was added to this anthropoidal squatting on their bottoms (not on their heels) which was essential for the improved manipulation of infants and other objects (that Reynolds recognised was implicit in their pelvic evolution), the further business of systematically hunting animals for food or robbing other carnivores of their prey, then the brandishing of clubs and flinging of rocks (which previously had been an occasional feat or temporary employment) became a vital necessity and, in consequence, the principal business of adolescent pre-human education.

With regard to fruits and cereals the South African flora is singularly lacking and there is no evidence of which I am aware, to indicate that our pre-human ancestors favoured either of these classes of vegetable food. Would not the varying colours of their potential enemies, both reptilian and mammalian, and the animals they hunted for food, be even more powerful stimuli for the evocation of colour-vision percepts in carnivorous creatures than are the colours of fruits to herbivorous creatures?

Since the Australopithecinae are the only pre-human creatures known to have had an erect posture and bipedal gait, and they lived in Early Pleistocene or Late Pliocene times, it can be said that man was erect before he became sufficiently manlike to be recognised by all scientists as human and that that was at least 1,000,000 years ago. It may have been twice as long.

According to G. B. Barbour (1949), the estimated time is that of Upper Pliocene or "distinctly more than a million years ago, and shortly before the onset of the colder climate which heralded the Great Ice Age in Europe and North America," and that Man lived in the caves of Makapansgat Valley in the Pliocene Epoch, at two stages in the Pleistocene, and again today. (*See* G. B. Barbour, *Makapansgat*, 1949, p. 146, for evidence of the use of fire; for further dating *see* Zeuner's *Dating the Past*, 1952.)

(The estimated time of the above-mentioned epochs is, according to Zeuner, for Holocene, or most recent, prehistory, 10,000 years; for Pleistocene, 1 million; for Pliocene, *ca.* 10 million; for Miocene, 15 million years in succession; the Holocene, or Postglacial, and the Pleistocene, or Ice Age, together make up the Quaternary Period, which followed the much longer Tertiary Period, consisting of Pliocene, Miocene, Oligocene, Eocene, and Paleocene Epochs, which together lasted approximately 58 million years.)

Professor Dart's conclusion is as follows:

So, disagreeable as it may be to contemplate, man appears to have become man by virtue of his ferocity. In this connection you may be interested to read Carveth Read's *The Origin of Man* in which he dealt with the hunting pack and its psychological inevitabilities. Despite what Elliot Smith had to say in *Human History* about the peace-loving characteristics of mankind as opposed to systematised war, we cannot avoid the philosophical implications of massacres, both those of historical record and those of prehistoric exposure, as at Krapina, Choukoutien, and Solo, to say naught of cannibalism both in fact and in ritual.

(For Krapina *see* Gorjanović-Kramberger; *cf. also* Weidenreich.)

Professor Dart's views may be further amplified by an excerpt from a letter from L. S. B. Leakey, curator of the Coryndon Museum, at Nairobi, Kenya, Africa. In his words:

I have no doubt at all that man originated in Africa, the presence of *Propliopithecus* in the Oligocene of Egypt; of the very numerous "apes" in the Lower Miocene of Kenya—*Proconsul* (3 species) and *Limnopithecus* (2 species) and *Sivapithecus;* and of the *Australopithecines* in South Africa, all point to this.

Equally, I have no doubt in my own mind that man never went through a highly arboreal stage or even a brachiating stage, but went direct from a quadrupedal animal living mainly on the ground and in open country (like Baboons do) to an upright gait.

I think the origin of man may be sought among the *Proconsul* and *Sivapithecus* group in the Lower Miocene of Kenya, and we have suggestions that their habitat was open country with *very numerous* fruits, nuts, and berries on bush rather than in forest.

(*Cf.* W. L Straus, Jr. 1949; Clark & Leakey 1950.)

There is evidence, according to Leakey, of some 158 different species of fruits and seeds not yet analyzed, found in the deposits of Kenya which yielded *Proconsul*, the associated fauna indicating a good deal of open grassland. The skeleton of this Ape suggests a quadrupedal gait, and its diet may also have included insects. The Australopithecinae, in the opinion of Leakey, are an offshoot from the human stock, and not direct ancestors.

The preceding quotations present a digest of the available information, and they illustrate the complexity of the problem of Man's rise to his present dominant place in nature. In the concluding sections of this chapter, we shall try to summarize our views on the subject and on the other problems related to it.

SEC. 9. REFLECTIONS ON *AUSTRALOPITHECUS* AND ON THE ORIGIN OF MANKIND

1. Reorganization of the quadrumanous body for bipedal gait, and its consequences.—The discovery of *Australopithecus*, the earliest known human-like Primate, is of great interest in several respects. He was the first member of this order on record to develop an upright posture and the use of bipedal gait as the preponderant mode of locomotion (with the exception of the leaping Tarsier). His arms and hands, in contrast with all other nontarsian Infrahuman Primates—irrespective of whether they were quadrumanous arboreal climbers, terrestrial walkers, or arboreal brachiators—became largely, perhaps entirely, emancipated from carrying the body weight. In consequence, his upper extremities became versatile tools and

instruments of mind by which objects could be examined, principally by vision, and used for a variety of purposes, including the handling of the tools and weapons (stones, bludgeons).

The other consequence of bipedal gait and upright body posture and the reorganization of the rest of the bodily machine was the effect on the intellect. The continuous handling of objects, their close scrutiny by the sense of touch, deep sense, taste, and smell, and, above all, sight, brought information to the mind in an abundance never achieved by any of the Anthropoids, including the most advanced now living species.

Bipedal gait, upright posture, and flexible neck also made possible freedom and continuity of observation of near and far objects by the distance senses, especially vision. When these changes had been accomplished, the point was apparently reached where Man's line definitely began to climb toward the human state.

Australopithecus, however, could not have been the first departure of the human line from the primate stem or chain but was merely a link in that chain (if not part of a side line). The human line seems to have parted much earlier from a more generalized, essentially monkey-like, stock during the Early Miocene (20–25 million years) and Oligocene Epochs (25–35 million years in the past) and in this way had avoided completely the brachiating arboreal specialization. The absence of clear signs of a pronounced brachiating phase in human organization, which is so striking a feature of the Gibbons and of the large Anthropomorphous Apes, agrees with this. (*See* W. L. Straus, Jr., "The Riddle of Man's Ancestry," Quart. Rev. Biol., v. 24, p. 200, 1949; *see also* Klaatsch; Boule; Osborn 1928; Broom & Schepers 1946; Le Gros Clark 1950, 1953, 1954, in contrast to W. K. Gregory 1916, 1927, 1928, 1930; and D. J. Morton 1924, 1927.)

The phylogenetical line which eventually culminated in Man must have started very much earlier in the paleontological past. This line at the australopithecine stage may already have had a long history whose beginnings at the primate stem cannot as yet be precisely determined. (*Cf.* J. T. Robinson 1952, 1953.)

Another problem is whether or not these discovered Australopithecinae were an actual link in the phylogenetical line of the true Hominidae. It is possible that the human line had an origin independent from the primate stem and that at the period corresponding to the now known Australopithecs, roughly estimated as the late Pliocene and early Pleistocene, it had already outstripped that of the Australopithecs, leaving them as a phylogenetical remnant, as some evidence of Broom & Robinson (1950) seems to indicate. But even if this were the case, the Australopithecinae illustrate "a hypothetical picture of the ancestral forms which must presumably have immediately preceded the *Pithecanthropus* phase of human evolution" (according to Le Gros Clark 1950). Other considerations indicate that the australopithecine and similar types were not confined to South Africa but had wide distribution in other parts of that continent and very likely were also present in Asia (*see* J. T. Robinson 1953). From any one of these, or from several, the true human line or lines may have originated.

2. Positive and negative factors in the advancement of Man's early progenitors. —The question may be raised as to whether or not the circumstances of the habitat and habits of *Australopithecus*, or similar types, could have been conducive to further development toward true human status, and how they could have worked.

We are aware of two positive factors likely to foster the emergence of human intelligence. The first was the apparent ability of Man's progenitor at an early stage to use, or to fashion, mechanical tools and weapons from pieces of stone, wood, and bone, which greatly increased the effectiveness of his arms and hands as the executive limbs of the mind. The other factor was his use of fire, an invention which was a product of his intellect and mechanical skill. This in turn made it possible for him to prepare meat for food, a material repugnant in a raw state as sole fare to most other primate species, with the exception of the crab-eating Macaques and the Tarsier (*see* chap. XIV, 12). (Even Baboons, contrary to the belief of the natives, do not hunt larger game animals, according to Zuckerman 1932, although they certainly would eat smaller animals such as Rats, according to Klüver's experience.)

The adverse factor was the diet of *Australopithecus*, which, according to Dart, appears to have consisted entirely of meat. To catch animals in a grassland such as South Africa, the hunter must be in possession of sharp senses, sufficient intelligence, swift locomotion, aggressive weapons, and physical power. The carnivorous animals of the same region, the Lion, Leopard, and Hyena, are well provided with all. *Australopithecus* was also well equipped in all but one. His senses, especially vision, must have been acute, his mental powers of observation and integration were of a high order, he was an enduring walker and a fast runner, he possessed commensurately great physical strength. In one respect he was singularly deficient. He did not possess aggressive weapons comparable to the huge canines and sharp, shearing premolar and molar teeth and the large claws of the Carnivores. The only instruments that *Australopithecus* could use were his arms and hands, employed as grabbing, beating, strangling, and pulling tools directed by sharp senses, quick and resourceful intellect, performing skilful motor acts. To the Human Ancestors this mode of acquiring food would have sufficed, however, only as long as they subsisted on a plant diet and on animals that could be mastered with bare hands. To acquire a more abundant food supply by hunting larger game, it was necessary to use mechanical tools and weapons. In this respect *Australopithecus* may perhaps serve as an illustration of the very first use of bones and possibly sticks and stones as hunting weapons.

The bipedal gait and the emancipation of the upper extremities from locomotion alone, obviously, could never have launched Man's Ancestors upon the road of intellectual progress. The Birds, whose terrestrial locomotion is bipedal, show this. Another example is the larger species of Kangaroos, where the entire labor of locomotion is also performed by the powerful hind legs (in addition to the strong tail), the smaller forelegs being free. But here the comparison ends. The rather small and weak upper extremities of the strictly herbivorous Kangaroos are useful only for holding the branches of shrubs in browsing and other similar and little-diversified acts not requiring great skill or much intelligence.

A very different situation obtained with *Australopithecus*. To catch game, he had to use his higher senses, primarily vision, to the limit, to observe the animal's habits and to interpret them correctly. Finally, he had to overcome it by the skilful use of his arms and hands, directed by his superior intelligence. He had to compensate for the deficiency of aggressive bodily equipment by the clever use of his "grabbing extremities," his intellectual capabilities, his cunning, and his inventiveness.

In the life of *Australopithecus* every act of procuring food became a venture which began with a premeditated plan, continued as an exciting drama, and terminated with a resolving climax. Upon its success depended his survival.

The mind of *Australopithecus* was, therefore, largely dominated by concepts of "planned aggression," whose execution depended upon the powers of his intellect. In his struggle for existence the brain of *Australopithecus* became most important as a medium to contrive the use of primitive weapons—large ungulate bones, sticks, or stones as clubs—by which the power of his hands and arms was very much increased.

3. CARNIVOROUS HABIT PROBABLE DETERRENT TO ACHIEVEMENT OF HUMAN STATE.—The bipedal locomotion of *Australopithecus* and the use of his upper extremities as instruments of the mind must have been a powerful stimulus toward human development. Doubt arises, however, in view of his exclusive meat diet. Such a habit may equally have been a deterrent. An example of this may be the Tarsier, whose purely carnivorous habit, in spite of an almost exclusive use of hind extremities for locomotion and the proportional emancipation of the arms and hands, did not help in the least to prevent it from becoming a living fossil, although the Tarsier's nocturnal adaptation was undoubtedly a potent factor which precluded any further advancement, as already discussed (*see* chap. XIV, 12).

Other primate experiments in the paleontological past which deviated from the preponderantly omnivorous trend by assuming rodent-like habits have all disappeared, with a single exception. Such were *Tetonius*, an Eocene Tarsioid, *Sinclairella* of the American Oligocene, *Carpolestes*, *Apatemys*, and *Plesiadapis* of the Paleocene and Eocene Epochs, which appar-

ently were also all Tarsioids. The only still living example of this adaptation is the Aye-Aye (*Chiromys* or *Daubentonia madagascariensis*), which possesses a single remaining pair of enlarged incisors which it uses in the fashion of Rodents to gnaw through the bark of trees in search of insects. (*See* Parker & Haswell 1940, v. 2, Fig. 511; Romer, *Vertebrate Paleontology*, Figs. 268, 269; Brehm's *Tierleben;* Zuckerman 1933, Fig. 4.)

It is therefore possible that the Australopithecinae represented an aberrant branch of the advanced Primates which may have bogged down in an excessively carnivorous specialization, as their massive jaws and teeth would indicate (*see* jaws described by Dart 1948 and 1954; Broom & Robinson 1950; and Le Gros Clark 1953). The more versatile, omnivorous, and therefore more adaptable principal stream of bipedal Primates went on under better conditions and succeeded in developing their bodily character and sensory-mental abilities more harmoniously.

The infancy of Mankind may not have been so completely carnivorous as it would appear in the perspective of the Australopithecinae. But they are a dramatic demonstration of the ferocious, aggressive traits and the "blood lust" which must have been a potent factor also in Man's direct ancestors. Or else Man would have never risen, literally and figuratively, on his "legs" and would have never developed his "arms" and "hands" as the exclusive tools of his intellect.

Man's aggressive traits are well documented by prehistory, history, and everyday experience. Certainly Mankind behaved and behaves much of the time as if directly descended from the Australopithecs, whose dominant feature of character was aggressiveness (as their exclusively carnivorous habit, as in other Carnivora, demanded). But in Man's direct ancestors the carnivorous propensities and "blood lust" may have erupted only at times, periodically, incited either by hunger, opportunity, or emotion. Hence the ferocious instincts may have remained dormant for longer or shorter periods, during which Man's Ancestors pursued more peaceful occupations, gathering the fruits of the earth, in addition to hunting various animals, which may have been their chief source of sustenance. Much of the time they may have been, therefore, peaceably inclined, but the "blood lust" was always there, ready to flare up at any opportune occasion.

As far as the newly discovered evidence shows, Man did not enter the world as an ascetic vegetarian and an angelic peace-lover, as the philosophers, moralists, and some overcharitable modern anthropologists would like us to believe, but as a clever competitor and a ruthless exploiter of the rest of nature.

4. Omnivorous habit an incentive to the rise of Man.—The appraisal of the living habits of the Australopithecinae points toward a stage in human evolution not greatly different, but with more emphasis on omnivorous habits. Such omnivorous habits could have been cultivated only in the part or parts of the world where natural conditions were less extreme, neither the dry, grassy lands lacking fruits as South Africa, which made a carnivorous habit mandatory, nor swampy jungles of the type found in parts of South America, where arboreal life alone is possible. Such extensive regions are present in many parts of Eurasia and Africa, while Australia and the two Americas, for zoögeographical reasons, seem to have remained outside this phase of primate evolution.

In contrast with the severe uniformity of Bechuanaland and the Transvaal, the home of Mankind must have been varied in topography, with fair rainfall, a more gentle climate, and abundant and more diversified floral and faunal products. Here the more fortunate Protohumans had all the necessary opportunity to perfect their bipedal gait, upright posture, and especially their manipulative abilities: in gathering the fruits grown on the trees and bushes, in digging for edible roots and tubers from the soil, in collecting shells, eggs, and small animal life, and in supplementing this by intermittent hunting. The use of the hands for skilled acts guided by vision and regulated by senso-mobility was perfected in this way. And in the exercise of these activities, with the co-operation of other members of his family, group, or tribe, Man's intelligence further increased and finally culminated in the development of speech from inarticulate utterances.

The thesis of the omnivorous habit of Human

Ancestors, a diet of edible fruits, roots, stems, leaves, tubers, every kind of seeds or grain, and other products of plants, in addition to animal food, is supported by much evidence, albeit indirect.

In the prehistoric lake settlements of Europe, erected on piles, wheat, barley, linseed, and many varieties of seeds and fruits were found, together with the bones of the Stag, Ox, Pig, Sheep, Goat, Beaver, Fox, and Bison. This indicates that there was already at that time a well-advanced state of agriculture combined with hunting. The origins of this agriculture must, therefore, lie many thousands of years in the past (Anonymous 1932).

In primitive present-day societies, still entirely built upon the pattern of the Stone Age, both plant products and animal food play an important role. An instructive example is the Pitjendadjara tribe of Central Australia whose habits have been recently studied by C. P. Mountford (1946, 1951). In their efforts to wring a livelihood from their inhospitable homeland, they use only five implements: a spear and a spear thrower (by men) and wooden carrying dishes, grinding stones, and digging sticks (by women). The boomerang, an important weapon in other parts of Australia, is unknown to them; hence this tribe is probably less well equipped than any other in existence. The Pitjendadjara natives have no clothing whatever, and their only protection against inclement weather is fire and a wind shield, behind which they sleep, and the fire stick which they carry to keep warm (the temperature in the area which they inhabit may occasionally drop to 17° F.).

The diet of the Pitjendadjara is quite varied, "in fact, they ate," according to Mountford, "everything that was edible—grubs, lizards, ants, kangaroos, emus, grasses, and seeds of many kinds," besides hunting for Dingo, the native Australian dog, and for the marsupial "cat." Honey Ants, which are "as sweet as any honey," are a special delicacy. Grass seeds appear to be as important a food item to them as are grains and cereals in our own society. They often get "meat-hungry," hence are eager to hunt kangaroos and emus. (*See also* D. F. Thomson 1948; Mountford & Walker 1949; and H. Walker 1949.)

In another contemporary Stone Age tribe recently discovered in a secluded valley of New Guinea, fruits, both cultivated and wild, and other plant products, in addition to domesticated animals and game, are the source of food (R. Archbold 1941; E. T. Gilliard 1953; *cf. also* M. C. Burkitt *et al.* 1932).

The food of the Anthropomorphous Apes derives, with few exceptions, from plants, even though the Chimpanzee can be taught to eat meat in human fashion, according to Klüver's experience. Most of the Monkeys also seem to be chiefly plant-eaters. The only strictly carnivorous Primate in existence, excepting possibly some Macaques, is the Tarsier (*see* chap. XIV, 12). Most Monkeys, e.g., Rhesus Macaques, according to our own experience, shun meat in any form, whether raw or prepared. The South American Platyrrhines, however, also eat small animals, such as insects, snails, slugs, scorpions, birds and their eggs, and the like, as well as fruits. The only Primates, besides Man, which may have developed the habit of hunting larger game are the Baboons. But this, too, has been questioned by Zuckerman (1932; *see* sec. 4, this chapter). The Baboons, in Klüver's experience, however, are eager to catch live Rats and eat them with relish.

5. Living habits of Man's Ancestors the cause of their intellectual advancement. —The activity of Man during his early period, as far as it can be reconstructed, indicates hunting as the principal, and at times possibly the only, source of food. The Paleolithic and the succeeding Neolithic Periods reveal themselves as being entirely based on Man's intelligent production of stone and bone tools and weapons, such as clubs, axes, knives, scrapers, drills, and the like. (*See* Oakley 1950; *cf. also* Gilliard 1953.)

The astonishingly lifelike figures covering the walls and ceilings of the caves at Altamira, Lascaux, and many other caves, dating back from twelve to twenty or more thousands of years, vividly illustrate the kind of game the early hunters chased, and occasionally also show men in the act of hunting and their technique. This shows indubitably that game animals were an important source of food.

The question still remains as to whether or

not, during any period in the past, Man's Ancestors subsisted entirely on an animal diet. The prehistoric tools, weapons, and pictures may merely indicate the most difficult problem of Man's life, the acquisition of meat, hence the one which had impressed itself most vividly upon his imagination (*see* Movius 1953).

The habits of primitive races, such as those inhabiting New Guinea and Australia, indicate that plant food is at least an important source of subsistence. This view may be further supported by the observation of primitive societies of the recent past. The North American Indians, for example, whose level of civilization during pre-Columbian times was of the Stone Age, subsisted on both animal and plant food. Their tools and weapons were entirely made of stone, bone, stag antlers, leather, wood, and plant material, except for the occasional use of copper. With their primitive weapons, in spite of the abundance of game, especially in the prairie region of the Middle West, the procurement of meat was difficult, which made them rely much upon fruits gathered in the prairies and woods. Similar conditions were, or still are, present in other parts of the world. The Eskimos, living in a climate adverse to plant growth, seem to be the only primitive people subsisting entirely upon an animal diet, and in this way rather emphasize the exception. Whether the Massai tribe of Kenya live on a diet of milk and blood alone is not known.

By far the most important source of sustenance of the Infrahuman Primates is plants. This is entirely true of the tropics, hence the Infrahuman Primates are largely restricted to the tropics. Here the fruits grow mainly on the upper parts of the branches and can therefore be reached only by the Birds, the arboreal Primates, and the fruit-eating Bats, according to Gundersen & Hastings (Scient. Monthly, v. 59, p. 63, 1944). These animals are not only the principal consumers of tropical fruits but also the distributors of their seeds.

In their interdependence, these animals and the fruit-bearing trees resemble the relationship of the nut-bearing trees and the Squirrels of the temperate regions. It stands to reason that this dependence must have been mutually advantageous, or else it would have been discarded as a failure. Its success, however, is attested by its long duration and the advantages accruing to both the plants and the animals.

The plants benefited from the perfection of animal senses, as increased acuity, more delicate color vision, better stereopsis, more refined taste and smell, and more efficient locomotor and manipulative abilities made the animals more acute observers, detectors, and distributors of the seeds, by which the better fruit trees were more widely propagated.

The advantage to the animals was the selective improvement of plants, which resulted in the production of more abundant and more nourishing fruits.

The present situation may be defined as a neatly balanced natural economy between the fruit-producing plants and the fruit-consuming and seed-distributing animals, largely Primates, as discussed in section 2, this chapter.

The fruits which the American Monkeys, according to Gundersen & Hastings, consume are Annonas, Sapodilla, and Brazil Nuts. For the Old World the fruits of the Mango, Banana, Litchi, Citrus fruits, and many others, are mentioned. (*See also* especially H. N. Ridley 1930.)

The relationship between fruits and Monkeys, which resembles commensalism, is found only in the warm parts of the world suitable for the growth of fruit-producing trees. In the treeless or less forested areas the Primates have largely reverted to life on the ground. The Macaques and the Baboons have not disappeared but have adapted themselves in a greater or lesser degree to a terrestrial existence, subsisting largely on roots, tubers, the pith of the *Aloe*, insects, ostrich eggs, and other small life and consumable parts of plants. In regions under cultivation, orchards are a special target of their raids.

The hypothetical picture which one could draw of the life of Man's simian-like ancestors would not greatly differ from that of the more terrestrial Macaques and Baboons. They, too, must have subsisted largely on all kinds of food, such as fruits, edible stems, tubers, roots, and leaves, as well as on animal products like eggs, slugs, insects, shells, crabs, lizards, and young birds. When an occasion offered itself, they hunted for larger animals. Some strains, like the Australopithecinae, finally became entirely carnivorous, which may have sealed their

doom. But in by far the greater area of the world populated by the primate material from which Mankind was gradually formed, the supply of meat was insufficient to permit, or to enforce, a strictly carnivorous habit. Hence the ancestors of Man had to draw on all available food supply, most of it grown on plants.

The gathering of fruits and other plant products, by and large, appears to have been the principal and older preoccupation of the Protohumans, as it is still by far the principal source of sustenance of the now living Primates. While this limited the origin of Mankind to the tropical and subtropical parts of the globe, within which the transition of the strictly simian-like forms into more definitely human types must have taken place, it proved to be no insurmountable obstacle. A primate type invading a country beyond the heavy jungle, with variety of landscape and products, would, by necessity, as easily become a strict biped and manipulator of objects under visual guidance as did the savanna-inhabiting animal-hunting, carnivorous *Australopithecus*.

The gathering of fruits from low trees and bushes is just as easy and is carried out with as little bodily strain in an upright bipedal posture by a manipulating terrestrial biped, as by a more or less arboreal Primate from the branches of tall trees. But the great advantage of bipedalism was the emancipation from the heavy jungle and the acquisition of means of covering large territories of open landscape in swift marches—hence the ability to draw on a much more abundant food supply.

Through bipedalism, Man's Ancestors acquired the ability to move about quickly, to utilize all kinds of products of plant life, while they also did not neglect those animal products which were easily acquired. The varieties of fruits and other plant products required constant use of the senses, particularly visual acuity, pattern vision, and color sense, and a harmonious development of the other senses and manual skills, which in the long run were a potent stimulus for the development of the intellect.

The use of some tools and weapons must have begun very early in human evolution. Together with the discriminating judgment of their use and the habit of working in social teams, it compensated for the lack of formidable dentition and superior physical power, assuring Man's survival in competition with other animals and the rest of nature. The development of articulate speech as a superior means of intellectual communication and exchange of ideas, wholly outside the domain of locomotion and manipulation, finally cemented other faculties into a solid basis upon which Man's supremacy was established.

Many more factors than those discussed here have contributed to the transformation of one or of several Infrahuman Primates into human beings. What these factors were and how they have, in a complex interplay, influenced Human Ancestors was ably presented by Charles R. Darwin in his classical books *The Origin of Species* and *The Descent of Man* under various titles such as the "struggle for existence," "natural selection," "the survival of the fittest," and "sexual selection." Many other factors in this great drama of anthropogenesis, however, still remain unknown.

6. The adaptability of Man, the prime cause of his wide distribution over the globe.—The changes in physical organization and mental makeup which transformed one or several Infrahuman Primates into Men had far-reaching consequences. They had enormously increased Man's ability to adapt himself to all climates, from the steaming tropical jungles and the dry, scorching deserts to the polar regions of eternal ice and snow. The advantage Man reaped from his adaptability in his "struggle for existence" over his primate rivals and other animals and over the many adversities of nature are demonstrated by his success.

The foremost advantage appears to be Man's adaptability to various climatic conditions and varieties of food. This advantage was primarily the consequence of Man's upright bipedal gait and of the emancipation of his arms and hands from locomotion and their exclusive use as the instruments of the mind. By this means civilization was created, that is, a better use of natural resources. This transformation made it possible for Man's Ancestors to spread beyond the tropical jungle, over the extensive hills and prairies of the temperate climates.

"Man," as Elliot Smith says, "has been a wanderer ever since he came into existence." Hence Man, more than all other Primates, long before the dawn of history was able to draw upon more abundant food supply and other natural resources, a tremendous advantage in comparison with other Primates, whose choice of foods and shelter was limited.

In this process of anthropogenesis, or the rise of Man, the brain, increasing in its powers, was more a consequence than a cause. It was a mighty assistant, enabling Man to exploit his surroundings to a far greater degree, but it does not seem to have been the primary agent. Marvelously organized as the human brain is, it is no more so than other bodily organs which perform specific functions.

7. THE BIRTHPLACE OF MAN.—Where the race or races of Mankind originated is a vast problem which can be reasonably solved only by long and diligent investigation. This is not the place to review, even sketchily, past efforts in this respect; therefore a few remarks may suffice.

Two of the Great Apes, the Gorilla and the Chimpanzee, Man's closest living relatives, inhabit Africa. Hence, with some reserve, Darwin's choice fell upon that continent. This view, because of the abundance of fossil australopithecine and Miocene pongid material, is also shared by Le Gros Clark, Dart, and Leakey (*see* preceding section). In this quite interesting and important problem, it will, however, be wise to postpone final judgment until more information is gathered about the past geological ages and more regions of the world are explored. Too little, unfortunately, is at present known to allow an apodictic statement.

The presence of the Orangutan and Gibbon in Malaya and on the neighboring islands, Dubois's discovery of *Pithecanthropus* in Java, the finds in Europe, India, and China, all indicate the spread of the Anthropomorphous Apes and early Hominidae over very extensive areas of the Old World. The discovery of the Taungs Ape-Man or *Australopithecus* again shows the great adaptability of the Primates to seemingly less favorable climatic conditions, such as South Africa, far away from abundant rainfall, great forests, and fruit-growing regions. The wide distribution of the Monkeys in Africa, Asia, and Europe, some in conditions little resembling the primeval jungles, as in North and South Africa, in the Himalayan Mountains, in China, and Japan, supports the same view.

"In the late Miocene of Europe and Africa and the Pliocene of Europe and southern Asia there are a considerable number of specimens seemingly representative of the higher anthropoids but for the most part of somewhat smaller size than the living chimpanzee and gorilla," according to A. S. Romer (1945). "These creatures were certainly anthropoid apes and not men . . . their characters, as far as known, would permit of their being ancestral to the chimpanzee and gorilla, and very probably they are close to the human line as well," according to the same author. The information available at present indicates a distribution of Primates over wide regions of the Old World, from whom Man's race or races had originated in a variety of places during the last 5 to 10 million years or earlier.

The immense territorial spread of the potential Human Ancestors and the actual early human remains, encompassing almost the entire Old World except Australia, ranging from North China and Borneo in the east, along the Himalaya Mountains to as far west as Spain, and to South Africa, is itself a demonstration of the great adaptability of the primate stock to diverse climatic and ecological conditions. But while the Great Apes and many Monkeys were more or less tied to the tropical zone, the ancestors of Man were very much more adaptable, which permitted them to spread, long before historic times, over vast parts of the globe.

This extensive territorial spread of the potential and actual Human Ancestors makes it more difficult to focus on any particular region as the true birthplace of Man. Moreover, it is highly probable that even those Primates directly in the line of human ancestry, during various succeeding phases of the evolution, did not remain at the same place but migrated over extensive territories, as their swift bipedal locomotion and omnivorous habits, in part at least, would demand and make possible.

This assumption, however, must be qualified by the fact of the presence of strongly differen-

tiated races, such as the Caucasians, Negroes, Mongolians, Malayans, Australian aborigines, central African pygmies, and others. This strictly premodern localization, indicative of local racial formation, supports rather strongly the theory of polyphyletic or multiple human origins. The interbreeding of sharply differentiated races, in view of such strongly pronounced racial characters, would seem not to be decisive evidence against this view but rather indicates the common origin of all Mankind from the same basic primate stock sometime in the distant past, the stock which still remains to be more precisely determined. (*Cf.* Gates 1948.)

EPILOGUE

Retrospect on the Role of Vision and Other Factors in the Origin of Man Together with a Speculation on the Future of Mankind

In the first part of this book we presented the investigations of the past by which the structure of the vertebrate eye and of the visual pathways and centers of the brain, that is, the material basis of vision, was disclosed. In the second and third parts the gross and minute structures were described which make up the visual system, together with their blood supply, and the principal defects that vision suffers in variously localized lesions in pathological processes. The fourth part of this book dealt with the problem of the origin of the vertebrate eye and the visual system, their varying organization depending on the mode of life of a particular animal species and on the role vision played in the origin of Man. In this terminal section we will try to summarize the factors, especially vision, whose complex interplay resulted in the rise of Man from an Infrahuman Primate, show how the same factors have molded the physical and mental character of Man, and tell what may reasonably be expected in the future.

Man, being a Primate, has naturally the same phylogenetical origin as other Primates, which is similar to that of other Vertebrates and, in a general way, to that of all other animals. The vertebrate origin has its roots in the dim past of the early period of organic life on this planet.

What the animal forms were which eventually became transformed into Vertebrates remains unknown. As far as it is possible to judge from the past record, illustrated by the early embryonic stages, the eye appears among the very first organs. It is the first and the largest part of the external cover, around which the young and as yet almost wholly undifferentiated neuroblastic cells gather and from which the nervous system, including the brain, develops.

The precociousness of the ontogenetic development of the eye may in turn be interpreted as an indication that the photosensitive animal substance and the photoreceptors represented the matrix from which the eye and the Vertebrates phylogenetically originated and that the principal agent responsible for their emergence was physical solar light. Other indications again favor the concept of light as an initiator of life on earth. It is upon light that all animals and plants alike, in the final analysis, depend for their origin and existence.

The manner and degree of dependence upon light in the animal world seem to be as many as there are animal forms. Even in the higher plants the utilization of light is not indiscriminate but is principally confined to the chlorophyll-containing leaves, although there are no specific photoreceptors here. A similar wholesale or undifferentiated utilization of light is found in numerous lowly organized animals. Here, however, various kinds of photoreceptor organs already appear where the light's action is concentrated or otherwise modified. This shows that the utilization of light by specific organs was and is the characteristic feature of all animal organization.

From the embryological evidence it may be assumed that at some time the Vertebrate Ancestors not only were sensitive to light but were able to concentrate and further to develop this photosensitiveness in special organs. These "optic primordia" in the very early period of vertebrate evolution became dominant organs, capable of acting as "organizers" of the cephalic end of the animal body. Possibly, they were

principally responsible for, or were the initiators of, the bisymmetric organization of the vertebrate body along the vertical sagittal plane, with differentiation of the "right" and "left" halves, whereas the segmental arrangement of the body may have been the preceding, original phase initiated by other and even more basic factors. Also, the "optic primordia" must be charged, at least in part, with the responsibility for differentiation of the "above" and "below," or "back" and "belly," an essential feature of all Vertebrates.

As the same embryological evidence shows, the orimental photoreceptor organs of the Vertebrate Ancestors must have given the impetus to the rise of a centralized nervous system, with all the consequences this implies for subsequent vertebrate evolution.

The Vertebrates, from as far back in the evolutionary past as it is possible to determine, were by choice the animals of light and sight. In virtue of this great affinity for light, they eventually developed true chamber eyes capable of producing images which permitted a more thorough utilization of light. Throughout their existence the Vertebrates remained faithful to their choice, the dependence on vision as their principal guide.

The highest forms of vertebrate life, the Birds and the Primates, are preponderantly guided by vision. A bird or a monkey with poor vision, not to speak of an absence of it, is un-

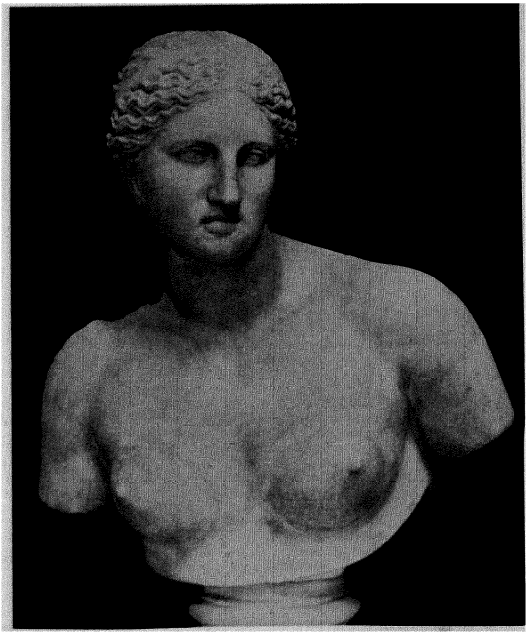

FIG. 541.—Classical marble sculpture, known as the "Aphrodite of Cnidos," the "foam-born" Goddess of Love and Beauty of Ancient Greece, identical with the Goddess Venus of the Romans. Representative of the feminine beauty and charm of the Caucasian Race. Undoubtedly, the Caucasian Race is a composite, consisting of numerous strains, as they became locally formed through relative isolation during past ages. But the type here represented is unquestionably a reproduction in marble of an actual living model, still found among the populations of southeastern Europe (Greeks, Serbs, Italians, perhaps French and Spaniards). It illustrates the final evolutionary product, in which the aesthetic visual sense, through the agency of sexual selection, has been the principal molding factor. Other branches of modern humanity, with different aesthetic concepts, have produced different types. By permission of the British Museum, London.

thinkable under natural conditions. The great dependence of Vertebrates upon vision is manifest, even though some and certainly many Mammals get along well with only a modicum of sight or none at all. How primate vision, under the influence of the arboreal habit, became perfected into a leading sense, was discussed in this and the preceding chapter. Many details of this absorbing story still remain obscure.

formance is reflected in the formidable increase of the human brain, in comparison with that of the Simians. This is most pronounced in the relative expansion of the "association regions," compared with the so-called "projection areae" of the cerebral cortex. These extensive regions, then, are the principal material substratum of Man's superior intellect. However, the increase and elaboration of the "projection areae" of the

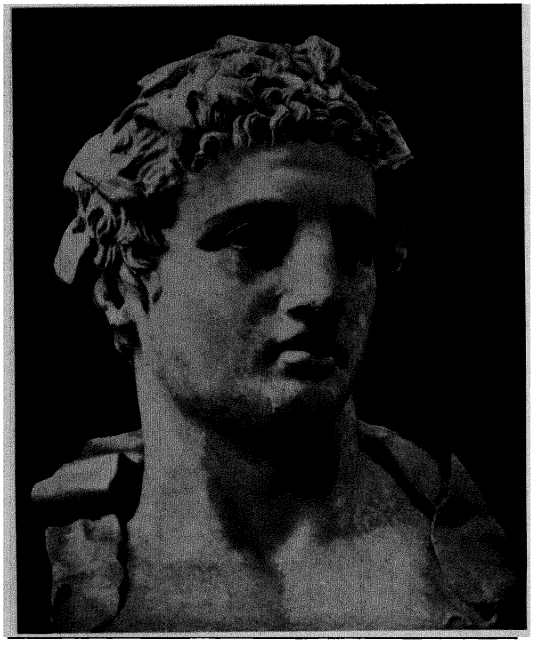

FIG. 542. Another classical marble statue, purporting to represent Heracles or Hercules, the mythological hero of Ancient Greece, who personified the manly strength and the adventurous spirit of youth. A realistic stone portrait of a living model, whose many representatives may still be found among the present population of Europe, especially in the territory of the ancient Roman Empire. It represents one of several types which incorporate the aesthetical concept of masculine beauty and strength of the Caucasian Race. It is the end-result of a long evolutionary process in which the aesthetic visual sense, besides the struggle for existence, has been the principal responsible factor. By permission of the British Museum, London.

Whatever the precise biological motivation of Man's emergence is, unbiased evidence points toward a common primate origin. Man's anatomical, physiological, mental, and emotional makeup springs from the same source as that of other Primates, even though it has immensely increased in scope and complexity. This development in psychomental and emotional per-

cortex and of other related parts of the brain also kept pace with the intellectualization of the human mind, as the very detailed cortical representation of parts of the extremities, such as the hands, fingers, tongue, and lips used in skilled acts and in speech shows.

Perhaps the greatest relative expansion and elaboration was achieved in parts of the brain

serving auditory sensorimotor and visual speech—the principal tools and, in fact, largely the embodiments of the human intellect. A detailed phylogenetical appraisal of the degree and pattern of the human cerebral machine must, however, be deferred until the functions of large areae of the cortex, as yet undisclosed, are identified and their minute structure, especially synaptical relationships, become known and understood.

direction and under the immediate control of vision. This strict control of manipulations by sight, or "supervision," is even more apparent during the process of learning, where every minute manipulative act is guided and tested by sight, before it becomes semiautomatic or entirely automatic.

The functional influencing of the manipulative sensorimotor acts through vision, however, works also in the opposite direction, vision itself

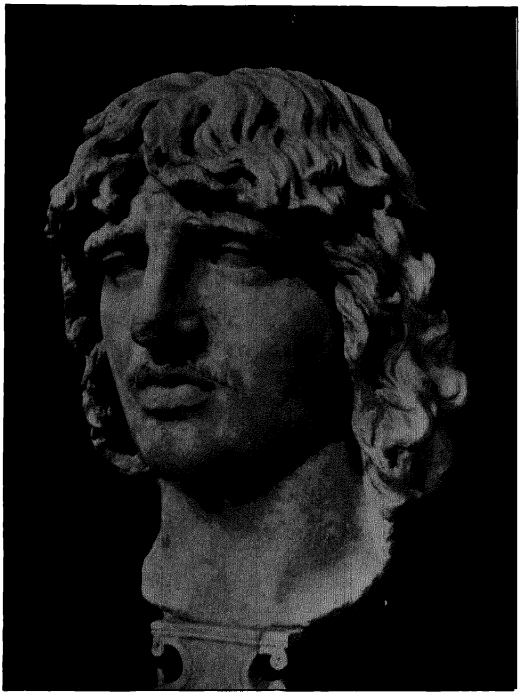

FIG. 543. Head of a Gaul, a classical marble portrait representing another variant in the manhood of the Caucasian Race. Same or similar type may frequently be found among the population of modern France and adjacent countries, in spite of the one hundred and more generations that have meanwhile come and gone since this realistic sculpture was made. By permission of the British Museum, London.

Man's superiority is principally based upon his upright gait and the emancipation of his arms and hands from locomotion. This made the upper extremities the exclusive mechanical instruments in the service of mind. The arms and hands became tools of the human "intellect" and "will," working closely under their

becoming more refined and the intellectual absorption and mental utilization more complete and lasting, as the skilled movements become more complex and more efficient. In what way, exactly, this manifest reciprocity was phylogenetically acquired and is individually achieved and what detailed anatomical, histological, a n

biochemical factors work together in this interplay may only be guessed, their disclosure remaining a future problem.

The human mind has the same phylogenetical roots and anatomical and physiological foundations as has the intellectual activity of the Infrahuman Primates. These roots and foundations are not greatly different from those of other Vertebrates and, in a more general sense, are the same as of all other animals. Hence the human mind must be organized upon essentially the same pattern as the mind of other animals, especially the Primates.

The principal foundation of the human mind, like that of other Primates, is vision, the others being audition and senso-motility. But more than in other Primates and other animals, the human mind developed to a degree where it became overwhelming, all-embracing. In human life the mind has a far more dominant role than has the mental factor in the life of any other animal, not excluding the most advanced. Yet the component elements are similar in all. The difference seems to be not in the essentials but only in the relative proportions and arrangement of the components, in the subtleties and complexities which may be defined as "integration," or ability to combine various experiences into more complex ideational formulas and kinetic melodies, and to store these in greater volume in memory, to re-create them in the same form or in new combinations, and to use

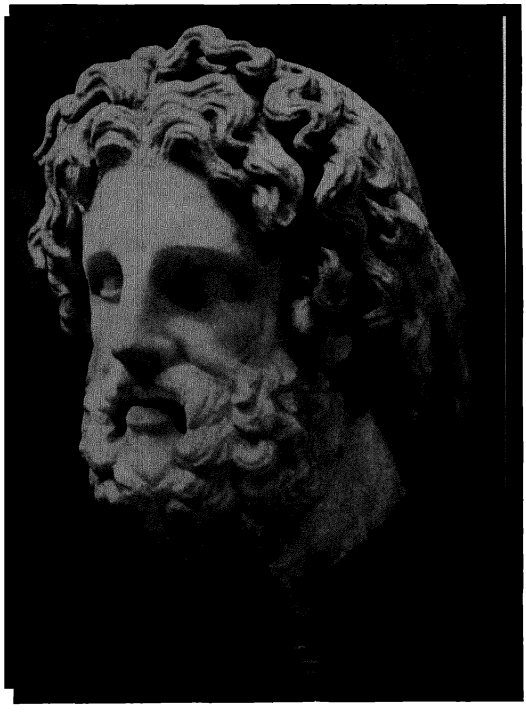

FIG. 544.—Asclepios, god of healing of the Ancient Greeks, equivalent of the Roman god Aesculapius. Another realistic portrait from the Classical Period, representing a fully mature masculine type of the Caucasian Race. Numerous representatives of this type may easily be seen among the present populations of central and northern Europe. By permission of the British Museum, London.

them either automatically or at will. Only in this restricted sense does the human species justify its scientific name *Homo sapiens* or "Wise" or "Prudent" Man.

What use Mankind has made in the past of its superior intellectual powers, how it behaved during history and behaves now, and what its past and present achievements, positive and negative, were and are, are recorded or stored in countless libraries, museums, and innumerable other places all over the face of the earth and can be seen everywhere.

What Man's conduct and accomplishments were during the much longer prehistoric times is but imperfectly disclosed through the study of less perishable products of his handiwork, such as stone implements and weapons, and from observations of primitive contemporary races. It would be futile to make even an attempt to summarize the contents of past human activity, because this has been done many times since Herodotus wrote his *History*.

Human achievements were possible, in the final analysis, because of the superb ability of Man's senses, especially vision, to observe objects and events and to store in mind the multitude of sensory impressions, to understand the meaning of these impressions, to integrate them in a logical way with one another, to communicate thoughts through articulate speech to other fellow-humans, to make intelligent plans for future conduct, and to put these plans into action through the use of the body and limbs, principally the hands and arms, largely under the control of vision.

Man's superior intelligence and logical thinking developed from modest beginnings during untold ages under the stimulus of upright posture and emancipation of arms and hands from locomotion, which, under visual guidance, became most versatile limbs devoted entirely to the service of the mind. This enabled Man to fashion every kind of tool and weapon, by means of which he became the master and exploiter of much of animate and inanimate nature. Man's intelligence thus became his most potent instrument in his struggle for existence.

In all his magnificence and with all his faults, Man is part and parcel of nature. Not a hair grows on his body, not a breath can he take, if all necessary conditions are not fulfilled. There is nothing supranatural in the origin and life of Man, as he persistently wishes to imagine. Man is very far from standing "alone in the universe," as declared by G. G. Simpson (1953) but is as much an integral part of the nature which molded him as is a Sparrow on the fence, a Rabbit in the bush, or a Dandelion on the lawn. He is the result of the interplay of incalculably complex forces and factors which we have been able to uncover in only the smallest degree. Neither are these forces and factors, except in dimensions and complexity, very different from those which have created a Shark, a Lizard, or a Dog, all of whom Man resembles during his phylogenetical and ontogenetical development. Nor is Man's rise to the pinnacle of the animal realm in the least due to his own merit, earned and deserved because of his own effort, but the result of fortunate circumstances which created him and which eventually will dispose of him.

Whether Mankind, in spite of its immensely advanced intellectual powers and accumulated knowledge, is conscious of its true place in nature and is capable of adjusting its individual and collective behavior accordingly is doubtful. Hence it is logical to find it unable to solve its long-range problems as intelligently as it is capable of attending to its immediate affairs. It is therefore probable that Mankind will continue as heretofore to stumble along the unknown path of destiny, driven by a primeval urge of blind biological instincts until the termination of its natural cycle, in the same way as did the mighty Dinosaurs and the giant Sequoias.

What the immediate future of humanity will be is more of a subject for legitimate speculation. Man's character, molded in the severe struggle of the past, is physically, intellectually, and emotionally so firmly intrenched in its grooves that no radical change is to be expected in his conduct in the foreseeable future.

At times Mankind may, therefore, continue along the road of intellectual and material progress. Human ingenuity will continue to invent new machines, gadgets, weapons, and processes which will make life even more pleasant and certainly more complex and dangerous. But such basic features of human character, as the eternal striving for knowledge, truth, and justice, contrasting with ignorant reliance on

irrational dogmas and mystic formulas; patient tolerance and passionate fanaticism; the lavish generosity and compassion and the greedy covetousness and envy; the tender love and the implacable hatred and violence, besides the primary physiobiologic urges of stilling the hunger and satisfying the instinct of procreation, will hardly be altered in any substantial way as the motives upon which human society is built.

astating destructiveness of Dart's "precocious *enfant terrible*" of the world merely increased their complexity and importance but did not essentially alter the relative influence of the two opposing motive forces. As in the past, what human hands create, other human hands destroy!

"Naked of body, delicate of skin, tender in both hand and foot, unfurnished with fangs or

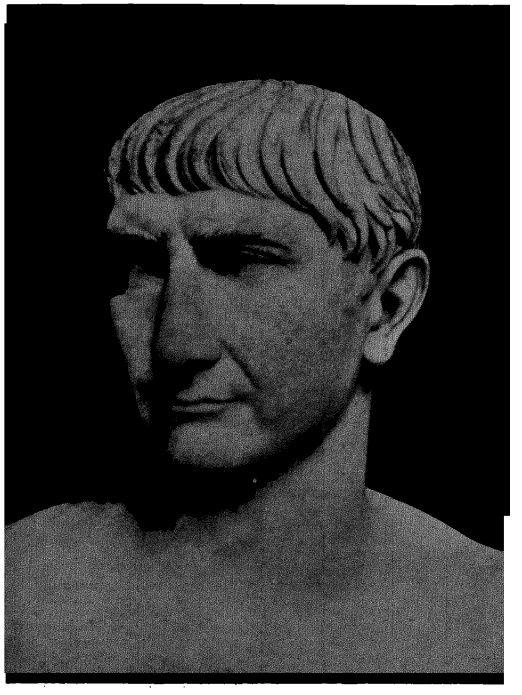

FIG. 545.—Marble bust of Marcus Ulpius Trajanus or Trajan (A.D. 52 or 53–117), one of the most energetic and successful Roman Emperors, representative of a forceful, determined masculine type of the Caucasian Race. By permission of the British Museum, London.

Mankind, as far as known in the past and up to the present, has exhibited two faces, one godly, the other beastly. In one hand it carries the torch of enlightenment and benevolence, in the other the sword of death and destruction. The two principles, inherited from long before the times of Australopithecs, Neanderthalians, and Cro-Magnons, are seemingly inseparably united. The intellectual advancement and dev-

claws, man," in Dart's words, "subsists not by physical strength and muscular force, but by intellectual stealth and cunningly applied manual violence."

Mankind during an incalculably long and complex evolutionary process rose from the primeval ooze through an incessant struggle for survival, principally through the instrumentality of vision and light, to the life of self-con-

sciousness and the realization of the world. Whether it will ever attain the status which would justify its name "Wise Man," given to it by Linné, is beyond our knowledge to foretell. To paraphrase Aristotle's words quoted in the Introduction—to foresee the fate of Mankind certainly is one of the most difficult things in the world!

Turning to the practical side of human affairs, vision, just like life, is a heavenly gift bestowed upon Man for whatever use he is capable of putting it to. With it we are able to see and appreciate and understand countless objects necessary in our daily life and make use of them in many practical ways.

But vision has also higher, spiritual attributes capable of elevating human beings above the level of mere brutes struggling for existence. Vision makes us see and appreciate the smile on a friendly face, enjoy the endless beauties of nature, the multicolored flowers, birds, and fruits, the green meadows and somber deserts, the glorious sunrise and sunset, the majesty of the tall mountains and the sweeping horizon of the ocean, the magnificence of an Alhambra and of a Taj Mahal, and all other things which make our visible world.

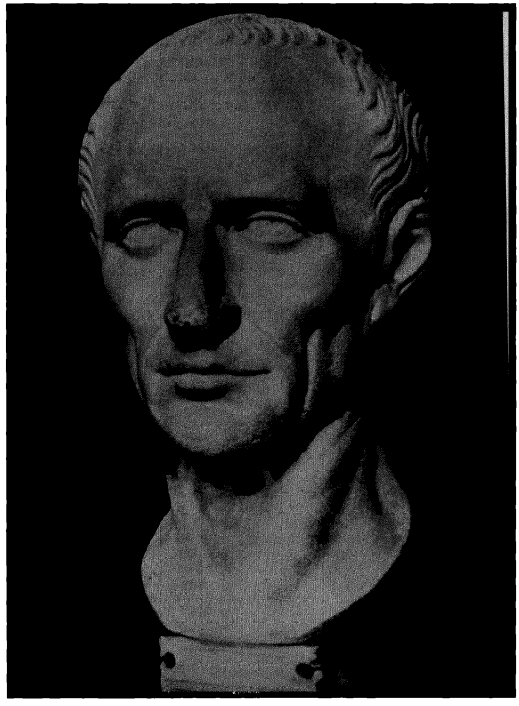

FIG. 546.—Gaius Julius Caesar (100–44 B.C.), famous general and statesman of Ancient Rome. Conqueror of Gaul and of Britain. First uncrowned ruler of the Roman Empire and prototype of the monarchical rulers during the succeeding twenty centuries. Author of the books *The Gallic War* and *The Civil War*. A realistic marble portrait representing the superior intellectual masculine type of the Caucasian Race, of which many representatives may be found among the modern nations of Europe and in America. By permission of the British Museum, London.

Through sight we judge our fellow-men and are principally guided in the choice of our friends and sexual mates. Through sight we ap-

preciate the innumerable works of art and, in civilized societies, receive and preserve most of our knowledge.

The gateway of vision to the human mind is wide open, the avenue that leads to it is smooth and broad. Man's opportunity given to him by nature is great.

investigators of, 799
types of, and their use, *798*

Eye socket, contents of, blood supply of, 597

Eyeball
blood supply of, 597, Fig. 365
summary of, 623
dimensions of, *209*
dioptrical landmarks of, *209*
topographical relationships of, *442*
tunics of, vertical section through, Fig. 127

Eyeglasses
concave, earliest mention of, 31
earliest mention of, 29
earliest picture of, 31
fitting of, in seventeenth century, Fig. 25
invention of, *28*
in seventeenth century, Figs. 25, 26
in sixteenth century, Figs. 24, 37

Eyesight; *see* Diurnality; Nocturnality; Vision; etc.

Fabricius ab Aquapendente, 23, 95, Fig. 21

Facilitation or inhibition mechanism, *579*

Falcon, and Swallow, visual apparatus of, 853

Falconiform Order, rise of, 936

Fallopius, 97

Falx of cerebrum, 391

Feline Dourioucouli, 281

Fernel, 90

Ferrier, David, 683, Fig. 97
experiments on localization of vision by, 147
significance of, *149*

Fetus
blood supply in, 615–17
development of eye and brain in, Figs. 434–35
retinal elements in, Fig. 143

Fiber systems
of brain
discovery of, *133*
Gratiolet's investigations of, *135*
of striate area, 507–10
S. Ramón y Cajal on, *518*

Fibers
afferent, in striate area, variety of, 533
association, and stripe of Gennari, 521
of striate area
centrifugal, 518
centripetal, 518

Fibrillar baskets in retina, 257

Fibrous astrocytes in retina, 258

Field 17 of Brodmann, 390, 404, 414; *see also* Striate area

Field 18 of Brodmann, 397

Field 19 of Brodmann, 397

Field defects
in achromatopia, 666
in amblyopia, 666
crescentic, interpretation of, 668–80
hemianopic, asymmetry and incongruity in, 679
interpretation of, 668–80
minute, theoretical importance of, 671

Field plotting, 646

Field rests
central, cerebral symptoms accompanying, 675
and color vision, 674, 676
hemianopic, *674*
central, interpretation of, 674
homonymous, causes of, 675
peripheral, interpretation of, 674
types of, 674
interpretation of, 668–80
pathologic basis of, 675
and visual acuity, 674, 676

Fields of view
and landmarks of, Fig. 381
testing and interpretation of, in central sparing, *687*
topographic representation of, in visual pathways and centers, Fig. 259

Finches, visual behavior of, 947

Fingerman, 801

Fire, first making of, 1036

Fish; *see also* Pike; Silverside; Sunfish; etc.
central area of, 282
central fovea of, *284*
chiasma of optic nerves in, 310, 323
diurnal, 971
earliest, appearance of, 768
early, photoreceptors of, in evolutionary progress, 954
eye of, 768, 958
monocular fields in, 787
nocturnal, 971
optic chiasma in, 158
optic nerves in, decussation of, 779, 780
retina of, visual violet in, 222
retinal projection in, 353
visual acuity in, 816

Fissure, calcarine; *see* Calcarine fissure
simian, 465

Fixation points, foveal cortex and, 432

Fixation techniques, early, 132

Flat-top bipolars, synaptical relationship of
with garland ganglion, 239
with shrub ganglion, 239
with umbrella ganglion, 239

Flatworms, vesicular eyes of, 786

Flechsig, Paul Emil, 155, 662, 683, Fig. 114
association area of, *174*, 470, 484
on course of visual radiation, 178
discovery of myelogenesis by, 172
discovery of origin of visual radiation by, *177*
fundamental law of myelogenesis of, 173
role of, in advancement of knowledge, 178
sensory and association areas of, Fig. 115
study of fiber tracts by, *173*
temporal loop of, discovery of, 178
visual radiation studies of, 405

Flemming, 543

Flicker, dissected head of, Fig. 471

Flourens, Marie Jean Pierre, 543, Fig. 85
brain experiments of, *126*, *127*
and cerebral functional omnivalence, *129*
and role of cerebral cortex in vision, *129*

Flycatcher, visual behavior of, 947

Flying ability, development of, 937

Foerster, O., 687
experiments on visual system by, 200

Förster, R., 164, 633, 646, 680, 685, 694, Fig. 104
case of, testing Munk's theory of "cortical blindness," 183
invention of perimeter by, 153, 163

Foix, 607

Fontana, Felix, 541
and functional organization of brain, 126
observation of retina by, 45
on structure of retina, 279

Foramen
central retinal, of Soemmerring, 279
of Monroe, 398
Forbes & Richardson, 805
Forebrain, Ibn al-Haitham on, 85
Forel, 154
commissure of, 303
and neuron theory, 65
Form perception in achromatopia, 665
Fornicate sulcus; *see* Cingular sulcus
Fovea,
in Birds, 233
blood vessels of, 599
central; *see also* Central fovea
inner layers of, *272*
radial fibers in, 257
cone system in, 252
pure, 254
diameter of, 264
neurons in, synaptical relationships of, 285
outer, 272
pseudo-, 688
representation in brain of, 339
simian, 233
terminology of, clarification of, 266
Foveal cortex
collateral circulation in, 616
and fixation points, 432
Foveal depression, functional significance of, *275*
Foveal-macular fibers, intraretinal decussation of, hypothesis on, *680*
Foveal photoreceptors, and brain, bilateral connections between, hypothesis of, *682*, 689
Foveal reflex, 264
Foveal representation in cortex, bilateral, hypothesis of, *683*
Foveola, *262*, 272
terminology of, clarification of, 266
Foville & Pinel-Grandchamp, and functional cerebral localization, 143
Foxes, Flying
retinal blood supply in, 601
striate area of, shape, extent, and location of, Fig. 309
Franke, Balado &, experiments on visual system by, 192
Franz, V., 788, 799
on neuroglial cells, 258
Frauenlob, Heinrich, earliest mention of reading glasses by, 29
Frequency modulation, in functioning of visual pathway, *575*
Frey, hypothalamic optic root of, 315
Friedemann, and pregeniculate gray nucleus, 192
Friedman, B., and blue arcs, 295
Frima, Bierens de Haan &, 970
Fritsch
and cerebral cortex, 451
on cone distribution in central fovea, 269
and discovery of somatomotor area, 143
Frog
Meadow or Leopard, head of, dissected to show brain and eyes, Fig. 461
retinal blood supply in, 601
Tree, retinal blood supply in, 601
Frontal lobe, anatomy of, 449
Froriep, 768
Fruits, samples of American Midwestern, Fig. 518A
Fuchs, W., 688
Fulton, Catchpole &, Tarsiers and, 909
Functional centers of human brain, Figs. 274, 275
Functional localization in human cerebral cortex, 451–58

Galagos; *see* Lemur
Galagos monteiri
retinal blood supply of, 601
survival of, 939
Galen, 11, 76, 789
anatomy and physiology of the visual system by, 77–78
and "animal spirit," *79*
description of nerves related to eye by, *77*
on function of brain, during post-Vesalian period, *96*
functional interpretation of optic nerves by, 80–81
on importance of brain, 80
influence on Arab and early Western science of, *77*
influence on Vesalius' views of, *96*
mistakes of, *82*
on optic chiasma, 109
physiology of visual system by, 78–80
compared with modern view, *82*
evaluation and critique of, 82–83
and "pneuma" or "spirit" as life's principle, *78*, *79*
on properties of "soul," 122
and "reasoning soul," 79
on retinal substance and brain, 41
Galileo, Galilei, Fig. 349
Gall, F. J., 117, 154, Figs. 83, 84
and cerebral cortex, 451
on cerebral functional localization, *122*, *123*
Gall & Spurzheim, 116
in early investigations of subcortical fiber systems, 132
and lateral geniculate nucleus, 115
Ganglion cell layer
of retina, *219*
of striate area, *506*, Fig. 314
minute structure of, *515*
Ganglion cells; *see also under* Garland; Giant; Midget; Parasol; Shrub; Small diffuse
of retina, 237–46
classification of, *237*
in cone system of neurons, 583, 585
after cutting or destroying optic nerve, tract, or nucleus, 292
degeneration of, 292
diffuse, synapses of, Fig. 177
discovery of, *47*
displaced, 292; *see also* Dogiel's cells
excitation of
course of, 587
quality of, 586
in function of cone system, 252
in function of rod system, 252
investigation of, history of, *242*
and retinal impulses, Figs. 178, 179
in retinal response, 255
in rod system of neurons, 582
synapses of
with brush and flat-top bipolars, *231*
with midget bipolars, 236
with mop bipolars, *230*
in striate area, 527
Ganser, 154
commissure of, 303
Garland ganglion, *239*
Gastropods, eyes of, 786
Gaul, head of a, Fig. 542
Gautrand, Monbrun &, 183
Genderen Stort, 571
Geniculo-calcarine tract; *see* Visual radiation
Gennari
in early investigation of cerebral cortex, 132
hardening technique of, 132
stripe of, 300, 394, 398, 414, 415, Fig. 86
and association fibers, 521
formation of, 520
identification of, 518
and striate cortex, 497
Geometrical axis of eyeball, 209
Gerard of Cremona, 22
Gerlach, 60, 541, 542
contribution to histology by, 170
introduction of carmine stain by, 61
on organization of nervous system, 63, 541
Germans, lunate sulcus in brains of, 474
Giambattista della Porta, Fig. 27
and early modern dioptrics, 35
Giant cells of striate area, 505, 506
Giant ganglions of retina, *239*
Gibbon
character and habits of, in captivity, *1004*
intelligence of, 987
in phylogenesis of cortical visual centers, 470
posture of, and evolution, 1029
use of hands and feet by, Fig. 531
various views of, Figs. 528, 529, 530, 531
vocalization of, 1006
White-handed, fundus of eye of, Fig. 167
Gifford, B. L., 335
Giovanardi
on brain in congenital anophthalmia, Fig. 108

Giovanardi—*Continued*
and occipital localisation of visual center, 165
Girardi, and medial geniculate nucleus, 115
Glassfish; *see* Silverside
Glaucoma, scotomas in, 638, 639
Glees, 558
Glees & Clark, on lateral geniculate nucleus, 369
Glioblastoma of brain
complete homonymous hemianopia from, case report, 698–702, Figs. 403, 404, 405
incomplete homonymous hemianopia from, case report of, 702–7, Figs. 406, 407, 408
quadrantic homonymous hemianopia from, case report of, 707–10, Figs. 409, 410
Gnosis, musical, and functional cerebral localization, 458, Fig. 275
Goat, striate and peristriate area of, shape, extent, and location of, Fig. 309
Goatsuckers, visual behavior of, 952
Godding, visual purple and, 222
Goldstein, 646
Golgi, Camillo G., 541, Fig. 344
contribution to histology by, 171
introduction of new histoanalytical method by, 61
Golgi cells
type I, 523
type II, 523
Golgi method
discovery of, influence on advances in knowledge of, *62*
introduction of, 61
staining method of
in identifying neuroglial cells of striate area, 536
in striate area, 510
Golgi technique in study of striate area, 523
Goltz
and cortical equivalence doctrine, *149*
experiments on cerebral function by, 149
Munk's critique of, *149*
Goodeve & Lythgoe, and visual purple absorption curve, 223
Gophers, visual behavior of, 948
Gordon
and lateral geniculate nucleus, 115
and pulvinar of thalamus, 115
Gordon, Bernhard, and reading glasses, 29
Gorilla
arterial supply of occipital operculum in, 616
"Bushman," 1018, 1020
portrait and attitudes of, Fig. 538
character, habitat, and behavior of, *997*
character and habits of, in captivity, *1014*
cortical visual center in, 478
eye of, dimensions of, 209
Mountain, habitat and habits of, 999
in phylogenesis of cortical visual centers, 470
sanctuary for, 1002
striate areae in, topographical relationships of, Fig. 286
use of hands and feet by, Figs. 539, 540
various views of, Figs. 536, 537, 538, 539, 540
Graefe, Albrecht von, Fig. 103
first interpretation of homonymous hemianopia by, 156
introduction of plotting of visual fields by, 153, 163, 633
Granit, Ragnar Arthur, Fig. 360
on role of visual purple, 223
Granular cell(s)
compared with solitary cell of Meynert, Fig. 337
of striate area, 513, 527, Fig. 339
Granular clods of Dogiel, 234
Granular layer of striate area
inner
inner lamina of, 506
lesion in, lateral geniculate nucleus and, 533
middle lamina of, *504*
minute structure of, *512*
outer lamina of, *503*
outer, *502*, Fig. 314
minute structure of, *511*
Granular lines of Ramón y Cajal
Granules, inner, in striate area, 513
Grassus, Benevenutus, 43
Gratiolet, Louis-Pierre, 154, 470, Fig. 92
discovery of visual radiation by, *135*, 147
dissection of visual pathway by, Fig. 93
external or perpendicular fissure of, 465
investigation of fiber systems of brain by, *135*, 147
and visual radiation termination, 165
Gratiolet's radiation; *see* Visual radiation
Gray Shrew, 866
Gray or white, sensations of, rods and, 578
Great Northern Pike; *see* Pike
Greek anatomy of brain and visual system, *74*
Greek catoptrics, *13*
Greek dioptrics, *13*
Greeks
early, and anatomy of eye, 9
"emanation hypothesis of," end of, 100
late, and anatomy of eye, 10
pneuma hypothesis of, *78*
Gregory, W. K., 768
Gregory & Raven, 1001
Grether, 987
Ground Hog, visual behavior of, 948
Grünbaum, 605
Gudden, Bernhard von, 154, Fig. 105
commissure of, 303
on lateral geniculate nucleus, 368
transverse peduncular tract of, 303, 310, 317
Guenther, K., 973
Guinea Pig
chiasma of optic nerves in, 323
and color vision, 886
optic chiasma structure in, Fig. 188
visual behavior of, 948
visual system of, *318*
Gull and Swallow, visual apparatus of, 853
Gunderson & Hastings, 1043
Gustatory center, location of, 174
Gymnura, 873
Tree Shrew and, 892
Gymnurinae, 962
Malayan, 936, 939
Gyrus(i)
angular, localization of visual center in, *147*
annectent, 470
cortical, in fetus, Fig. 270
cuneolingual, 462, Fig. 278
evolution of, 471
posterior
in evolutionary process, 480
in Man and Chimpanzee, 478
and sulcus(i) of brain, Fig. 271

Haab, on visual disturbance due to lesions of calcarine region of occipital lobes, Fig. 109
Haab & Huguenin, and occipital localization of visual center, 165
Haberlandt, 796
Haeckel, Ernst Heinrich, 765, Fig. 521
biogenetical law of, 173
monerans of, 569
Hagfish, eye of, 768
Haller, A., 38, 112, 118, 771, Fig. 80
arterial circle of, 598
on cerebral function, *119*, *121*
on cerebral functional localization, 122
and functional organization of brain, 126
on "seat of soul," 118
Haller, B., 542
Hamberger, 37
Hamilton, on Shrew, 867
Hand-clasp synapse of Herrick, 236
Hands, grasping ability of, in primate evolution, 938
Hannover, 51, 680
contribution to histology by, 49, 170
in early investigation of cerebral cortex, 132
and tissue fixation, 541
Hannover & Obersteiner, ansate commissure of, 303
Hansemann, 475
Hanström, 801
Hardesty on neuroglial cells, 258
Harpman, 558
Hastings, Gunderson &, 1043

Hawk
fields of view of, 787
Red-tailed, visual behavior of, 950
Sparrow, visual behavior of, 950
and Swallow, visual apparatus of, 853
vision of, 947
Hayashi, Polyak &, experiments on visual system by, 200
Head, X-ray of, showing topographic relationships of visual system, Fig. 269
Head and brain, blood supply of, sources of, Fig. 362
Hearing
role of, in Man's pre-eminence, 985
sense of, cerebral cortical center of, 453
Heart, as "seat of soul," 75
Hechst, experiments on visual system by, 192
Heck, L., 863, 991
Hedgehog, 873
ancient, head and skull of, Fig. 477
cortical visual center of, 469
European
cortical visual centers in, Fig. 309
striate area of, location and extent of, 490
vision of, in evolutionary progress, 961
Hegemonikón, 74
Heidenhain, 561
Heine, 683
decussating callosal bundle of, 428
on the extent of central sparing, 649
hypothesis of macular projection as advocated by, Fig. 401
Heinicke, Vater &, 156
first correct interpretation of homonymous hemianopia by, 114
Held, 542, 543
on neuroglial cells, 258
on peripheral nervous system, 544
Heliodóros
and light, 13
and theory of vision, 12
Helmholtz, Hermann Ludwig Ferdinand, 51, 792, Figs. 101, 356
brain of, 475
discovery of ophthalmoscope by, 152
on histologic structure of nervous tissue, 60
investigation of retinal structure by, 50
ophthalmoscope invented by, Fig. 102
Hemiachromatopia, 665–68
complications in, *666*
homonymous, bilateral, *667*
pathoanatomical basis of, *666*
pathophysiological deductions from, 667
quadrantic homonymous hemianopia with, case report of, 717–24, Figs. 413, 414, 415, 416
Hemiagnosia, visual, 666
Hemiamblyopia, 665
bilateral, *667*
central sparing as special form of, *685*
complications in, *666*
homonymous
crescentic hemianopia in, 676
right, with temporal crescent scotoma, Fig. 399
pathoanatomical basis of, *666*
Hemianopia(s)
absolute congruity in, 679
asymmetry and incongruity in, 679
bilateral incomplete, from cystic multiform glioblastoma, case report of, 707
binasal, due to lesions of optic chiasma, *639*
bitemporal, due to lesions of optic chiasma, *639*
central sparing in
Ferrier on, *148*
functional and anatomical factors underlying, 687–94
origin of concept of, *680*
recent speculations regarding, *688*
cerebral blood supply and central sparing in, *620*
crescentic, 676
left temporal, Fig. 398
optic chiasma in, 641
differential diagnostic tests in, 646
early modern investigation of, *156*
as evidence of partial crossing in the chiasma, 330
heteronymous, due to lesions of optic chiasma, 639
homonymous
basic types of, *646*
bilateral
with central sparing, 674
left complete, with right central sparing, Fig. 397
visual fields in, Fig. 392
wedge-shaped rests in, Fig 392
causes of, 643
central pseudo-sparing in, 688
central sparing in, 614, 673, 680–87
anatomical factors responsible for, *691*
attempted explanations of, Fig. 400
Ferrier on, *148*
without central sparing, case report of, *698*
combined left, visual fields in, Fig. 391
complete, 646, *647*
case report of, 698–702, Figs. 403, 404, 405
visual fields in, Fig. 385
complications in, *646*, *650*
definition of, 642
detection of, 646
earliest correct interpretation of, 114
first interpretation of, 156
general remarks on, *643*
incomplete, 646, *648*
case report of, 702–7, 747–50, Figs. 406, 407, 408
with central sparings, case report of, Fig. 428
progression of, 653
transformed into bilateral incomplete, Fig. 387
visual fields in, Fig. 386
due to lesions of optic tracts, 643
in migraine, vascular pathology of, 620
partial left-sided, visual fields in, Fig. 393
quadrantic, 654
anatomical basis of, 294, *655*
case report of, 707–10
due to cortical lesion along calcarine fissure, Fig. 112
expanding into bilateral incomplete, case report of, 707–10, Figs. 409, 410
with hemiachromatopia, case report of, 717–24, Figs. 413, 414, 415, 416
incomplete, case report of, 710–17, Figs. 411, 412
as symptom of brain damage, 655
theoretical interpretation of, *655*
with sparing of peripheral monocular crescent, 674
subjective experience in, 645
as symptom of organic brain damage, 653
types of, anatomical basis of, 647–54
horizontal or altitudinal, *664*
and mental blindness, case report of, 724–32, Figs. 417, 418, 419, 420, 421, 422
incomplete, bilateral
bitemporal, and complete binasal, Fig. 384
case report of, 707–10
from quadrantic homonymous, case report of, 707–10, Figs. 409, 410
scotoma in, 660
incongruous, 679
anatomic explanation of, 636
inferior horizontal or altitudinal
with central sparings, Fig. 395
visual fields in, Fig. 389
lateral; *see* Hemianopia, homonymous
nasal or binasal
and incomplete bitemporal, visual field in, Fig. 384
optic chiasma in, 640
unilateral, due to lesions of optic chiasma, *639*
and nerve fiber arrangement, 386
partial, and their anatomical basis, 654–65
quadrantic
and organization of visual radiation, 657
superior, interpretation of, 662
reorganization of vision in, 646
surplus, 648
temporal or bitemporal
optic chiasma in, 640
unilateral, due to lesions of optic chiasma, *639*

Hemianopia(s)—*Continued*

Tree Squirrel; *see* Squirrel

Trendelenburg, and visual purple absorption curve, 223

Treviranus
description of retina by, 47, 67
and lateral geniculate nucleus, 115
and microscopy of retina, 46
and partial decussation, 116
retinal structures observed by, Figs. 42, 43, 44

Triassic Period, 869, 893, 962

Trout, 825–30
behavior of, 827
characteristics of, *826*
eye of, *828*
fields of view of, 787
Northern Brook, Fig. 455
physiological considerations of, *829*
retina of, *828*
taxonomy of, 825
visual acuity in, 830
visual apparatus of, 827

Tsai, tegmental optic nucleus of, 318

Tschermak, 787

Tubular vision, after war injuries to striate area, 652

Türck, contribution to histology by, 170

Türck's fiber bundle, origin of, 457, Fig. 274

Tupaia, in primate phylum, 891, 892

Turtle, Painted
dissected head of, showing brain and eyes, Fig. 466
visual behavior of, *942*

Uexküll, 788

Uhthoff, 183
on macular bundle, 160

Umbrella ganglions of retina, *239*
character of, 370
synapses of, with bipolars, 239
terminations of, in lateral geniculate nucleus, *573*

Urogale, in early mammalian ancestry, 891

Urogale everetti, Fig. 485; *see also* Tree Shrew, Philippine
retinal blood supply of, 601

Usher & Dean, experiments on visual system by, 189

Uvea
blood supply of, 597
structure and function of, 210
veins of, 598

"Vacuoles" in retina, 224

Valsalva, 45
on structure of retina, 279

Valverda, 95
on optic chiasma, 199

Van der Horst, 801

Van Eyck, Jan, and eyeglasses, 31

Van Gehuchten, 541
on lateral geniculate nucleus, 365
and neuron theory, 65

Van Heuven, experiments on visual system by, 200

Van Soest, Conrad, and early pictures of eyeglasses, 31

Varoli (Varolius)
basal aspect of brain according to, Fig. 67
first adequate depiction of infranuclear visual pathways by, 98

Vascular cone of Lizards in retinal blood supply, 598

Vascular disturbances, scotomas from, 669

Vater & Heinicke, 156
first correct interpretation of homonymous hemianopia by, 114

Vein(s)
facial, common, 597
jugular, and venous blood from orbital contents, 597
macular, 598
nasal, 598
nasofrontal, and venous blood from orbital contents, 597
ophthalmic, 597
palatine, 597
retinal, central, course of, 598
temporal, 598

Venderovich, experiments on visual system by, 196

Ventricles, lateral, topography of, Figs. 231, 232, 233

Verrier, 799

Vertebrate Ancestors and utilization of light, *770*

Vertebrate life, general considerations of, *794*

Vertebrates, Inframmalian, retinal blood supply in, 598, 601

Vesalius, Andreas, 90, Figs. 15, 64
and anatomy and physiology of visual pathways, 92–96
base of brain according to, Fig. 65
eye diagrams by, 23, Figs. 16, 17
influence of Galen's views on, *96*
on optic chiasma, 109
reform in anatomy introduced by, *92*

Vesling, on optic chiasma, 109

Vicq-d'Azyr
in early investigation of cerebral cortex, 132
fiber layer of; *see* Granular layer
fixation and hardening technique of, 132
hippocampus minor of, 394
and lateral geniculate nucleus, 115
on optic nerve, 115
and pulvinar, 115
stripe of, 390, 394, 398, 414, 415, Fig. 36; *see also* Gennari, stripe of
identification of, 518

Vieussens, Raymond, 106, 116, 117, 394, Fig. 75
and "animal spirit" concept, 96, 122
and corona radiata, 133
and earliest intimation of visual radiation, 107
fixation and hardening technique of, 132
on optic nerve, 115
and "seat of soul," 118

Vintschgau, description of retinal layers by, 50

Vision; *see also* Visual function
anatomical substratum of, *540*
Arab interest in, 15
biological problems of, *3*
color, impairment of; *see* Achromatopia; Hemiachromatopia
dependence of Vertebrates on, *958*
disturbances of, 629–94; *see also* Visual fields, defects of
due to lesions in calcarine region of occipital lobes, first verified case of, Fig. 109
due to lesions of lateral geniculate nuclei, *644*
due to lesions of optic tracts, *643*
due to optic nerve pathology, 636–42
due to pathology of optic chiasma, 636–42
due to retinal pathology, 636–42
due to suprachiasmal pathology, 642–46
earliest anatomically verified clinical cases of, 163
dullness of; *see* Hemiamblyopia
duplexity theory of, 61
in economy of Vertebrates, *957*
epicritic, 645
chamber eye and, 786
evolutionary adaptations of, 959
fields of; *see* Visual fields
interest in, *1*
localization in cerebral cortex of, early attempts at, 147–49
occipital lobe localization of, history of, 149–52
and origin of Mammals, *959*
physiology of
Arab, 17
Greek, *11*
of Primates
character of, and origin of Primates, *963*
foundations of, *963*
origin of, *965*
problem of, *1*
protopathic, 645
role of
in evolution of Man, *1032*
in evolution of Primates, 873
in maintenance of animal life, 794–803
in Man's pre-eminence, *984*
in origin of Man, 957–1055, in origin of Primates, 957
sense of, and brain, 452
tubular, after war injuries to striate area, 652
vascular factors in, 594

Visual acuity, 278
in achromatopia, 665
central, in homonymous hemianopia, 680
cones in, 584
definition of, 967
diurnality and, *968*
of early Mammals, living habits and, *968*
midget ganglions in, 574, 587
role of, in evolutionary progress, 969
visual radiation and, 441

Visual adjustment, mechanism of, 288

Visual area, cortical, Munk's conclusions on retinotopical organization of, *152*

Visual behavior
of animals 941–56; *see also* under names of specific animals
twenty-four-hour variations in, *949*

Visual blue, 222

Visual cells, 220–28

Visual center(s)
accessory subcortical, discovery of, 192
blood supply of, general remarks on, 593–97
cortical, 446–539
of advanced Monkeys and Apes, *470*
anatomy of, gross, 460–66
definition of, *487*
evolution of, phylogenetic factors responsible for, *478*
first evidence of retinotopical organization of, *199*
gross anatomy of, 460–66
Henschen on location and functional organization of, 183
of infant
neurons from 4th layer of, Fig. 320
neurons from 5th and 6th layers of, Fig. 325
of modern Man, *474*
phylogeny of
1st stage in, 469
2d stage in, 469
3d stage in, 470
4th stage in, 470
5th stage in, 472
in prehistoric humans, *472*
racial characteristics in, 476
section through, showing stratification of nerve cells and fibers, Fig. 316
in stages of evolution of Primate Mammals, Fig. 279
location of, 174
occipital, historical establishment of, 168
organization of, hypothesis of "diffuse" or "plastic," 184–88
pathophysiology of, *629*
subcortical, 250
early modern search for, *154*
organization of, 290
retinal representation in, 334–53

Visual cortex
association fibers of, *495*
connection of, with other parts of brain, 434–42

Visual field(s)
disturbances of, case reports of, clinical and pathoanatomical, 695–759
and landmarks of, Fig. 381
plotting of, introduction of, 152
and relation to retinal surface, *629*
