THE VERTEBRATE VISUAL SYSTEM

Its origin, structure, and function and its manifestations in disease with an analysis of its role in the life of animals and in the origin of man

Preceded by a historical review of investigations of the eye, and of the visual pathways and centers of the brain

Foreword

"To achieve this, the lives of many gifted men, and infinite labor and patience were expended." Thus Dr. Polyak, on page 202 of the present book, recapitulates past efforts concerned with discovering "the principal features of the visual system, from the eye to the visual centers in the cerebral cortex. . . ." Almost thirty years of his own life were expended on work devoted to *The Vertebrate Visual System*—years of "almost continuous labor," to use his expression. But fortunately, unlike Kinnier Wilson's *Neurology*, Stephen Polyak's magnum opus was finally completed, although in a race with death. The present book, as the author modestly claims, ". . . treats the subject of vision chiefly as an anatomical problem." A glance at the Table of Contents, however, shows that this treatment rests on a very broad basis indeed and that the author's "desire to understand better the anatomical structures underlying vision, the way in which they work, and how they originated" has led him far beyond the confines of anatomical and histological problems into the pathology and biology of the vertebrate visual system and into long-continued researches dealing with the history of investigations in these fields. "For generations to come," Ragnar Granit recently wrote (Science, v. 122, p. 64, 1955) in an appraisal of Stephen Polyak's previous book, *The Retina*, "his work will be the leading source of reference for those interested in the way in which the retina collects and elaborates information for delivery to the higher centers." The present book, aside from embodying the results previously published in *The Retina* (1941) and in *The Main Afferent Fiber Systems of the Cerebral Cortex in Primates* (1932), represents an account—in fact, a rather condensed account—of the work to which Stephen Polyak devoted almost his entire scientific life and of the relevant findings on the visual system as reported by others in the world literature. There is little doubt that *The Vertebrate Visual System*, as a compendium of currently available knowledge in this field, will, for generations to come, be consulted by all investigators seeking information on the relations of vision to the retina, the visual pathways, and the subcortical and cortical visual centers, as well as by all students interested in the structure and function of the central nervous system in general.

It is evident from a study of this volume that the author, in analyzing problems of vision, starts from and always returns to anatomical structures and their interrelations. He took the occasion, again, to emphasize this chief concern with anatomical structures when he penned the Preface to this book in January, 1955. A few months later, on March 9, death terminated his activities, even the last day of his life having been spent in working on this book. It is of some interest in this connection that a century before his death in 1[illegible]

in 1897, still voiced the hope of explana
physiological phenomena on "an anatomical basis" but who, on meeting Apáthy in Naples before the turn of the century, soon insisted on

substituting "functional" for "anatomical" explanations, to become one of the most vehement opponents of the neuron theory, that is, taking a stand radically different from the one taken in the pages of this book. While it is true that we now live in an age abounding in "functional" and "dynamic" approaches, such approaches again and again appear to demand a return to "form" and "structure." Even in a field as modern as enzyme research, the final goal, as Hugo Theorell (Science, v. 124, p. 467, 1956) has recently pointed out, can be nothing but "the filling of the yawning gulf between biochemistry and morphology."

The fact that "structure" was of central importance to Stephen Polyak does not mean that "function" was foreign to his thinking. It merely means that he could not conceive of a "physiology without anatomy" or of, what Flourens in 1824 called, *une anatomie sans physiologie*. If it had not been for a period of ill health during the last ten years of his life, he would have enlarged this book to include chap-

ective" psychology.

Throughout the book, especially in the chapters dealing with the "principal theme," the author has made extensive use of data based on experimental work with monkeys and apes. Unfortunately, it was only a few months before his death that the scientific world also lost Wood Jones and Arthur Keith, two of the investigators widely known for their studies of the comparative anatomy of the Primates. As regards the central nervous system, Stephen Polyak's statement of 1932– "the brain of the lower primates is . . . in its essential features and in its finer structure a simplified replica of the human brain"– will still go unchallenged among neuroanatomists and neurophysiologists, and his strong emphasis on material from non-human Primates will probably be even more readily appreciated now than it was several decades ago. It is not surprising, however, that the author, who himself, both in this country and in Europe, was a clinician for many years, felt that, no matter how convincing the deductions from experiments on animals, "the true sense of the reality is obtained only by a study of patients suffering from disturbed vision." There is no doubt that the part of the book dealing with the pathology of the retina and of the visual pathways and centers will be as much welcomed by clinicians as by those who are interested in a better understanding of the fundamental mechanisms operative in the visual sector of the central nervous system.

It is not surprising, furthermore, that Stephen Polyak should have become so greatly interested in the history of the investigations in his chosen field of research. In fact, it appears that he was destined to develop strong interests in the historical aspects of his scientific endeavors. Born in Yugoslavia, that is, in a part of the world which for centuries was the frontier between the Mohammedan East and the Christian West of Europe, he became at an early age sensitized to phenomena in the historical realm; he acquired a wide knowledge of ancient and modern European languages, including the Slavic tongues; his scientific training and his work in the research centers of various countries never suppressed his joy of discovery in tracing the origins of our present-day knowledge and seeing how certain problems were finally solved and how others, still unsolved, provided suggestions and stimulus for the investigations of tomorrow. But more than anything else, it was his deeply felt desire to give full acknowledgment to the work of others and do justice to the men on whose shoulders we stand that motivated his occupation with

historical matters. As the result of his efforts, the historical part of this book has therefore turned into more than merely a history of investigations of the structure and function of the vertebrate visual system from the days of classical antiquity to the present day; it has turned into a general account of the growth of our knowledge of the brain and, in fact, into a masterly introduction to the history of neuroanatomy, neurology, ophthalmology, and allied fields that will not easily find its equal. It almost supersedes the necessity of perusing the preceding authors, except perhaps for those interested in more specialized lines of investigation. Besides, the book contains more than one hundred portraits: a memorial to those who, in the author's opinion, have contributed significantly to developing our knowledge of the visual system.

The Bibliography, covering three hundred pages, is probably unique in these days of joint authorship of papers with scanty references and in an age in which ignorance of past efforts often passes for originality. It is probably unique, not in the sense that it covers, or is meant to cover, the world's visual literature, but in the sense of being a monument to the heroic efforts of a modern investigator determined to collect, digest, and cope with that part of the literature that is relevant for his own area of research. As a rich source of information, the student of vision will again and again consult the references of this Bibliography culled from the literature of all ages and of all civilized nations and dealing with anatomical as well as numerous other aspects of the subject.

Even a preliminary study of the fifteen chapters of *The Vertebrate Visual System* is certain to convince the reader that it was the intention of the author to write not only for the scholar and advanced investigator but also—and perhaps first of all—for the student and beginner in neuroanatomy, neurophysiology, clinical neurology, ophthalmology, and related fields. It is told that a report to the Admiralty on methods of shipbuilding furnished in 1811 by Thomas Young, the "founder of modern physiological optics," called forth the comment: "Though science is much respected by their Lordships and your paper is much esteemed, it is too learned." In striving for lucidity and brevity; in adopting an "architecture" of presentation that makes for clarity and enables the reader to cope easily with an enormous amount of material conveniently organized into chapters with sections and subsections; in avoiding unnecessary technical terms and introducing, whenever possible, English terms, Stephen Polyak has produced a book that, aside from being a mine of information for the expert, is admirably suitable for purposes of teaching. No serious student will ever, like the Admiralty official of Thomas Young's days, find that the text is too heavy-going or "too learned."

Although not an anatomist *von Fach*, I had promised the author before his death to see his magnum opus through the press. I could perhaps lay claim to being, to some extent, at home in the general area of research considered in his book; I had known the author for almost three decades and was familiar with his outlook in scientific matters; I knew his intentions, aspirations, and high standards in regard to his own scientific work and the methods of presenting it; in fact, for many years we had shared monkeys, ideas, and books in the very

that, in brief, I should find
on thousands of points, including
scientific nature, quotations, references,
even microscopic sections. At the end of my efforts I am ready to conclude, however, that the book as it appears now is, to all extents, the book as it left Stephen Polyak's pen and represents in all its details the kind of book he

wanted it to be. The 551 illustrations are those which he himself had carefully selected: none has been added and none has been eliminated. No doubt, if sufficient time had been his to finish the job himself, this would have been a more perfect book. And, if perfect health had been his, he would have continued with studies and experimentation in the laboratory (his files are full of "plans for further experiments"), and this book would not have been published for years to come—if ever.

It is often the fate even of eminent scientists that records of their lives rapidly vanish or become unobtainable. The author of this book, for instance, often failed to obtain the portrait of a man whom he wished to memorialize and at times even failed in the case of scientists who had made their great contributions as late as this century. It is fortunate that Stephen Polyak himself will not share the fate of such men, since Mr. Christian Abrahamsen, one of the prominent portrait painters in America now residing in Chicago, painted him in 1953, a reproduction of this

merely attempted—like [illegible]y did in the case of Hume [illegible]p posterity in the difficult business of [illegible]owing what to add" to such an epitaph. I myself, after his passing away, have "added" the following words (see Bibliography):

Being devoid of personal ambition, he lived a life in which ultimately nothing mattered except his scientific work, and the problems, demands, and exigencies arising in connection with this work. Those words of Francis Bacon that have subsequently been used to introduce one of the most famous books ever produced in the history of Western thought appear to be the very words written across all of Stephen Polyak's scientific endeavors: *De nobis ipsis silemus.* . . .

HEINRICH KLÜVER

CULVER HALL
UNIVERSITY OF CHICAGO

During the last few years of Stephen Polyak's life he was in ill-health; sudden death or total blindness was his future. His constant worry was that one or the other might strike before he completed the manuscript for *The Vertebrate Visual System*. His long-time friend, colleague, and confidant, Heinrich Klüver, relieved him somewhat by promising to complete the work, should he leave it unfinished. Although Professor Polyak worked beyond normal endurance and part of the manuscript was in the hands of the publisher, much remained to be done at the time of his death.

Professor Klüver, true to his promise, laid aside his own scientific work and took on the full responsibility for bringing the book to publication. Some of the work was in unchecked page proof, some in galley proof, some in manuscript form; cuts had been made for the 551 illustrations and the legends written, but they had never been put together; the Index had to be made.

Day after day for two years Professor Klüver checked and rechecked, matched illustrations with legends, read proof, and prepared the Index. Because of his unflagging devotion, the work has come to publication in a form which, as he says in his Preface, "is, to all extents, the book as it left Stephen Polyak's pen and represents in all its details the kind of book he wanted it to be."

THE PUBLISHER

Preface

This book, *The Vertebrate Visual System*, like its forerunner, *The Retina*, originated in the desire to understand better the anatomical structures underlying vision, the way in which they work, and how they originated.

The book is in four parts: historical, anatomical, pathological, and biological.

The first part is an attempt to present the development of our knowledge of the bodily mechanisms underlying vision from the earliest efforts through the following ages to our own time. Historical investigation not only satisfied my curiosity concerning the origin of the concepts and ideas and their interaction but revealed both the temporal sequence of the discoveries and, more important, the ideological motivation for subsequent investigations. This was also the source from which the stimulus for my own research originated. This section is also intended to be a memorial to the many workers who gave us our present knowledge.

The second part, the anatomical, describes the gross and fine structures which constitute the vertebrate visual system, principally in Man, Apes, and Monkeys.

The third part deals with the pathoanatomical basis of disturbed vision, especially of the various visual field defects. This part may be helpful not only in understanding the pathology of vision, but it may also materially add to our understanding of the organization of the visual apparatus and its normal function.

In the fourth part I discuss the intriguing problem of the origin and development of the vertebrate eye, how the eye may have initiated the formation of the brain, and how vision in turn has given an evolutionary impetus to the rise of the Primates, eventually culminating in the advent of Man.

The problem of vertebrate vision transcends the time limits and powers of any individual life, and I am aware of the many shortcomings of this book. Especially I regret not having been able to analyze the minute structure of the visual centers of the brain far more thoroughly, as this is necessary for the understanding of vision. I hope, therefore, that this book will prove to be an incentive to further investigation of the visual organs and of the synaptical relationships of neurons in the nervous organs in general. It is here that we know least and here that the answer to the riddle of the material basis of vision, and of the brain in general, seems to lie.

The numerous illustrations were prepared or collected by myself or made from my own sketches by Esther Bohlman Patterson, Elaine Kern (Mrs. John R. Weigel), Harietta Elisabeth Story, and Agnes Nixon.

I borrowed, in addition, a considerable number of figures, mostly in order to illustrate the historical parts of the book. In all cases I have indicated the source from which the figure was taken.

The voluminous references I have mostly c
lected from the original sources.

Abbott Memorial Fund of the University of Chicago for the grants-in-aid, received during many years, which made my work possible; the John Simon Guggenheim Memorial Foundation of New York for a grant of a fellowship for the completion of this work; the Public Health Service of the National Institutes of Health, in Washington, especially Dr. Pearce Bailey and Dr. Charles P. Huttrer, for the generous subsidies which enabled me to complete this book and to publish the numerous illustrations, including the colored plates; the National Science Foundation in Washington for a substantial contribution toward the publication of this book; Dorothy Prchal (Mrs. W. J. Gaspar) for the faithful and intelligent service given me during many years in my laboratory work; Olive Falls for the many ways in which she conscientiously assisted me; Edward Poser, M.D., ophthalmologist in Chicago, for his most generous attention to my difficult problems; and Donna Irene Polyak and Stephen Francis Polyak, my wife and son, for all the help given me, without which my task would have been even more burdensome.

The editing of the manuscript was expertly carried out by Ann Scott Overton, the typing by Mrs. Marvel D. Jensen, both of Chicago.

Note on the Use of References

The terminal bibliography contains approximately 10,000 references and is reasonably complete. It consists principally of books and papers of immediate interest to the problem of vision and the visual organs and includes most publications related to the anatomy of this subject. However, only a selected number of items concerning the physiology, pathology, and biology of vision are included, which may serve as a source for further information.

The references appended to most sections, or in the text, give only the authors' names and years of publication. These will be of assistance in finding the complete references in the terminal bibliography.

In the case of two or more references quoted with the same author and date in the terminal bibliography, it will depend on the reader's discretion to identify the particular reference from the subject discussed in the text.

References to publications written by two or more authors are identified by the sign "&" instead of the word "and," the latter always indicating separate publications.

A very few references, difficult of access, remain incomplete and may be completed by those to whom they are of special interest.

In some chapters most or all references are found at the end of the chapter.

The cross-references within the text and the legends describing the illustrations give the chapter, section, and subsection in the following form: (*Cf.* chap. IV, 7 [1]). The first Arabic figure refers to the center heading so numbered, and the figure in brackets refers to the numbered subsection or side heading within that section.

Technical Note

Since the publication of *The Retina* in 1941 I have made further attempts to improve the staining of the retina with silver bichromate, the Golgi method. In these attempts other factors, such as the technique of injecting the eyeball with osmium and bichromate solution, the fixation, imbedding, cutting, and mounting of sections, and covering the slides with coverslips by a "dry procedure" were practiced as described in chapter IV of *The Retina*. In order to increase the probability of a successful stain, I found it advantageous to extend the time of fixation. A useful combination that, even with difficult material such as monkeys' and lizards' eyes, frequently gave good results, was as follows:

Fixation of the eyes in 1 part of 1% perosmic acid and 4 parts of 2 or 3% potassium dichromate 5 days at ordinary temperature, followed by 8–10 days in fresh fixative in incubator at [illegible] centigrade; leaving in same fixative for an-[illegible]-2 days at ordinary temperature; trans-[illegible]7% silver nitrate (with or without [illegible]re formic acid to 250 cc.) for 30 [illegible]fer to same Golgi fixative for another 30 minutes; transfer to same 0.5–0.7% silver nitrate, and gentle shaking for a few minutes until visible precipitation is no longer formed; transfer into a fresh change of same silver nitrate for 2–3 days at ordinary temperature; dehydration in $\frac{1}{3}$ pure acetone and $\frac{2}{3}$ absolute alcohol in a bottle over a layer of dehydrated copper sulphate, in incubator at 55° centigrade, during 1–$1\frac{1}{2}$ hours; washing out in repeated changes of absolute alcohol to remove acetone; imbedding in thick celloidin (Randolph Products Co.) in refrigerator, in a "quick way" (during 2–3 hours); hardening in liquid chloroform; transfer for $\frac{1}{2}$–1 hour to 75–80% alcohol (one or two changes); sectioning at 30–60 or more microns; clearing in 1:3 carbolic acid and toluene; mounting on slides in clarite or purified neutral Canada balsam; drying over a hot plate; covering in a "dry way"; pressing with weights.

Prepared in this way, slides remain preserved for many years and may be examined with high-power oil-immersion objectives which possess long working distance, such as the *Ultropak* systems of Leitz.

Introduction

1. THE PROBLEM OF VISION. What vision is, has been and still remains one of the mysteries that have challenged human thought since the beginning of civilization. What agents and forces intervene between the observing eye and the observed object? How is the eye built, and how does it work in order to convey to the discerning mind the wealth of forms and colors that make up the visible environment? What are the cerebral mechanisms connected with the eye, how are they organized, and how do they work in order to elicit subjective visual responses to the visible objects that represent the surrounding world? These are the basic questions to which, for more than two thousand years, human intelligence has sought, and only partly found, the answers.

2. HUMAN INTEREST IN VISION. As far back in the human past as there is a record, the supreme importance of vision and of its instrument, the eye, has been recognized. In the prescientific era the interpretation was purely allegorical. Very early, however, a practical interest was manifested in empirical attempts to preserve or restore the precious faculty of sight by the healing art of ancient civilized nations: Hindus, Babylonians, Chinese, Egyptians, and others.

During Classical Antiquity this persistent interest in vision, as in other bodily functions and in nature in general, gave rise to the doctrines and theories of Greek philosophers, naturalists, and medical men. The ancient Greek knowledge of the eye, of its function, its pathology and treatment, preserved during the Middle Ages by the learned men of the Arab world, finally developed in modern times into a great body of knowledge encompassing a number of allied fields, such as the anatomy, physiology, psychology, and pathology of the visual organs and centers. Intimately connected with these disciplines were efforts to discover the physical aspect of sight, in particular the nature and properties of "light" and its behavior under various conditions.

The result of these numerous and various efforts was the formulation of the laws of optics, the discovery of the structure of the eye and its connections with the brain, and the body of knowledge incorporated in modern physiology and pathology of vision and of the visual organs.

3. PRACTICAL AND TRANSCENDENTAL MOTIVATION OF INTEREST IN VISION. The persistent interest in the organs of vision manifested by all advanced societies during enlightened epochs of the human past can easily be understood because of the overwhelming importance that vision has in human life. Anything likely to increase knowledge of the visual organs and centers and thus help to preserve their normal function or to restore defective eyesight may be expected to be held in high esteem and eagerly sought. But the nonutilitarian motives arising from intellectual and often unconscious emotional sources have played a great and probably decisive role in keeping the problem of vision alive. The fascination that the eye, its workings, and its intimate relation to psychic life have always held for the curious is revealed in numerous writings of the last twenty centuries. The obtrusive reality and indispensability of the subjective phenomenon of vision, the manifest connection of sight with its anatomical instrument, the eye, and the close relation of the eye to the brain, have always had a vivid appeal for all who have a profound interest in human nature.

The motives for the sustained interest of the thinking part of humanity in the organs of vision have been admirably expressed by Sir David Brewster, a great student of vision, in his *Letters on Natural Magic* (1862, p. 19) addressed to Sir Walter Scott, in the following words:

> Of all the organs by which we acquire a knowledge of external nature the eye is the most remarkable and

the most important. By our other senses the information we obtain is comparatively limited. The touch and the taste extend no further than the surface of our own bodies. The sense of smell is exercised within a very narrow sphere, and that of recognizing sounds is limited to the distance at which we hear the bursting of a meteor and the crash of a thunderbolt. But the eye enjoys a boundless range of observation. It takes cognizance, not only of other worlds belonging to the solar system, but of other systems of worlds infinitely removed into the immensity of space; and when aided by the telescope, the invention of human wisdom, it is able to discover the forms, the phenomena, and the movements of bodies whose distance is as inexpressible in language as it is inconceivable in thought.

The same conviction of the overwhelming importance of sight in the intellectual life of man and in his existence as the supreme intellectual being on earth is reflected in a single sentence of a lifelong student of the brain and the visual centers, Sir Grafton Elliot Smith, in an article published in *Nature* (v. 125, p. 822, 1930): "Vision is the foundation of intelligence and the chief source of our knowledge."

4. SCOPE AND SUBJECT OF THIS BOOK: BODILY MECHANISMS OF VISION.—The persistent interest of inquisitive minds in vision, in its bodily instruments and its physical factors, has resulted in an accumulation of information too great for any single person to master. It would be presumptuous for any but the specialist merely to review such fields as the photophysics and photochemistry, the physiology, psychology, and pathology, of vision and the visual organs. The accomplishments in these fields and the problems still to be solved constitute a task for those well acquainted with these subjects. The range of the present book is more limited. It treats the subject of vision chiefly as an anatomical problem. Whatever the factors are that make us see, vision as we know it and subjectively experience it is entirely dependent upon specific structures of the body maintained in proper working order. When these are interfered with or destroyed, the faculty of vision is impaired or destroyed. Vision, though absolutely dependent upon the physical world, is a performance of our visual apparatus.

One more step in this logical postulation brings us to the realization that "vision" is no more than an abstraction, the concrete reality of which is our bodily visual mechanism. We see as our visual system sees, that is, within the limits and capacities of its intrinsic, inherent organization. "Vision," in fact, is nothing more than our visual apparatus working under adequate physiological conditions.

5. THE INTRINSIC ORGANIZATION OF THE VISUAL SYSTEM AND VISION.—Heretofore vision has mostly been treated as a psychophysiological problem, with structures playing a subsidiary role. Since, however, the various visual phenomena are manifestations of the activity of the visual system and vary with the intrinsic organization of its different parts and in different animal species and are variously disturbed by discrete pathological processes, it is quite proper to look upon the structural organization of this system as the core of the problem of vision.

In the physiology of the peripheral organ the eyeball—and of the oculomotor apparatus, this is self-evident. This viewpoint is also accepted for the gross anatomical features of the visual pathways and centers of the brain. The minute structures that make up the peripheral photoreceptor the retinal membrane of the eye may likewise largely be interpreted in terms of the known manifestations of the visual phenomenon. However, beyond the retina, in the brain, few structures have been discovered so far which could be usefully interpreted either grossly or in their minute relationships. Yet, like the structures of the eyeball and retina, the remaining larger and more complicated part of the visual system must be viewed as the principal carrier of the processes which, in their totality, we summarize under the term "vision."

The first step in understanding the phenomenon of vision, therefore, is to disclose the intrinsic organization of the visual system as completely as present scientific technique permits. While it is possible to study separately the structure of the eye or of the visual pathways or of the visual centers of the brain, to understand the anatomical basis of vision it is necessary to consider the entire visual apparatus.

6. GROSS ANATOMICAL RELATIONS OF THE VISUAL SYSTEM.—The vertebrate visual sys-

tem, beginning with the retinal membrane, is principally an assemblage of nervous tissue; hence the same general approach has to be applied to its study as to that of any other part of the nervous system. Embryologically, the entire visual system proper, including the retina, is a derivative of the brain and, in its fully differentiated state, bears the character of, and in fact is a part of, the central organ. In the study of the visual system, the gross arrangement must first be determined, that is, the thickness, length, course, topographical relationships, and other particulars of the optic nerves, chiasma, and tracts; the subcortical terminal stations of the midbrain and betweenbrain; the visual radiations, their beginnings, course, topographical relations, and cortical termination; the striate areas of the occipital lobes where the radiations terminate, and their extent, shape, position, topographical relations, and connections with other areas of the cortex and subcortical regions.

Next, more important in the visual than in any other system is the topographical projection of the stimuli-receiving retinal surface on the intermediate subcortical stations and on the cortical terminal visual areas. On the proper elucidation of this depends the understanding of how the two discrete images formed in both eyes are projected upon the two visual cortical centers the striate areas- by mediation of which they evoke a single visual impression in our consciousness.

Closely related to the subject of the topographical organization of the visual system is the problem of the oculomotor apparatus, including the muscles moving the two eyeballs; the nerves and subcortical and cortical centers by which the gaze of both eyes is co-ordinated and directed toward the common point of fixation; and the dioptrical systems of the eyes accommodated to the distance of the viewed object—all factors essential for the normal visual act.

One of the most important anatomical items is the blood supply of the eyes and of the visual pathways and centers. For, as elsewhere in the living body, no part of the visual system, whether a large or microscopic structure, can perform its proper function if not adequately supplied with blood. Knowledge of the blood supply is of paramount importance in the pathology of vision; this, in turn, may elucidate certain subtle aspects of the organization of the central visual apparatus, such as the cortical representation of the all-important central foveae and areae, the "maculae" of the retina, and their preservation in disturbances of vision of cerebral origin.

This leads to the study of representative human pathological cases where impaired vision was observed during life. These, together with experiments executed on suitable animals, especially on manlike apes and monkeys, may reveal organizational points that could never be understood on the basis of an investigation of normal anatomical material alone. Human clinical observations are invaluable, especially when correlated with macro- and microscopic examination of pathological material, since this is the only way to make us understand the subtle and multifarious processes of the human pathology of vision and its related functions.

The last and perhaps the most important item in the problem of vision is general biology: How and from what incipient sources did the faculty of vision originate in the animal kingdom? What, especially, were the origins of visual organs in early animals that eventually culminated in the development of the eyes and visual organs of Vertebrates, including Man? In which of many ways, essentially similar and yet infinitely varying from species to species, have the different Vertebrates solved the problem of visual relationship to the environment in which they live? And how have they adjusted themselves, by means of varied visual mechanisms, to their particular conditions and satisfied their basic requirements, acquiring food, procreating and saving themselves from extinction? By the answers to these questions the background necessary for an understanding of the individual roles of all living beings, large and small, may be acquired.

7. Routine methods of investigation, their usefulness and limitations.—Whereas the gross anatomical and general histological methods spoken of previously have played a capital role in the collection of the information we now possess about the visual system, they did not penetrate to the core of its intrinsic or-

ganization. Since the inception of modern microscopy, particularly during the first half of the twentieth century, the minute structure of the eyeball, of the retinal membrane, and of the visual pathways and centers have been thoroughly investigated. The layer of retinal photoreceptors—the rods and cones—has been repeatedly studied in modern times, ever since the pioneer researches of Bowman, H. Müller, Koelliker, and M. Schultze. The various gray nuclei and cortical areas related to vision have also been the subject of much fine work. We know now in detail the composition of the photoreceptor layer in numerous animal species, the various structures of the brain stem, and the specific areas of the gray cover of the brain, or cortex, that are directly related to the normal act of vision; and we are rather well acquainted with numerous disturbances resulting from lesions of these various parts of the visual apparatus.

Furthermore, since modern anatomohistological and experimental physiological methods of investigation have been devised, numerous papers have been published describing in detail the character and arrangement of the nerve cells, fibers, and other constituent elements of each of the parts of the visual apparatus; and a good start has been made with modern electrophysiological methods, to reveal dynamic factors involved in vision. But, in spite of all this, the final answer to the question "What are the minute mechanisms of the brain that are the material basis of sight?" still eludes us.

8. Nervous constituents of the visual system: the nerve cells, carriers of visual function. The particular function of every part of our bodily machine is understood to be an expression of its specific organization and relationships: the kind of structural elements constituting it, the way these elements are put together, the way they are related to one another and to other structures, and the influences by which they are regulated or through which they influence other parts. If the same principle is applied to the visual system, there is little doubt that the specific constituent "functional parenchyma" of this system is the nerve cells, or "neurons." By analogy with other parts of our organism, the neurons that make up our visual system are the true substratum or carriers of the specific faculty of vision. "Vision," potential and actual, is the total of specific responsiveness or activity of the living neurons of the visual system. All other parts of its tissue, such as the supporting connective and neuroglial cells and fibers and the blood vessels, necessary though they are, are merely a matrix or bedding within which the visual neurons are lodged, held in proper arrangement, and nourished. The gross physical and chemical constitution of the tissue, being much like that of other parts of the brain, likewise may be largely nonspecific.

The specific function of the visual mechanisms may be considered to be an expression principally of two factors: first, of the specific organization of the peripheral visual photoreceptor, the eye, and, above all, of the retina; and, second, of the particular kind of its constituent "neurons," their varieties, their mutual synaptical relationships, and their inherent dynamical capacities.

Since the structure of the eye and, in particular, the layer of photoreceptors are by now sufficiently well known, the principal remaining task is to find out what varieties of neurons there are in each link of the complex visual mechanism, how they are distributed and arranged with respect to one another, and, most important, in what synaptical relationship each particular neuron variety stands with other related neuron varieties. Such investigation may make it possible to identify the innumerable minute channels along which the nerve excitations, after being generated in the retinal rods and cones by light, are propagated; and a likely estimate therefrom may be made as to the probable changes in intensity, quality, spread, and other modifications which these excitations undergo as they pass from neuron to neuron.

When these questions are answered satisfactorily, an attempt may finally be made to correlate the various known visual phenomena with particular sets of neurons or their arrangement. This task, one of the most difficult in contemporary science, appears to be the only promising road to the interpretation of vision by means of concrete natural factors, above all, by means of the structures of the brain that are

unquestionably the instruments by means of which we see.

What additional problems may arise, the future progress of man's knowledge alone will show.

9. HISTORICAL RETROSPECT OF PAST EFFORTS TO UNDERSTAND VISION. What vision—a faculty almost as overwhelmingly striking as life itself is, has been, as initially stated, a problem in the focus of Man's attention ever since he began to reflect on himself and nature. Throughout Man's development he has tried to understand vision according to his means, from savages barely conscious of the precious gift they possessed to modern scientists measuring with the most refined instruments the wave lengths of light or trying to disentangle, by means of the microscope, the complex relationships of the visual nerve cells of the brain.

To learn about these efforts and to present them briefly has constituted one of the chief by-products of writing this book. To trace when, where, and why the first attempts were made and subsequent progress achieved in the optical sciences, in the anatomy and physiology of the eye and of the brain, and in the pathology and biology of vision was both absorbing and indispensable. In many instances it illuminated the problems of vision and pointed the way to their solution.

Such delving into ancient times reveals Man's character and his intellectual interests and strivings as essentially the same throughout the ages. From the darkness of barbarous ignorance, by a process of long, slow, laborious toil, helped by fortune and hampered by adversity, Man gradually learned to observe, to improve his tools of research, to profit from logic as well as from the errors of his predecessors, until he accumulated a knowledge of himself and of nature of which the gods of the past may well have been envious.

Torn between the flashy sophistry of the clever, verbose dialectic of a Plato and the methodical examinations and clear logic of an Aristotle, Man still plods on toward the goal which he has not attained, even though he may have advanced toward it: to know his place in nature, and thus to know himself. It is a formidable task, as indicated almost twenty-five centuries ago by Aristotle in his treatise *On the Soul* (*De Anima*, Περὶ ψυχῆς), book 1, par. 10: "To attain any assured knowledge about the soul is one of the most difficult things in the world."

The task becomes yet more formidable when the limitations of human existence are taken into consideration. With a sense of apology for the shortcomings of this book, I may quote a sentence attributed to Hippocrates, "father of medicine," from his *Aphorisms*, book 1, chapter 1 (Littré, IV, 458): "Life is short, art is long, opportunity is elusive, experience is deceptive, judgment difficult."

PART I

History of Investigations of the Structure and Function of the Eye and of the Visual Pathways and Centers of the Brain

Chapter I

History of the Investigation of the Structure and Function of the Eye and the Development of the Optical Sciences

SEC. 1. EARLIEST INVESTIGATIONS OF THE EYE AND THE BEGINNING OF OPTICS

1. ANCIENT ANATOMY OF THE EYE. Knowledge of the structure of the eye, of its normal function, and of its ailments and their treatment closely reflects the intellectual and material conditions of the age and place which produced it. How much, or how little, the earliest civilized nations—the Sumerians, Assyrians, Babylonians, Egyptians, and Persians knew about the eye is unknown, except for a few hints indicating an empirical-practical treatment of diseases of the eye. (*See* Wölfflin 1922; Krause 1933; Ranke 1933; Meyerhof 1940; Gordon 1942; Steindorff; Leix; Campbell Thompson; Elgood 1951; Laignel-Lavastine.)

The ancient Hindus, on the other hand, seem to have made some beginnings both in general medicine and surgery and in ophthalmology, according to Bidhyādar (1939). Since, however, the date of Susruta's book *Samhitā Uttara Tantra*, a manual of medical methodology, is still in dispute, some claiming it was written about 1000 B.C., while others put its origin at the beginning of the present era (Esser 1934), the appraisal of early Hindu medicine remains a problem. In any case, Susruta's description of the eye was extremely brief and inaccurate: the eye, according to him, is made up of six layers, two of which are the lids and four of which make up the eyeball proper. These may be identified tentatively as the cornea, containing the aqueous and possibly the lens, the ciliary region, the vitreous, and the retina. Despite the theoretical shortcomings of the Hindus, Dutt (1938) believes they were the first successfully to perform the operation for cataract. "India," according to Dutt, "is a land of cataracts.—No wonder that the first operation for cataract was devised and performed in India." (*Cf.* sec. 3 [2], this chapter, for conditions in Arab lands; sec. 3 [3] for cataract operation by Arabs.)

The early Greek writers were not much more advanced. Demócritos of Abdera (Δημόκριτος, 460–370 B.C.), according to H. Magnus (1900), described two tunics of the eye—a thick, firm outer one, called the "fibrous tunic" in modern terminology, comprising the cornea and sclera, in which he distinguished a "delicate tunic" (cornea), and a spongy inner tunic with a pupil (*κόρη, kóre* or "maiden"), that may be identified with the uvea, including the chorioid, ciliary body, and iris.

Aristotle (Ἀριστοτέλης, Aristotéles, 384–322 B.C., *see also* Fig. 1; chap. II, 2), called "The Father of Natural Sciences," also discussed the eye very briefly, mentioning only the parts easily seen in a living person and saying that it contained water. His idea of the nature and property of light and of the visual act (*see* subsec. 2, below) was closer to modern views than that of most other Greek naturalists and philosophers. (*See* chap. II, 1 [4], for Aristotle's anatomy of nerve supply of the eyeball.)

A somewhat more detailed description of ocular structures is found in the writings of Hippocrates (Ἱπποκράτης, 460?–377 B.C.), "The Father of Medicine," according to Magnus. He distinguished three tunics: first, an outer white one (sclera), with an anterior transparent part (cornea); second, a delicate middle tunic, with an anterior colored portion (iris), a "crown" (ciliary body and root of the iris), and a central opening, or pupil (*κόρη, kóre*, "maiden"; *ὄψις, opsis*, "view" or "sight"), together forming

what is now called the uveal tunic; the third was the inner tunic, the retina, of which nothing was known except that it was extremely delicate. Within the eyeball there was a single space filled with "water." The crystalline lens was not known. The water was believed to originate in the brain and was considered to be a true photoreceptor or photosensitive substance by the Hippocratic School.

The first truly scientific description of the structures of the eye dates from the Alexandrine or Hellenistic Period (323–212 B.C.). This late Greek anatomy of the eye is attributed to Heróphilos (Ἡρόφιλος, 344–280 B.C.), the first great pioneer in anatomy and physiology. His description is preserved in a treatise *On Medicine* by Aulus Cornelius Celsus (1st century, Christian Era), a Roman author, and in the

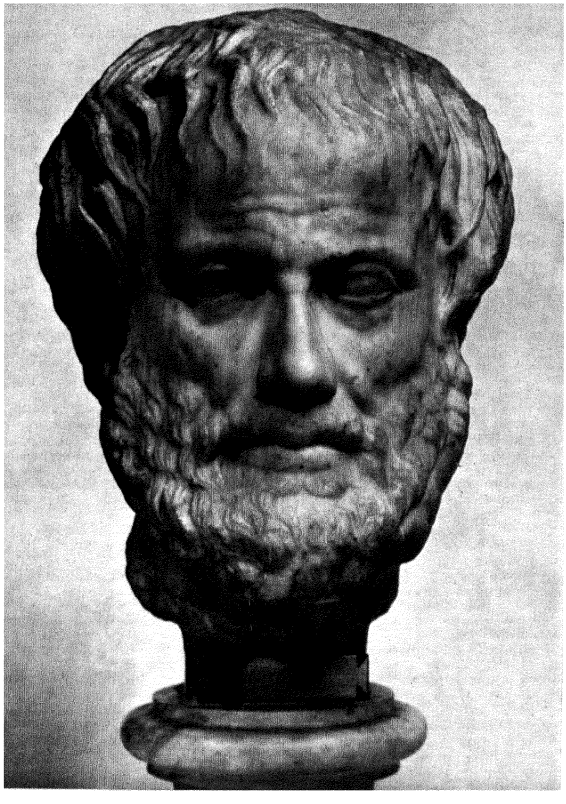

FIG. 1.—Aristotle of Stágeira (Aristotéles, 384–322 B.C.), "Father of Natural Science." The most encyclopedic naturalist of Classical Antiquity and one of the foremost philosophers of Ancient Greece. Teacher of Alexander the Great. Author of the earliest description of the vertebrate eye. Proponent of the most correct interpretation of the function of the eye and of vision in general ever made by the Greeks. A marble copy made in Roman times from a contemporary realistic portrait by an unknown sculptor of the late fourth century, according to M. Rostovtzeff (1926). Original in the Kunsthistorisches Museum (Museum of the History of Art), Vienna, Austria. Courtesy of Kunsthistorisches Museum, Vienna. (For other portraits of Aristotle *see* Bernoulli, *Griechische Iconographie*, v. 2, p. 96; Studniczka, *Das Bildnis des Aristoteles*, Leipzig, 1908; Hekler, *Die Bildniskunst der Griechen und Römer;* Hekler, *Bildnisse berühmter Griechen;* Charles Singer 1921, v. 2, Pl. II; G. Sarton, *Lychnos*, 1944–45.)

writings of Rûfos of Ephesos (Ῥοῦφος, Rhûphos; he flourished at the end of the first, and during the beginning of the second, century of the present era), and especially in the thick volumes of Galen of Pérgamos (Γαληνός, Galenós, A.D. 129–201?), the greatest authority of Antiquity on medical science except Hippocrates. Its merit was that it was based upon knowledge gained directly from dissection of animal eyes. This Alexandrine or Galenian anatomy of the eye became almost the only source of information during the subsequent Arab period, when, because of Mohammedan religious scruples, no dissection was practiced. Toward the end of the Middle Ages and at the beginning of the Renaissance, when the interest in anatomy and natural sciences revived, it was passed from the Arabs to the early European anatomists.

The Greek anatomists, exemplified by Rûfos and Galen, distinguished the following coats of the eyeball: the cornea (*keratoëidés hitón*, "horn-like tunic"); sclera (*leukós* or *sklerós hitón*, "white" or "horny tunic"); uvea or iris (*rhagoëidés hitón*, "grapelike tunic"); chorioid (*chorioëidés hitón*, "chorion-like tunic"); the anterior lens capsule with the ciliary zonule or suspensory ligament of Zinn (*phakoëidés hitón*, "lenticular tunic," or *krystallocidés hitón*, "crystalline tunic"); and the retina (older term *arachnoëidés hitón*, "spiderweb tunic," also *hyaloëidés hitón*, "glassy tunic," later term *amphiblestroëidés hitón*, "netlike tunic"). Their order or sequence was, roughly, correct. Of the transparent media which fill the eyeball, they knew the aqueous (*hydatoëidés hygrón*, "water-like humor"), vitreous (*hyaloëidés hygrón*, "glasslike humor"), and the crystalline lens (*krystalloëidés hygrón*, "icelike humor"). From this it is apparent that the ancient Greek anatomists correctly identified and appraised all the parts of the eye which could be observed without benefit of magnifying glasses or could be seen at low magnification (*see* sec. 2, this chapter). (For a more detailed history of early anatomical studies of the eye *see* Polyak, *The Retina*, 1941, 1948.)

2. Greek physiology of vision.—Whereas the Greeks missed or erred in but few of the anatomical details, their functional interpretation of the structures of the eye was, for the most part, faulty. They were mistaken when they believed the lens to be in the center of the eye. Furthermore, since the laws of light refraction, and hence the formation of the retinal image, were unknown to them (*see* sec. 2, this chapter), they assumed that the lens was the actual photoreceptor or principal organ of sight. The retina, because of its numerous blood vessels, they came to consider as both an organ of nutrition for the lens and a conveyor of the "visual spirit"—the mysterious element or force by which vision was thought to be effected—to and from the lens. The chorioid, rich in blood vessels, they believed to be the nutritive organ of the retina, which they thought nourished the vitreous, which in turn nourished the lens, thus freeing the latter of obstructing vascular structures.

Nevertheless, it was the Greeks, and particularly Galen, who noticed the resemblance of the retina in color and consistency to the substance of the brain and correctly guessed it to be a displaced part of the cerebrum (*see* sec. 6 [1], this chapter, and chap. II, 5 [1]). They erred, however, in their belief that the optic nerves were hollow channels, wherein a peculiar, subtle substance, the "luminous air" or "visual spirit" (*pneuma*) originating in the cerebral ventricles, was supposed to circulate to the eye and reach the lens, whence, after meeting the "visual rays" returning from outside, the *pneuma* would again flow back to the brain charged with images of observed objects. (*See* chap. II, 2 and 3.)

The chief reason for this erroneous functional interpretation of ocular structures was the fact that nothing positive was known about physical "light," and but little about its dissemination (*see* sec. 2, this chapter). In order to explain the phenomenon of vision, the majority of Greek philosophers and students of nature, apparently beginning with Empedoclés (Ἐμπεδοκλῆς, 5th century B.C.), assumed the presence of certain "visual rays" (ὄψις, *ópsis*, originally meaning "look," "appearance," "vision," "eyesight," or "view"; *see* Aristotle, *De Sensu*, book 2, chaps. 6–9; *Meteora*, chaps. 1, 2, 5, 6, 9, 18; and Plato, *Timáios*, pars. 45C, 46B). Galen compared these very thin rays to delicate threads of cobweb. Emerging from the eye—which in this respect the Greek scholars and philosophers compared to the sun (e.g., Helio-

dóros of Larissa, 4th century, Christian Era)—these visual rays, they thought, spread with immeasurable speed in straight lines in the form of a rectangular cone whose summit was in the pupil and whose base was at the observed object. When these rays touched the object, the visual act was consummated in a manner similar to a blind person finding his way about with the help of a walking stick. This was the simplest version of the "emanation hypothesis of vision" proposed by Pythagóras (Πυθαγόρας, 532 B.C.) and accepted by his followers Euclid (Εὐκλείδης, *ca.* 290 B.C.), Hípparchos of Nicea (Ἵππαρχος, 2d century B.C.), the most renowned astronomer of Antiquity, and by Théon of Alexandria (Θέων, 4th century, Christian Era). Under the influence of Euclid's authority, this hypothesis found wide acceptance among such students of geometrical optics as Héron of Alexandria (Ἥρων, *ca.* 1st century B.C.), Ptolemy (Πτολεμαῖος, Ptolemáios, *ca.* A.D. 100-161 or 178), Cleomédes (Κλεομέδης, early 3d century, Christian Era), and Heliodóros of Larissa (Ἡλιοδώρος Λαρισσαίος, early 4th century, Christian Era). During the centuries following Pythagóras, the emanation doctrine of vision underwent numerous changes and adaptations to suit particular views.

Of the rival theories, the one proposed by Demócritos stated that all objects continuously send forth images of themselves to the surrounding air, which are somewhat like the imprint that a seal makes in wax. Another hypothesis, by Epícuros (Ἐπίκουρος, 341–270 B.C.), assumed a discharge of countless shell-like casts or "eidols" (εἴδος, *eídos*, "image," "form," or "shape") made up of very thin matter. These eidols, or "impressions," by moving in straight lines, reached the visual organs and caused objects to be perceived.

While, in the hypothesis of visual rays, the subjective, and, in those of the eidols or impressions, the objective, factor dominated, each to the exclusion of the other, the hypothesis of "synaugy" (συναύγεια, *synáugeia*) or union of inner and outer visual rays, advocated by Plato (Πλάτων, 427–347 B.C.), represented an attempt to combine both. According to his view, the rays of "inner light" issuing from the pupils, in order to accomplish the visual act, were supposed to unite with the rays of "outer light" originating from the source of light, such as the sun, and reflected by the observed objects.

Common to all early hypotheses of the visual act, in particular the one adhered to by the Stoics, was the implication that the sensations elicited in the crystalline lens are conveyed to the brain along with the "luminous pneuma" or "inner light," where they educe subjective visual appreciation. (*Cf.* chap. II, 3 [3].)

A very different interpretation of the visual act was proposed by Aristotle in his treatises *De Anima* (book 2, chap. 7; *Parva Naturalia, De Sensu*, chap. 2). The essence of his speculation was the assumption of an immaterial mediator—the "something" or "transparency" which, according to modern thought, corresponds to the "ether" (ἀιθήρ), by means of which viewed objects affect the visual organs. Aristotle's idea, which alone among those of the Classical Period was capable of further development, was unfortunately opposed by the majority of Greek thinkers, even though it found vigorous support in some (for example, Alexander of Aphrodisías, who flourished *ca.* A.D. 200).

Since the indispensable prerequisite theoretical knowledge of light refraction—was lacking during the Classical Period, there could have been no understanding then of the formation of the visual image on the retina or of the true role of the dioptrical media of the eye.

It is of interest to note, however, that Galen's explanation of the flattened lentil-like shape of the crystalline lens as more advantageous than a spherical shape for the reception of visual stimuli indicates perhaps some vague presentiment of the part the refractive surfaces of the transparent ocular media play in the formation of the retinal image (*see* Galen, *De Usu Partium*, or *On the Use of Parts*, book 10, chap. 15).

SEC. 2. BEGINNING OF OPTICS AMONG THE EARLY CIVILIZED NATIONS

1. Discovery of the rectilinear propagation of light and Greek catoptrics.—What the ancient nations of the Near East, such as the Babylonians, Phoenicians, and Egyptians, knew about light and how it behaves when it is reflected from polished and variously curved surfaces or when it passes through transparent bodies is unknown. It seems probable that they knew little more than could be deduced from simple observation of everyday phenomena.

With the Greeks it was otherwise. Such notable students of the physical phenomena of nature as Euclid, Archimédes (Ἀρχιμέδης, 287–212 B.C.), Héron of Alexandria, and their successors, Ptolemy, Heliodóros of Larissa, and others, observed a fundamental property of light: that it travels in straight lines. In the course of time, the Greek physicists succeeded in collecting a considerable number of observations based upon this fact and in organizing them into a system. Their knowledge, however, was almost entirely limited to "catoptrics," or the study of light reflected from polished plane or curved surfaces, such as variously shaped mirrors: plane, concave, convex, spherical, and cylindrical.

2. Greek dioptrics.—The experience of the Greeks and their pupils, the Romans, in "dioptrics," or understanding the principles and rules according to which light is refracted when it passes through variously shaped and polished transparent bodies of different optical properties, in contrast with their knowledge of "catoptrics," was rather slight (Euclid, Héron of Alexandria).

Nevertheless, the ancient nations seem to have possessed enough empirical knowledge of dioptrics to make considerable practical use of it. A number of lenses manufactured of glass or of transparent stone, mostly of Greek and Roman origin, found at Nineveh (Assyria), Nola and Pompeii (Italy), Mainz (Germany), London, and various places in France are evidence of this. They all are of a biconvex or planoconvex type and of short focus.

The lens found in 1854 during the excavations in *Via Stabia* in Pompeii (destroyed A.D. 79), now preserved at Naples, is of a planoconvex shape, 4 cm. or $1\frac{9}{16}$ in. in diameter, and, according to Cuming, "with the edge ground as if it had been set in a frame." Another lens, a fragment of which was found in London, is biconvex, with a diameter of almost $5\frac{1}{2}$ cm. or $2\frac{1}{8}$ in., and had a thickness of 1 cm. or $\frac{3}{8}$ in. The dimensions of yet another lens found at Mainz, according to Sacken, are: diameter 5.5 cm., axial thickness 5.9 mm., marginal thickness 1.8 mm., probable focal length between 18 and 19 cm. (the lens could have been used as both a "reading" and a "burning glass").

It is probable that such lenses, as well as the *specula* (sing. *speculum*), or magnifying concave mirrors, were used by ancient artists as magnifying utensils in making miniature engravings of precious and semiprecious stones, such as the *cameos* and *intaglios*, and probably also in making dies for coins. At any rate, the minute details of design and their exquisite execution

[illegible], for [illegible] executed Greek and Roman coins; *see also* "Gems, in Art," *Encyclopaedia Britannica.*

There is also evidence that the magnifying property and the heat-collecting power of biconvex lenses and of spherical bottles filled with water were well known, even though not understood. In the case of the bottles the magnifying power was interpreted as the property of water itself (by Seneca; the only exception seems to have been Heliodóros of Larissa, who alone explained these phenomena by the refraction of light). In England such spherical bottles, precursors of the "crystals of augury" used by modern fortunetellers, were known as "Seneca's microscopes." In German lands they were called *Schusterkugeln*, or "cobblers' lamps," because they were used by the shoemakers in nightwork. Occasionally, similar illuminators are used at present in microscopy. That such bottles and lenses were in general use as "burning glasses" by surgeons in both Greece and Rome can be deduced from the writings of Aristophanes (*Clouds*, vs. 767), and of Pliny the Elder (*Plinius*, A.D. 23–79, *Hist. Nat.*, book 37, chap. 10). It is less certain whether the Greeks and Romans had any knowledge of concave lenses or polished stones and their optical properties. A passage in Pliny telling of the Emperor Nero's use of a concave emerald to correct his myopia when attending gladiatorial combats was interpreted in this sense by Rohr (1920) and by Landolt (1926). (*See* sec. 5 [2], this chapter, for a discussion of the origin of eyeglasses.)

Simple dioptrical phenomena, such as the apparent break in a rod or paddle when it is partly submerged in water (Lucretius); the "rising" of a ring or coin from the bottom of an empty vessel, which becomes visible when the vessel is filled with water (Cleomédes, Seneca, Ptolemy), letters when viewed through a bottle filled with water, and a more beautiful appearance of fruit when submerged in water, etc. (Seneca); perception of the sun and stars before they have actually risen or after they have set below the horizon (Cleomédes, Ptolemy), were recognized by many Greek and Roman writers as caused by refraction—although not of light but of "visual rays" coming from the eyes—at the point of entry into a denser or less dense medium. (*See also* Archimédes, Damianós, Heliodóros, Nemésios, Philipónos.)

Similar advanced views of optical phenomena were expressed, above all, by Ptolemy, celebrated Alexandrine astronomer, physicist, and geographer. His measurement of the relationships of the angle of incidence to the angle of refraction for different degrees of incidence and various combinations of transparent media—air and water, air and glass, and water and glass—may be considered the beginning of the science of dioptrics in the modern sense.

There is little doubt that the Greeks and Romans established a good foundation in optics. Unfortunately, the events which brought to an end the entire structure of Classical Civilization, its ethical, political, social, and economic disintegration, terminating in the invasion of the barbarians, stopped all advancement of science, in spite of a few late efforts by Théon of Alexandria and a few others.

SEC. 3. ARAB KNOWLEDGE OF THE STRUCTURE AND FUNCTION OF THE EYE AND OF OPTICS

1. The rise of Arab Civilization and learning.—After the moral and material disintegration of the Roman Empire and the Classical Civilization it preserved, there was a long period of political confusion and economic decay and a general intellectual reversion to pre-Classical primitiveness and barbarism throughout most of Europe. This epoch, the

so-called Dark Ages, lasted from approximately the fifth to the tenth century. Only in the Near East, parts of Asia Minor, and Syria did a few scattered groups of scholars, principally the Nestorian and Jacobite Christians, manage to salvage vestiges of ancient Greek learning. Such were the religious communities in Urfa or Edessa (Al-Ruhā'), Antioch (Antakya), and Damascus (Dimashq al-Shām, Damas). Banished from the Byzantine Empire during the fifth and sixth centuries, these Christians finally found refuge in Persia or Iran, where the city of Gondē-Shāpūr became their center (probably the present village of Shahabad, near Kermanshah, in Khuzistan).

In Alexandria and in Egypt the ancient "Academy" was still continuing its precarious existence, pushed as it was into obscurity by cataclysmic events, the rise of an obscurantist intolerance, and a general decline of civilization.

From these scattered remnants of Greek learning, in the course of the seventh and eighth centuries after the rise of Islam to world importance, a new enlightenment developed known as "Arab Civilization." Its zenith was reached under the wise rule of the caliphs, or emperors, Al-Manṣūr (A.D. 754–75), Hārūn al-Rashīd (A.D. 786–809), Al-Ma'mūn (A.D. 813–33), and Al-Mu'taṣim (A.D. 833–42). This Arab Civilization subsequently spread over all the Mohammedan countries, westward across Egypt and North Africa to Spain, and eastward across Persia to Central Asia, India, and, to some extent, as far as China. Within this spacious territory numerous centers of learning developed, the earliest and most splendid in Baghdad, capital of Iraq and residence of the caliph. The influence of this civilization upon the character of the nations within its sphere was profound and lasting.

It was through Arab Civilization that ancient Greek learning was preserved and transmitted to Europe. It was the fountainhead of the Renaissance and the foundation on which modern Western Civilization has been built. (*See* chap. II, 6.)

2. ARAB INTEREST IN OPHTHALMOLOGY AND SCIENCES RELATED TO THE EYE AND VISION. Among the branches of learning to which the Arabs and other nations under their sway paid particular attention were the mathematical sciences, optics, astronomy, and medicine. Of the medical sciences, ophthalmology was one of the most favored. The obvious reason for this was the prevalence in the Near East of infectious eye diseases, especially trachoma, also called "Egyptian ophthalmia." (For the history of the term "trachoma" *see* Paparcone; for a vivid description of conditions in Syria and Palestine a century ago *see* Mark Twain's *Innocents Abroad*, chap. 45; for similar conditions prevalent in modern India *see* R. H. Elliot and C. G. Henderson; for conditions in ancient and modern Egypt *see* J. Hirschberg 1890 and Castiglioni 1947.)

The result of this persistent Arab interest in the eye is a considerable number of treatises on ophthalmology. The most ancient of them was written by Ḥunain ibn Isḥāḳ (Latin Johannitius, 809–73), a famous translator of Greek writings into Arabic. Other Arabic books on ophthalmology in their chronological order were those written by Alī ibn Īsā (Alī ben Issā, died 1010), Ammār (*ca.* 1010), Zarrīn-Dast (1087), Ibn Abī Uṣaibi'ah (1203/4–70), Khalīfa (*ca.* 1260), and Ṣalāḥ al-Dīn (*ca.* 1297). Of these, the best known is *Kitāb Ḥunain ibn Isḥāḳ fi tarṭībi al-'aini wa-'ilalihā wa-'ilajihā alā rā'i Abuḳrāt wa Jālīnūs wa hiyā 'ashr makālāt*, or *The Book of Ḥunain ibn Isḥāḳ on the Structures of the Eye, Its Diseases, and Their Treatment, According to the Teaching of Hippocrates and Galen, in Ten Treatises*, written during the ninth century and translated into English by Meyerhof (1928). Another well-known book is *Tadhkirat al-kaḥḥalīn*, or *The Oculist's Memorandum Book* by Alī ibn Īsā, a native of Persia, written during the eleventh century and translated by A. C. Wood (1936).

The most prominent of the Arabic treatises on optics is *Kitāb al-manāẓir*, or *Book of Optics*, known in Latin under the title *Opticae Thesaurus*, by Ibn al-Haitham (Lat. Alhazen or Alhacen, b. 965 A.D. at Basra, in Iraq; d. 1039 A.D. in Cairo, Egypt). This treatise, apparently based chiefly on Euclid and Ptolemy, was written in Cairo during the early part of the eleventh century. Arabic manuscripts, considered lost until a few years ago, have recently been discovered in Istanbul, Turkey; a few

Latin manuscripts have been preserved in Britain and elsewhere, while a printed Latin edition was published in Basel (1572). Another similar treatise, *Kitāb tanqīh al-manāẓir li-dawī al-abṣār wa al-baṣā ir*, or *Making Optics Understandable for Those Who Possess Perspicacity and Insight*, by Kamāl al-Dīn Abū l Ḥassan al-Fārisī, a learned Persian, looked upon as a commentary to Ibn al-Haitham's *Book of Optics*, important than the text, which are the earliest pictorial representations in existence of the structures of the eye, the optic nerves, and the brain. Such figures are found in the manuscripts of Ibn al-Haitham (MS dated 1083; Fig. 56), of Ḥunain ibn Isḥāḳ (MS dated 1197; Figs. 2, 3; *see also* Meyerhof 1928; Meyerhof & Prüfer); of Khalīfa (MS dated 1266; *see* Hirschberg 1908); of Salāḥ al-Dīn (MS dated 1296; *see*

Fig. 2. Photographic reproduction of a diagram of the eye from a manuscript written by Ḥunain ibn Isḥāk entitled *Ten Treatises on the Structure of the Eye, Its Diseases, and Their Treatment*. Date of the manuscript in which the figure was found, A.D. 1197; date of the manuscript from which it was copied, A.D. 1003; approximate date of the original manuscript, A.D. 860. From M. Meyerhof & C. Prüfer, Arch. f. d. Gesch. d. Med. (Sudhoff), v. 4, p. 163, 1911.

was written about 1316 and exists in both Arabic and Latin manuscripts, as well as in a modern Arabic edition (1928–30).

3. Arab anatomy of the eye. A common feature of all Arabic treatises and textbooks on ophthalmology and optics is a detailed description of the structure and function of the visual organs. They also contain diagrams, even more Hirschberg; Pansier 1903, p. 89); and of Kamāl al-Dīn Abu l-Ḥassan al-Fārisī (MS dated 1316; *see* Fig. 4). These and possibly other Arab diagrams mentioned by Pansier in the writings of Morehed de Errafequy (Escorial Library No. 835, *ancient* 830), Salāh Eddin (Bibliothèque Nationale, No. 1012 du Fond Arabe, Paris), and of Al-Quazwinī (Wiedemann 1912), as well as the texts, clearly show the extent and kind of

knowledge that Arab ophthalmologists and writers on optics had of the structures of the eye and their mechanics. Since Mohammedan tenets prohibited dissection of the human and animal body even more strictly than did Christian beliefs, no active anatomical investigation was possible during the Arab period. This made Arab writers wholly dependent upon Greek sources. It is probable that the Arab diagrams also are copies of, or adaptations from, ancient Greek illustrations now lost, which makes them even more valuable as historical documents. (*Cf.* K. Sudhoff 1912.)

"water"—hence "waterfall" (καταρράκτης, or "cataract"). (*See* sec. I [1], this chapter, for information on Hindu operations for cataract.)

4. ARAB PHYSIOLOGY OF VISION. — The learned men of the Arab period, seriously handicapped as they were in their researches by their religious customs, also depended upon the Greeks for the functional interpretation of eye structures. It is to their credit that the most prominent among those ancient scholars raised their voices in protest against the "emanation hypothesis of vision." However, there was a

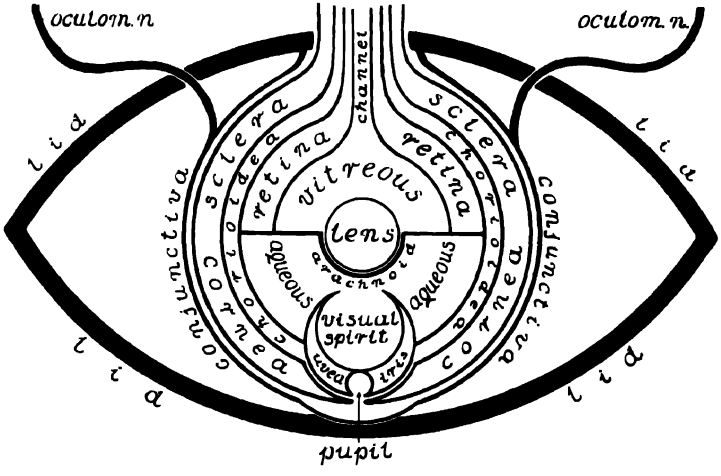

FIG. 3. — Drawing of the Arabic diagram shown in Fig. 2, with the various parts of the eye labeled in English

Knowing the derivative character of the Arab ophthalmological sciences, it is not surprising to see Arab students of the eye repeating all the familiar mistakes found in the Greek originals: central location of the crystalline lens; the belief that the optic nerves are hollow; belief in a "visual spirit"; the photoreceptor role of the crystalline lens; and the "emanation hypothesis" of vision. It is remarkable that, in spite of these theoretical errors, Arab ophthalmic surgeons devised the method of aspiration with a hollow needle for removal of a macerated lens in cases of cataract, which they, accepting the mistaken interpretation of their Greek teachers, considered to be an accumulation of

significant difference between the Arab and Greek criticism of this theory. Among the Greeks its opponents were students of nature, such as Demócritos, Alexander of Aphrodisías, Themístios, and Aristotle, against the speculators and clever dialecticians of the Platonic School; in the Arab Period the opposition to the absurd emanation doctrine arose chiefly from physicists and philosophers, against the practical ophthalmologists.

The following phrases of the most prominent Arab student of optics, Ibn al-Haitham, or Alhazen, leave no doubt as to his viewpoint in this matter: "The act of vision is not accomplished by means of rays emitted from the visu-

al organ"; and "The belief of those who think that something comes out of the visual organ is false" (Alhazen, *Opticae Thesaurus*, 1572, book 1, chap. 5, theor. 23); and "Vision is accomplished by rays coming from external objects and entering into the visual organ" (*ibid.*, theor. 14). These were the ideas which almost literally repeat the words Aristotle used more than one thousand years earlier to oppose the emanation hypothesis of his contemporaries (*De Sensu*, chap. 2, *Parva Nat.*); insignificant though these ideas may seem to have been, they had a number of prominent adherents throughout the Arab world: Al-Fārābī (870–950), Al-Rāzī (Fahr al-Dīn al-R., Lat. Rhazes, *ca.* 850–932), Ibn Sīnā (Lat. Avicenna, 980–1037), Ibn Rushd (Lat. Averroës, 1126–98), and Ṣalāḥ al-Dīn. The full importance of Ibn al-Haitham's convictions became apparent much later, when the correct interpretation of the structures of the

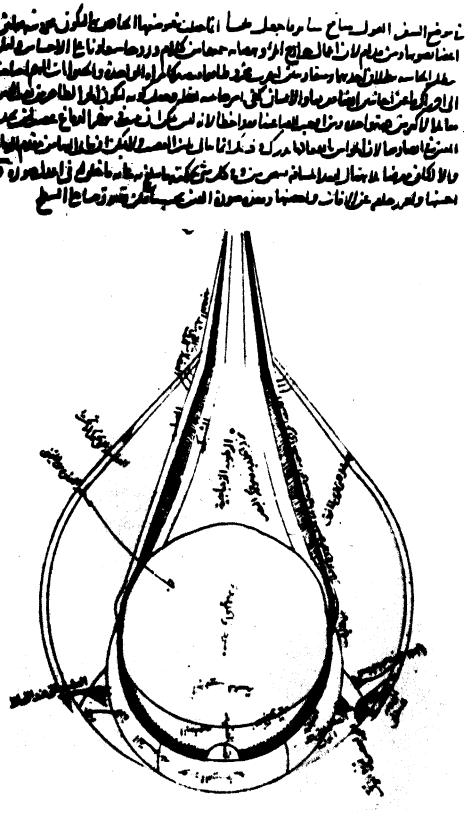

FIG. 4.—Eye diagram from an Arabic manuscript entitled *Tanqūh al-manāẓir* or *Explanation of Optics*, written A.D. 1316 by Kamāl al-Dīn Abu'l-Ḥasan al-Fārisī, a Persian writer on optics. Ahmet Salis Library, Topkapu Saray, Istanbul, Turkey.

eye was made possible by the advancement of optical sciences and optical technique (*see* sec. 5, this chapter).

5. Arab optics.—The knowledge of optics which Arab scholars adopted from their Greek masters was preponderantly catoptrics, or the science concerned with light reflected from polished plane and curved surfaces, e.g., variously shaped mirrors. Dioptrics, or the science of the refraction of light, was in its infancy during the Greek Period and experienced but little advancement during the Arab Period. The lack of dioptrics, in turn, was an insurmountable obstacle to correct functional interpretation of the eye. The idea of the formation of a visual image which Ibn al-Haitham had was inadequate, even though it represented a step in the right direction. Its fundamental defect was that he considered perpendicular rays only, thus missing the main factor, which is the diverging radiation of light rays in all directions from every point of an illuminated surface. Another error of the Arab concept was placing the "visu-

Fig. 5.—Title-page of the oldest manuscript of *Kitāb al-manāẓir* or *Book of Optics*, written 1083 by Ibn al-Haitham, an Arabic scholar, known to the Latin West as Alhazen. Ayasofya Library, Istanbul, Turkey.

al pyramid" at the posterior surface of the "glacial sphere" instead of upon the retina (*see* Ibn al-Haitham, *Opticae Thesaurus*, book 1, chap. 5, theor. 24). If the glacial sphere in his figure be identified with the lens, the visual image would be far in front of the retina (Fig. 4). It is true that in a few places in Ibn al-Haitham's book the text lends itself to a different interpretation (book 2, chap. 1, theor. 8). According to this, the glacial sphere would comprise both the lens and the vitreous humor, which would put the image almost upon the retina. There is, however, reason to think that the latter version was purely accidental and was caused by an insufficient acquaintance with the structure of the eye.

Be this as it may, Ibn al-Haitham advanced considerably beyond the Greeks, abandoning the emanation doctrine altogether. His frank comparison of the eye with a "dark chamber" went a long way toward the correct understanding of ocular structures (*op. cit.*, p. 17). From his detailed description of the "dark chamber" there is no doubt that he, as far as he went, had quite a correct idea of the formation of the image in it. This was true particularly of the inversion, and possibly also of the diminished size of the image. Since no refraction is involved in a simple pinhole camera, however, it is apparent that not much was gained thereby for the immediate development of ocular dioptrics. (*See* Polyak, *The Retina*, p. 133.)

Incidentally, Ibn al-Haitham's writings prove that the dark chamber (*camera obscura*, or "pinhole camera"), the precursor of the modern photographic camera, was well known to Arab scholars. They also support the view that the dark chamber was used by them (e.g., by Ibn al-Haitham and Kamāl al-Fārisī) in their

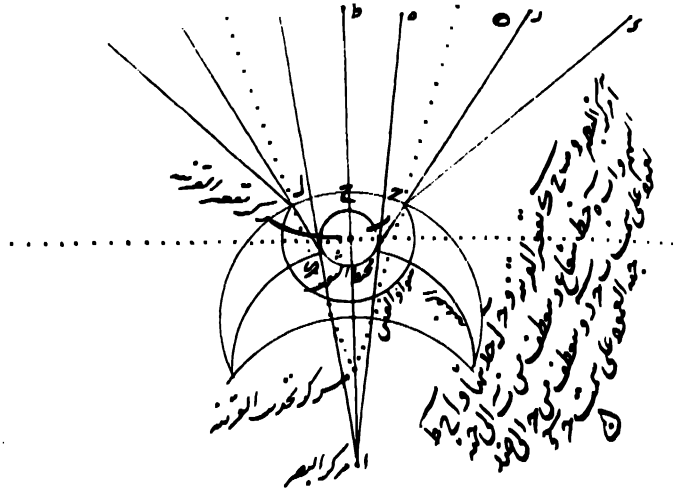

FIG. 6.—Diagram explaining the function of the eye, from *Kitāb al-baṣā'ir fī'ilm al-manāẓir*, or *Book of Reflexions on the Science of Optics* by Kamāl al-Dīn Abu'l-Ḥasan al-Fārisī, dated 1433. Ayasofya Library, Istanbul, Turkey.

observations of solar and lunar eclipses centuries before it became known to Europeans (e.g., Leonardo da Vinci, Giambattista della Porta, and many others to whom its discovery has mistakenly been attributed).

(*See* Curtze; Pauschmann; Polyak; Wiedemann 1910, 1912, 1914, 1923; *Encyc. Brit.*, 14th ed., "Camera Obscura," unsigned article, prob. by J. Waterhouse.)

SEC. 4. INTRODUCTION OF THE ARAB ARTS AND SCIENCES INTO EUROPE, AND THE EUROPEAN RENAISSANCE

1. The role of Arab learning in the European Revival of Arts and Sciences.—Toward the end of the eleventh century, and more especially during the twelfth, fragments of Classical Greek medicine and other learning, preserved, changed, and added to by Arab scholars, began to filter into Western Europe. To a small extent this knowledge came directly from Byzantion by way of southern Italy (Constantine the African of Monte Cassino; Magister Zacharias; Salernitan School; Sicily), but arrived chiefly through Spain ("Translator School" of Toledo, the "shiny center," founded by Gerhardus Cremonensis, or Gerard of Cremona, 1114–87). After a millennium of intellectual darkness, the nations of Southern and Western Europe began gradually to awaken by a stimulus coming from the Arab world.

By a curious fate, this occurred at the time when Arab Civilization itself showed signs of decline: in 1058, Seljuk Turks under Togrul conquered the city of Baghdad and with it almost the entire Near East; next, the Christian Crusades stirred up an intolerant orthodox reaction among the Arabs; thereafter came destructive invasions by the Mongols, first under Temūchin or Genghis Khan, and later under Timūr i Leng or Tamerlane. A final blow was delivered by the Mongols under Hulagu in 1258, by the destruction of Baghdad and by the invasion of Ottoman Turks. In the West, Córdoba, in 1236, and Seville, in 1248, were reconquered by Christian Spaniards.

The time of early Arab influence upon Southwestern Europe may be considered the beginning of the Modern Period of Western Civilization. Here, too, as in the oriental model after which it was patterned, medicine and the science of optics were among the most esteemed of several branches of learning. The science of optics, since its introduction into Western Europe at the beginning of the second millennium, exerted a powerful influence upon generations of learned men interested in the relationship of the human mind to the body, in life, and in the physical world in general.

Their interest eventually brought about the discovery of the laws of optics, the correct understanding of ocular structures and their functions, and the invention of ingenious optical instruments, such as the telescope and microscope.

Early Western anatomy and physiology of the eye and early European optics were borrowed from the Arabs. The Arab treatises translated into Latin (Ibn Sīnā or Avicenna, *Al-qānūn fī al-ṭibb*, or *Canon of Medicine;* Ibn al-Haitham, or Alhazen, *Kitāb al-manāẓir* or *Book of Optics;* Kamāl al-Fārisī, *Kitāb tanqīḥ al-manāẓir*, or *Making Optics Understandable*), as well as many others, became standard texts and remained supreme authorities for several centuries to come.

2. Early Western European treatises on optics.—The nations of Europe, still deeply

enveloped in barbarism, were as yet ill prepared to accept and to digest the wealth of new information, and even less to add significant contributions.

The earliest Western treatises on optics, quite naturally, were hardly more than compilations from Ibn al-Haitham's *Thesaurus*, rendered into Latin sometime during the twelfth century by an unknown translator, possibly Gerard of Cremona or one of his Toledan "School of Translators." This was true of the first treatise written in Europe about 1270, the voluminous *Perspectiva* or *Ten Books of Optics*,

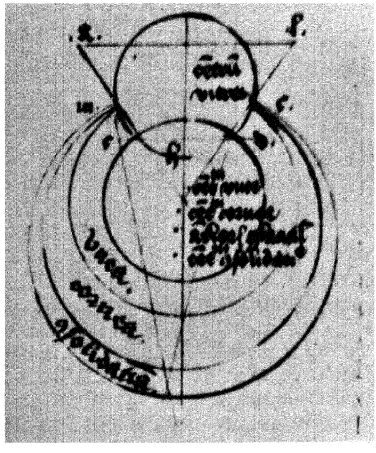

FIG. 7.—Geometrical eye diagram from *Opus Maius* by Roger Bacon, *doctor mirabilis*, the learned English Franciscan friar, of Oxford. From a fifteenth-century manuscript, at Bodleian Library, Oxford, England.

by Vitello (Witelo, incorrectly also Vitellio, 1220 or 1230–70 or 1278), a native of Silesia, then a part of Poland (he was therefore called *Thuringopolonus*, that is, a German-Pole).

Two other treatises, very similar to Vitello's book, written at about the same time in England, which became standard textbooks during the remainder of the Middle Ages, are the *Perspectiva* of the learned friar Roger Bacon of Oxford (1214–92) and the *Perspectiva Communis* of John Peckham, archbishop of Canterbury (approx. 1228 or 1240–91 or 1292). In these compilations the Greek sources then available (e.g., Euclid; Ptolemy; Apollónios, 3d or 2d century B.C.; Theodósios, 2d century B.C.; Menélaos, end of 1st century, Christian Era; Páppos, end of 3d and early part of 4th century, Christian Era; Théon, 4th century, Christian Era; Próclos, 410–85) were likewise used, particularly by Vitello and Bacon; but the chief source remained Ibn al-Haitham's *Thesaurus* and, in the following centuries, apparently also Kamāl al-Fārisī's *Tanqīḥ*. The scope and standard of all these early Western books on optics was naturally Greek and Arab, with all the virtues and faults of the originals.

3. EARLY EUROPEAN ANATOMY AND PHYSIOLOGY OF THE EYE.—The mistakes of the Greeks and Arabs concerning the structure of the eye and its functional interpretation are all encountered in the early Western treatises. For example, in the writings of Roger Bacon we find references to the central location of the crystalline lens, the lens as an actual photoreceptor, the cavity in the optic nerves, the "emanation hypothesis of vision," and the existence of a *pneuma* or "visual spirit." The problem of light refraction and of the formation of a visual image and hence the true functional significance of the retina remained as yet unconsidered. Nor did European anatomy and ophthalmic surgery of the Late Middle Ages, primitive and crude as they were, do much to advance knowledge or correct erroneous concepts. (Alcoatin 1159; Benevenutus Grassus of Jerusalem; Henry de Mondeville 1304; Mondino de'Luzzi or Mundinus 1315; Guy de Chauliac or Cauliacus 1363; Manfredi 1490; Fernel 1542; Du Laurens 1599.)

In fact, from that period until far into Modern Times, there was hardly any independent Western anatomy and physiology of the eye worthy of the name.

(On early European ophthalmology and surgery, *see* Pansier 1908, v. 2, p. 99, and Hirschberg 1908.)

4. EARLY WESTERN EYE DIAGRAMS.—Western dependence upon Arab sources is nowhere better manifested than in the various eye diagrams found in the manuscripts and early printed books and treatises on optics of this period, which are all adaptations from the Arabic originals. Even the best of these diagrams for example, those found in the various Latin manu-

scripts of Roger Bacon (Figs. 7, 8), of John Peckham (Fig. 9), of Ibn al-Haitham's *Opticae Thesaurus* (Fig. 10), of Vitello's *Ten Books of Optics* (Fig. 11), and in other similar writings of the Late Middle Ages—are a jumble of circles and lines, with hardly a semblance of anatomical reality. Even so, all the early Western eye diagrams betray their Arabic, and hence Greek, origin, of which they are mostly inept, degraded copies. (Alhazen 1572; Avicenna; Bacon; Barber of Anatomy" (1513 or 1514–61, portrait Fig. 15; *see also* Figs. 16, 17); in the figure of Felix Platter (1583, 1603; *see* Fig. 19); and in that of Aguilonius (1613, Fig. 20).

Not before the work of Girolamo Fabrizi d'Aquapendente (Lat. Hieronymus Fabricius ab Aquapendente, 1600, portrait Fig. 21), and of Christopher Scheiner (1619; *see* Fig. 22 and portrait, Fig. 30), both based upon personal experience, was there, in fact, a break with the

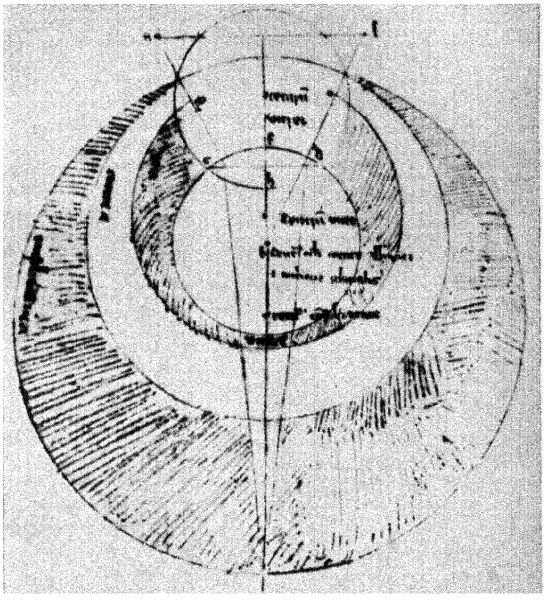

FIG. 8.—Another eye diagram by Roger Bacon, found in a fifteenth-century manuscript of his *Perspectiva*. Bodleian Library, Oxford, England.

tisch; *Codex Lipsiensis* No. 1183; Maurolycus; Peckham; Reisch; Ryff; Vitello; Vogtherr; *see also* Choulant; Crew; Polyak 1941 or 1948; Rohr 1924; Sudhoff 1907, 1915; *cf.* Figs. 12, 13, 14, 16, 18, 19, 20.)

Even later, Arab influence is still clearly noticeable. It can be traced in various sketches of the eye by Leonardo da Vinci (1452–1519), the encyclopedic genius of the Italian Renaissance; in the somewhat improved diagram and plate of Andreas Vesalius (1543), the "Reformerroneous views on the internal structure of the eye inherited from the Greek period of almost two thousand years before (*see also* R. Columbus). The cruder, external parts of the eye, in contrast, had already become better known from Vesalius' description (Fig. 17). (For further information on history, eye diagrams, legends, and quotations *see* Polyak 1941 or 1948.)

SEC. 5. EARLY MODERN OPTICS AND DISCOVERY OF THE RETINAL IMAGE

1. KNOWLEDGE OF THE STRUCTURE OF THE EYE AND THE ADVANCEMENT OF EARLY WESTERN OPTICS.—Since the vertebrate eye is a dioptrical apparatus constructed according to the principles of physical optics, in particular those of light refraction, its correct interpretation was not possible until the basic laws of refraction had been formulated. In turn, the discovery of laws of refraction, or the behavior of light when it passes through the variously propertied and differently shaped transparent bodies, depended to a great extent upon the correct under-

standing of ocular structures. The solution of these mutually interdependent problems was a long process, which ultimately led to the highly advanced modern physiology of vision and modern optics.

2. Invention of eyeglasses.—The earliest attempts at a practical application of dioptrics were made during Classical Antiquity (*see* sec. 2, this chapter). There is no sure evidence that the Greeks or Romans or any other nation of the Ancient World had either sufficient theoretical knowledge or practical experience in making objects of glass to make lenses that would be of much use as aids to defective vision (*see* sec. 2 [2], this chapter). It is certain that spectacles were not known during Classical Antiquity or during the greater part of the Middle Ages.

Neither is the thesis of a non-European ori-

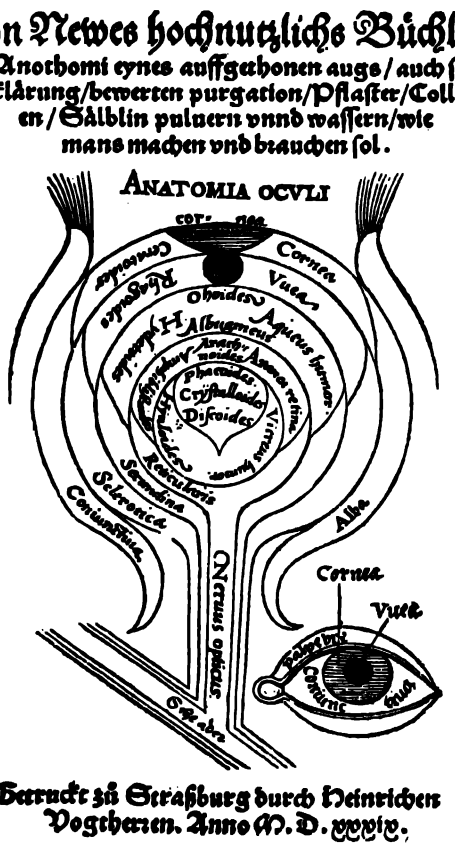

Fig. 13.—Structure and external view of the eye from *A New Most Highly Useful Little Book, and Anothomy of an Open Eye, Together with Its Explanation, Well-tried Purgation, Application, Poultice, Fine Salves, Powders and Waters, and How To Make Them and To Use Them*, by Heinrich Vogtherr, printed in Strassburg, 1539. Note all labeling in Latin except the optic nerve, which is also called, in German, *Sehader*, or "visual vessel," referring to the ancient concept of the optic nerves as hollow channels. From K. Sudhoff, Stud. z. Gesch. d. Med., Fasc. 1, p. 24. J. A. Barth, Leipzig, 1907.

gin of spectacles well documented. In China the use of spectacles cannot be traced with certainty earlier than the time of Marco Polo's travels (1271–95). It is probable that the knowledge of how to make spectacles had spread from Europe to China, rather than from China to Europe. This knowledge could most reasonably have been passed along the trade routes opened by the temporary political and economic unification of most of Eurasia in the wake of Mongol conquests initiated by Genghis Khan (Temüchin), the "Perfect Warrior," during the early part of the thirteenth century. A contrary statement by Cuming (1855) concerning the antiquity of Chinese spectacles and of the *ocularia* supposedly in use at Constantinople as early as A.D. 1150, requires careful modern verification. This applies also to a statement on the great age of Chinese lenses made in a pamphlet on *Ophthalmic Lenses, etc.*, published by Bausch & Lomb (1935).

The preliminary step toward the advancement of optics and toward a correct interpretation of structures of the eye was made with the discovery, doubtless purely empirical, of eyeglasses, about A.D. 1285. There is little reason to think that this discovery was made by Roger Bacon (1214–94), of Oxford, even though he may have gained some rudimentary knowledge of the action of convex and concave lenses (*Opus Maius*, 1268). Overwhelming evidence points rather toward Northern Italy.

The identity of the discoverer is uncertain. That this was S. d'Armato degli Armati, a Florentine nobleman, as was claimed, is not probable. There are some indications that the discoverer may have been A. Spina, a Dominican friar in Pisa (d. 1313). After sifting the scanty information on the subject, it appears probable that eyeglasses gradually developed from a "reading glass," a rather large plano-convex lens to be put upon a page in order to facilitate reading by making the letters bigger. At any rate, such reading glasses were mentioned by the poets and writers of the second half of the thirteenth century as one of the wonders of the age. (*See also* G. Ten Doesschate 1946.)

The earliest written mention of reading glasses was made by Heinrich Frauenlob (1250–1318), a German poet; the second by Bernhard Gordon of Montpellier in *Lilium Medicinae* (1303); the next by Guy de Chauliac (1363) and by the Italian poet Francesco Petrarca (Petrarch, 1304–74). Roger Bacon gave a good description of the use of the reading glass (*see* Clay & Court, pp. 4, 5). The subsequent step in the evolution of eyeglasses was to provide the reading glass with a handle in order to hold it close to the eye.

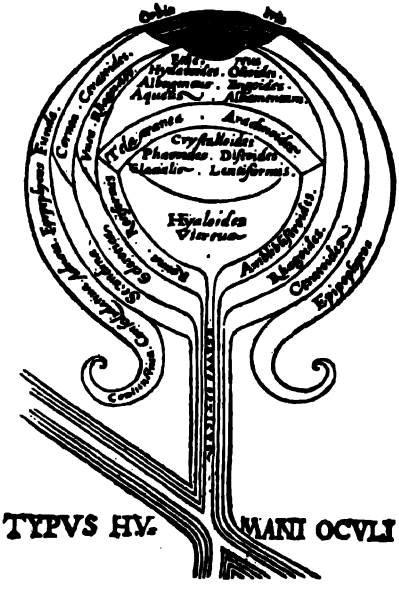

FIG. 14.—Structure of the human eye from a book by Walter Hermann Ryff printed in Strassburg, 1541. Note that the optic nerves are presented, as in the preceding figure, as hollow channels meeting in the chiasma. From K. Sudhoff, Stud. z. Gesch. d. Med., Fasc. 1. J. A. Barth, Leipzig, 1907.

The most likely locality of the first attempt to fit two smaller reading glasses together in a frame of horn, leather, bone, or metal and attach them close to the eyes was Venice, one of the great focal points of trade, wealth, and culture of the time. Or, rather, it was Murano, a Venetian suburb on the mainland, an ancient seat of the glass-blowing industry. In any case, the manufacture of *perspicilla*, *ocularia* or "beryls," *occhiali*, *besicles*, *antojos* or *anteojos*, *Brillen*, *Augenspiegel*, *ougspiegel*, and *spectacles*,

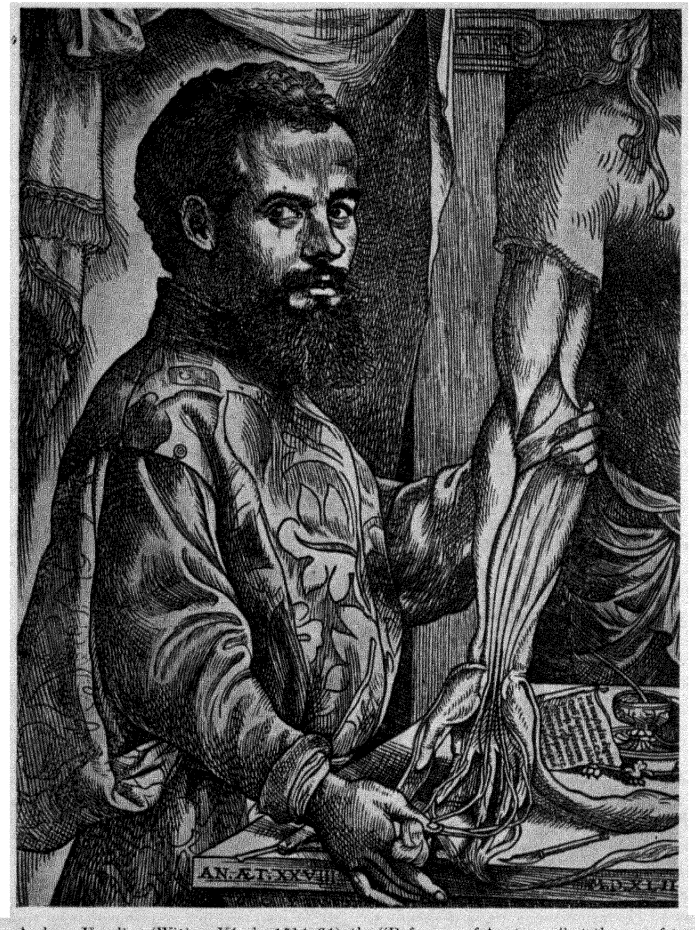

FIG. 15.—Andreas Vesalius (Witing, Vésale, 1514–64), the "Reformer of Anatomy," at the age of twenty-eight. Woodcut portrait engraved by an unknown artist from a drawing by Jan Stephan van Calcar, Vesalius' friend and illustrator of his famous textbook of anatomy, drawn in 1542. Frontispiece from the first edition of Vesalius' *De Corporis Humani Fabrica*, printed at Basel, 1543. From M. H. Spielmann, *The Iconography of Andreas Vesalius*. J. Bale, Sons & Danielsson (Staples Press, Ltd.), London, 1925. (*Cf. also* Fig. 64, and a portrait by Tintoretto in R. N. Wegner 1939, Fig. 6.)

as these early eyeglasses usually made of semi-precious beryllium or emerald were called in the various idioms, was well established in that region during the first half of the fourteenth century. (The original Greek word for emerald was ἡ βήρυλλοσ, ὁ βηρύλλιοσ, or ὁ βηρυλλιτ-λίθοσ, diminutive το βηρύλλιον.)

With the development of other centers of manufacture at Nuremberg (Nürnberg), Rouen, and in Flanders, the use of eyeglasses became fairly common toward the middle of that century. For a long time, only convex glasses for the correction of presbyopia were made. It is significant that concave glasses for the correction of myopia did not appear until the middle or end of the fifteenth century, shortly after the invention of printing. Concave eyeglasses were first mentioned by Nicolaus Cusanus (1401–64) in his book *De Beryllo*, the earliest monograph on spectacles.

The oldest pictorial presentation of eyeglasses appears to be in a painting by Tommaso di Modena, dated 1352, at Treviso, in Northern Italy. This was a single reading glass or a magnifier held before the eye. Tommaso painted another picture in which a double glass was shown. Another example, which may be as old as the preceding, is in a picture by a painter of the Giotto School which is now in the Figdor Gallery in Vienna. The next oldest picture of eyeglasses seems to be in a miniature painting in a manuscript Bible of the year 1380, in the possession of the Bibliothèque Nationale in Paris. The third in chronological order is the painting by Conrad van Soest (C. de Susato), dated 1404, in the church in Niederwildungen, Germany. Another is the painting by Jan van Eyck, dated 1436.

Other early representations of spectacles mentioned by Sacken (1879) are those by Domenico dal Ghirlandajo in the church of S. Trinità, in Florence, and one by Quintin Matsys at Windsor. The first printed picture of eyeglasses appeared in Hartman Schedel's *Chronicle*, Nuremberg (Nürnberg), Bavaria, 1493. Hogarth, regarded as a "supreme pictorial satirist," immortalized nose-spectacles in his painting "The Politician." (*See* Sacken; *cf.* Figs. 23–26.)

The invention of eyeglasses and their gradual perfection, a slow process extending over several centuries, coincided with the beginning of a new era of civilization. It was a necessary technical prerequisite for the rise and advancement of the science of optics and, above all, of modern dioptrics. It was the first step which made possible the invention of the telescope and microscope, two instruments which have immeasurably increased our knowledge of life and the universe and have profoundly influenced the practical side of human affairs. (*See* Clay & Court 1932; Disney, Hill & Baker 1928, Gunther 1923–45.)

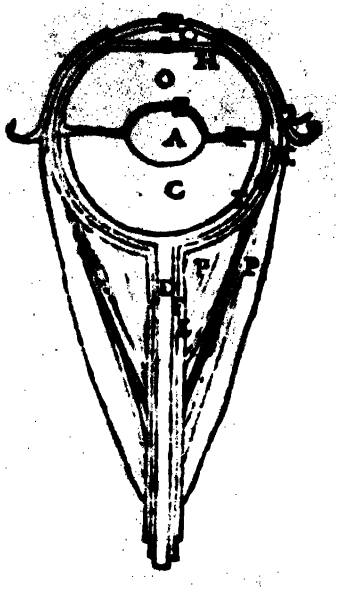

FIG. 16.—Eye diagram from the first edition of *De Corporis Humani Fabrica* by Vesalius, printed in 1543. Compare its essential features with the Arab diagrams in Figs. 2, 3, 4. Courtesy Professor J. F. Fulton, Yale University, New Haven, Conn.

3. ITALIAN RENAISSANCE AND EARLY MODERN ATTEMPTS TO EXPLAIN THE DIOPTRICAL APPARATUS OF THE EYE.—The development of the glass industry and the invention of eyeglasses, lenses, and other optical instruments were part of a historical change which was taking place in Southern and Western Europe and, above all,

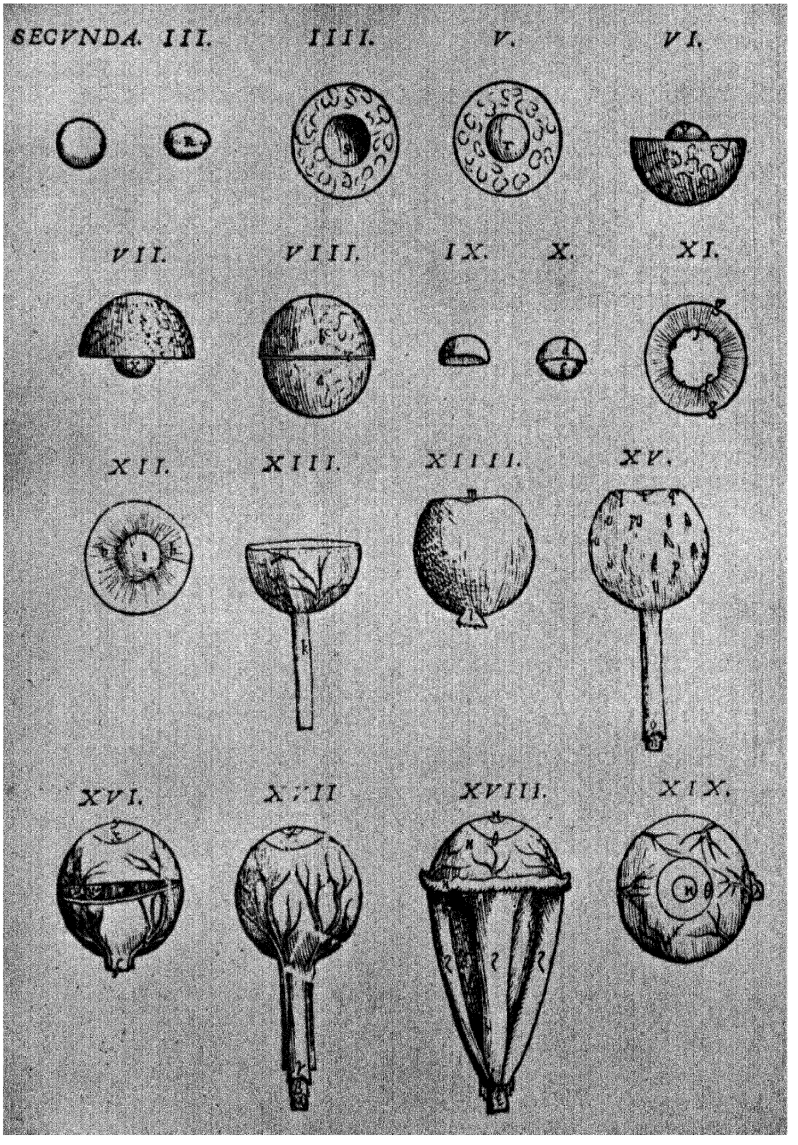

FIG. 17. Woodcut plate showing parts making up the human eye. From the first edition of *De Corporis Humani Fabrica* of Vesalius (1543). Courtesy Professor J. F. Fulton, Yale University, New Haven, Conn.

in Italy. This period, thought of as a revival or rebirth of Classical Civilization, was, in fact, the beginning of a new epoch of human history which brought the Dark Ages to an end. This great material and intellectual change was manifested in the stability of political, economic, and social orders, which resulted in improved

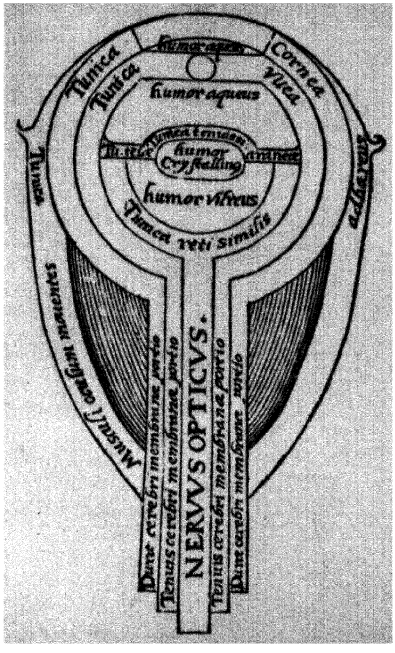

FIG. 18.—Eye diagram from the joint volume of Alhazen's *Opticae Thesaurus* and Vitello's *Opticae Libri X*, published at Basel, 1572. This diagram is obviously an adaptation of the figure found in Vesalius' *Fabrica* (Fig. 16) rather than of the diagrams found either in the Latin or in the Arabic manuscripts of Ibn al-Haitham's *Book of Optics*, known during the Late Middle Ages (Figs. 2, 3, 4, 9, 10, 11).

living conditions, gentler manners, and an awakening of interest in the arts and sciences, including knowledge of the human body and of nature in general.

Leonardo da Vinci (1452–1519, portrait Fig. 61), probably influenced by Ibn al-Haitham, Ibn Rushd, or Vitello, arrived at a full realization of the dioptrical role of the transparent media of the eye. He became convinced that a visual image or images is or are formed in the eye, but he was not able to explain how. With the basic preliminary work in dioptrics still to be done, this was not yet possible. Another factor which helped obscure the problem was Leonardo's obsession with the idea of an erect image, which he, on logical and psychological grounds, postulated (for otherwise, he thought, one would see the object upside down!). Nor was his knowledge of ocular structures based

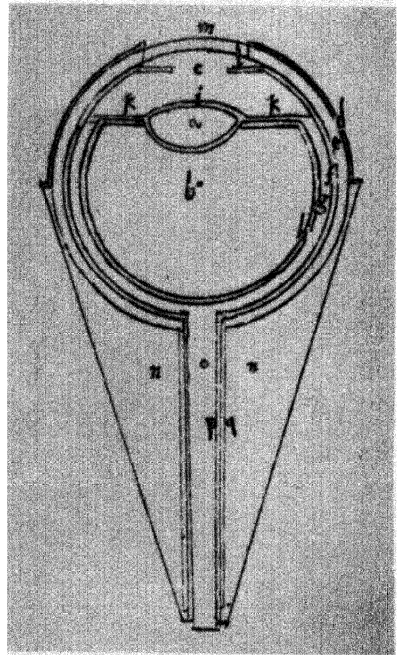

FIG. 19.—Eye diagram from Platter's *De Corporis Humani Structura et Usu*, published at Basel in 1603. It is an almost accurate copy of Vesalius' figure, with, however, one important innovation: the crystalline lens is now placed closer to the iris, even though it still does not touch it, while in Vesalius' presentation the lens has a central location, as in the Arabic diagrams.

upon personal experimentation. His attempts to solve the problem with pen and paper naturally failed. His fantastic sketches, showing a double refraction in the eye but no collecting action by the cornea and lens, were pure specu-

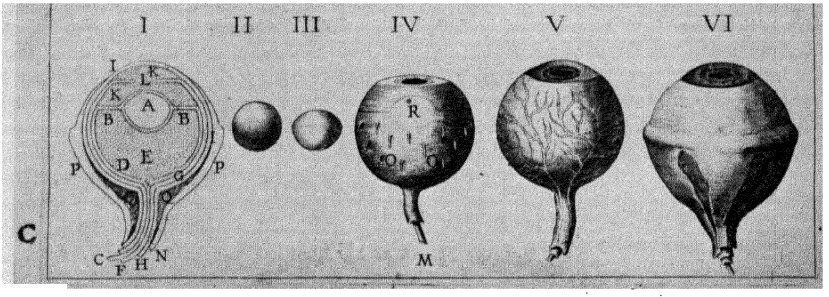

FIG. 20. Component parts of the human eye, left-hand sketch representing a section showing the lens, the iris, and the several coats of the eye. From F. Aguilonius, *Opticorum Libri Sex*, Antwerpiae, 1613.

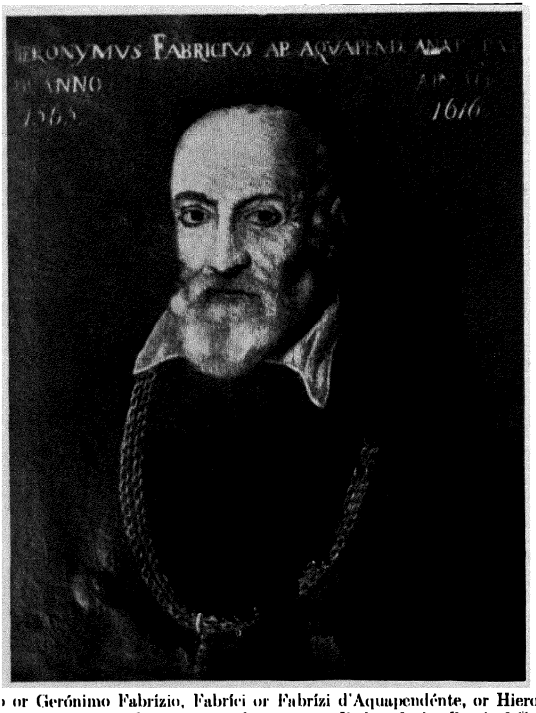

FIG. 21.—Girólamo or Gerónimo Fabrizio, Fabrici or Fabrizi d'Aquapendénte, or Hieronymus Fabricius ab Aquapendente (1537–1619), professor of anatomy and surgery at Padua, Italy. Pupil of Gabriele Falloppio and teacher of William Harvey. Investigator of the eye, ear, and the organ of voice. First demonstrated the correct position of the crystalline lens in the anterior portion of the eye, just behind the iris, instead of in the center of the eye, where it was believed to be by the Greeks, Arabs, and the early western Europeans: Vitello, Leonardo da Vinci, and Vesalius. From P. Capparoni, *Profili bio-bibliografici*, 1928 32. Original at Istituto Anatomico della Università, Padova, Italy.

lation, void both of anatomy and of all the essentials of physiological optics (*see* Polyak, *The Retina*, Fig. 24).

And yet, wrong as Leonardo was in all details, his thinking moved in the right direction. This was also true of many other men of that time who were eager for more knowledge. Maurolycus of Messina, Sicily, apparently was more successful (1494–1575; his book was written in 1554 but published in 1617). He was the first to understand that rays of light radiating from a luminous or illuminated point are again collected by a lens at one point. Unfortunately, Maurolycus, influenced by ideas from the past, primarily the belief in the photoreceptor function of the crystalline lens, failed to recognize that the sum of such focal points symmetrically distributed over the retina would form an image on it, instead of on the surface of the lens, where he placed it.

Even stranger is the case of Giambattista della Porta (1589, portrait Fig. 27). Following Daniello Barbaro (1568), he first added a convex lens to the pinhole camera, or *camera obscura*, in this way making the similarity of this contrivance to the eye more apparent. Yet, in spite of this, Porta never understood either the principles of dioptrics or their application to the eye, and he continued in his belief that the visual image was formed on the surface of the lens.

4. Discovery of the photoreceptor role of the retinal membrane by Platter. The first clear pronouncement of the photoreceptor function of the retinal membrane and the subsidiary, purely physical, role of the crystalline lens of the eye was made by Platter, an anatomist at Basel (Platerus, 1536–1614, portrait Fig. 28; book published first in 1583 and again in 1603). For him the lens was not the true photoreceptor that it was to the Greek and Arab scholars and their European followers of the Middle Ages, but only a collector of the rays falling into the eye, a *perspicillum nervi visorii*, or "spectacle of the optic nerve" (that is, of the retina). The true photoreceptor, in his opinion, was the retina, while the lens merely collected light and distributed it over the expanse of the former.

It is true that the same idea was occasionally expressed by others, for example, by Ibn Rushd, the famous Spanish-Arab scholar who lived four centuries earlier and from whose writings the students of the Renaissance, such as Leonardo da Vinci, Pozzi (*see* Edinger 1892), and indirectly possibly Vesalius, and even Platter himself may have received a suggestion. Yet the undeniable fact remains that in Platter's time the mistaken Greek idea of the photoreceptor role of the crystalline lens still found universal acceptance, as is attested by numerous celebrities in the fields of optics, anatomy, and physiology, such as Maurolycus, Porta, Du Laurens, Bauhin, and even Hieronymus Fabricius ab Aquapendente himself.

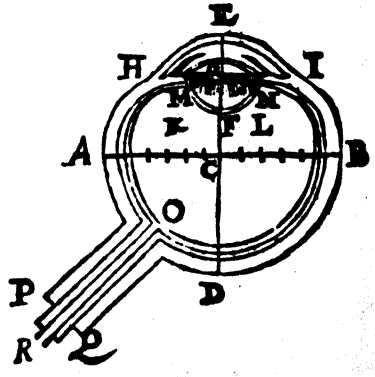

Fig. 22.—Earliest diagram of the human eye in which relative proportions and arrangement of structures approach the normal. From Christopher Scheiner's *Oculus*, etc., published at Innsbruck, Austria, 1649. Courtesy U.S. Army Medical Library, Washington, D.C.

In order to disprove it against formidable opposition Platter performed an experiment. In it he cut the so-called "araneal tunic"—now called suspensory ligament of the lens or zonule of Zinn—along which, according to the hypothesis of the photoreceptor function of the lens, the visual impulses were supposed to pass from the latter to the retina and thence to the optic nerve and brain. Since, in spite of the severance

of the zonular attachment of the lens, vision was still possible, Platter's experiment demonstrated the functional role of the lens to be purely physical (*see* Plehn 1922, p. 204).

5. KEPLER'S EVIDENCE OF THE RETINAL IMAGE.—Platter's opinion, logical and based upon experimental evidence, did not seem to carry much weight with his contemporaries, principally because it lacked a clear dioptrical interpretation and was otherwise defective in certain

FIG. 23.—One of the earliest representations of spectacles and their use. From a painting in the parish church at Rothenburg ob der Tauber, in Bavaria, Germany, executed by F. Herlin in the year 1466. From A. von Pflugk, Ztschr. f. ophth. Optik, v. 14, p. 140, 1927.

details. It is probable that it would not have prevailed against the dominant view of the time, had it not come to the attention of Johannes Kepler (1571–1630, portrait Fig. 29), the foremost mathematician, student of optics, and astronomer of his time (for Kepler's biography see *Naturwissenschaften*, v. 30, 1930).

According to Kepler's explanation (1604), the visual image was not caught by the lens, as Porta insisted, but was "painted" on the retina. Furthermore, the retinal image was not the result merely of an intercrossing of the rays of light that enter the eye through the pupil (as is the case in the simple pinhole camera with which Ibn al-Haitham compared the eye, a factor Leonardo da Vinci alone considered) but was a product both of the collecting and the refracting power of the cornea and of the lens. In fact, as Kepler insisted, the retinal image was an aggregation of as many focal points ("image points") of as many "pairs of cones" of light rays as there were points on the object seen ("object points"), the bases of the cones coinciding with the portion of the lens not covered by the iris. In this way a "real" and inverted image, clear in detail, although diminished in size, was produced on the retinal backscreen.

This and other discoveries of Kepler (for example, a correct interpretation of presbyopic and myopic spectacles) not only gave a satisfactory explanation of ocular structures but also furnished a reliable basis for the modern science of optics (Mach 1925; Rohr 1925).

Kepler's efforts in optics and allied fields had opened a new era of investigation. Mach says:

"In his *Dioptrice* (1611) which has but eighty pages, Kepler established the fundamental scientific principles of dioptries." Subsequently, Kepler's pioneer work was followed by a series of important discoveries by some of the most brilliant students of the physics and of the physiology of the eye, by which physical and physiological optics was brought to its present state (Grimaldi, W. Snell, Huygens, Thos. Young, Porterfield, Euler, Fresnel, Malus, Arago, Brewster, Fraunhoffer, Fizeau, Gauss, Listing, Maxwell, Hertz, Donders, Helmholtz, Abbé, Mach, Michelson, Gullstrand, Rohr, *et al.*).

6. SCHEINER'S EXPERIMENTAL DEMONSTRATION OF THE RETINAL IMAGE. The conviction of the reality of a retinal image became even firmer through the efforts of a series of notable students of optics during subsequent decades: Christopher Scheiner (1575–1650), Willebrord Snell (1591–1626), René Des Cartes (Cartesius, 1596–1650), Christiaan Huygens (1629–95), Isaac Newton (1642–1727), Molyneaux (1692), Hamberger (1696), and others. Their merit was to have placed the study of ocular dioptrics and of optics in general on a solid scientific, experimental foundation.

FIG. 24.—Picture of the circumcision of Jesus, in which the rabbi performing the operation uses *pince-nez*, or "nose-clip" eyeglasses, which permit the use of both hands. Part of an engraving made by C. Schoneus, 1594. Courtesy Professor W. Bloom, University of Chicago.

Kepler's views were largely theoretical deductions based upon computations which, even though probable, required testing by experiment. The first practical proof of the presence of a retinal image, following Kepler's suggestion, was furnished by Pater Scheiner (portrait Figure 30). He made the image formed on the retina directly visible, first in animal eyes and then in the human eye, by removing part of the opaque coats in the back of the eyeball (1625; *see* Rohr 1919, p. 129). A similar experiment was performed even earlier by Aranzi (1595, p. 70), but, having been made before Kepler's lucid interpretation and with no knowledge of dioptries, it remained without effect.

During the century following Scheiner, the experiment with the retinal image was repeated by numerous investigators, the more prominent among them being F. Sylvius de la Boë (1614–72), Kircher (1646; portrait Fig. 32; experiment, Fig. 33, *left*), T. Bartholin (1651), A. Haller (1769), Buzzi (1782), and Magendie (1816). In modern times, finally, it was possible to produce the permanent "optogram" by fixing the retinal image chemically. (Kühne 1877, 1878; *see also* Gerling; Grether 1940; Hidano; Lashley 1932; Uexküll & Brock; similar studies were recently made by D. D. Michaels.)

As a result of the preceding efforts, the view that "the eye is nothing but a natural pinhole camera, and that the pinhole camera in turn is an artificial eye" (Kohlhans, Sturm) became universally accepted, in spite of occasional opposition, such as that voiced by J. Campbell, De la Hire, Horn, Le Cat, Lehot, Mariotte,

SEC. 6. INVESTIGATIONS OF THE RETINA FROM THE EARLIEST TIMES TO THE RISE OF MODERN MICROSCOPY

1. Investigation of the retina during Classical Antiquity. The investigation of an organ apparently so insignificant as the retina could have been initiated only after its importance in vision had been established.

From what has been said about the development of physiological optics and the interpretation of the ocular structures, it is apparent that the true function of the retinal membrane as a photoreceptor or a sensitive backscreen of the living "dark chamber," the eye, had been recognized relatively late. It may, therefore, seem remarkable that the Greek anatomists of the Hellenistic or Alexandrine Period (*ca.* 300 B.C.) paid any attention to this membrane at all. This was probably because of the belief of the Ancients in the role of the retina as a conveyer of the "visual spirit" from the optic nerve, hence from the brain, to the crystalline lens, which, in their opinion, was the actual photoreceptor. Another probable reason was their belief that the retina served, in its second capacity, as a transmitter from which the visual impressions or sensations elicited in the lens passed to the optic nerve and along the optic nerve to the brain. In the opinion of the Greek anatomists and physiologists, the retina was well suited for both these functions, since it was attached to the lens by means of the araneal tunic, or zonular ligament, and was continuous with the optic nerve.

There was yet a third reason: the belief, be-

FIG. 27.—Giambattista della Porta (1536-1615), an encyclopedic student and writer on physics, chemistry, optics, and various natural phenomena during the Italian Renaissance. An experimenter with the *camera obscura* or "dark chamber," a forerunner of the photographic camera. Author of *Natural Magick in XX Bookes*, a widely read compendium of that time. From E. Mach, *The Principles of Physical Optics*, Methuen & Co., London, 1925.

cause of its abundant blood supply, in the nutritive role of the retina, which the Greeks thought brought nourishment to the vitreous, that, in turn, nourished the crystalline lens, both therefore being able to preserve their transparency. (*Cf.* sec. I [2], this chapter.)

It is remarkable that even at that early date, when the science of optics and optical technology were practically nonexistent, an acute observer like Galen noticed the similarity between the appearance of the retinal substance and that of the brain, an observation whose true cause was discovered only in modern times. (*See* Galen, *De Hippocr. et Plat. Decr.*, book 7, chap. 5; *De Usu Part.*, book 10, chap. 1.) One is inclined to suspect that in Galen's case the reason for his emphasis on this structural similarity was his desire to discover a conveyer of the "visual

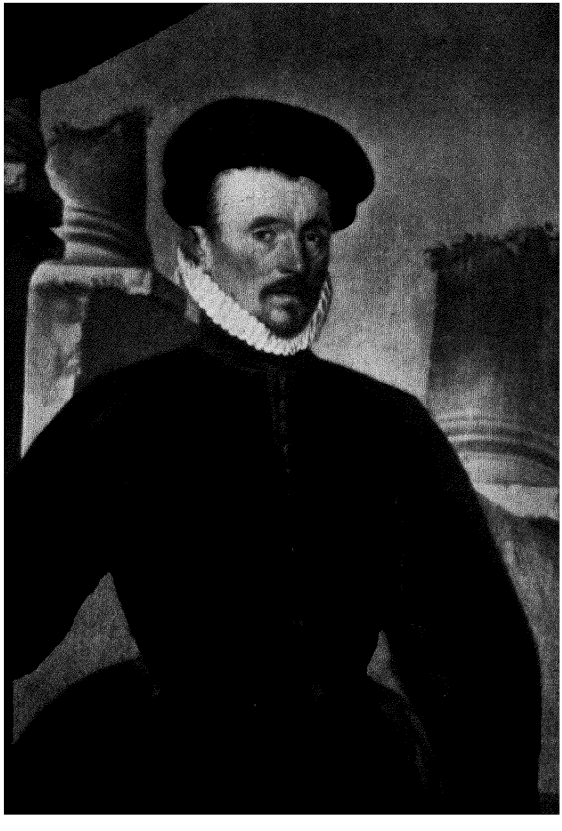

FIG. 28.- Felix Platter (Platerus, 1536-1614), professor of anatomy at Basel. First investigator definitely to consider the retinal membrane of the eye a true photoreceptor, and the crystalline lens as its "spectacle" or a dioptrical medium. In order to prove his view, he severed the suspensory ligament or Zinn's zonule, by which the lens is attached to the inner coats of the eye, without impairing the vision. In this way he demonstrated the falsity of the ancient Greek and Arab view, in which the lens was the true photoreceptor and the ciliary ligament and retina were conductors of the visual impressions to the optic nerve and brain. From a painting by Hans Bock, Sr., 1584, in the Oeffentliche Kunstsammlung, Kunstmuseum Basel, Switzerland.

spirit" from the brain to the crystalline lens via the optic nerve and retina, rather than actual observation (*see* chap. II, 3 [3]).

2. KNOWLEDGE OF THE RETINAL MEMBRANE DURING THE MIDDLE AGES. During the Middle Ages, especially the darkest period from the sixth to the eleventh century, with an almost complete cessation of interest in the human body and in nature in general, nothing was added to the knowledge of the retina or of the eye. Even the most zealous among the Arab scholars Ḥunain ibn Isḥāḳ, Alī ibn ʿĪsā, ʿAlī ibn al- Abbās, and Ibn Sīnā could do no other service than to preserve part of the anatomical knowledge bequeathed by the Greeks, since the Mohammedan religion forbade dissection.

In this connection it is of interest to mention

FIG. 29. – Johannes Kepler (1571–1630), court astrologer to the German emperor and one of the foremost mathematicians and astronomers of all times. Discoverer of the laws of planetary motion known as "Kepler's laws." Pioneer student of physical and physiological optics. First correctly interpreted the action of the dioptrical media of the eye and of the formation of the ocular image on the retina. From E. Mach, *The Principles of Physical Optics*, 1925, Methuen & Co., London. For biography *see* Naturwiss., v. 18, 1930.

the origin of the modern word "retina," which is a Latin translation of the Arabic word *al-shabakīyya*, or "the netlike tunic," which, in turn, was a translation of the Greek name ἀμφιβληστροειδὴς χιτών, or *amphiblestroïdés hitón*. This name was given to the retina by Herophilos, its discoverer, because of its resemblance, when collapsed, to a folded fishing net, as this membrane usually appears in a carelessly dissected eye. The Arabic term was preserved by Ibn Sīnā, or Avicenna, in his *Canon of Medicine*, a medical encyclopedia of the Middle Ages. After the translation of the *Canon* into Latin by Gerard of Cremona during the twelfth century, the term became generally known in Europe.

Productive investigation of the retina may be said to have begun with early microscopy. What was known about it by the compiling anatomists of the late Middle Ages and of early Modern Times went little further than a recognition of structures easily observable with the unaided eye: the blood vessels and bundles of myelinated nerve fibers, both of which could easily be seen in various domestic and other easily procured animals, e.g., a Hare and a Rabbit. The presence of retinal "veins" and nerve fibers was mentioned by several writers during the Middle Ages, for example, by Alī ibn Īsā (10th century), Alcoatin (1159), and Vitello, while the absence of color in the retina was noticed by Benevenutus Grassus (*ca.* 12th century), for which reason he called it *discolorata*. This may perhaps indicate the beginning, even at that early date, of an active interest in things anatomical.

Except for these few instances, even the foremost anatomists of the remainder of the Middle Ages and of early Modern Times up to Platter (1583), Kepler (1604, 1611), and Scheiner (1619) paid but little attention to the retina or ignored it altogether (Fernelius, Vesalius, Falloppio, Aranzi). Even later, after its function was known, it did not become the subject of more detailed investigation until optical technology had advanced enough to permit employment of magnifying glasses.

3. EARLY MICROSCOPIC INVESTIGATION OF THE RETINAL STRUCTURE. The first investigator to examine the retinal structure microscopically was Antonie van Leeuwenhoek, a learned draper, sexton, and town chamberlain of Delft, Holland (1632–1723, portrait Fig. 31). This remarkable autodidact ground his own biconvex lenses and made his own simple but effective "microscopes." (*See* Fig. 35; *see also* Allen 1940; H. Baker 1743; Carpenter 1901; Cittert 1933; Conn, 1948; Dobell; Leikind 1941; Locy 1901, 1910; A. W. Meyer; Priestley; Roseboom; Singer 1914; A. Wolff 1935; and Turtox Microscopy Booklet 1946.)

FIG. 30.—Christopher Scheiner (1579–1650), a Jesuit friar, born at Wald in Schwaben, Bavaria, Germany; died at Neisse, in Silesia. A noted astronomer still adhering to Ptolemy's geocentric hypothesis of solar system and a diligent student of the eye and of optics. First, in the wake of Platter's and Kepler's postulations, to furnish experimental evidence of the formation of a retinal image in the eye. From Albert König, *Fernrohre und Entfernungsmesser*, 1937. Courtesy J. Springer, Berlin.

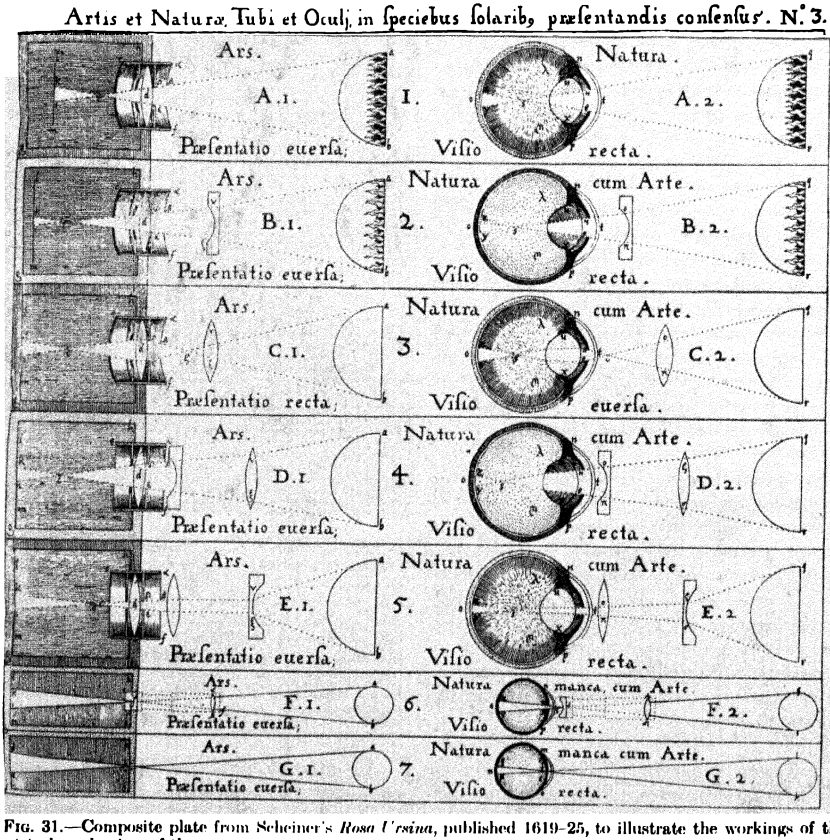
An interesting piece of information on the equipment of Leeuwenhoek's microscopes may be found in a book entitled *The Microscope Made Easy* by Henry Baker, himself a pioneer

microscopist, published in London in 1743. In a footnote to page 7, Baker writes:

> Several writers represent the glasses Mr. Leeuwenhoek made use of in his microscopes to be little globules or spheres of glass, which mistake most probably arises from their undertaking to describe what they had never seen; for at the time I am writing this, the cabinet of microscopes left by that famous Man, at his death, to the *Royal Society*, as a legacy, is standing upon my table; and I can assure the world, that every one of the twenty-six microscopes contained therein is a double convex lens, and not a sphere or globule.

The structures which Leeuwenhoek observed on two occasions (1674 and 1684) in a cow and a frog specimen of the retina were blood vessels containing blood corpuscles and some small globules of rather oblong shape adhering to the vessels, which may have been either the rods and cones or the nerve cells.

Ruysch (1700), another deft Hollander, showed the retina to be composed of both blood vessels and nerve fibers. Thereafter many other anatomists and physiologists, physicists, and philosophers described and discussed various retinal structures, some real and others whose presence they postulated purely speculatively. Most of the investigators of this period believed the retina to be a simple expansion of the optic nerve, which may explain the German term



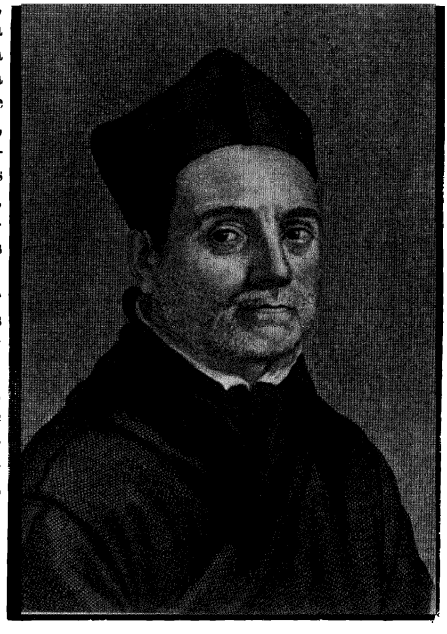


FIG. 31.—Composite plate from Scheiner's *Rosa Ursina*, published 1619–25, to illustrate the workings of the dioptrical mechanism of the eye.

Faserhaut, or "fibrous membrane," occasionally met with in older writings (*see* Burdach 1822, p. 177). Only a few, those more critically inclined, as, for example, Winslow, thought this membrane to be composed of cellular elements as well as of nerve fibers and blood vessels.

These observations and assumptions, still largely vague, began to acquire substance with the work of Briggs (1676), Morgagni (1719), Maître-Jan (1707), Zinn (1755), Valsalva (1740), Fontana (1782), and others. Fontana clearly showed for the first time that the retina contained not only blood vessels and nerve fibers but also a pulpy or medullary substance, made up of small, spheroidal bodies held together by very thin, transparent membranes and fine filaments. He found that these globules, which looked as if they were made of a transparent jelly, greatly resembled similar globules in the brain. What he saw both in the retina and in the brain undoubtedly were spherical nerve cells. The framework of delicate membranes which held the globules together, described by him, was very likely the neuroglial stroma.

Interesting as all these observations were, they were still a long way from answering the questions raised by those interested in the correlation of the retinal structures with the principal visual phenomena. One of these problems was the direct continuity between the retinal nerve fibers and the fibers of the optic nerve. Another concerned the size of the fibers and their distribution over the surface of the retinal membrane. While some investigators assumed a uniform distribution, others believed the fibers to be distributed unevenly. An observation made by Maître-Jan, that the retina was thicker in the fundus of the eye than near the *ora serrata*, seemed to support the latter view.

The "yellow spot," or *macula lutea*, and central fovea, both first observed by Buzzi in Milan (1782, 1784) and independently rediscovered by S. Th. Soemmerring (1795, portrait Fig. 37), could also have been held to contribute to this interpretation. These discoveries, important though they were, were but preliminaries to the wealth of information which followed the development of modern microscopy.

SEC. 7. EARLY MODERN INVESTIGATION OF THE STRUCTURE AND FUNCTION OF THE RETINA

1. INVENTION OF THE COMPOUND MICROSCOPE AND THE RISE OF MODERN MICROSCOPY.— A systematic microscopic investigation of the retina began with the work of Treviranus (1835–38). In human anatomy, by this time, the organs and structures which could be investigated without the aid of strong magnifying glasses had become rather well known. Interest was now directed toward the study of structures small enough to be beyond the reach of the unaided eye or simple magnifying glasses, which required microscopes of high power. This was possible because of the development of optical instruments, culminating in the discovery and perfection of the compound microscope. (*See* Abbé 1904–6; Adams 1746; R. M. Allen 1947; H. Baker 1743; W. B. Carpenter 1901; Clay 1938; Clay & Court 1932; Disney, Hill & Baker 1928; Gage 1941; Heschl 1880; F. Merkel 1893; *see* Figs. 38–41.)

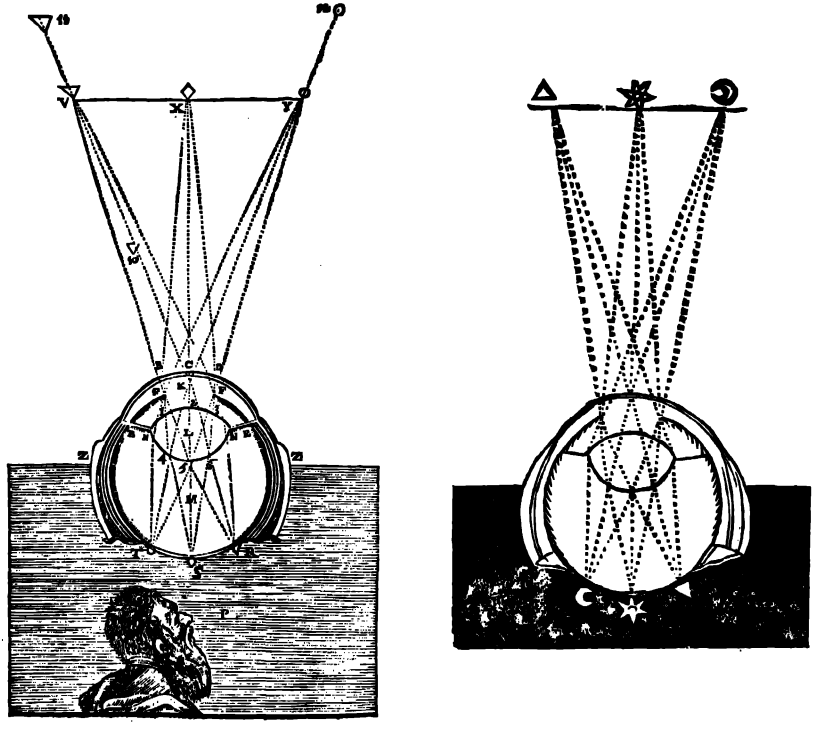

FIG. 33.—Diagrams showing the formation of the retinal image, *left* from Kircher in *Ars Magna Lucis et Umbrae* (1646); *right* from Des Cartes's *Tractatus de Homine* (1677). (*See also* Figs. 32, 68, 69, 70.)

2. Discovery of rods, cones, and retinal ganglion cells.—In the investigation of the retina two questions were of primary interest. The first concerned the identity of the structures to be considered true photoreceptors, capable of responding to stimulation by physical light. The second question concerned the way these photoreceptors were related to the optic nerve fibers. Treviranus (1776–1837), a German naturalist, believed he had answered both. He found a number of cylindrical, globular, and nipple-like structures which he called *papillae* and which he thought were the terminal ends of optic nerve fibers. From his description and even more clearly from his diagrams interpreted in the light of present knowledge, it is certain that some of his *papillae* actually were rods and cones, while others were ganglion cells (Figs. 42, 43, 44).

Treviranus, unfortunately, never understood the real significance of all these structures. He was the first to describe retinal layers, but he presented them upside down, with the optic nerve fibers on the outside, facing the chorioid. The fibers, radiating from the disk of the optic nerve, he believed, turned in toward the vitre-

Fig. 34.—Antoni van Leeuwenhoek (1632–1723), the scholarly draper, sexton, and town chamberlain of Delft, in the Netherlands, at the age of fifty-four. Together with M. Malpighi (*see* Fig. 36), the principal pioneer of microscopy (the others being R. Hooke, 1635–1703, J. Swammerdam, 1637–80, and N. Grew, 1641–1712). Self-taught, made his own simple but effective microscopes, with which he investigated the minute structure of numerous parts of the human and animal bodies and plants, including the eye and the brain. First investigated the crystalline lens and the retina of the eye. Photo of the original painting by Jan Verkelje made in 1686. Courtesy Rijksmuseum, Amsterdam, Netherlands. (*Cf. also* following figure.)

ous, at points varying with each fiber. After penetrating the thickness of the retinal membrane, each fiber supposedly terminated either as an individual *papilla* or as several fibers merged into a single *papilla* of a larger size. Treviranus believed the *papillae*, which in his opinion were the true photoreceptors, to be on the vitreal side of the retina (as the ganglion cells actually are). In this way he satisfied the logical expectations of his time, according to which the photoreceptors were the first of the errors were eliminated and the correct interpretation found.

First, Bidder (1839) found the correct topographical position of the rods and cones on the outer or scleral face of the retina, where they make up the second or bacillary layer (Fig. 128, *2*). In the functional interpretation of the rod structures, however, Bidder, under the influence of contemporary prejudice or misconception, was at fault. Since, according to the idea generally accepted at that time, the photoreceptors

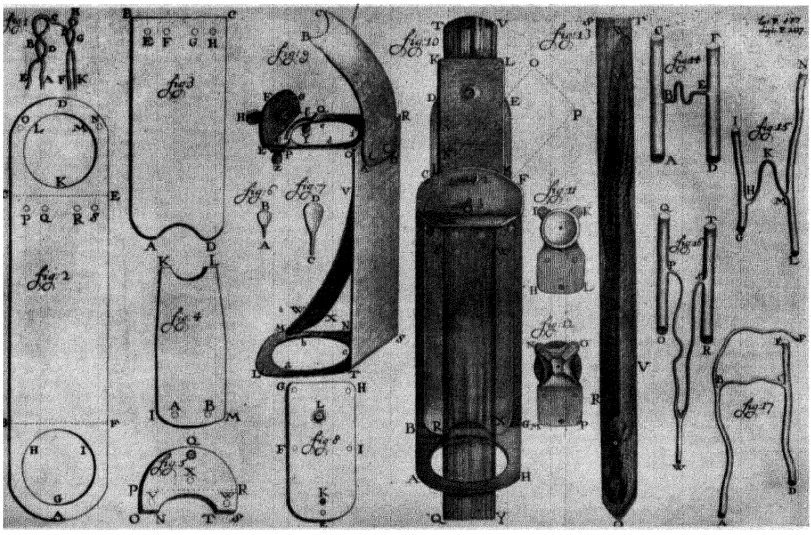

FIG. 35.—Leeuwenhoek's "microscope" and accessories, according to his own description. Fig. *1*, connection between arteries and veins; Figs. *2–7*, parts of a copper frame for the "microscope" shown in Fig. *9*; *L* in Fig. *8*, the "microscope" or a small biconvex lens mounted between two thin copper or silver plates fastened together by five small bolts; *K*, hole for a screw which held the lens plate to the frame; Fig. *9*, frame without the lens plate; Fig. *10*, complete "microscope," with all parts put together: *IKLM*, lens plate; *QRSTVWXY*, a glass tube for observation of living animals, in Fig. *13* shown separately containing a young eel; Figs. *14–17*, blood vessels. From A. Leeuwenhoek's *Arcana Naturae Detecta*, published in 1722.

retinal structures to be reached by rays of light entering the eye.

3. "Catoptric hypothesis" of rod function.—The work of Treviranus, though erroneous in almost every point, was beneficial because it stimulated an immediate series of investigations (Huschke; Gottsche; G. A. Michaelis; Johannes Müller 1837; Valentin; Henle; Remak 1839; Hannover 1840). Step by step his were to line the inner face of the retina, as they actually do in Cephalopods, Snails, the parietal eye of Tuatára (*Sphenodon*), and some other Lizards, Bidder decided that outwardly placed rods could not be the photoreceptors. For the same reason he denied even their nervous character. The rods, according to him, were merely some sort of mirror structures, a catoptrical mechanism, from which rays of light, after having passed through the thickness of the retina,

are once more reflected in the opposite direction, toward the pupil. In this way light, passing for the second time through the optic nerve fibers spread over the vitreal face of the retina, which, to Bidder as to Treviranus, were the true photoreceptors, reinforced the stimulus elicited by the first passage. This "catoptric hypothesis" of the bacillary structures, an unwitting precursor of the functional explanation of the *tapetum* found in the chorioid membrane of many crepuscular and nocturnal Vertebrates, was widely accepted for a time. (*See also* Brücke, Goodsir, Hannover, Wilson 1855.)

4. Discovery of the true order of retinal layers. The prospects for unraveling the complex structure of the retinal membrane improved with Hannover's (1840) introduction of chromic acid into histological laboratory technique.

Until then the usual procedure had been to study the retina spread out in "whole-mounts," while fresh and still transparent. Much of the confusion prevalent until that time, especially as to the number and sequence of layers, it seems, was caused by the difficulty of getting properly oriented in such preparations. In con-

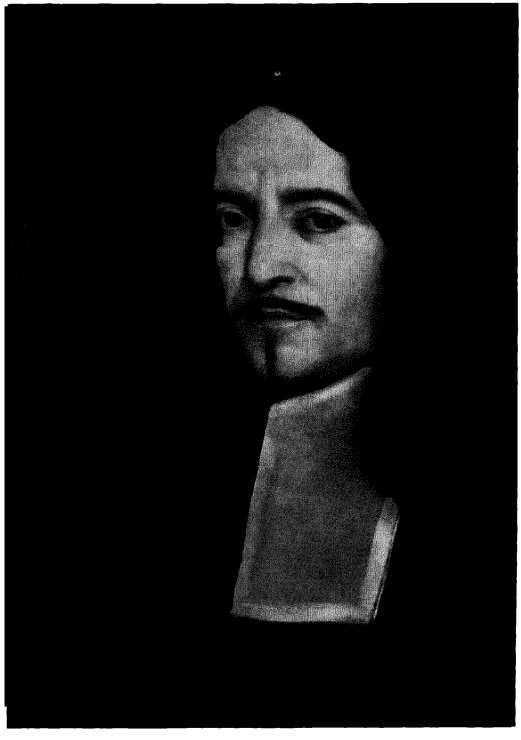

Fig. 36.— Marcello Malpighi (Malpighius, 1628–94), anatomist, physiologist, and botanist of Messina, Bologna, and Rome. Together with Leeuwenhoek (*see* Fig. 34), the principal pioneer microscopist of animal and vegetable tissues. Photo made from the original portrait by J. Tabor and presented by Malpighi to the Royal Society of London, of which Malpighi was a member. Courtesy Royal Society of London. For biography *see* A. W. Meyer in Science, v. 72, p. 234, 1930.

trast to this, the fixation and hardening of the specimens in chromic acid permitted the making of sections vertical to the retinal surface.

Even better results were obtained with chromic salts, the "Müller solution," introduced by H. Müller (1859). With the use of this improved technique, Pacini (1845), Bowman (1849, portrait Fig. 45), Koelliker (1852–54, portrait Fig. 47), Vintschgau (1853), and, most important, Heinrich Müller (1856–57, portrait Fig. 46) described correctly the sequence of the retinal layers and their exact position relative to the outer and inner face of the membrane, with the bacillary layer on the outside, the optic nerve fibers and ganglion cells on the inside, and the granular layers in between.

When, in addition, Helmholtz (1843), Corti (1850, 1854), and Koelliker (1854) demonstrated the continuity of the nerve fibers and of the ganglion cells, a firm foundation was laid for the understanding of the retina and the nervous structure in general.

SÖMMERRING.

Fig. 37. - Samuel Thomas von Soemmerring (1755–1830), anatomist, physiologist, and physician at Mainz, Frankfurt, and Munich, Germany. Student of the structure of the eye, discoverer (with Buzzi of Milan) of the "yellow spot," or *macula flava*, and of the central fovea of the human eye. Investigator of the brain. Friend of Immanuel Kant, the famous German philosopher of Königsberg (Fig. 353). Postulated a homogeneous organization of the brain as a material substratum of the transcendental soul, contrasting with the concept of a composite organization championed by Gall (*see* Figs. 83, 84). Frontispiece in H. F. Kilian, *Die Universitäten Deutschlands.*

5. Rods and cones recognized as true photoreceptors.—Of the important problems that remained unsolved at that time, that of the true photoreceptors was one. Various structures had been suggested as the possible photoreceptors, but without wide acceptance.

It was fairly certain that the optic nerve fibers themselves were not photosensitive, an idea propagated by the sponsors of the "catoptric hypothesis" of the bacillary layer—Bidder, Hannover, and Brücke—because the optic disk, although it contains many fibers, is blind (corresponding to Mariotte's "blind spot" in the field of view). The other alternative, that the ganglion cells were photoreceptors, advocated by Bowman and by Helmholtz (1851), also was in clear disagreement with the absence of ganglion cells in the territory of the optic disk.

The vexing problem of the identity of the photoreceptors seemed to be approaching its solution, when H. Müller (1851) discovered the "radial fibers," which were named by Koelliker "Müller's fibers" (for biography *see* H. Müller 1872, Koelliker 1866–67, and Fig. 46). Arranged vertically, these fibers pass through nearly the entire thickness of the retinal mem-

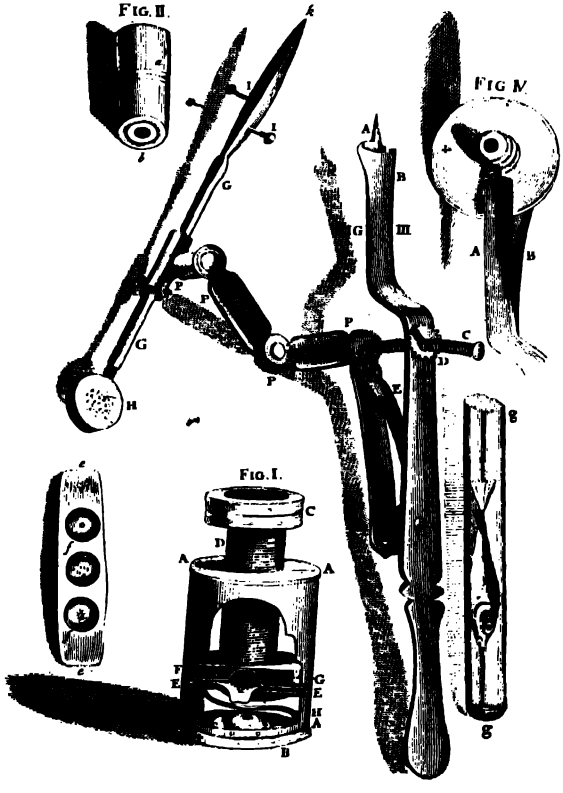

FIG. 38.—So-called "pocket microscope," *I*, of James Wilson (1702–3), with accessories: low-power magnifier used independently, *II;* one branch of the handle, *III*, to which, at *A*, one of seven magnifying lenses of different power could be attached (per sketch *IV*), while the examined object was held either by a mounting forceps *k* or on a small ivory carrier *H*, one side of which was white, the other black; *g*, a glass tube for viewing living objects (as in Leeuwenhoek's equipment). From Phil. Tr. Roy. Soc. London, v. 23, 1704.

brane (Figs. 48, 50). They seemed to be the structures connecting the bacillary layer with the layers of ganglion cells and optic nerve fibers. Contrary to Bidder's "catoptric hypothesis" of rod function and to Treviranus' *papillae* as photosensitive structures on the vitreal face of the retina, Müller's discovery showed that the elements of the bacillary layer may well be the terminal structures of the optic nerve fibers, hence the true photoreceptors, even though they are located on the outer, scleral face of this membrane.

These important discoveries helped to substantiate the thesis of the photoreceptor function of the rods and cones. Even when it was shown later that Müller's "radial fibers" belonged to the supporting neuroglial tissue and were, therefore, unfit to conduct nerve impulses, Müller's basic concept remained unshaken, since other, thinner threads and fibers, undoubtedly nervous and also arranged radially, were found that could well serve as the links connecting the outwardly placed rods and cones with the inner layers (Fig. 50). Additional evi-

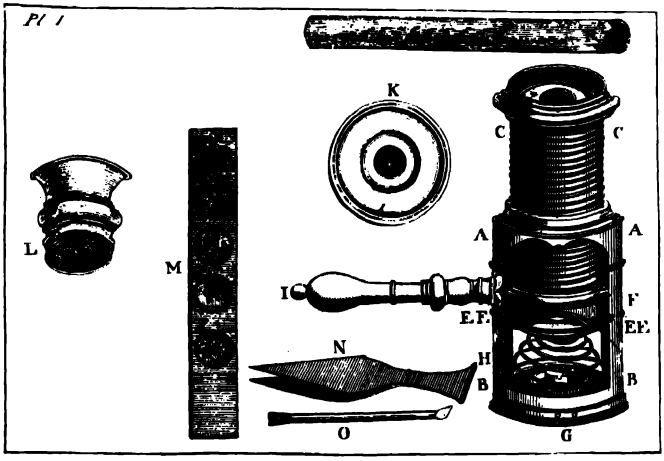

FIG. 39.—Wilson's "single pocket microscope" with accessories: *A*, *B*, body; *C*, movable tube; *EE*, brass plates to hold slide; *G*, near end of tube; *H*, steel spring; *I*, handle; *K*, one of six magnifying lenses of different power to be screwed onto *G*; *L*, low-power magnifier to be used independently; *M*, slide with four specimens mounted between plates of glass or mica; *N*, nippers; *O*, hair brush; *P*, glass tube for living objects "such as frogs, fishes, etc., in order to discover the blood, as it streams along the veins and arteries"; *, one of several brass rings of varying aperture used as diaphragms. The linear magnification claimed for this microscope was from 16 to 400×. The instrument was, accordingly, more versatile than Leeuwenhoek's but gave only a little more magnification. From Henry Baker, *The Microscope Made Easy*, London, 1743.

Müller (1853, 1854, 1856–57), furthermore, was able to furnish experimental physiological evidence of a photoreceptor function of the bacillary layer. This he did with the help of a parallactic displacement of shadows of the retinal blood vessels, which cause "Purkinje's figure" to be perceived entoptically. The distance computed by Müller proved to be identical with that between the larger blood vessels on the inner, vitreal, face and the bacillary layer on the outer, scleral, face of the retina, as measured in preparations.

dence gathered during the next several decades, mainly the discovery by Boll (1877) of rhodopsin, or erythropsin, also called "visual purple," a photosensitive substance contained in the outer rod segments, put Müller's claim beyond reasonable doubt.

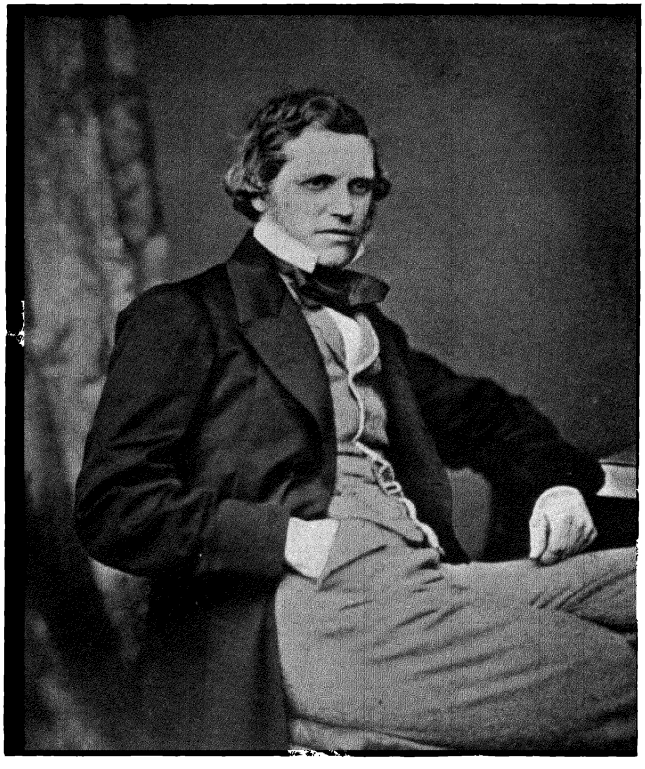

FIG. 45. William Bowman (1816–92) at the age of forty-five. An anatomist, physiologist, and renowned ophthalmologist of London. Together with Helmholtz, Graefe, and Donders, a founder of modern ophthalmology. Discoverer of "Bowman's membrane" or the cornea and of "Bowman's capsule" in the Malpighian glomeruli of the kidneys. First who nearly correctly described and depicted the layers of the retinal membrane. From J. Hirschberg, in Graefe & Saemisch, *Handb. d. ges. Augenh.*, 2d ed., v. 14 (4), p. 203, 1914.

SEC. 8. THE PROBLEM OF THE INTRINSIC ORGANIZATION OF THE RETINA AND MODERN EFFORTS TO SOLVE IT

1. EARLY ATTEMPTS TO UNRAVEL THE MINUTE STRUCTURE OF NERVOUS TISSUE. The information about the minute organization of the nervous system which the histologists of the eighteenth and the greater part of the nineteenth centuries possessed was acquired from

studying fresh specimens or those fixed, though unstained, which were either "whole-mounts" or "teased preparations," that is, pieces of tissue dissected with needles.

Even after the introduction of the technique of fixation, hardening, and cutting of sections, and staining with various dyes, the appearance of structures composing a nervous organ the nerve cells, the fibers and their various envelopes, the supporting tissue, and the blood vessels was rather uniform. In such preparations, in spite of varying intensity and tint, the chance of determining subtle and intricate relationships of some particular histological constituents was small.

In what soon came to be regarded as the core of the problem of the histophysiological constitution of nervous tissue the relationship of the nerve cells to one another the primitive technique of early modern histology mostly failed. With much effort and disproportionate investment of time, histologists of the mid-

FIG. 46.—Heinrich Müller (1820-64), professor of anatomy, at Würzburg, Bavaria, Germany. A pioneer in modern anatomy and physiology of the eye and, in particular, of the retina. Founder of ophthalmic pathology. Described the principal layers of the retina and their correct arrangement, with rods and cones outermost. By a physiological experiment—the displacement of entoptically perceived shadows of the retinal blood vessels, or "Purkinje's vascular tree"—he furnished the evidence in support of the photoreceptor function of rods and cones. Described supporting structures of the retinal tissue, since called "Müller's radial fibers." Discovered the central area surrounding the foveal depression; the multiple foveae in the eye of Birds; the circular muscle fibers in the ciliary body; the smooth muscle of the eye socket, innervated by sympathetic nerves ("Müller muscle"), etc. Portrait enlarged by Mrs. J. R. Weigel (Miss Eileen Kern) from an original by J. Hirschberg, in Graefe & Saemisch, *Handb. d. ges. Augenh.*, 2d ed., v. 15 (2), p. 243, 1918.

nineteenth century—Remak (1839, 1853, 1854), Helmholtz (1843, portrait Figs. 102, 356), Corti (1850, 1854), Koelliker (1854, portrait Fig. 47), J. von Gerlach (1858), B. Stilling (1859), Deiters (1865), M. Schultze (1866, 1869, 1872, 1873, portrait Fig. 49), and others succeeded in discovering the most important facts: that nerve fibers were not independent structures but were expansions of the nerve cells and that there were two kinds of such expansions, long ones, which were named "axis cylinders" or "axons," and short ones, named "dendrites." But the details of how the nerve cells and their expansions were related to one another remained outside the reach of available techniques. (*Cf.* Obersteiner 1892; Stieda 1899; S. Ramón y Cajal 1909–11; Edinger 1911; *see also* Conn 1948.)

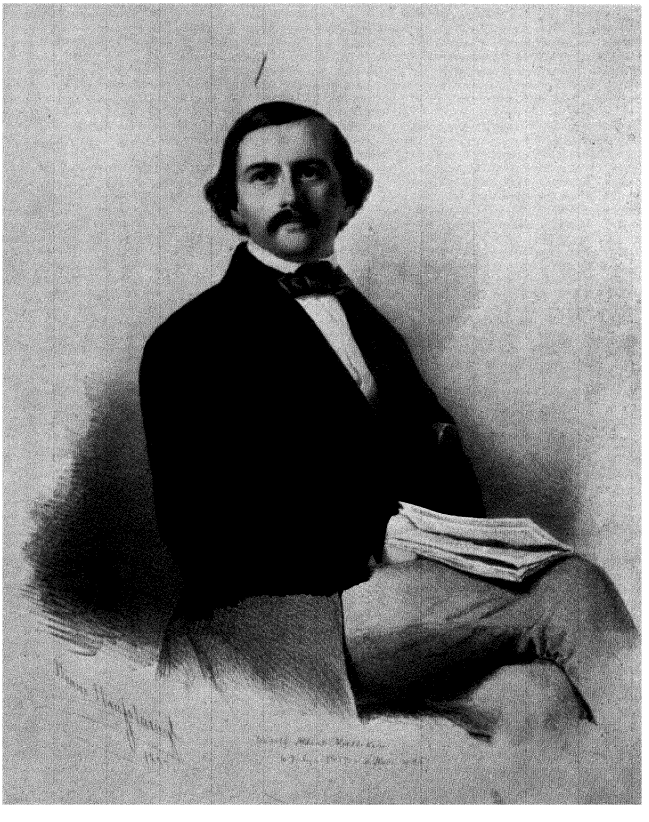

FIG. 47.—Rudolf Albert von Kölliker (1817–1905), professor of anatomy, microscopy, and embryology at Würzburg, Bavaria, Germany. One of the most productive morphobiologists of his age. A pioneer of modern microscopy and a most accomplished connoisseur of bodily tissues in his time, according to C. S. Minot. Together with Heinrich Müller (Fig. 46), his friend and collaborator, he first determined the correct order of the retinal layers and analyzed the minute structure of the retinal tissue (Fig. 48). Engraving by H. Hanfstaengl, made in 1855 from a painting by Clementine Stockar-Escher. Courtesy Dr. Jeannette Obenchain and Professor R. R. Bensley, of the University of Chicago. For Kölliker's autobiography see *Erinnerungen aus meinem Leben*, 1899; W. Waldeyer 1906, and Haymaker & Baer, *The Founders of Neurology*, 1953.

2. LIMITS OF PREANALYTIC HISTOLOGICAL TECHNIQUES AS APPLIED TO THE RETINA.—In the investigation of the retina the farthest point reached by the end of the third quarter of the nineteenth century is represented in the admirable work of Max Schultze (especially 1866, 1872–73, portrait Fig. 49; for biography *see* G. Schwalbe 1874). In it the principal features, such as the distribution of cellular and fibrous elements into ten layers, the appearance and distribution of the photoreceptors, the structural characteristics of the foveal cones, and many other details, were correctly presented (Fig. 50).

Also, Schultze was the first to suggest that the two varieties of photoreceptors were concerned with different functions, the rods being instrumental in nocturnal or scotopic vision, and the cones in daylight or photopic vision, an idea which has since developed into the modern "duplexity theory of vision" or "duplex retina" of Parinaud, Kries, *et al.*

Yet, fundamental as these discoveries were and in spite of the painstaking labors of Schultze, Schwalbe, and many other retinologists of that period, who relied chiefly upon the "maceration" and "teasing" technique, the problem of precisely how the various histological components of the retinal membrane are integrated into a complex tissue and what the particular functions of each of them are defied solution. A special obstacle proved to be the two plexiform layers, through which the fibers could not be followed with certainty.

Finally, Schultze felt it necessary to admit that a direct histophysiological connection of the photosensitive rods and cones on the scleral side with the optic nerve fibers on the vitreal side of the retinal membrane, believed in by most investigators since H. Müller's discovery of "radial fibers," was more a conviction than positive knowledge based upon observation.

3. INTRODUCTION OF HISTOANALYTICAL METHODS IN THE STUDY OF NERVOUS TISSUE.—The possibility of a complete histological analysis of complex nervous tissue arrived when new neurohistological methods were devised.

The first, accidentally discovered by an Italian investigator, Camillo Golgi (1873, 1878, portrait Fig. 344), consisted in staining, in a weak silver nitrate solution, specimens previously fixed and hardened in a solution of potassium dichromate, in "Müller's solution," or in a mixture of potassium dichromate and osmium tetroxide: the "Golgi method." The sections made from such blocks showed a peculiarity not found in the preparations treated with any of the earlier methods, as, for example, Gerlach's carmine stain introduced in 1858. In-

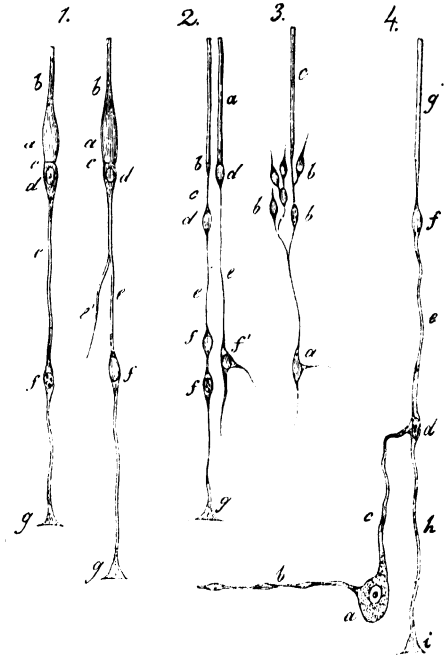

FIG. 48.—Rods, cones, nuclear and ganglion cells of the retina and their relationships, as conceived by Heinrich Müller (1852, 1854) and by Kölliker (1854). Sketch *1* illustrates the hypothetical connection of the cones (*b*), and sketches *2*, *3*, and *4* that of the rods (*a*, *c*, *g*), with various cells of the retina, for example, with the outer nuclear cells (*d* in sketches *1* and *2*; *b* in sketch *3*; *f* in sketch *4*), with the inner nuclear cells (*f* in sketches *1*, *2*; *a* in sketch *3*; *d* in sketch *4*), and with the ganglion cells (*a* in sketch *4*) by means of Müller's "radial fibers" (*c*, *e*, *g*, *h*). No distinction was as yet made between the nervous fibers proper and the supporting neuroglial fibers. In sketch *4* a nerve fiber *b* with typical spindle-shaped varicosities continues to the brain. From A. Kölliker, *Mikroskopische Anatomie oder Gewebelehre des Menschen* and *Manual of Human Microscopical Anatomy*, 1854, Figs. 302, 411.

stead of all cells and fibers being more or less diffusely stained, only some were found to be blackened, while the others remained unstained. In such preparations, if the nerve cells were stained completely, as often happened, the expansions could be followed to the very finest of their terminal branches, and their relationship to other nerve cells or to nonnervous structures could thus be determined.

lich (1886), consisted in injecting a weak solution of methylene blue, an aniline dye, into a living animal, whose nervous tissue made the blue dye colorless within a short time. When the tissue was exposed to the action of air, the nervous structures appeared selectively stained in blue. (For a description of methods of Golgi and Ehrlich *see* Polyak, *The Retina*, chap. 4, 1941, 1948.)

FIG. 49.—**Max Johann Sigismund Schultze** (1825–74), professor of anatomy at Halle and Bonn in Prussia, Germany. Pioneer of modern microscopy. Cofounder, with Theodor Schwann and M. J. Schleiden, of modern cell theory of animal tissues. A diligent student of the minute structure of the retinal membrane. Originator of the concept of the double function of the retina, or so-called "duplexity theory," later amplified by Parinaud and by Kries, according to which the cones are active in daylight and are instrumental in color vision, whereas the rods are instrumental in twilight vision. Frontispiece in Schultze's Arch. f. mikr. Anat., v. 10, 1874. (*See here* obituary by G. Schwalbe.)

With one stroke the Golgi method not only revealed an undreamed-of complexity of nerve centers but also furnished the means for a successful histological analysis of the entire nervous system.

Another histoanalytical method, the "vital methylene blue stain," discovered by Paul Ehr-

4. Influence of histoanalytical techniques upon concepts of the organization of the nervous system.—The effect of the methods of Golgi and Ehrlich upon the subsequent course of neurological disciplines was profound. It unleashed a flood of investigations which threw light on many parts of the nervous

system which had been obscure until then. Even more important was the effect of the new technique upon the general theory of the nervous system.

Until that time the concept of the minute organization and working of the nervous organs had been vague and confused. For example, J. Gerlach (1872), one of the leading anatomists of his time, believed that the nerve fibers of the nerve fibers to the central *reticulum* and to the nerve cells, however, remained undisclosed.

The idea of a "diffuse nerve net," "punctate substance," "neuropil," and what-not has persisted ever since, even though later investigations abundantly demonstrated the fallacy of Gerlach's concept. Golgi himself subscribed to it in describing a *rete nervosa diffusa*, or "diffuse nerve net."

FIG. 49*A*.—**Jakob Henle (1809–85),** professor of anatomy in Zürich, Heidelberg, and Göttingen. First described the pupillary membrane in the eye of an embryo, and the outer fiber layer of the retina named in his honor "Henle's outer fiber layer." Discovered "epithelium" as a lining of the surface of various organs. Described simultaneously with Meynert the alternating cell and fiber laminae in the human lateral geniculate nucleus. Author of the *General Anatomy of Bodily Tissues* and of the classical *Handbuch der systematischen Anatomie des Menschen* in three volumes. Reformer of physiological pathology, and a cofounder (with Pfeufer) of the Zeitschrift für rationelle Medicin. Frontispiece from F. Merkel, *Gedächtnisrede* (commemoration speech), 1909. For biography *see* F. Merkel, *Jacob Henle, ein deutsches Gelehrtenleben*, F. Vieweg & Sohn, Braunschweig, 1891.

posterior roots, after entering the spinal cord, divide into numerous branches, which together produce a diffuse nerve net, or *reticulum*, in the gray substance. The threads of this *reticulum*, by merging again, he thought, formed the anterior spinal roots. The precise relation of the

The most radical form this idea assumed in modern times was the concept of a "universal neuroreticulum" or *neurencytium*, which supposedly permeated the tissues of the whole organism and would be the guarantor of its functional unity (Held 1927, 1929). What the count-

less varieties of nerve cells and their connections were for and what the precise histophysiological basis of locally diversified functions of nervous organs was, the advocates of the "neuroreticulum hypothesis" have never explained intelligently. (*See* chap. IX.)

Very different ideas arose in the minds of another group of investigators, chiefly under the stimulus and influence of the newly discovered histoanalytical technique. The embryological studies of W. His (1886, 1889, 1904, portrait Fig. 343; *also* Mall 1905) led him to a conviction

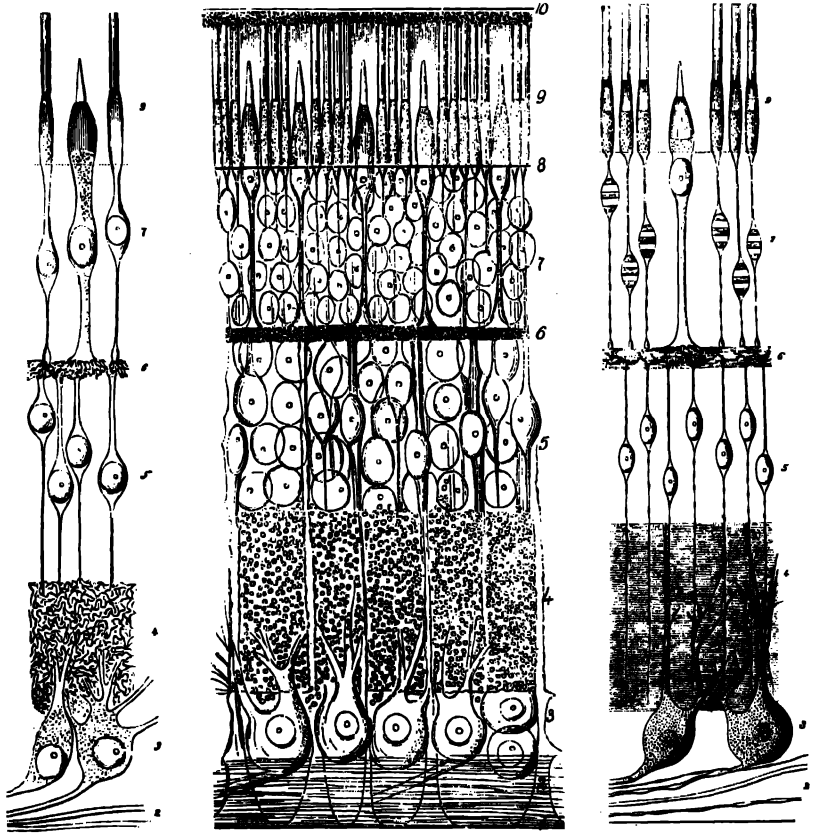

FIG. 50.—Arrangement and relationships of constituent nerve cells and fibers of human retina as conceived at the close of the pre-Golgi period of modern microscopy. Left-hand and middle diagrams from M. Schultze (1872, Figs. 344, 357); right-hand diagram from Schwalbe (1874, Fig. 51). Layer *1*, inner limiting membrane; *2*, layer of optic nerve fibers; *3*, ganglion cell layer; *4*, inner "granular," now inner plexiform layer; *5*, inner nuclear layer; *6*, outer "granular," now outer plexiform layer; *7*, outer nuclear layer; *8*, outer limiting membrane; *9*, bacillary layer of rods and cones; *10*, pigment epithelium. (For modern terms *see* Fig. 128.) In contrast with Kölliker's figure (Fig. 48), two varieties of "radial fibers" were now distinguished: nervous, identified with the outer and inner expansions of nerve cells, or rods and cones, and the nonnervous Müller's "radial fibers" which belonged to the supporting neuroglial framework. The nervous radial fibers were presented as intimately connected with plexiform layers *4* and *6*. The primitive histological technique exemplified in this figure left the principal problem, that concerning the true significance of the plexiform layers, unsolved. (*Cf.* Figs. 53, 54, 55.)

that in the early stages of fetal development the histological elements from which the nervous system is built are individual, independent young cells, the "neuroblasts," of rather uniform appearance. In pursuing the same line of thought, other neuroanatomists recognized that the relative independence or individuality of the nerve cells remains preserved in the more

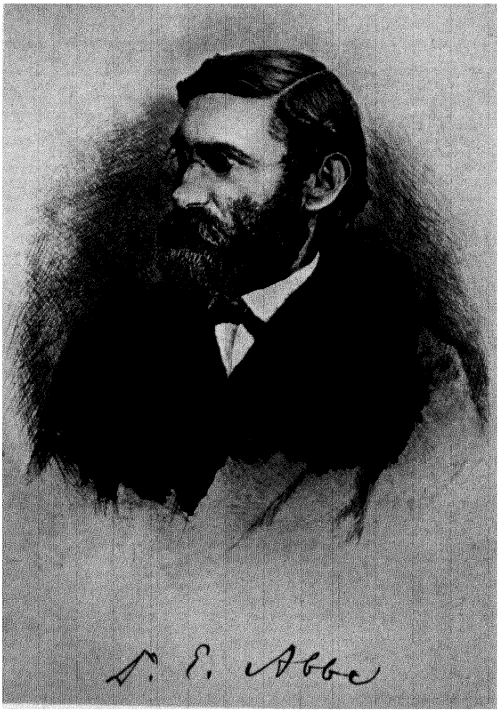

FIG. 51.—Ernst Abbé (1840–1905), mathematician and student of physical optics, at the age of forty-four. Considered the "world's greatest genius in scientific optics." Cofounder and research director of K. Zeiss Optical Company at Jena, Germany. Inventor of oil-immersion lenses and of the stage condenser for the microscope, which made the advancement of modern microscopy possible. From Abbé's *Gesammelte Abhandlungen*, G. Fischer, Jena, 1904–6.

advanced stages as well, including the fully differentiated tissue of the adult organs. The observations and interpretations of Forel, Waldeyer, Lenhossék, Gehuchten, Retzius, *et al.*, and, above all, the brilliant and indefatigable S. Ramón y Cajal (1888–1935, portrait Figs. 52, 131, 317), well substantiated by Harrison's experiments, finally crystallized in the "neuron theory." (*See* chap. IX.)

5. NEURON THEORY OF THE NERVOUS SYSTEM. Following are the essential tenets of the neuron theory. Each individual nerve cell, with all its expansions or processes, is to be considered as a histological and functional entity, a "neuron," which is to a certain degree independent of other neurons of the same organism. The individual neurons are related to one another not by "anastomosis," or merging of their processes, but by means of more or less intimate contact, and the boundaries at the points of contact are real. A *neuroreticulum* or *neuren-*

cytium is only apparent, owing to inadequate technique and to faulty interpretation. Each nerve cell, each neuron, is a morphodynamical microcosm whose various parts are differentiated into distinct functional organelles. The cell body and the shorter and usually more numerous "protoplasmic expansions" of Deiters, called "dendrites," are the receptor organelles of a neuron capable of receiving stimuli or impulses from other neurons or from other structures or agents. The other and usually single, long or short "axis cylinder" of Deiters, or "axon," the "nerve fiber" in common parlance, terminating at its far end in an arborization, or "teledendron," is a discharging organelle of the neuron, along which the "impulses" are transmitted to other neurons, glands, or muscles. The points at which a more or less intimate contact is established between the related neurons, called "synapses," barring a few exceptions requiring further study and interpretation, are organized unidirectionally or in a way which permits a flow of the influences in one direction only, specifically from the teledendron of one neuron to the cell body or dendrites of another related neuron, while at the same time inhibiting the influence from spreading in the opposite direction. This is called the "dynamic or functional polarity of a neuron."

The neuron theory, briefly, maintains that the entire nervous system is made up of countless dynamically or functionally polarized neurons of the most varied shapes and types, concatenated in an orderly manner into many different patterns, which, in addition, vary from place to place.

There is, furthermore, substantial evidence that the inherent functional capacities of morphologically differing neuron varieties are not of the same kind but vary from species to species of the nerve cell. In other words, each neuron variety should be regarded as dynamically responsive in one way only, and therefore functionally reacting in one way only, peculiar to or specific for it, different from the modes of reaction of all other neuron varieties of the same animal species. This is called "dynamic or functional specificity of neurons." The specific mode or modes of dynamic and, therefore, physiological reaction of a neuron is or are determined not only by such factors as the position of a neuron in the tissue or its synaptical relationship to other neurons or tissues, and by various exogenous factors, such as the kind and intensity of the stimulus, but also especially by its own innate or inherent biochemical and biodynamical properties and capacities.

The organization of the nervous system, central and peripheral, according to these principles, fully accounts for both the diversity and the complex character of nervous functions and also seems a sufficient material substratum by means of which an individual organism is created and preserved as a biological and psychic entity.

The neuron theory as the basis of a concept of the intimate organization of the nervous system, tested by decades of hard experience and severe criticism, has, on the whole, been satisfactory in explaining the principal phenomena of normal nervous functioning and the reaction of nervous organs under pathological conditions. Also the theory has proved flexible enough to permit amplification, modification, and further adaptation in detail to the new and heretofore unknown facts or requirements arising from additional observations and wider experience.

SEC. 9. THE NEURON THEORY AND THE MODERN CONCEPT OF STRUCTURE AND FUNCTION OF THE VERTEBRATE RETINA

1. VARIETIES OF RETINAL NEURONS AND THEIR SYNAPTICAL RELATIONSHIPS. The influence which the neuron theory exerted upon the concept of the minute organization of the retina and upon its interpretation in terms of functions was far reaching. The continuous connections of the photosensitive rods and cones and of the optic nerve fibers, which the older investigators—Treviranus, Koelliker, H. Müller, M. Schultze, Dogiel, Tartuferi, and many others—tried to establish, S. Ramón y Cajal proved did not exist (1888, 1892–93, 1909–11, 1934, 1935; Figs. 52, 131, 317). Instead, he found the retina to be composed of three superimposed series of neurons or individual nerve cells related to one another by means of synapses (Figs. 53, 54, 55). The first series, represented by the rods and cones, was the most

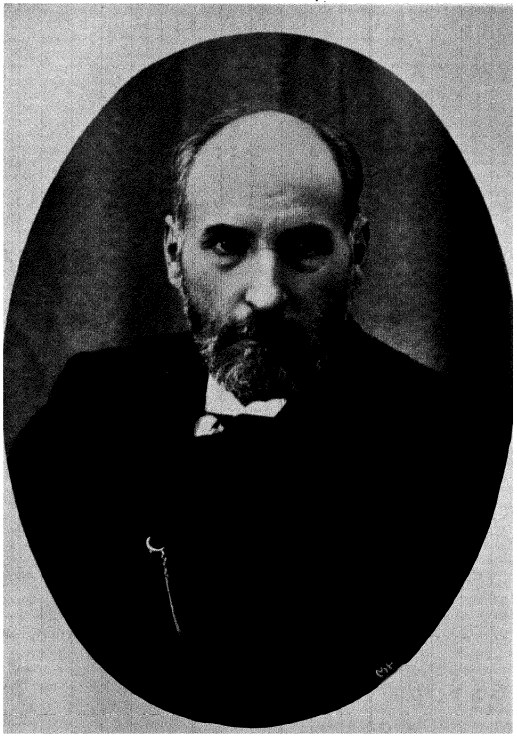

FIG. 52.—Santiago Ramón y Cajal (1852–1934), the foremost modern neurohistologist, at the age of fifty-five. Professor at the universities of Valencia, Barcelona, and Madrid. Most accomplished investigator of the minute structure of the nervous system, its development, and its pathology. Author of *Les nouvelles idées sur la fine anatomie des centres nerveux*, Paris, 1894; *Textura del sistema nervioso del hombre y de los vertebrados*, Madrid, 1897–1904, translated into French, *Histologie du système nerveux, etc.*, Paris 1909–11, etc.; Nobel laureate, with Golgi, for the year 1906. Portrait from München. med. Wchnschr., v. 54, 1907 (for other portraits *see* Figs. 131, 317). For autobiography *see* his *Recuerdos de mi vida* (also in English); for biography *see* Ariëns Kappers 1934; Lenhossék 1935; Sprong 1935; Tello 1935; Villaverde 1935; P. Laín Entralgo 1947; Haymaker 1948; Cannon 1949; Trueta 1952; Haymaker & Baer 1953; and Polyak 1953. *See also* Figs. 53, 54, 55.

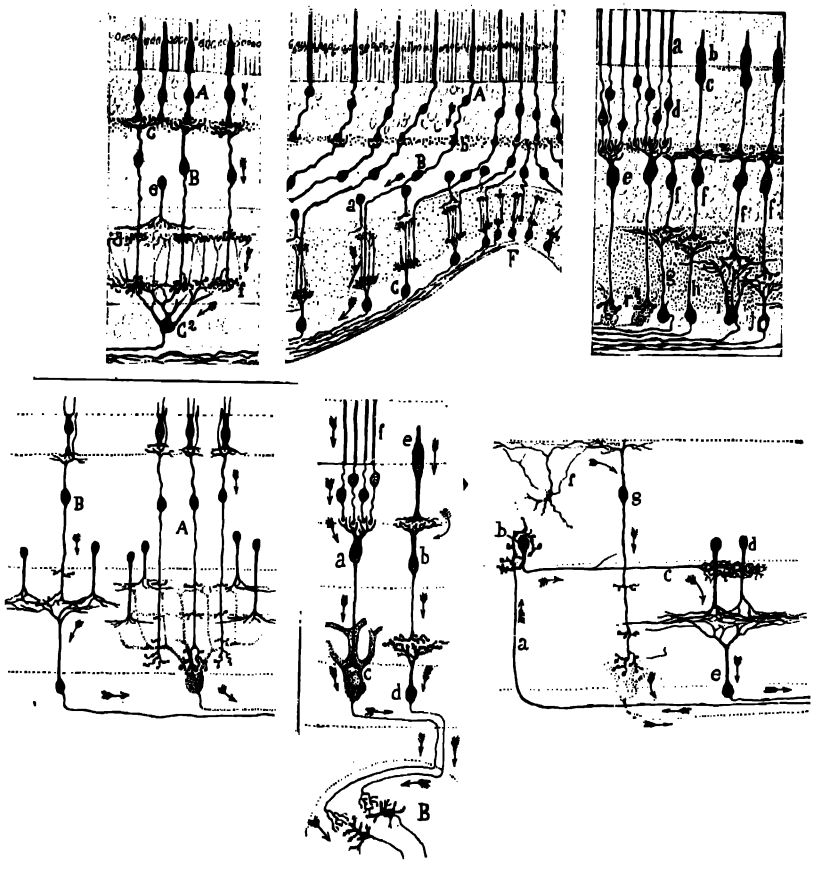

FIG. 53.—S. Ramón y Cajal's diagrams illustrating types of neurons of the vertebrate retina and visual system, their synaptical relationships, and their probable functional significance. *Upper row, left and middle sketch:* mechanism for color and visual space perception in retinal periphery and in the fovea (*F*), made up of cones (*A*), bipolars (*B*), and ganglion cells (*C*); right-hand sketch showing his concept of two sets or systems of receptors and conductors: the rod system instrumental in colorless twilight vision (*a, d, e, r*), and the cone system for color perception in daylight vision (*b, c, f, g, h, i, j*), embodying "duplexity theory" of Schultze, Parinaud, and Kries. *Lower row, left sketch:* synaptical relations of one cone to one bipolar cell (*B*), and through it to one ganglion cell and to two amacrine cells, and again three cones singly related to three bipolars (*A*), and through these to several amacrines and to one ganglion cell (all in Bird's retina); *central sketch:* illustrates achromatic (*f, a, c*) and chromatic (*e, b, d*) constituents of the visual system from the retina to the brain (*B*); *right-hand sketch:* illustrates complex relationships in Bird's retina: a centripetal pathway made up of a bipolar (*g*) and a ganglion cell (*shaded*), also a centrifugal pathway composed of a fiber (*a*) originating in the brain and terminating around an amacrine cell (*b*), which, in turn, by way of its axon fiber (*c*) and amacrine cells (*d*), influences a ganglion cell (*e*), and in this way influences the centripetal system of neurons. From Ramón y Cajal, *Recuerdos de mi vida*, 1923.

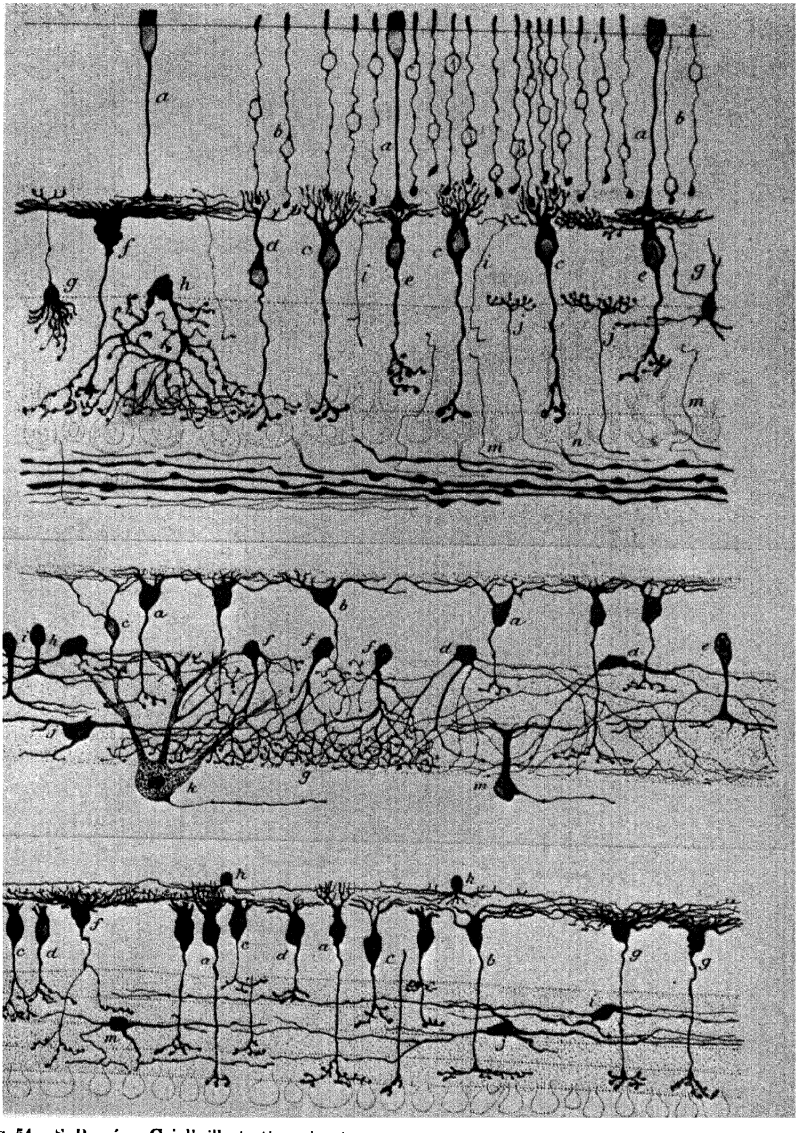

FIG. 54.—S. Ramón y Cajal's illustrations showing neuron varieties composing the retinal membrane and their synaptical relationships. Upper sketch represents Dog's retina: cones (*a*), rods (*b*), "rod bipolars" (*c*), "cone bipolars" (*e*), "giant bipolar" (*f*), cell with an ascending axon (*g*), amacrine cell (*h*), fibers and terminations probably of extraretinal origin (*i*, *j*, *m*), and ganglion cells in outline (*n*). Middle and lower sketches, from the retina of an Ox, showing bipolars, amacrines, ganglions, and horizontal cells. From Ramón y Cajal, Cellule, v. 9, 1892-93; and Trav. du lab. de recherches biol. Madrid, v. 28, 1933.

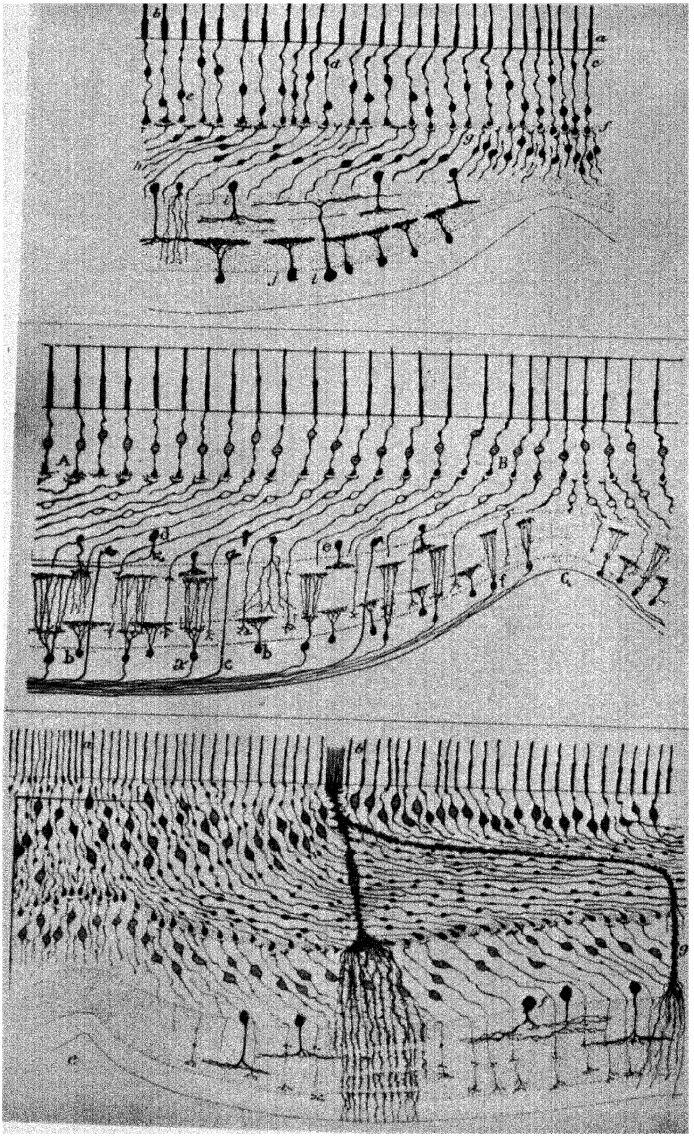

FIG. 55.— S. Ramón y Cajal's presentation of the minute structure of the fovea in various Vertebrates: upper sketch of a Greenfinch (*Fringilla* or *Ligurinus chloris*), middle sketch of a House Sparrow (*Passer domesticus*), lower sketch of a Chameleon (*Chamaeleon vulgaris*). Note that the cones of the bacillary layer are thinner and more numerous in the center of the fovea than outside; synaptical relationships of the foveal cones and bipolars are individualized; lateral displacement and slanting course either of bipolars or of both the cones and bipolars (as in Chameleon), all caused by the formation of a foveal excavation. From Ramón y Cajal, Cellule, v. 9, 1892–93, and Trav. du lab. de recherches biol. Madrid, v. 28, 1933.

peripheral (both topographically and in the functional sense). Here the electromagnetic vibrations of hypothetical "ether," which make up physical "light," elicit nervous "impulses" which are forwarded to the second series of neurons represented by the bipolar cells. From these, the "impulses" are further transmitted to the third series of neurons, the ganglion cells, along whose axis cylinders, or optic nerve fibers, they travel until they finally reach the brain.

2. RETINAL STRUCTURES, PERCEPTION OF LIGHT AND COLORS ("DUPLEXITY THEORY"), AND VISUAL SPACE PERCEPTION.— The hypothesis of two functionally different varieties of photoreceptors proposed by Max Schultze suggested to S. Ramón y Cajal a similar cleavage or differentiation among the remainder of the structures of the retina and the visual pathways. Just as there are two kinds of photoreceptors, the rods and the cones, so there should be in the second series of the retinal neurons two varieties of bipolars—the "rod bipolars" related to the rods and the "cone bipolars" related to the cones.

Among the neurons of the third series, Ramón y Cajal distinguished several varieties, although he was less explicit in assigning them definite synaptical relationships. Even so, he assumed a separation of the two sets of neurons as far as the brain, one set conducting the impulses generated in the rods and the other conducting the cone impulses. This he regarded as an anatomical substantiation of the "duplexity theory" of Max Schultze, Parinaud, and Kries, according to which the cones are active only during the day and are instrumental in color perception (photopic vision), while the low-threshold rods mediate the perception of the various shades of colorless "gray" elicited by the weak stimuli under nocturnal conditions (scotopic vision).

Another important observation by Ramón y Cajal concerned the individual synapses between the cones and the bipolars and again between the bipolars and the ganglion cells. He found such a one-to-one synaptical relationship in the central fovea of Birds and Lizards and considered this to be the structural basis of the greater acuity of "central" or direct vision in the fovea, in contrast to the more diffuse synaptical relationships of the extrafoveal territory of the retina, corresponding with the less distinct "peripheral" or indirect vision.

Besides these basic structures, Ramón y Cajal found other types of neurons in the retina, such as the "horizontal cells" and "amacrine cells," and also efferent or exogenous fibers, which presumably serve more complex functions of "association."

3. CRITIQUE OF S. RAMÓN Y CAJAL'S INTERPRETATION OF RETINAL STRUCTURES.—Great as was the advance in the fundamental understanding of the retinal mechanism as a result of Ramón y Cajal's discoveries, much in his scheme and interpretation was doubtful and incomplete. The first objection is to the material used, for all of his work was done with the infraprimate Vertebrates, whose vision conceivably differs in many respects from Man, Monkeys, and Apes. Nor had there been a later systematic investigation of the primate retina by means of the histoanalytical procedures of Golgi and of Ehrlich. The few serious efforts of this kind, for example, by Dogiel (1891, 1892, 1893) and Balbuena (1922, 1923, 1925, 1929, 1936), unfortunately fell short of their goal.

The functional interpretation of the retinal structures given by Ramón y Cajal also appears to be weak. Experimental physiology and psychology of vision suggest that certain complex dynamic processes which had formerly been assigned to the brain take place in the photoreceptor organ. If Ramón y Cajal's schemes were truly representative of the relationships of the retinal neurons, this membrane would be comparable to an aggregation of simple receptors such as are found in the skin. Such structures would account only for the simple reactions to light stimuli and for the transmission of impulses to the brain, but not for the more complex processes--the reciprocal influencing, selection, intensification, and inhibition of the impulses, and the like--functions which, according to some physiologists, are carried out by the retinal neurons (Kohlrausch 1931; Granit; Bartley 1941).

Such a relegation of the role of the retina to a simple photoreceptor is disproved by even a casual examination of sections of successfully

stained preparations, which show a remarkable wealth of nerve cells arranged in a way suggestive of a structure of higher nerve centers, especially of the cerebral and cerebellar cortex. It then becomes apparent that, in order to appreciate fully the functions which the retina performs in the visual act and to bring its morphology abreast of modern physiological concepts of the visual act, a complete analysis of this organ was necessary, particularly in various primate species and in Man.

(For a description of neuron varieties of the retina, their synaptical relationships, and their probable functional role, in Man and in other Primates, *see* chaps. V, IX; *see also* Polyak, *The Retina*, 1941, 1948; *Retinal Structure and Colour Vision*, in Doc. Ophth., v. 3, 1949, and the article "Eye," in *Encyclopaedia Britannica* 1955.)

Chapter II

Investigation of the Visual Pathways and Centers during Classical Antiquity, the Middle Ages, and the Early Period of the Modern Scientific Era

SEC. 1. INVESTIGATION OF THE VISUAL SYSTEM DURING THE EARLY PERIOD OF CLASSICAL ANTIQUITY

1. IMPORTANCE OF THE VISUAL SYSTEM FOR THE UNDERSTANDING OF THE BRAIN.—Of the many parts of the nervous system, few attracted the attention of the philosophers, naturalists, and physicians of bygone ages as did those related to the eye. During ancient Greek and Roman Times, the Arab Period, and the Middle Ages in Europe, the ideas derived from the study of the eye and the optic nerves were a major influence in the formation of the concept of the structure and function of the entire nervous system. In modern times, too, no other part of the brain has been investigated with greater zeal than the visual pathway.

Indeed, it was precisely the visual system that in our time was used as a weapon with which some of the major battles were fought concerning the intimate organization of the brain, its function, and its reaction in pathological conditions. The review of past efforts directed toward the elucidation of visual mechanisms is, therefore, in great measure the history of neurology. The close relationship of the nervous system to the rest of the organism again connects the problem of the visual apparatus with the investigation of other bodily systems, their anatomical organization, and their function, all, in turn, having a share in forming our concepts of the brain and the sense organs.

2. BEGINNINGS OF ANATOMY.—What knowledge, if any, the ancient Egyptians, Sumerians, Assyrians, Babylonians, Hindus, and other preclassical civilized peoples had of the optic nerves and their connection with the brain is difficult to evaluate because of the scarcity of evidence and the lack of systematic investigations in this field. Whether sacrificial practices and customs, such as the embalming of human bodies in ancient Egypt, or the practical experience gained by surgeons in treating wounds of the head were in any way helpful in expanding knowledge of the visual organs and centers beyond the merest rudiments is doubtful. The crudity of their procedures may be judged from the writings of the "Father of History," Heródotos of Halicarnassós (Ἡρόδοτος Ἁλικαρνασσεύς, 484–425 B.C.; see Heródotos, *History*, book 2), and of Diodóros of Sicily (first century B.C.; *see* Le Clerc 1729, p. 712).

The same unfavorable impression is gathered from the Edwin Smith Papyrus and other sources. (*See* Breasted 1930; A. C. Krause 1933; Ranke 1933; Mendelsohn 1944.) Equally bad for any naturalistic approach to the study of the human and animal body were the conditions in India and in China, the other two ancient spheres of civilization, since the rise of the ruling religions of Brahmanism and Buddhism, both of which were inimical to scientific inquiry. (*See* E. Clark, Simhajī, Zimmer, Wong & Lien-Teh, *et al.*)

Until further indisputable evidence to the contrary is furnished, it must be concluded that knowledge of the structure of the human body and its workings and almost as much the understanding of disease and its treatment, in those vast territories up to and largely also during our own times, had been entirely dominated by magic and mysticism, qualified but little by

practical experience. (*See also* Le Clerc 1729; Daremberg 1869, 1870; Thorndike; Singer 1925, 1928, 1931; *cf.* chap. I, 1 [1].)

Only a small part of the foundation of modern knowledge of the human and animal body and of Western medicine in general is, accordingly, to be found in any of the Pre-Classical Civilizations. Rather, its origin is in the practical, everyday experience of the peoples and tribes that populated the region around the Mediterranean Sea before the dawn of recorded history. These peoples of the Balkan Peninsula and Italy and of other near-by parts of Europe and western Asia gained their livelihood from primitive agriculture and stock raising, subsisted upon herds of sheep, goats, and cattle and to some extent upon the wild animals which they hunted. They were not bound by the inhibitions of a too intricate and rigid system of taboos such as was already rising in India, Egypt, and elsewhere. Their food was derived to a considerable extent from their domestic animals. In their free consumption of animal food these ancient goatherds and shepherds merely continued a habit inherited from their Late Stone Age forefathers, for whom, as hunters, meat was a very important source of subsistence (*cf.* Breuil & Obermaier, N. Casteret, H. L. Movius). It was natural for them to assume that the animal food that was good for them was as palatable to the gods with which their fancy populated the fields, forests, skies, rivers, and caves of their native lands.

In offering animal sacrifices to their deities, they gradually developed a ritual performed according to certain rules. Such sacrificial practices, in turn, furnished ample opportunity to learn much about the principal organs, their appearance, size, location, and arrangement in the body. Upon this rich, varied, constantly exercised, and direct experience was gradually built the original anatomical terminology of the common Aryan language and its later derivatives: Greek, Latin, Celtic, Germanic, and Slavonic.

It was but a short step for the bright minds of late Mediterranean prehistory to make a comparison between animal and human organization and to draw conclusions concerning its similarities and differences, as Greek folklore and mythology amply illustrate. Their anatomical knowledge was further amplified and corrected by the observation of wounds inflicted in frequent combats between the numerous tribes and communities that constituted this primitive, atomized society. When, about the middle of the first pre-Christian millennium in post-Homeric Greece, more settled conditions emerged from this chaos, the Greek language already possessed a rich anatomical vocabulary, found most useful by the newly rising class of healers or precursors of medical professionals needed in an emerging urban civilization. When at last Ancient Greece blossomed out into a phenomenon unique in the Ancient World, conditions developed which permitted and fostered free inquiry into all the phases and phenomena of life: native gifts of the race, economic progress and urbanization, commercial freedom, and, probably most important, a lack of enforced religious, political, economic, and social uniformity. (*See* Daremberg 1865, 1869; Soury 1899; J. Jolly 1901; Hopf 1904; Rostovtzeff 1926).

3. Greek anatomy of the brain and of the visual system. In contrast to the remainder of the Ancient World, the Greeks had already acquired, particularly during the time of Heródotos, considerable knowledge of the anatomy and physiology of the brain, as they had of practical medicine in general (the school of Hippocrátes of Cos, Ἱπποκράτης, "Father of Scientific Medicine," 460–380 B.C.). The few scattered hints found in classical Greek writings indicate this. Alkmáion, or Alemáeon of Croton (Ἀλκμαίων, *ca.* 520 B.C.), a physician by profession, is reputed to have been the first to dissect human bodies. He knew the role of the brain in sensation, movement, and thinking and considered it to be the seat of *hegemonikón* or the "ruling soul." (*See* Soury 1899; W. Sudhoff 1914.) Anaxagóras of Klazomenai (Ἀναξαγόρας *ca.* 500 B.C.) was the first to dissect the brain systematically. Another sage of Hellenized southern Italy, Philólaos of Croton or Tarent (Φιλόλαος, approx. 400 B.C.), considered the brain to be the seat of intelligence and the heart the seat of ἡγεμονικον (*hegemonikón*), or the principal of several souls animating the living body, and of sensation. (*See* Brunet & Mieli 1936.) The fact that the Hippocratic School considered the seat

of epilepsy to be in the brain and interpreted it as being caused by a cerebral edema also shows that the early Greek physicians had arrived at the idea of the brain as a substratum of nervous action. (*See* Hippokrátes, Περὶ ἱερῆς νόσου or *νούσου, De Morbo Sacro*, or *On the Sacred Disease; see* Temkin.)

An advancement in the knowledge of the brain is even more probable during the time immediately preceding the Hellenistic or Alexandrine period (to 323 B.C.). During this period the natural sciences began to flourish, as evidenced by the writings of Aristotle (*cf.* chap. I, 1 [1]). Thereafter, for a hundred years or so, from 323 to 212 B.C., in Alexandria, Egypt, which was founded in 332 B.C. by Aristotle's pupil Alexander III of Macedon, after the establishment of Greek dominion in Egypt under King Ptolemy Sotér, Alexander's general, Greek science reached a level never equaled or even approached either before or after, until the advent of Modern Times.

During the Roman Empire and the subsequent ages of decadence following its disintegration, Hellenistic or Alexandrine anatomy and physiology, especially of the brain, served as a foundation and an inexhaustible source of instruction. Later, during the Renaissance in western Europe, this ancient Greek knowledge furnished the tools with which our own modern sciences and medicine were built. (*See* Breasted; Brunet & Mieli; Cantor; Le Clerc; Soury.)

4. ARISTOTLE'S KNOWLEDGE OF OPTIC NERVES AND THEIR CONNECTIONS. - The first written record of the anatomy of the brain and the cranial nerves dates from Aristotle, the encyclopedic Greek naturalist and philosopher (*see* chap. I, 1 [1]). His description of the connections of the eyes with the brain, however, is extremely sketchy:

> From the eye there go three ducts to the brain: the largest and the medium-sized to the cerebellum, the least to the brain itself; and the least is the one situated nearest to the nostrils. The two largest ones, then, run side by side and do not meet; the medium-sized ones meet—and this is particularly visible in Fishes—for they lie nearer than the large ones to the brain; the smallest pair are the most widely separated from one another, and do not meet [Aristotle, Περὶ τα ζῷα ἱστορία, or *Historia Animalium*, chap. 16].

Tentatively, the largest of the three nerves related to the orbit may be identified with the fifth or trigeminal nerve, the medium-sized with the optic nerve proper, and the third and thinnest one probably with the olfactory nerve. The reference to the "meeting" of the medium-sized nerves of both sides clearly indicates the chiasma of the two optic nerves.

Aristotle's meager account is, perhaps, all that could be expected from a great naturalist and thinker, busy with the innumerable problems of life and the world and living in a time of cataclysmic events: the downfall of Greece as a political power, the conquest of Persia and Egypt by Alexander, the creation of Alexander's empire, with its rapid disintegration and the struggle of the Diadochs, or Alexander's "heirs," for the division of the spoils after Alexander's death.

Another detrimental factor which probably prevented him from paying more attention to the particular question of the optic nerves was his concept of the functional role of the brain in general. For in his opinion this organ was merely an accessory to the heart, which, by implication, was the true seat of the "soul." The brain, accordingly, was not supposed to feel and could not be connected with the sense organs. In any case, it is a strange conclusion by such an acute observer, who undoubtedly had dissected many and various animals. (*See* Aristotle Περὶ ζῴων μορίων, *De Partibus Animalium*, or *On the Parts of Animals*, book 2, chap. 7.)

The concept of the heart as the seat of the soul, at any rate of its highest principle, *hegemonikón*, was later accepted and further elaborated by the ideologists of early Christianity, for example, by Tertullian (*De Anima, Of the Soul, ca.* A.D. 210).

5. ANATOMY AND PHYSIOLOGY OF THE VISUAL SYSTEM DURING THE ALEXANDRINE AND EARLY ROMAN PERIODS. - The sketchy description of the nerves more or less related to the eye by Aristotle was soon followed by the first systematic anatomical investigation during the most advanced, the Alexandrine or Hellenistic, period of Greek science. This, according to the scanty information available, was based chiefly on the dissection of human bodies. In order, in the words of Celsus, to learn better "the correct

position, color, form, size, relative situation, hardness, softness, smoothness, the connection, and the way the various internal organs, concealed by nature, are fitted into one another," Heróphilos and Erasístratos (Ἐρασίστρατος, d. 258 B.C.), the pioneers of Alexandrine anatomy and medicine, it is said, dissected alive hundreds of criminals delivered to them by the order of the king. Their knowledge, accordingly, was obtained through direct observation.

It is probable that this was more than an allegation, in spite of the denial of some modern historians, judging by the vehement accusation against Heróphilos by Tertullian, "Founder of Latin Christianity" and an inveterate adversary of science, who calls him "that doctor or butcher, who hated man in order to learn about him." (*See* Tertullian, *op. cit.*, chap. 10, par. 4.)

An even more weighty indication that there was a concrete basis for Tertullian's complaint is found in a detailed discussion of the attitudes of the various medical "sects" or schools toward human vivisection, related by the famous Roman medical writer, Aulus Cornelius Celsus (*ca.* A.D. 20), in the first book of *De Re Medica*, or *On Medicine*, the oldest medical writing after Hippocrates. According to Celsus, some schools favored this practice, while others, e.g., the "Empirics," disputed its usefulness and also rejected it on ethical grounds. Celsus states his own opinion as follows: "How is it, in fact, possible to understand the seat of an illness, if one does not know the place of each internal organ? How to treat a sick organ without knowing what it is? And it is not cruelty, as many pretend, to sacrifice a few criminals in the interest of the innocent of the centuries to come!" (*Cf.* Vesalius, sec. 8 [1], this chapter.)

Whatever the truth in the matter of human vivisection, the unquestionable fact remains that the early part of the Alexandrine period (third century B.C.) was most fertile in advancing knowledge of the human body. Later, toward the beginning and during the first few centuries of the Christian Era, coinciding with the Late Roman Republic and the Empire after Caesar, when the humanitarian principles and religious prejudices of an overcivilized Roman public made the dissection of dead human bodies rare, animals, sometimes monkeys, were dissected almost exclusively, as expressly stated by Rûfos and by Galen (*see* Rûfos, *On Naming the Parts of the Human Body*; Galen, Περὶ τῶν ἀνατομικῶν ἐγχειρήσεων, *De Anatomicis Administrationibus*, or *On the Practice of Anatomy*).

During the general decay of intellectual life that followed the collapse of the Western Roman Empire, during the Dark Ages, finally even the use of animal bodies was discontinued, and the few ignorant "medics" and barber-surgeons had to rely upon the scant information left from Classical times.

The earliest systematic description of the nervous system including the optic nerves is contained in a little book by Rûfos of Ephésos, entitled: Περὶ ὀνομασίας τῶν τοῦ ἀνθρώπου μορίων, or *On Naming the Parts of the Human Body*, apparently a compilation from older Greek sources, probably from Heróphilos, Erasístratos, and Éudemos (Εὔδημος, 3d century B.C.; *see* chap. I, 1 [1]). This description of the brain and the optic nerves is rather scanty. Rûfos mentioned the two meninges, the "varicose surface" or convolutions of the brain, the brain's base, cerebellum, ventricles, chorioid tunic—now called chorioid plexus and chorioid tela—and the spinal cord. Among the nerves, he distinguished sensory and motor, and, following the interpretation by Alkmaíon of Croton and by Demókritos of Abdera, he considered them to be hollow conductors or channels (*póroi*, *hodói*, or *ochetói*). The optic nerves (*póroi optikói* or "optic channels") he believed emerged from the base of the brain and divided into two branches, which, by coursing obliquely, entered the eyes. (*See also* Rûfos, *Anepígraphon*, par. 3, in Daremberg & Ruelle's trans.)

SEC. 2. GALEN'S ANATOMY AND PHYSIOLOGY OF THE VISUAL SYSTEM

1. GALEN'S MEDICAL WRITINGS AND THEIR INFLUENCE UPON ARAB AND EARLY WESTERN SCIENCE.—The most prolific writer of Classical Antiquity on anatomy, physiology, and other medical subjects was Galen, called the "Prince of the Physicians" (Γαληνός, Galenós). Born A.D. 129 in Pérgamos or Pérgamon, an ancient seat of learning in western Asia Minor, of Greek or Hellenized parentage, he enjoyed a careful medical and general education, first in his native city and later in other cities, including the most important, Alexandria, the medical center of the Roman Empire. Thereafter he practiced medicine, first in Pérgamos and later in Rome. Here he met with singular success, becoming a friend of the Emperor-Philosopher Marcus Aurelius Antoninus (A.D. 121–80). After a life filled with many varied activities, Galen died about A.D. 201 either in the capital or in his native city.

The influence of Galen's anatomy and physiology, of his views concerning the organization and workings of the brain and of every other part of the body, under both normal and pathological conditions, was profound and of long duration. The importance of his voluminous writings, which represent the best and most complete exposition of Greek knowledge of medical subjects, especially anatomy and physiology, was enormous because they became the chief source of information during the Arab period and, through the Arab writings, of western Europe during the period of Revival in the Late Middle Ages and early Modern Times.

A description of the nervous parts concerned in vision is found in several treatises: Περὶ χρείας μορίων or Περὶ χρείας τῶν ἐν ἀνθρώπου σώματος μορίων, *De Usu Partium Corporis Humani libri XVII*, or *On the Use of Parts of the Human Body*; Περὶ τῶν καθ'Ἱπποκράτην καὶ Πλάτωνα δογμάτων, *De Hippocratis et Platonis Placitis libri IX*, or *On the Teachings of Hippocrates and Plato*; Περὶ τῶν ἀνατομικῶν ἐγχειρήσεων, *De Anatomicis Administrationibus libri XV*, or *The Practice or Procedure of Anatomy*; Περὶ νεύρων ἀνατομῆς βιβλίον τοῖς εἰσαγωμένοις, *De Nervorum Dissectione ad Tyrones Liber*, or *The Book on the Dissection of Nerves for Beginners*. (For translations *see* Daremberg, Töply, Wiberg; for biography, etc., *see* Allbutt 1921; Daremberg 1854–56, 1865, 1870; Ilberg 1905; Chas. Singer 1922, 1928; Ullrich 1919; J. Walsh; also private information from Mr. W. J. Wilson, Army Medical Library, Cleveland.)

2. GALEN'S DESCRIPTION OF THE NERVES RELATED TO THE EYE.—In general, Galen distinguished two varieties of nerves: "hard nerves," which he considered to be motor in function, and "soft," or sensory, nerves. The eye is supplied by both. The hard nerves are attached to the extrinsic eye muscles (actual oculomotor, trochlear, and abducent nerves). The optic nerves proper, on the contrary, are soft; and, following his Greek forerunners, Alkmáion, Demókritos, Heróphilos, and others, he believed them to be hollow or tubelike and thicker than any other nerves of the body. In spite of their softness, the optic nerves, like the other nerves, are much tougher, though not much harder, than the brain. In one respect, however, the optic nerves differ from other nerves: they are not true nerves but are expansions of the brain itself. (This idea, apparently was taken over from Aristotle, *see De Sensu*, chap. 2, in *Parva Naturalia*.) Even so, Galen counted the optic nerves as the first pair of cranial nerves. Incidentally, the application of the term "optic nerve" to the entire stretch from the eye to the subcortical visual centers, which also includes the optic tracts in modern terminology, as practiced by Galen, remained customary until Vicq-d'Azyr (1786–90) (*see* sec. 12 [7], this chapter).

Galen designated two localities of the brain as the origin of the optic nerves, precisely the

sides of the two anterior cerebral cavities which he called *thalami* (sing. *thalamus*), now termed lateral ventricles, a discovery which, in his own words, had until then remained unknown to the anatomists. To make the optic nerves originate from the cavities seemed to him quite logical, in view of his idea about the origin of the "visual spirit" in the brain, and its role in vision (*see* sec. 3, this chapter, and chap. I, 1 [2]). It was therefore unavoidable for him to miss the large, solid masses of gray substance, to which the term *thalamus* is applied in modern anatomy, and their true relations to the optic nerves.

Galen's use of the Greek word θαλάμη *thalámë* (meaning a "hole," "cave," or "cavity," akin to θάλαμος, *thálamos*, meaning an "inner room" or "chamber" of a house, or the "inner space" of a ship), thus becomes understandable. The term probably derived from the Egyptian word *thalam*, which meant the "inner space" or "sanctum" of a temple, and Galen's application of it to the cerebral ventricles bears its original sense.

In this connection it is perhaps of some interest to mention that the word *thalám* is now used in modern Malayalám, a composite Tamil-Sanskrit language spoken by the preponderantly Dravidian population along the Malabar coast of South India, the ancient "Land of Spices," according to Dr. L. Chacko. The meaning of the word in Malayalam is precisely the same as in Ancient Greek and Ancient Egyptian. This may, perhaps, not be pure coincidence, in view of the close commercial relationship between Ancient Egypt and India.

Galen also thought the substance of the brain softer in its anterior portion, where the sensory nerves were supposed to originate (forebrain), and harder posteriorly, where the motor nerves seemed to him to arise (cerebellum and the adjoining parts of the brain stem, in modern terminology). The "hard" oculomotor nerve was the only exception to this rule, since it originated from the anterior portion of the brain. In the chiasma the two optic nerves only apparently intercross. In reality, they merely join here in order to bring their channels together.

The optic nerves terminate in the eyes by means of a thinned-out expansion, the retinal tunic, at the crystalline lens, in particular at its capsule, the lens in Galen's opinion being "the principal and essential organ of vision," or, in modern terminology, the actual photoreceptor. This concept of the photoreceptor function of the crystalline lens was later taken over by Arab scholars and bequeathed by them to their European pupils, among whom it was held in high esteem until the beginning of the seventeenth century (*see* chap. I, 1 [2]; 3 [3, 4]; 5).

Galen accepted and further elaborated upon the idea that the optic nerves were tubelike and functioned as conducting channels of the "visual spirit," proposed by Alkmáion, and taught by Demókritos, Heróphilos, and Éudemos, since, of all nerves, the optic nerves alone seem to show a visible *lumen* or opening. During the subsequent fifteen centuries this imaginary channel played a prominent role in shaping the concept of the functions of the visual system and of the brain. The Arab scholars and, among the European anatomists, Eustachio (in *Tabulae Anatomicae*, written *ca.* 1560, but published 1714) were firmly convinced of the reality of this channel and represented it regularly in their illustrations (Figs. 56–60; *see also* Figs. 7–12 in Polyak, *The Retina*, 1941, 1948).

Walsh; J. Wilberg; E. Zeller 1920–23.

SEC. 3. GALEN'S PHYSIOLOGY OF THE VISUAL SYSTEM

1. The Greek hypothesis of "pneuma" or "spirit" as life's principle.—Even more interesting and far more important are Galen's ideas about the factors involved in the visual act and about the role the brain plays in it. The eyes, in Man, he considered dominant sense or-

gans. They are placed in the most elevated part of the body because of the obvious advantage deriving from this position. The brain is situated in the head because of the eyes, while all other sense organs, in turn, are placed in the head because of the brain's location there. (*Cf.* chap. XIII.)

From the heart, "a center of the arterial system," the brain receives through the arteries a "vital spirit" or "vital air" (*πνεῦμα ζωοτικόν, pnéuma zoötikón*). The "vital spirit," in turn, is an elaboration of an elemental "natural spirit" (*πνεῦμα φυσικόν, pnéuma physikón*), originating from the liver, "the center of the venous system," a mysterious substance indispensable for life. This relatively crude "vital spirit," arriving in the brain with the arterial blood, is further transformed therein into a more refined "animal spirit" (*πνεῦμα ψυχικόν, pnéuma psychikón*). A necessary ingredient for this is the air inspired into the cerebral ventricles through the nostrils, the cribriform plate of the ethmoidal bone of the skull, the olfactory nerves, bulbs, and tracts.

The transformation of the "vital spirit" into an "animal spirit" takes place in the *rete mirabile*, a dense arterial network at the base of the brain. Here it may be mentioned that such a network is present in some mammals, such as sheep, but not in Man, where it may be homologized roughly with the branches of the inner carotid and the vertebral arteries, including their anastomoses, which together form the arterial circle of Willis and its subsidiaries (*see* Fig. 368). This and other similar features of Galen's description show that his knowledge was mainly or entirely based on the dissection of animal bodies, prevented, as he was, from using human bodies for his studies by current prejudice.

2. THE BRAIN—A REPOSITORY OF THE "ANIMAL SPIRIT" AND OF THE "REASONING SOUL."—Most of the "animal spirit," according to Galen is deposited in the brain, an organ with which we think and which is the seat of the "reasoning soul" (*ψυχὴ λογιστική, psyché logistiké;* Aristotle's *νόος* or *νοῦς, nóös* or *nöös*, "mind" or "reason"; this soul corresponds to the noblest of Plato's three souls, the *ἡγεμονικόν, hegemonikón*, or a ruling or supreme principle residing in the human body, immortal according to Plato, but hardly so according to Galen). A certain quantity of "animal spirit" was present in the entire brain, both the substance and the ventricles. The cerebral ventricles served as a special repository of the "animal spirit," an idea that originated with Heróphilos, as one learns from Galen's treatise *On the History of Philosophy* (*De Historia Philosophiae, liber spurius*, chap. 38; *see* W. Sudhoff, 1914, p. 154; *see also* Aaftios or Aëtios, *ca.* A.D. 500). This soul, filling the ventricles, Heróphilos named *τὸ τῆς ψυχῆς ἡγεμονικόν*, or "the dominant spirit."

From the brain the "animal spirit" spreads to all nerves, including the optic, whose channels, in Galen's view, communicate directly with the cerebral ventricles. Since these ventricles expand and contract the way the heart does, the "animal spirit" is continuously being propelled from the brain into the nervous channels and in this way is distributed all over the body.

3. THE EYES—REPOSITORIES OF THE "VISUAL SPIRIT."—That part of the "animal spirit" which passes through the optic channels to the eyes is the "visual spirit" (*πνεῦμα ὁρατικόν, pnéuma horatikón*). In the eyes the "visual spirit" spreads along the thinned-out portion of the brain—the retina—as far as the pupil. Finally, it passes to the crystalline lens, the supposed "principal organ of sight," or, in modern parlance, the "photoreceptor," to which Galen believed the retina was directly attached. This "visual spirit" or "luminous air," a sort of ethereal fluid, also fills the anterior chamber of the eye, where it mixes with the aqueous or albugineous humor. The anterior chamber and the pupil, therefore, are the localities where "outer light," coming from outside, and "inner light," coming from the brain, meet (*cf.* this with Plato's "synaugy," chap. I, 1 [2]). To Galen it seemed clear that the brain extends as far as the eyes in the form of the optic nerves, that these nerves become soft and membranous in the eyes (that is, are transformed into retinal membranes), and that the optic nerves alone are excavated (a tacit implication being that all these factors facilitate the intimacy of the contact with the supposed photoreceptor, the crystalline lens).

The flow of the "visual spirit" from the brain

to the eyes, however, is only a part of a complete process, the other part being a flow in the opposite direction, from the eyes to the brain. Both these movements, or processes, Galen obviously considered indispensable, the act of vision being consummated only when the "visual spirit" returns to the brain with the impressions received in the crystalline lens.

Galen's idea of the brain's importance, in contrast to the ideas of Aristotle and many other Greek naturalists and thinkers, was quite modern. For he was firmly convinced that the brain was "an organ where all sensations arrive, and where all mental images, and all intelligent ideas arise," a "place of imagination, memory, and comprehension." (*Cf.* chap. I, 1 [2], and 6 [1].)

SEC. 4. GALEN'S FUNCTIONAL INTERPRETATION OF THE CHIASMA AND OF OTHER FEATURES PECULIAR TO THE VISUAL SYSTEM

1. EXPLANATION OF THE DOUBLE CEREBRAL ORIGIN OF OPTIC NERVES.—Galen's analysis and interpretation of the anatomical features peculiar to the visual system is interesting and even ingenious, though in places naïve, obscure, and confused.

First, the reason Galen gives to explain why each optic nerve originates from the brain independently instead of together (even though a common origin would be more advantageous for the unity of the visual impressions) is fantastic: the necessity to place the cerebral infundibulum (through which the brain was supposed to discharge its impurities into the nasal cavity) at the very point of a potential central origin of the optic nerves, the central position of the infundibulum in turn being determined by the central position of the nose! As if Almighty Zeus or Mother Nature, had they so willed, had not been able to create two infundibulums and two noses, one on each side, in order to make the optic nerves originate from a single central point!

The arrangement of the parts which compose the visual system, Galen insisted, follows the principles of geometry and is determined during intrauterine development. From the point of their junction in the chiasma to the eyes, the optic nerves may be compared with two straight lines meeting in one point and placed in a single plane. The other principal constituents of the visual system: the visual axes and pupils of both eyes and the optic nerves from the *papillae* (where, according to Galen, the summits of the "visual cones," or visual axes, rest) to the chiasmal juncture all follow straight lines and are arranged in the same plane. In this way, Galen imagined, diplopia or double vision is avoided, and the single image is achieved in the binocular visual act or in seeing with both eyes.

2. FUNCTIONAL ROLE OF THE CHIASMA.—In discussing the functional significance of the junction of the optic nerves in the chiasma, Galen mentions several previous hypotheses made by those interested in this subject.

The first explanation was mechanical. According to this, the purpose of the chiasma was to avoid damage to the optic nerves, which might easily occur if they were straight and tightly drawn (presumably in the case of tension on the nerves when the eyes rotate).

Another opinion held that the function of the chiasma was to enable the optic nerves to exchange sensations or affections and thus to reduce the "pain" suffered by the stimulated optic nerve. This opinion was based upon an ancient doctrine, according to which all sensations were essentially painful. (*Cf.* the terms "pathos," "sympathy," "compassion," "passive," etc.)

According to a third view, the optic nerves, since they supply two different peripheral organs, must ultimately come together in one point, presumably in order to bring about unity of visual impressions received through both eyes.

Not being satisfied with any of these theories, Galen suggested as the most plausible function of the chiasma the proper distribution of the "visual spirit" coming from the brain to both eyes. In the case of shutting or losing one eye, all *pneuma*, he thought, would pass over to the other eye and, by doubling its power, would compensate for the loss. In order to prove his thesis, Galen describes the following test: if one holds a hand or a board vertical to the tip of the nose, one sees only imperfectly with each eye. But if one eye is shut, sight improves as if the visual power that was divided until then passed entirely to the other eye.

Still another purpose of the chiasmal junction, Galen thought, was to bring about simple binocular vision by eliminating diplopia or double vision, or, in modern parlance, the creation of a "functional cyclopean eye" (*cf.* chap. XIII, 3 [6]). These ideas of Galen's, which may have originated partly or entirely with the Alexandrine School, inadequate as they are, appear to be the earliest recorded attempt to interpret binocular single vision in terms of anatomical structures. (*See* sec. 11 [4, 5], this chapter.)

3. DIVINE FORCE—GALEN'S DEFENSE AGAINST THE PREJUDICE OF THE ROMAN PUBLIC.—Galen's effort to solve one of the riddles of the human constitution—binocular single vision—is of interest from yet another angle. The hypothesis of the chiasmal function, as well as the idea of a geometrical organization of the visual system, as he modestly admits, were, in reality, not his own but were suggested to him in a dream by a god not further identified. This god may have been Apollo, patron of the arts and of healing, or his son, Asklepiós or Aesculápius, God of Medicine, although Galen, like his imperial friend, Marcus Aurelius, and many other educated persons of his age, certainly was acquainted with the precepts of the Hebrews and the Christians, not to speak of the philosophical concepts professed by Socrates and Plato, which amounted virtually to monotheism.

Whether Galen, imbued as he was with religious feeling and superstition, sincerely believed this story or whether his introduction of the divine powers into the physiology of vision was merely a trick to guard himself against the fanaticism and religious prejudice of the reactionary Roman populace, and perhaps also designed to avoid adverse action of the jealous Roman doctors, his professional competitors, there is no way of telling.

From the remarks scattered in his writings, however, one is to believe that his friendship with the Emperor, his popularity with patients, and, most of all, his financial success must have aroused great envy among the greedy, narrow-minded, poorly educated, and numerous Roman "medics." Which reminds one of an old Latin proverb: *Homo homini lupus, medicus medico lupissimus!* or "Man is a wolf to another man, but most wolfish is a doctor to another doctor!"

Nor did the encyclopedic Galen, who loved to theorize, to speculate, and to criticize, alleviate this situation by his show of contempt for his professional Roman colleagues, who, as he complains, had no interest in such useless intellectual pursuits as "mathematics, astronomy, and music."

In these circumstances Galen, the successful but hated outsider, a *Graeculus* or "petty Greek," may have felt it advisable to hide behind a divine shield in order to avert a fate similar to the one which befell Socrates, and almost befell Plato and Aristotle: to be indicted and executed for "corrupting the youth" and "for introducing novel practices in religion."

Similarly, Galen's failure to mention human vivisection, a subject even more obnoxious to the spirit of his time, which Celsus had discussed at length less than two centuries earlier, may have been motivated by opportunism rather than by ignorance (*cf.* sec. 1 [5], this chapter).

SEC. 5. EVALUATION AND CRITIQUE OF GALEN'S CONCEPT OF THE VISUAL MECHANISMS

1. SIMILARITIES AND DIFFERENCES BETWEEN GALEN'S THEORIES AND THE MODERN VIEW OF THE FUNCTION OF THE VISUAL SYSTEM.—Galen's views about the function of the visual system, which in a sense embody the best knowledge of Classical Greek and Roman times, in spite of many inaccuracies, are fundamentally, when properly translated into modern terms, amazingly close to our own.

The retina, for example, Galen, like Aristotle before him, correctly recognized as a displaced portion of the brain. This view, obviously, could not have been based upon histological and embryological data but was prompted by speculation. The closer and more intimate the relationship between the brain and the crystalline lens—the alleged photoreceptor—the easier the flow of the "visual spirit" from the brain to the lens and from the lens back to the brain (after having been charged with the impressions or sensations in the lens). Considering the general state of knowledge, especially the absence of dioptrics and magnifying apparatus, Galen's reasoning was the best that could be expected at that time. (*Cf.* chap. I, 1 [2] and 2.)

Of the visual pathway, Galen knew the infranuclear division, from the eye to the brain. The subcortical visual centers, visual radiations, and the visual centers in the cerebral cortex were all unknown to him and remained unknown until modern times (*see* chap. III, 7, 8, 9). Under the circumstances, it is to his credit to have made an effort to investigate those parts which he knew, especially the chiasma, and the "origin" of the optic nerves in the brain.

Galen's opinion that each optic nerve and tract remains on its own side of the brain, that is, that there is neither a partial nor a total crossing in the chiasma, remains, of course, inconsistent with the facts (*see* chap. VI, 4, 5, 6). If, however, one considers that until the beginning of the twentieth century some of the foremost microscopists (e.g., Koelliker) still struggled with the essential arrangement of fibers in the human chiasma and denied the partial decussation in it, our judgment of Galen's mistakes will be less harsh (*see* chap. III, 9 [3]). But the basic idea of the merging of the two "optic channels" in order to permit the "exchange" of the "visual spirit," archaic as it appears, is not far from the anatomical and physiological reality of a partial crossing of the optic nerve fibers and the functional collaboration of both eyes in single vision. To Galen, the function of the chiasma was to make it possible to compensate for the loss of one eye by doubling the power of the other. The modern interpretation is that its function is to bring about a stereoscopic effect in the normal binocular visual act and to enable both cerebral hemispheres to see the larger portion of the common cyclopean field of vision in case one eye is lost.

Galen's assumption of the presence of a hollow channel within the optic nerves was an outright error (except as it concerns the early period of embryonic development, of which he could have had no knowledge; *see* chap. XIII, 1, and Fig. 435). In his defense one should recall the channel-like cavity in the olfactory tracts and bulbs in many Vertebrates, with which he was probably familiar. Also, the excavation of the optic papilla may easily have suggested a "peripheral orifice" of a channel. A "central end" of a channel in the lateral ventricles, too, could easily have been found in the slitlike spaces between the "roots" of the optic tracts and the surrounding structures, especially around the hippocampal fissure. The difficulty of convincing one's self of the presence of a channel in the course of the optic nerve could also have been overcome if the analogy of empty, contracted blood vessels were invoked. For here, too, an arterial *lumen* or opening is often easier to assume than to see. Finally, an actual channel in the optic tract, probably resulting from developmental irregularities, has been described by J. Stilling (1882, p. 12, footnote) and may be seen on rare occasions (as I know from my own observation).

2. GALEN'S MISTAKES—THE RESULT OF HIS DESIRE TO EXPLAIN THE ORGANIZATION OF THE VISUAL SYSTEM WITH INADEQUATE MEANS.—The idea of a channel in the optic nerves through which an active principle—the visual spirit or visual *pneuma*—circulates is worthy of

attention because of the general physiological interest which it represents.

Like the other Greek anatomists and physiologists, Galen was naturally ignorant of the bioelectric forces in the living nervous substance responsible for the "transmission" of "nerve impulses"--a basic concept of modern neurophysiology. He was, therefore, unable to conceive of the propagation of nervous influences through solids, such as the nerves, in fact, are.

In this connection one may recall similar difficulties encountered by the early modern microscopists and physiologists, e.g., Malpighi, Vieussens, Diemerbroeck, Ridley, A. Haller, S. Th. Soemmerring, and all investigators of the period preceding the discoveries of Galvani (1780) and Volta (1800). They, too, and for the same reason as Galen, were prompted to regard the myelinated nerve fibers as "tubes" with a hollow central lumen or passageway- which, in reality, was the axis cylinder enveloped in a myelin sheath--along which an extremely thin substance, a hypothetical *fluidum nerveum*, *succus nervosus*, or "nervous fluid" or "nervous juice," was supposed to circulate.

Galen's desire for a plausible explanation of nervous transmission logically demanded a palpable substratum. Such was the material "spirit" or *pneuma* moving within the visible space of the "nerve channels" from the brain to the eyes and back again to the brain, in analogy with the circulation of the blood in the arterial channels and particularly in the veins (inadequate as the Greek concept of the function of the vascular system otherwise was).

But, in spite of this seemingly mechanical analogy, a fluid vehicle or carrier of visual sensations, the "luminous air," imagined by Galen, was not so crudely material as the blood and other humors found in the organism. The "visual spirit," as conceived by Galen, was a principle, refined, subtilized, and sublimated to a degree where it almost ceased to be material. Obviously, only such an ethereal *pneuma* was fit to serve a function as subtle and delicate as Galen considered vision to be. Seen in this light, his concept of visual mechanisms approaches modern views much more closely, in spite of the naïve terms and phrases, long since outdated, in which his ideas are clothed.

SEC. 6. ANATOMY AND PHYSIOLOGY OF THE VISUAL PATHWAYS AND CENTERS DURING THE MIDDLE AGES AMONG THE NATIONS INFLUENCED BY ARAB CIVILIZATION

1. Cessation of scientific interest in Europe during the Dark Ages; the Arabs as the heirs of Greek science and medicine.

During the thousand years or so following Galen's death (*ca.* 200, Christian Era), especially after the collapse of the Western Roman Empire and Classical civilization, interest in anatomy and physiology, as in the natural sciences in general, almost vanished. The arts and sciences created and accumulated during Classical times gradually disappeared from Europe in the chaos of the Dark Ages, which lasted well into the second millennium of the present era. In this process of gradual reversion to a barbarous state, a condition was reached where all incentive ceased, both for active research and for the preservation of previously acquired knowledge. Under such conditions of total cultural disintegration, most of the writings of the Greek scholars, including those of Galen, were lost in the European West.

A different situation, fortunately, obtained in the newly arisen Arab dominions of the Near East and among other nations influenced by Arab civilization. Here most of Galen's treatises were preserved and became the principal source from which Arab scholars derived their information about anatomy, physiology, and allied subjects (*see* chap. I, 3). Unfortunately, however, the Mohammedan creed, just as the Brahman, Buddhist, Jewish, and Christian creeds did until late into the Middle Ages, opposed the dissection of human and animal bodies, which circumstance proved to be an insurmountable barrier to progress in anatomical and medical research. Arab anatomy and physiology to a far

greater degree than practical medicine, astronomy, mathematics, physics, including optics, chemistry, and other sciences, remained a passive digestion of ideas preserved in the Greek writings.

The presentation of the visual pathway, by Ḥunain ibn Isḥāḳ, for example, was in substance merely an abstraction from Galen, although arranged more logically than in the rambling Greek original (*cf.* Figs. 56–60). In it all the principal ideas—the hollowness of the optic nerves, their merging in the chiasma "so that their two cavities become one," the "origin" of the optic nerves from the cerebral ventricles, and the existence of a "psychic spirit" which constantly circulates from the ventricles to the eye in great quantity—are expressed in approximately the same way as in Galen's writings, the source being duly acknowledged by the author.

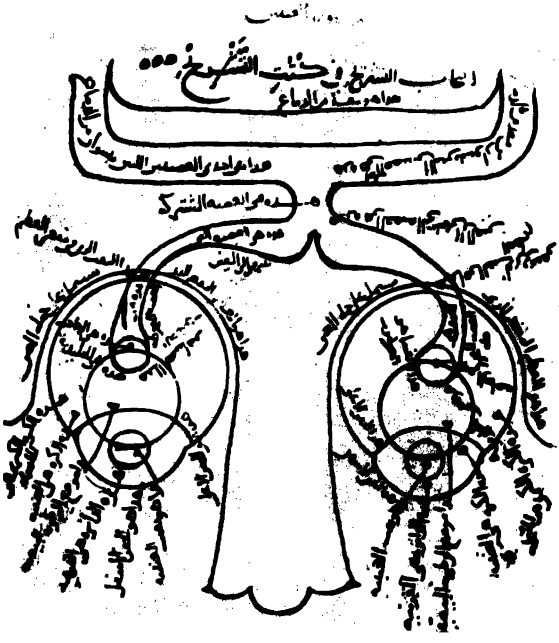

Fig. 56.—Diagram of the visual system from the oldest existing copy of *Kitāb al-manāẓir* or *Book of Optics* by Ibn al-Haitham or Alhazen. Manuscript written A.D. 1083, in possession of Fatih Library at Istanbul or Constantinople, Turkey. For English terms *see* Fig. 8, in S. Polyak, *The Retina*.

The same may be said about other Arab descriptions of the visual system found in the books of ʿAlī ibn ʿĪsā, Ibn al-Haitham (Alhazen), and others. The only exceptions were Al Rāzī (Rhazes or Rasis), and Ibn Sīnā (Avicenna), who described the optic nerves in the chi-

asma as completely crossed (*see* Avicenna's *Canon of Medicine*, book 3, fen 3, chap. 32).

2. IBN AL-HAITHAM (ALHAZEN), A PRECURSOR OF MODERN VIEWS ON THE FUNCTIONAL ORGANIZATION OF THE VISUAL SYSTEM.—Of considerable interest is Ibn al-Haitham's presentation of the physical side of the working of the visual mechanisms, which to him, primarily a physicist, was of principal interest. The title of the pertinent theorem 18, in the first book of his *Thesaurus of Optics* (early part of 11th century, *cf.* chap. I, 3 [2]), reads: "Distinct vision is accomplished by means of perpendicular lines drawn from the objects seen to the surface of the organ of sight. In this way each point of the object is related to a point of the surface of the visual organ having the same position as in the object seen."

Ibn al-Haitham even contemplated an unaltered transmission of "figures" from the posterior surface of the "glacial sphere" or lens, where they were supposedly formed, along the retina and the hollow optic nerve, to the brain, which, in his opinion, was the *ultimum sensus, sentiens ultimum*, or "final arbiter" of all subjective photic experiences and responses.

These ideas of Ibn al-Haitham plainly express the rudiments of the concept of a "projection" or topographical representation of the retinal surface in the cerebrum, which in modern times has played a spectacular role in the investigation of the visual and other systems, although Ibn al-Haitham's concept of the physical process in vision, as the reference to "perpendicular lines" shows, was inadequate (*cf.* chap. I, 3 [3, 5]; chap. IV, 4; and sec. 10, this chapter).

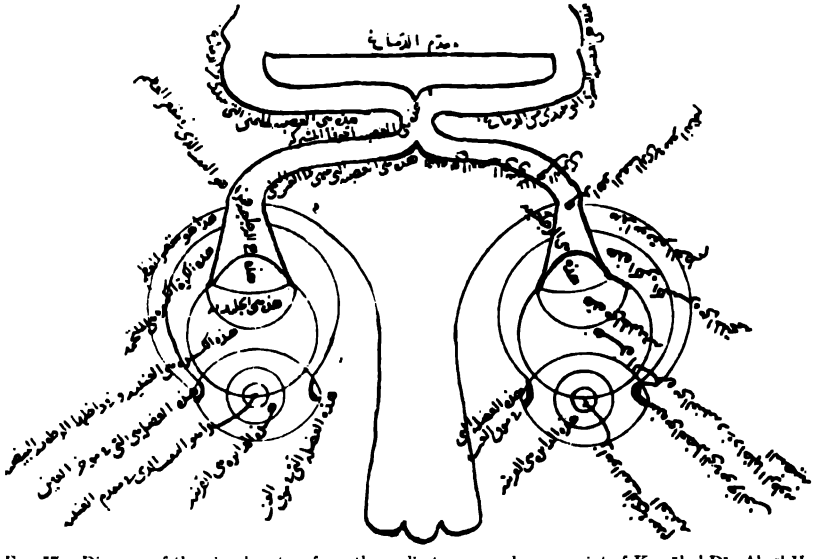

FIG. 57.—Diagram of the visual system from the earliest preserved manuscript of Kamāl al-Dīn Abu'l-Hasan al-Fārisī, a Persian scholar, dated Anno Hegirae 716, or A.D. 1316. Courtesy of the Ahmet Salis Library, Topkapu Saray, Istanbul, Turkey. (*Cf.* Fig. 11 in S. Polyak, *The Retina.*)

As the seat of the "final arbiter" of the visual functions Ibn al-Haitham, following Galen, designated the forebrain, where the optic nerves supposedly originated (Fig. 56; *see also The Retina*, Fig. 8). The functional role of the chiasma, according to him, was evidently decisive, since only after the superposition and fusion of the two monocular images in it, he thought, can the "final arbiter" unify them into a single visual experience. (*Cf.* chap. I, 3, 4 [1], and chap. XIII, 3.)

SEC. 7. WESTERN EUROPEAN KNOWLEDGE OF THE VISUAL SYSTEM PRECEDING AND DURING THE RENAISSANCE

1. EARLY EUROPEAN ANATOMISTS AND THEIR KNOWLEDGE OF THE VISUAL SYSTEM.—During the later part of the Middle Ages, from the twelfth to the fifteenth centuries, western Europeans became acquainted with the Arab writings and, through them, with those of the Greek naturalists, anatomists, and writers on medicine. During this period the knowledge of the visual pathway and of the functions, ailments, and treatment of other parts of the human body, possessed by them, was limited to that found in the afore-mentioned writings. Even this was little understood by men who, for the most part, had never used a dissecting knife and therefore had no personal experience. Such were the earliest writers, mostly monastic schol-

ars: Alcoatin (1159), Vitello (*ca.* 1270), Roger Bacon (13th century), and John Peckham (13th century), some of them rated the foremost thinkers of their time. Theirs was pure book learning, and whatever they knew about the optic nerves, their "origin" in the brain, the chiasma, and other details was taken from the Greeks, either directly or by way of the Arabs.

FIG. 59.—Visual system and its working, from an Arabic treatise on the practice of ophthalmology by Shams al-Dīn Mohammed Ibn al-Ḥasan al-Kaḥḥāl, a Persian eye doctor known as Bāward, dating from A.D. 1690. The sketch purports to show the itinerary of the "visual spirit" from the liver, lung, and heart (*lower part*) to the ventricle of the brain, whence it was, according to Galen's teaching, supposed to spread along the optic nerves to the crystalline lenses of the eyes. From M. Meyerhof & C. Prüfer, Arch. f. Gesch. d. Med. (Sudhoff), v. 6, 1913.

The first active anatomical investigation in the south and west of Europe came with the appearance of a class of practical surgeon-anatomists in Italy and in France, connected with the newly organized universities: William of Saliceto (*ca.* 1215–*ca.* 1280), Mondino de'Luzzi (Mundinus, 1315), and Guy de Chauliac (Cauliacus, 1363). These were followed later by Manfredi (1490), Zerbi (1502), Achillini (1516), Berengario da Carpi, recte Barigazzi, or Carpensis (1521), Massa (1536), and Landi (1542).

Small as their anatomical knowledge was, these early investigators had already acquired considerable personal experience (*see* Singer 1917). They knew, for example, of the so-called "optic thalami," which they called *anchae*,

coxae, *nates*, and *glutea*, meaning "hips" and "buttocks" of the brain, although they seem not to have recognized their relationship to the optic nerves. These terms were apparently applied to the entire mass of the basal nuclei, including the thalamus proper and the corpus striatum (*see also* Burdach 1822, p. 339; Stein 1834). On the question of the optic chiasma they disagreed, some assuming a complete crossing (e.g., Vitello), others merely a merging. In all other respects, however, these early "Western" anatomists and physiologists echoed the mistaken Greek beliefs, especially as regards the hollowness of the optic nerves, in whose channels a visual spirit was supposed to circulate.

Along with this belief, and in strange contradiction to it, was a view already current at that early date, according to which the optic nerve and its termination, the retina, was made up of

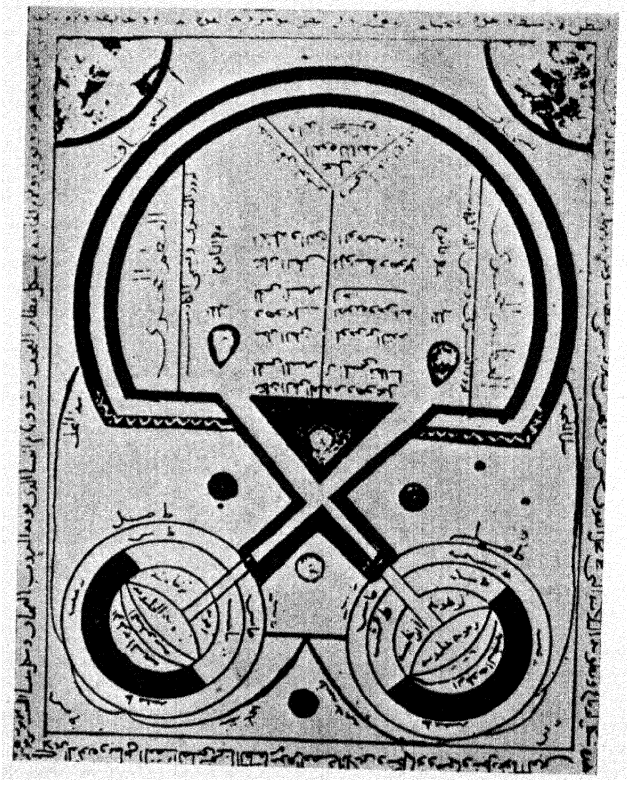

FIG. 60.—Diagram of the visual system and its relation to the brain. The upper part represents the two lateral ventricles, with the third and fourth ventricles of the brain in the mid-line. The ventricles are enveloped by hard and soft meninges on the outside, in turn inclosed by the *periosteum* and the bony shell of the skull. From the ventricles arise optic nerves which contain channels. The nerves decussate in the chiasma and form the two eyeballs (in the lower portion of the diagram). These consist of the fibrous tunic, the chorioid, and the retina. The other parts of the eyes are the vitreous, crystalline lens, arachnoid, aqueous, uvea (iris) with the pupil, the cornea, and conjunctiva. The interpretation follows, in general, that of other Arabic figures and the texts. The original diagram found in an Arabic manuscript of Khalifa written about A.D. 1266 and published in A. Castiglioni, *A History of Medicine*, P. B. Hoeber, New York. The interpretation according to a schematized presentation by J. Hirschberg in Graefe & Saemisch, *Handb. d. ges. Augenh.*, 2d ed., v. 13, p. 151, 1908.

extremely delicate fibers (Vitello). Where this idea originated remains obscure, although it seems probable that it was taken over from Arab writers such as ʿAlī ibn ʿIsā and Alcoatin (*see* chap. I, 6 [2]).

The visual center was considered to be in the anterior portion of the brain, a view also taken over from Galen via the Arabs.

The knowledge of the visual pathways possessed by the learned men of Europe during the later part of the Middle Ages was, on the whole, quite meager and sterile and amounted to even less than the little they knew about the structure of the eye (*see* chap. I, 4 [3]). Essentially, this knowledge consisted of a recognition of the fact that the peripheral organ of vision, the eye, was anatomically connected with the brain, which in some way was concerned with the function of vision. (*See* A. Haller 1769, v. 4, p. 51; and Singer.)

2. Leonardo da Vinci's knowledge of the visual pathways and centers. The almost complete ignorance of any part of the brain involved in vision had in no way been relieved during the general Revival of the Arts and Learning in Europe.

This situation is well attested by the figures of Leonardo da Vinci (1452–1519, portrait Fig. 61), the many-sided genius of the Italian Renaissance (Figs. 62, 63). These sketches, in spite of their artistic aspect, merely show how complete his ignorance was of the anatomy of the brain and especially of the parts related to the eye. Those details of his figures which show the superficial and therefore more accessible structures of the head he represented accurately. Contrasting with these are the deeper, hidden parts which are either distorted or are simply the naïve products of a rich imagination.

Contrary to Leonardo's principle, adhered to in his sketches of other parts of the body, where he truthfully depicted the anatomical structures which he actually saw, in the case of the brain and the visual system, evidently under the influence of Galen and the speculative scholastic writers, he permitted himself to draw imaginary organs which he could not have seen.

In one of his fantastic drawings, for example, the eye is shown connected by means of the optic nerve to a sausage-like cavity extending into the brain (Fig. 62). The cavity is subdivided into three compartments purporting to represent the three cerebral ventricles. These three spaces evidently correspond to the three hypothetical cerebral "cells," which the speculating anatomists and philosophers of the Middle Ages regarded as repositories of the three hypothetical principal mental faculties: a *cellula phantastica* for perception, a *cellula logistica* for thinking and reasoning, and a *cellula memorialis* for memory. (According to Flechsig 1896, p. 36, it was Nemesius, Church Father and philosopher of the fourth century, who originated the idea of three cerebral cells, a concept later accepted by Albertus Magnus, celebrated philosopher and "universal doctor" of the thirteenth century.)

This is the more astonishing, since, from Leonardo's own account and sketches, it is certain that he had dissected the brain and should have acquired a somewhat truer knowledge of the number, shape, and arrangement of the cerebral ventricles, of which he was the first to make wax casts (Fig. 63).

In Leonardo's figures, at last, Galen's idea of the cerebral cavities as the most important part of the central nervous system, considered by the latter as repositories of the all-important "animal spirit," until then clothed in the elastic phrases and ambiguous words of a clever, verbose *Graeculus*, had, in all its glaring impossibility, become exposed to the scrutiny of a merciless posterity (*see* sec. 3, this chapter). Leonardo's figures, if anything, show that no amount of ingenuity and imagination can compensate for the absence of positive knowledge based upon direct examination and logical judgment.

Leonardo's figures, jealously kept from publicity by their ignorant possessors, did not influence the development of anatomy. To the historian they are of interest because they show the farthest point reached by the dissecting knife and imagination of one of the keenest minds of his age.

Other anatomists of that time, true to the medieval spirit, blindly relied upon the Greek authorities, limiting themselves to inept abstracting of Galen's writings, instead of dissecting the structures they were describing. This state of affairs, exemplified by a perfectly sterile

account of the visual system in the writings of Fernel (Joannes Fernelius Ambianates, 1542), lasted until the great reform brought about one year later by Andreas Vesalius (1543).

McMurrick, *Leonardo da Vinci, the Anatomist*, 1930. Courtesy Carnegie Institution of Washington, D.C. (*Cf.* following two figures.)

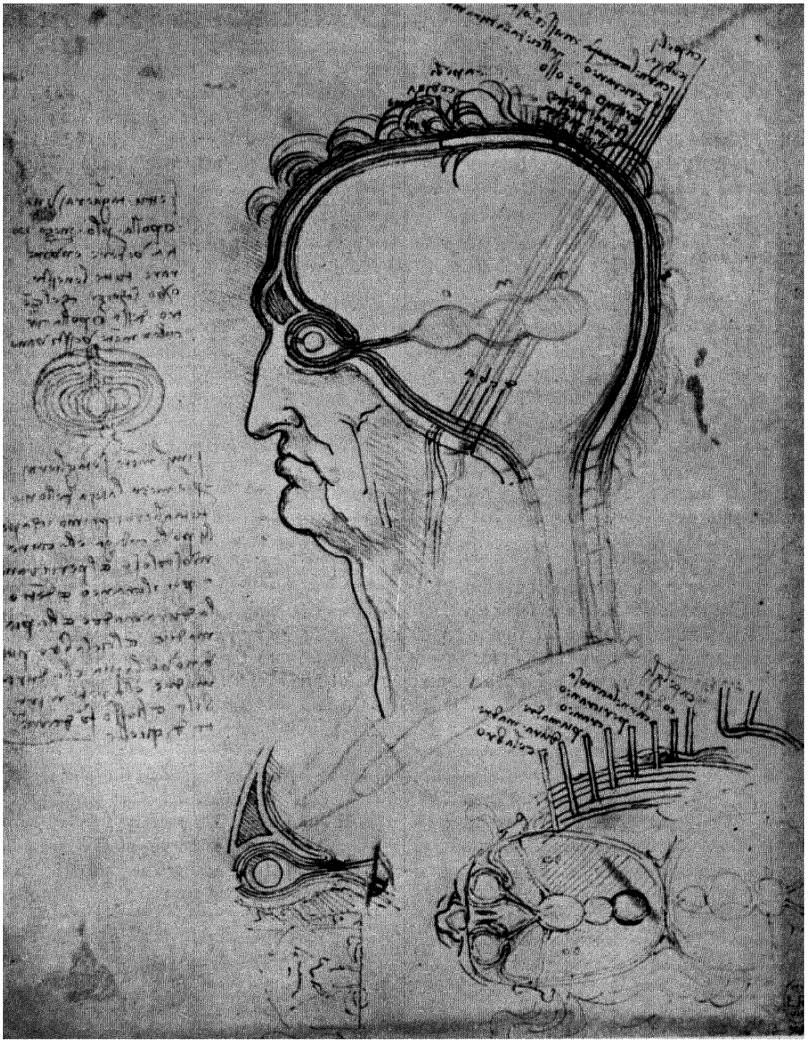

FIG. 62.—**Sketches illustrating Leonardo da Vinci's concept of the contents of the human head, in particular, of the relationship of the eyes to the brain. In his own words: "If you cut an onion through the middle" (*see* left-hand sketch), "you will be able to see and count all the covers or rinds which surround its center on all sides. Just so if you cut a man's head in the middle, you will cut first hair, then the coating and the muscular flesh and peri-cranium, then the cranium and, within, the dura mater and pia mater and the cerebrum, then again the pia and dura mater, and the *rete mirabile* and the fundamentum of this, the bone." Noteworthy is the direct connection of the eyes, through the optic nerves, with the cerebral ventricles (*O, M, N*) which are presented as three round cavities arranged in a line and communicating with one another. From Leonardo da Vinci's *Quaderni d'anatomia*, v. 5, fol. 6, *verso*.**

SEC. 8. VESALIUS AND THE ANATOMY AND PHYSIOLOGY OF THE VISUAL PATHWAYS

1. The reform in anatomy introduced by Vesalius.– With the appearance of Andreas Vesalius' *De Humani Corporis Fabrica*, or *On the Structure of the Human Body* (1543), the first period of Postclassical European anatomy, characterized by a helpless dependence upon the written word of the Greek and Arab authorities, often erroneous or based upon animal rather than human sources, was at an end. (Vesalius was born 1513 or 1514; died 1564; originally called Wyting or Witting, assumed name Wesel, meaning "weasel," probably taken either from the town Wesel situated on the right bank of the lower Rhine or from a village of the same name southwest of the town of Nymwegen, where his family came from; Latinized form Vesalius or Wesalius, French Vésale; portrait Figs. 15, 64.)

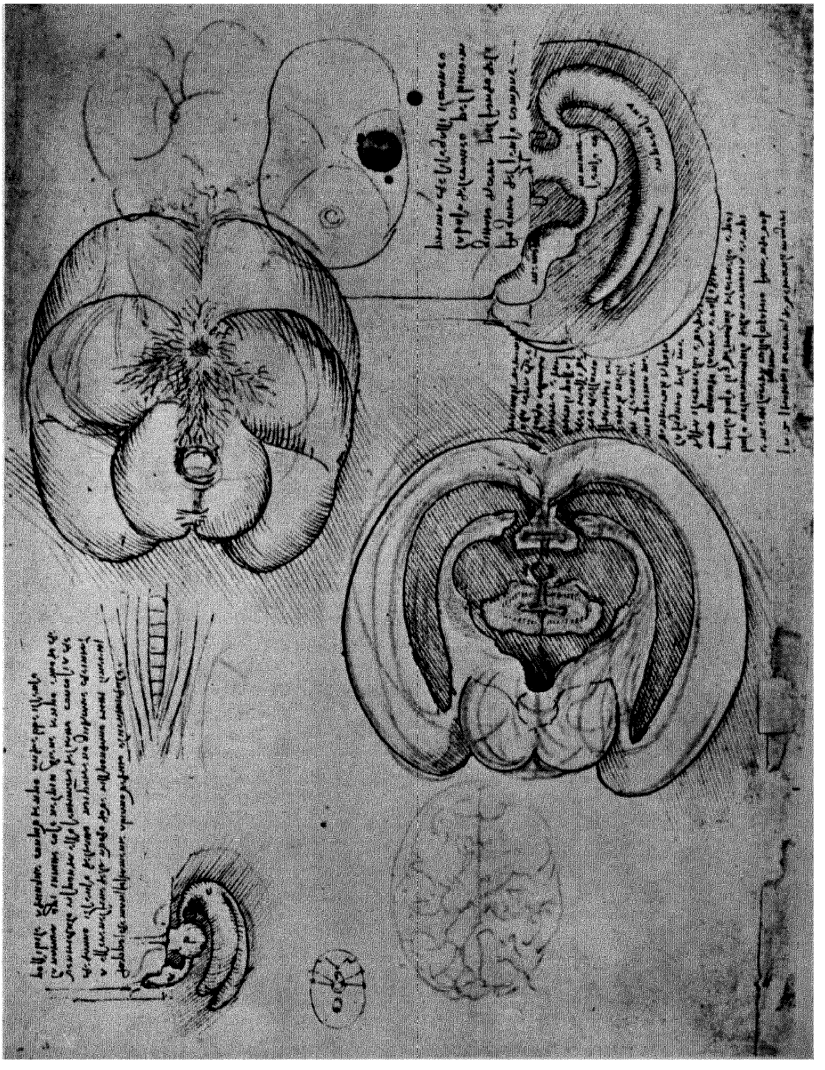
Beginning with the work of Vesalius, the guiding principle in anatomy was the emphasis upon personal dissection of human and animal bodies and to some degree also upon the observation of human pathological cases and experimentation on living animals. The knowledge taken over from the past was, of course, by no means discarded. The reborn science of anatomy was neither strong enough for this nor so blind as not to see much that was good in the old books. But a more critical attitude was assumed toward the ancient authorities, especially Galen, and every tenet was tested at the dissecting table. In this way an unlimited field of inquiry into the structure and working of the normal and ailing human body was opened, and an age of fruitful study of nature in general was initiated. (For the similarity of the Vesalian viewpoint and that of the Ancient Greek and Roman writers *see* Celsus, in sec. 1 [5], this chapter.)

2. Improvement in neuroanatomy instituted by Vesalius.– The achievements of Vesalius and his immediate successors in the field of neuroanatomy and of the anatomy of the brain, in particular, in spite of the new spirit, were in no way overwhelming. His chief merit was a systematic, compact, and lucid presentation of the principal parts easily seen by the unaided eye during a careful dissection, in contrast to Galen's rambling description.

The lucidity of Vesalius' style was in no small degree assisted by the numerous artistic woodcuts executed by his friend, Jan Stevenszoon van Calcar or Kalcker, all materially helped by the printing process (*see* Figs. 16, 17, 65). But more than the concrete discoveries, careful arrangement of the material according to the logic of the dissecting procedure was the distinguishing feature of his chapter on the brain.

There is, in fact, little on the visual system in Vesalius' thick volume that was not mentioned by Galen. He merely referred to the "origin" of the optic nerves at the base of the brain, without indicating the thalamus or any other particular structure in the modern sense as related to the visual system.

3. Vesalius' skepticism about the cavity of the optic nerves.– The attitude of Vesalius toward the channel or cavity in the optic nerves, one of the dogmatic cornerstones of Galenian teaching, was skeptical. No matter how often he tried to find it in various anatomical specimens, for which purpose he dissected living animals, he was not able to convince himself of the existence of a channel. Undoubtedly, he used living animals because of Galen's assertion that the cavity was visible only in freshly



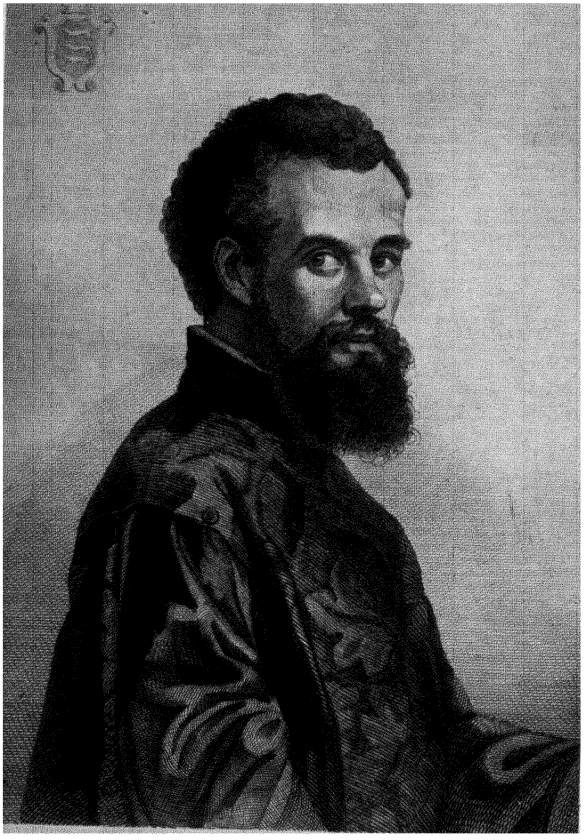


FIG. 63.—Læonardo da Vinci's presentation of the base of brain and of the cerebral ventricles, together with instructions for making casts of the ventricles by means of molten wax. From Læonardo da Vinci's ***Quaderni d'anatomia***, v. 5, fol. 7, ***recto***.

killed animals (*see* Galen, *De Hippocr. et Plat. Decr.*, book 7, chap. 4).

Nor was Vesalius more successful in finding a cavity in the human optic nerves he examined at executions, not more than a quarter of an hour after death and while the head was still warm and after having taken the precaution of immediately putting it into warm water (apparently in order to prevent or retard the loss of *pneuma*). The only probable exception was the chiasma, where he thought the cavity was noticeable.

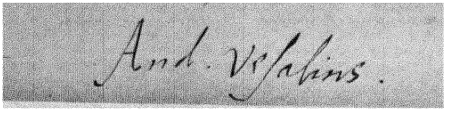

FIG. 64. – Andreas Vesalius (1514-64), the "Reformer of Anatomy," at the age of twenty-eight. A steel engraving by Charles Onghena made around 1840 from the original woodcut portrait in Vesalius' *Fabrica* (*cf.* Fig. 15 in this book). Frontispiece in A. Burggraeve, *Études sur André Vésale*, Gand, 1841.

This bona fide skepticism of Vesalius is the more praiseworthy, since it went against the opinion of his times, expressed by another Renaissance anatomist and rival of Vesalius, Bartolommeo Eustachio (Fig. 66), who not only believed he had seen this cavity but took pains to depict it in one of his plates published posthumously. (*See also* Zinn, 1755.)

4. Vesalius' view on the structure of the chiasma.—Concerning the relationship of the two optic nerves in the chiasma, Vesalius' interpretation did not appreciably differ from Galen's. According to him, too, the connection was only an apparent one, each nerve, in fact, remaining on its own side along its entire course, from its apparent origin in the brain to its seeming termination in the eye at the same side. A small diagram given on page 329 of the first edition of his book, *Fabrica*, leaves no doubt about this.

Vesalius' view, notwithstanding its being a mistake, as his own figure shows (Fig. 65, *H*), was based on two observations: one of a youth whose eye, apparently as a punishment for some crime, had been torn out (!) a year before he died on the gallows, and another of a woman who suffered the same cruel fate and one of whose eyes had been atrophic since childhood (her crime may have been to look like a witch with an "evil eye"!). In both cases Vesalius' dissection showed the "nerve," or rather tract, on the side of the removed eye to be thinner, somewhat indurated, and of a reddish color.

Other cases of an absence of optic chiasma, apparent or real, were subsequently reported by Valverda, Fabricius ab Aquapendente, and Pasinus, as one learns from a remark in Henle's

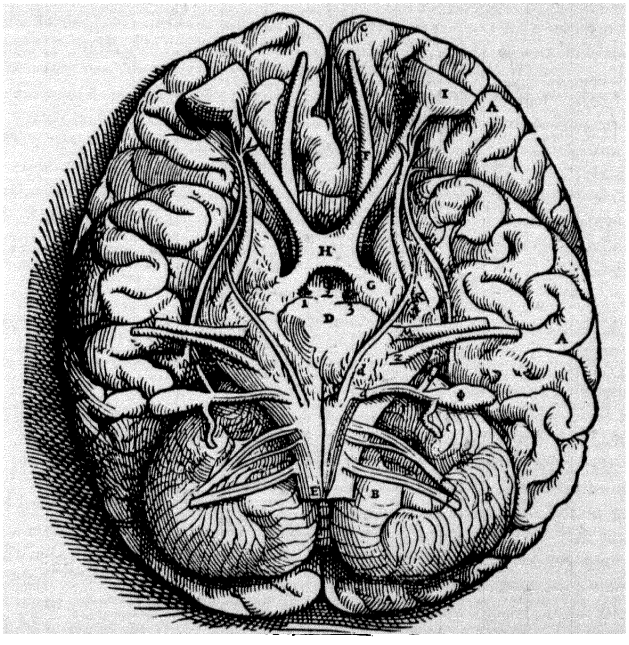

Fig. 65.—Woodcut figure from Vesalius' *Fabrica*, 1555, showing the basal aspect of the brain, with the origin of cranial nerves, and the brain stem. *A*, brain; *B*, cerebellum; *D*, origin of "spinal cord" (modern pons and medulla oblongata); *E*, cut-off stump of same; *F*, olfactory bulbs and tracts; *G*, optic nerves ("first cranial pair," according to Vesalius); *H*, optic chiasma; *I*, retina formed by the expansion of optic nerve; Φ, auditory and vestibular nerves. book (1879, p. 393; *cf.* Meckel 1812–18, v. 1, p. 398; Henle in his *Nervenlehre*, 1871, p. 348, or 1879, p. 393; Gudden 1879; Little 1886; Hovelaque, p. 49).

5. GALEN'S INFLUENCE ON VIEWS OF THE BRAIN'S FUNCTION PROFESSED BY VESALIUS.— In the functional interpretation of cerebral structures Vesalius was still under the spell of Galen's ideas (*cf.* sec. 3 [2], this chapter). For him, too, the brain was a place where the "animal spirit" was produced partly from the "vital spirit," which arrived with the blood from the heart, and partly from the air which entered through the nose. The "animal spirit," after having been further elaborated in the brain, was, in turn, propelled along the nerves to all sensory and motor organs of the body. The brain, accordingly, was a sort of nervous heart, and the nerves were its vessels, by analogy with the vascular system proper (forty years later, characteristically, Platter classified the nerves as *vasa*, or "vessels").

Concerning a more detailed interpretation of the function of the cerebral ventricles, the focal point of the brain in Greek, Arab, and early European anatomy and physiology, Vesalius, as on some other controversial questions, wisely abstained from committing himself. In this respect he favorably contrasts with most other anatomists of his time, whose thick volumes are filled with pages packed with learned nonsense.

SEC. 9. POST-VESALIAN PERIOD IN BRAIN ANATOMY AND PHYSIOLOGY

1. PERSISTENCE OF GALEN'S IDEAS ON THE BRAIN'S FUNCTION AFTER THE VESALIAN REFORMS.— The level which brain anatomy and physiology reached with Vesalius remained substantially the same for about two hundred years. Certain of his views, in fact, lasted until the beginning of the modern microscopic era, during the first half of the nineteenth century. During this long period many concepts incorporated in Galen's teaching still held sway, their replacement by more modern and, in general, more accurate views being quite slow.

Especially persistent and slow to be relinquished was the Galenian functional interpretation of the brain and the visual system. Here the quasi-material and, at the same time, almost transcendent *pneuma* or "visual spirit," that product of Greek speculation, still reigned supreme. It is remarkable—and significant for the appraisal of the maturity of scientific thinking of that period—that even the most emancipated among the "Vesalian Epigoni" (such as Platter, Du Laurens, Kepler, Scheiner, Willis, Des Cartes, and Vieussens) were still under the complete domination of the idea of a mysterious "animal spirit" supposed to fill the brain ventricles.

According to Vieussens' definition (1684, portrait Fig. 75), this "animal spirit" was now conceived as an imperceptible, very thin, volatile substance of an ethereal nature, which, owing to its extremely subtle properties, could not be seen; whereas the *succus nervosus* or "nervous fluid," apparently identical with the cerebrospinal fluid, was a watery substance supposed to be secreted by the gray matter (*cf.* Burdach, v. 2, p. 264). A particular variety of *pneuma*, the "visual spirit," was believed to circulate in the visual pathways.

The only difference, in comparison with the past, was that the retina, finally recognized as the actual photoreceptor, was now considered the farthest point reached by the "visual spirit," and not the lens, to which was now assigned a passive, purely dioptrical, role in the visual act.

Even at that time, however, some lucid intellects, such as Wepfer (1658), Schneider (1660), and Stensen (1668, in Winslow's book 1733), either disclaimed the presence of the

"spirit" in the brain or were quite critical of it.

Some residue of this intellectual inheritance from the dawn of Western Civilization, disguised in modern dress, has managed to survive until now and has played an important role in the shaping of certain contemporary concepts of the working of the nervous system. (*See* chap. III.)

FIG. 66.—**Bartolommeo Eustachio (Eustachius,** *ca.* 1524–74), at the age of forty-nine. One of the founders of modern anatomy and among the first to recognize the connection of the optic nerves with the thalamus. From C. A. Manzini, *L'occhiale all'occhio*, Bologna, 1660.

2. EARLY MODERN CONTRIBUTIONS TO THE ANATOMY OF THE VISUAL SYSTEM. The immediate successors of Vesalius contributed little to the understanding of the visual pathway. Falloppio (Fallopius or Falopius, 1523–62; book pub. 1561) paid no attention to the subject at all. Nor did Aranzi (Arantius, 1537–1619; book written before 1586, pub. 1595) produce anything of importance in this connection.

Eustachio (Eustacchi, Eustachius, 1520–74, portrait Fig. 66) was first among the Westerners to depict in his *Tabulae Anatomicae* the visual pathway, more correctly recognizing the supposed "origin" of the "optic nerves" in the posterior portion of the thalamus instead of in

the lateral ventricles, as Galen insisted. Unfortunately, since his plates, apparently completed around 1552, remained in obscurity until 1714, when they were published by Lancisi, his observation escaped notice of the subsequent anatomists (*see* Eustachio 1714, Pl. 17, Fig. 6).

For this reason Varoli (Varolius, 1543–78, book pub. 1573) seems to have been the first to publish a text with a figure adequately illustrating the infranuclear division of the visual pathways, including the eyes, optic nerves, tracts,

3. Du Laurens' view of the brain as the seat of a "general sense."—More information about the visual pathway and its function is to be found in the voluminous book of the noted French anatomist and physician Du Laurens (Laurentius, 1599, portrait Fig. 68).

He opposed the view both of a simple contact and of a complete crossing in the chiasma. His functional interpretation, however, was still quite Galenian, even though he never observed a cavity in the optic nerves. Concerning the

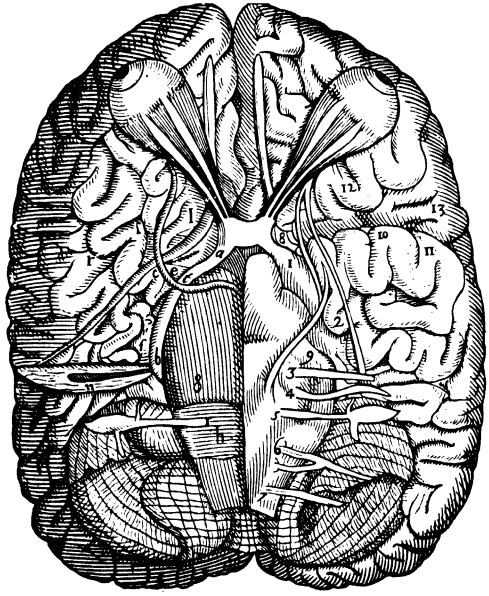

Fig. 67.—Basal aspect of human brain, from C. Varolio, *De Nervis Opticis*, Padua, 1573. Facsimile from J. G. de Lint, *Atlas of the History of Medicine*, P. B. Hoeber, New York, 1926. According to the common belief of the anatomists of that time, there were seven pairs of cranial nerves (*right half of figure*): *1*, origin of optic nerves; *2*, origin of oculomotor nerves; *3–7*, "all other nerves whose origin from the spinal cord was investigated by Vesalius"; *8*, locality where olfactory apparatus originates; *9*, beginnings of spinal cord; *10*, *11*, "middle prominence of brain" (temporal lobe); *12*, *13*, boundary of the frontal and parietal lobes toward temporal lobe. In the left half of the figure, *a* and *b* show a portion of the optic nerve, now termed "optic tract," unknown to Vesalius' contemporaries, which at *b* turns into posterior portion of "spinal cord" (present midbrain and thalamus); *h*, pons of cerebellum; *i*, origin of acoustic nerve.

their thalamic origin, and the chiasma (Fig. 67). This may explain why Platter, in his notable book (1603, p. 122), refers to Varoli as the discoverer of the origin of the optic nerves. (On other early anatomists who published illustrations of the brain's base, *see* S. Th. Soemmerring 1778.)

anatomical connections of the optic nerves with the brain, Du Laurens limited himself to Galen's view that the role of the brain was to unite all special sensations without being subservient to any one in particular. The brain, as the seat of a *sensus communis*, a "general sense," "neither sees, nor hears, nor feels."

In these words of Du Laurens the idea of a "functional equivalence" or "omnivalence" of all parts of the brain, as opposed to the concept of the "localization of cerebral functions," found its first expression. (*Cf.* Gall & Spurzheim, Flourens, Hitzig, Munk, Goltz, Flechsig, Monakow, Brodmann, Henschen, Lashley, *et al.*, in chaps. III and IV.)

4. THE WORKING OF THE "VISUAL SPIRIT" IN THE EYE AND BRAIN, ACCORDING TO DU LAURENS.—In still another respect Du Laurens' idea about the working of the visual system is of interest. The *visilis spiritus*, or "visual spirit," coming from the brain, according to his view, spreads by means of the retina throughout the crystalline lens and over the entire eye. The same membrane in turn perceives the changes in the lens and transmits the impressions of the seen objects to the brain, which acts in the role of a judge.

In the foregoing concept, expressed contemporaneously with Platter's quite different ideas and but a few years prior to the revealing work of Kepler (*see* chap. I, 5 [4 6]), there was hardly a hint of comprehension of the true functional significance of the dioptrical apparatus of the eye and of the formation of the retinal image. In his own words: "The eye, accordingly,

FIG. 68.—André du Laurens (Andreas Laurentius, 1558–1609) at the age of thirty-nine. Professor of anatomy at the University of Montpellier, in France, and a physician to the French King Henri IV and to Queen Marie de Médicis. Writer on visual organs, their anatomy, physiology, and pathology. Considered the brain as the seat of the *sensus communis* or a "general sense" uniting several special senses, without serving any one in particular. A copper engraving probably made by Jacques de Weert, in the 2d ed. of Du Laurens' *Historia Anatomica Corporis Humani*, Paris, 1600. Courtesy of Universitäts- und Landesbibliothek Halle a.S., Sachsen-Anhalt, Germany.

seems to act like a mirror. It receives the images of the external objects without emitting anything. From the mirror the eye differs only in that in the former there is no animate principle by means of which the received image would be transferred to a higher resort which would act as an arbiter" (Laurentius 1599, p. 419).

5. Locus of the perception of visual images, according to Du Laurens.—Considering the various views as to whether the brain (since Galen's doctrine teaches that all sensation derives from it) or the pupil (according to Aristotle) or the "arachnoid membrane" of the eye (the lens capsule) or the chiasma of the optic nerves (according to Avicenna) is the locus of visual perception, Du Laurens expressed the following conciliatory opinion:

> We believe the reception of the images to be in the crystalline lens, since this is the principal and foremost organ of sight, situated in the center of the eye, and different from other parts in its substance, its shape, and other properties. If you nevertheless desire to reconcile all the above-mentioned views, say that reception takes place in the lens, refraction in the tunics, perfection in the chiasma, perception in the brain [Laurentius 1599, p. 420].

This clever definition of the working of the visual mechanism, worthy of a true scientific opportunist, filled with meaningless words, was as empty as the words of a proverbial "windbag" politician, trying to satisfy everybody. It certainly was the least propitious way to try to find a successful solution of one of the most difficult problems of human organization.

6. Gradual emergence of modern ideas concerning the relationship of the eye and brain.—Better than a lengthy description, the preceding quotation shows how, at the end of the sixteenth century, even the leading authorities were uncertain and confused about both the anatomical mechanisms and the physiological processes involved in vision.

This ignorant hesitancy may seem the more remarkable, since a correct interpretation by Platter (1583, 1603), Kepler (1604, 1611), and Scheiner (1619, 1626–30) was already in sight (*see* chap. I, 5 [4, 5, 6]). With the publication of their discoveries, computations, and experiments, the ancient Greek "emanation hypothesis" of the "visual rays" emitted from the eye, after having bedeviled scientific thinking for two thousand years, finally had to go.

The other source of confusion, Galen's "visual spirit," even though quite critically treated by Stensen (Steno 1668, Fig. 72), continued to circulate for a while in an unaccountable way from the brain to the eyes and back again.

In spite of this and other mental inhibitions inherited from the times of magic and ignorance, the idea of functional changes caused within the eye by external physical stimuli and a transmission of impulses, thus elicited, to the brain was by now becoming fairly well established. The problems which, from the early seventeenth century on, became gradually more apparent in the consciousness of the learned inquirers concerned with the problem of vision were more concrete and of a less magical character: the exact route by which the visual impulses reach the brain; the physiological nature of these impulses; and where in the brain, and precisely how, the central reactions to the photogenic impulses take place.

SEC. 10. EARLIEST MECHANISTIC EXPLANATION OF THE VISUAL SYSTEM

1. Cartesian speculations about the anatomical basis of vision.—During the early Modern period, in spite of the Vesalian reforms, most of Galen's ideas concerning the anatomy and physiology of the human body, particularly of the sense organs and the brain, were still firmly intrenched in the convictions of those concerned with these problems. There were notable exceptions, however. Some of the keenest minds of that period, unable to find complete satisfaction in Galen's simple formulas, began to search for a more plausible explanation of the anatomical substratum of the human mind.

One of these pioneers was the French philosopher René Des Cartes (Descartes, Cartesius, 1596–1650, portrait Fig. 69). Among his numerous speculations, he produced a remarkable

hypothesis of the intrinsic organization of the visual system which was far ahead of his time (1638, 1662). A confirmed dualist and a devout believer, he nevertheless tried his best to use the few positive anatomical facts known to him in order to explain the phenomenon of vision mechanistically. Even though he formally denied any direct dependence of the "psychic" functions upon the crudely material parts of the brain, the factors which he used in his hypothesis were all essentially material and anatomical.

There were three such factors: the "spirits," which he conceived to be vapor-like or gaseous, originating from the heart (still essentially a Greek-Galenian idea of *pneuma*); the "pores" of the cerebrum, through which these "spirits" passed (this, too, was but a refined modification of the Greek idea of "visual channels"); and, lastly, the mode of distribution of the "spirits"

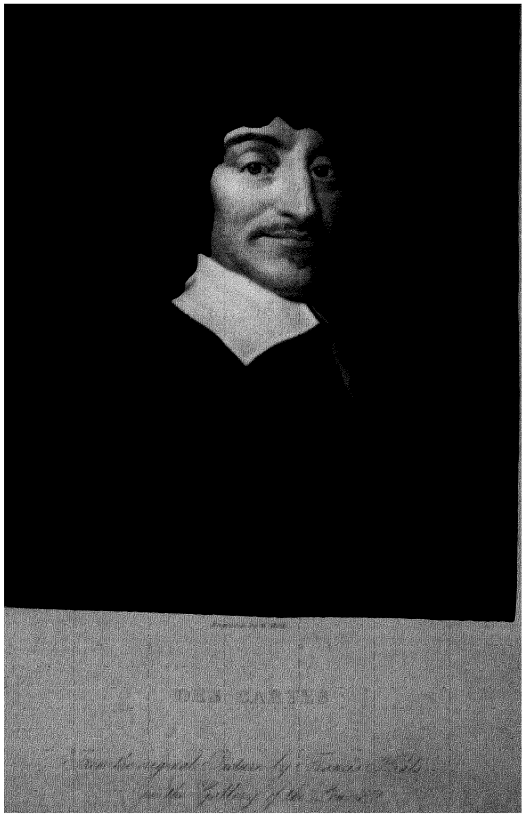

FIG. 69.—**René Des Cartes de la Haye (Descartes, Cartesius, 1596–1650), scientist, mathematician, and philosopher. Author of the earliest mechanistic explanation of the intrinsic organization of the visual system, according to which each sensitive point of the retina of each eye has its own, discrete representation in the brain. Engraving by W. Holl from an original painting by Frans Hals in the Louvre, Paris. Courtesy Crerar Library, Dr. Sonnenschein Collection, Chicago.** (For biography *see* E. S. Haldane 1905.)

in the "pores," or, in modern language, the arrangement of the nerve fibers in the visual system.

This new idea of "projection," in the light of modern knowledge the most important of the three factors, even though hinted at several centuries before by Ibn al-Haitham, was apparently Des Cartes's own.

2. CARTESIAN HYPOTHESIS OF A TOPOGRAPHICAL REPRESENTATION OF THE RETINA IN THE BRAIN.—The nerve fibers which make up the visual system, according to Des Cartes, are not arranged haphazardly but follow a definite order. At their place of "origin" in the lateral ventricles of the brain, each fiber or a small bundle of fibers arises from a definite locality in the ventricular surface (Fig. 71, *2*, *4*, *6*). In the optic nerves and tracts, which he, like Galen and Vesalius, thought of as completely separated from one another in the chiasma, the fibers and bundles pursue a course parallel with each other as far as the retina, where they "terminate" discretely (Fig. 71, *1*, *3*, *5*). To each point of the ventricular surface, accordingly, there corresponds a point in the sensitive retinal surface. By means of this mechanism, the images painted upon the retinal membrane are reproduced accurately and with fidelity in the cerebral ventricles. (*Cf.* sec. 11 [6], this chapter.)

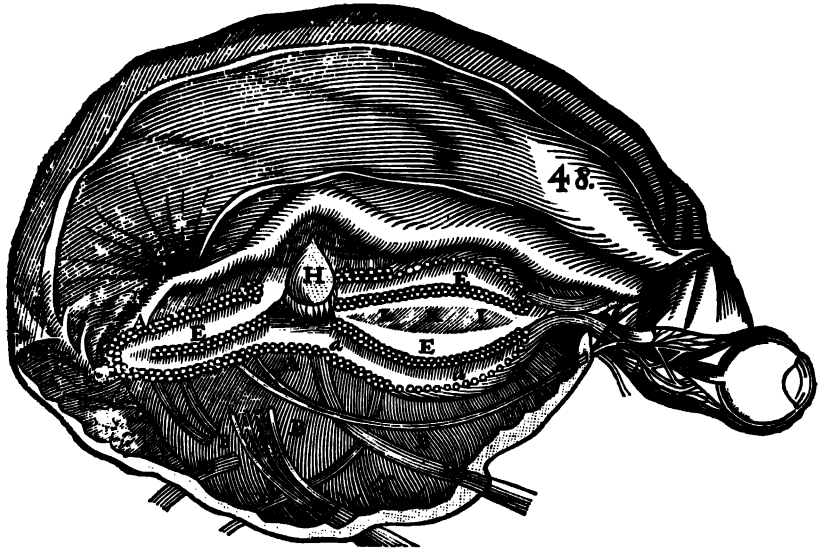

FIG. 70.—Human visual system, according to Des Cartes in his *Tractatus de Homine* or *A Treatise on Man*, written 1660, published 1686. The optic nerve consists of parallel fibers originating from evenly distributed points on the surface of the cerebral ventricles. In the chiasma the two optic nerves are supposed to be merely in contact, without exchanging their fibers. The peripheral end of the optic nerve merges with the retina of the eyeball. The extrinsic eye muscles are supplied by the branches of oculomotor nerve originating from the posterior extremity of the ventricle. Other peripheral nerves leave the brain in various directions. In the center of the brain is the pineal gland, *H*, which Des Cartes looked upon as the "seat of the soul," where ideas are formed. The figure illustrates a queer combination of the anatomical facts discovered since the time of Vesalius, and the products of speculation influenced by Galen's writings. (*Cf.* Fig. 71.)

Des Cartes likewise tried to explain the single subjective experience in the binocular visual act. According to him, the single monocular impressions impinging upon the "corresponding points" of both retinae were further transmitted to the pineal gland (*H*). This organ, because of its central location in the brain, its special connections with the optic nerves, and its rich

blood supply, was, in Des Cartes's opinion, eminently suited to serve as a unifying focus.

In the pineal gland the distribution of nerves was also orderly, each monocular impression arriving from a "corresponding point" of one retina and meeting its "corresponding mate" from the other retina (*a*, *b*, *c*). In this way the two single monocular retinal impressions merged in the pineal gland, the "seat of the soul" or conscious appreciation, according to Des Cartes, into a single psychic experience. The meeting of the conjugated or syndynamical impressions in the central organ would be accomplished by a hypothetical partial crossing of the central conductors in the brain itself, instead of in the chiasma, where, following Galen and Vesalius, Des Cartes assumed a complete separation of the optic nerves.

Altogether, Des Cartes tried to explain mechanically, by anatomical structures, not only a "point-to-point" transmission of each monocular retinal image upon its own area of the brain but also an orderly formation of a single cerebral mental image made up of "corresponding retinal points," united according to their functional values and arranged topographically in space to reproduce an accurate cerebral copy of the observed visual object.

Naïve and vacuous though Des Cartes's speculation may now appear, it is worth while to consider that it contained, for the first time, a clearly conceived and expressed idea of a topographical projection or representation of the retina in the brain (*cf.* chap. IV, 4; chap. VI, 7; chap. VII, 4, 5, 6). However subtle and elusive the forces, such as the "spirits" elicited by the stimulation of the retina, they had to follow preformed anatomical pathways on their way to the brain.

The essentially mechanistic character of Des Cartes's speculation is not weakened by his fantastic elaboration upon it, according to which the "animal spirits" were supposed to enter from the ventricles into "pores" or minute spaces between the fibers of the optic nerves and tracts; the ventricular images were supposed to be further transmitted, first to the pineal gland, the "seat of the soul," where they formed the "ideas" of external objects, after which they were finally deposited in the brain

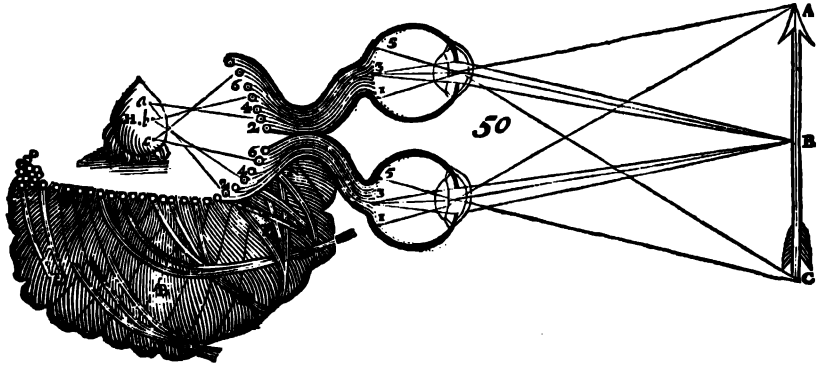

FIG. 71.—Binocular stereoscopic visual system and its working, as imagined by Des Cartes. The two retinal images of a single object are accurately, point-for-point, projected upon the surface of the cerebral ventricles, whence they are further transmitted to the centrally located pineal gland, *H*, the supposed "seat of imagination and common sense." Here the homonymous "corresponding" or "syndynamical" impressions merge into a single visual "idea"—for example, of the object point *A*, via two retinal points *1* and *1*, along the two ventricular points *2* and *2*, ultimately meeting in a common point *a* of the pineal gland (*H*). In this way a single binocular visual experience would be achieved, in spite of complete separation in the chiasma, a mistaken belief which Des Cartes took over from Galen and Vesalius. After the union of the two monocular images in the pineal gland, the impressions would be further transmitted to the brain substance, *B* and *B*, and deposited in it as a memory image. The problem of how the "corresponding impressions" are made to unite remained thus unexplained. From *Tractatus de Homine* or *Traité de l'homme*, written 1660 and published 1686. (*Cf.* also Figs. 33, 69, 70.)

substance itself, where they served as a substratum of the "memory" (Fig. 71, *B*, *B*).

3. MISTAKES AND MERITS OF DES CARTES'S SPECULATIONS. Whatever the obvious faults of Des Cartes's speculations in the light of present knowledge, the fact remains that he was the first to make an honest effort to explain the visual act in terms of anatomical structures known to him or conceived by him, instead of

duced Malpighi, one of the founders of modern microscopy, to correct its glaring inaccuracies, such as the supposed origin of the optic nerves in the cerebral ventricles and their hypothetical connection with the pineal gland (Malpighi 1687, v. 2, p. 123). But, with the erasure of Des Cartes's anatomical errors, his most valuable idea—that of a topographical relationship of a peripheral receptor surface, such as the retina, to the brain, first announced by Ibn al-Haitham

FIG. 72.—Niels Stensen (Nicolas or Nicolaus Steno, or Stenonius, 1638–87), noted Danish anatomist, active in Paris, Florence, and Copenhagen. From C. G. Cumston, *Introduction to the History of Medicine*, 1926. According to a painting made in 1669 by an unknown painter, now in Pitti Gallery, Florence, Italy. Courtesy of Pitti Gallery.

comfortably putting the entire burden upon the equipotentialist properties of a transcendental "spirit" or "soul." In this sense his hypothesis was a precursor of the modern idea of functional cerebral localization.

The influence of Des Cartes's hypothesis upon further efforts to understand the nervous system, unfortunately, was very small. It in-

half a millennium earlier (*see* sec. 6 [2], this chapter)—was also lost from the consciousness of the scientific world. In consequence, more than two centuries later this idea had to be rediscovered, until it now forms the very foundation of our concept of the visual system. (For an able critique of Cartesian ideas, *see* Steno's dissertation in Winslow's *Anatomy*, 1733, sec. 10,

par. 10, p. 56; for Briggs's and Taylor's speculations, *see* sec. 11 [2, 5, 6], this chapter; for Steno's portrait *see* Fig. 72.)

SEC. 11. ANATOMY AND PHYSIOLOGY OF THE VISUAL PATHWAYS AND CENTERS FROM DES CARTES TO ALBRECHT VON HALLER

1. BEGINNINGS OF MODERN NEUROANATOMY AND THE VISUAL SYSTEM.—The earliest systematic presentation of the anatomy of the brain, including the visual pathway, in Man and in other Vertebrates, after the Revival of Learning came from Thomas Willis (1621–75, portrait Fig. 73). Through his book, *Cerebri Anatome* (1664), the gap of the fifteen centuries—which separated the last productive period of Greek anatomy and physiology of the brain, represented by Galen, from modern times—was definitely bridged. His monograph not only embodied a comprehensive survey of all that was known at that time about the structure and function of the brain but also included numerous personal observations, especially comparative.

Following are the main points of Willis' work, as far as it concerns the visual pathway. The "optic nerves' (presently tracts) "originate" from parts of the brain called the "optic thalami," or *thalami nervorum opticorum* (term from Riolan 1618), *juga nervi optici*, *juga crurum medullarium*, or *secunda sectio crurum medullarium*. These are the backward extensions behind the striate bodies, distinguished by their somewhat darker color.

According to Willis' subdivision, the thalami were a part of the *medulla oblongata*, to which he assigned not only the midbrain, pons, and bulb or *medulla oblongata* of modern terminology, that is, the entire "brain stem," but also the "striate bodies," including the lentiform nucleus. From the "optic nerves" (i.e., tracts) the medullary processes extend toward the root of the pineal gland. Apparently it was these structures that induced Des Cartes to include this gland in the visual system (*see* sec. 10, this chapter). Differing from Des Cartes, however, Willis considered these processes to be a sort of commissure between the two optic nerves (later a similar view was suggested by Charcot, in order to explain the "contralateral amaurosis" of one eye caused by unilateral brain lèsion (*see* chap. III, 9 [6]). Of the other parts of the brain more or less related to the visual system, Willis described the larger superior, and the smaller inferior, colliculi, or *protuberantiae orbiculares natiformes* or *nates*, and the *protuberantiae minores* or *testes*, in Galenian terminology, and their connections

In contrast to his accurate presentation of the anatomical facts, Willis' functional interpretation of the various parts of the visual system, of the production and distribution of "animal spirits," of the role of the optic chiasma, and the like was completely Galenian.

Of interest, finally, is the fact that even so assiduous an anatomist as Willis looked upon the apparent origin of the optic nerves in the thalami as the end of the visual system. His attention, like that of other contemporary anatomists, was still completely absorbed by the lower parts of the central organ. Even though he knew something of the *corona radiata*, he entirely missed the supranuclear division, chiefly represented by visual radiation, and thus he overlooked the importance of the cerebral cortex. This, in view of the technical difficulties of his time, is understandable. (*See* Niels Stensen, or Steno, 1668.)

Although Willis' anatomy of the visual system did not differ a great deal from Galen's, it nevertheless showed some progress. In the first place, it was accurate, the pleasing illustrations drawn by Sir Christopher Wren, the "English Leonardo da Vinci," celebrated architect and builder of St. Paul's Church in London, adding much to this. In both points Willis' work contrasts favorably with the verbose, vague, and inadequately illustrated descriptions of most of the preceding writers.

Nor was there any mention made by him of the "channels" of optic nerves, which, until then, had played a prominent role. The optic

nerves were not hollow tubes but were made up of bundles of nerve fibers, a fact confirmed and depicted but a few decades later by Briggs (1676–85, Fig. 74) and verified by a number of investigators of renown, such as Diemerbroeck (1683, p. 375), Vieussens (1684, p. 165, portrait Fig. 75), Bidloo (1685), and Malpighi (1687, v. 2, p. 121; portrait Fig. 36).

This and other fundamental discoveries in cerebral anatomy and physiology made at that time induced the more critical minds of the following period to doubt the whole Galenian concept of "animal spirits," their generation in the cerebral ventricles, and their propagation in the peripheral nerves, thus preparing the way for modern research. (*See* Steno 1668; Malpighi, *Op. Omn.*, 1687, v. 2, p. 121.)

2. Successors of Willis and their contributions to the knowledge of the visual

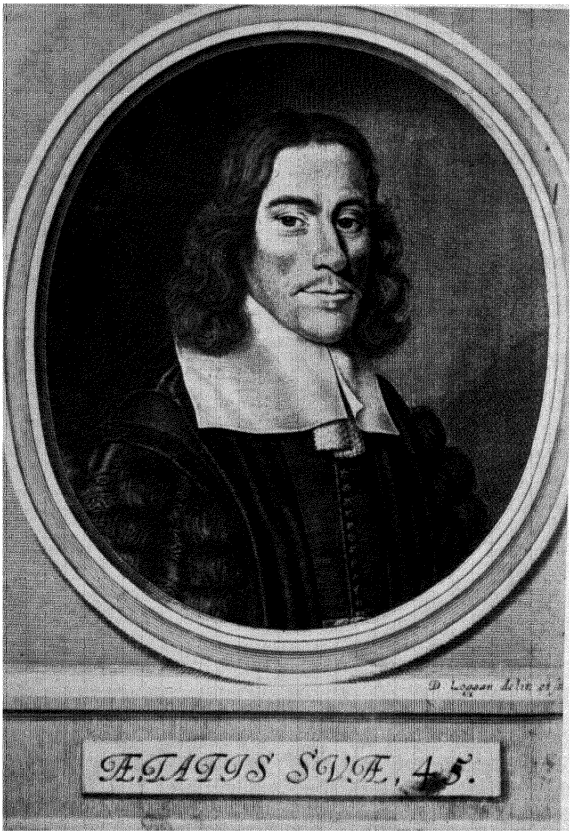

Fig. 73.– Thomas Willis (1621–75) at the age of forty-five. Professor of natural philosophy at Oxford, England. Physician and noted brain anatomist. Described the "arterial circle of Willis" at the base of the brain. Author of the *Cerebri Anatome*, 1664, the earliest modern comprehensive treatise on the brain. Writer on physiology and pathology of the nervous system (*De Anima Brutorum* or *On the Soul of Animals*). Founder of the Royal Society of London. Courtesy of Dr. Francis F. R. Walshe, London, England. *See also* frontispiece in Willis' *Pharmaceutica Rationalis*, Oxford, 1673.

SYSTEM.—During the century and a half following Willis, there was but little advancement made in the anatomy of the visual pathways. In fact, until the first quarter of the nineteenth century, this subject stagnated at approximately the level to which it had been brought by the impetus of the pioneers of the Renaissance and their immediate followers.

An exception was Briggs, who in his *Nova Visionis Theoria* continued to speculate along gained further ground, even though it was, as yet, based upon pure speculation.

Here mention may be made of a curious opinion of the French anatomist Vieussens, according to which the optic nerves continued as far as the cerebral cortex. This appears to be the earliest intimation of visual radiations and of the cortical visual centers (*cf.* Gratiolet, chap. III, 5 [5]). This suggestion, which might have redirected investigation of the brain into more

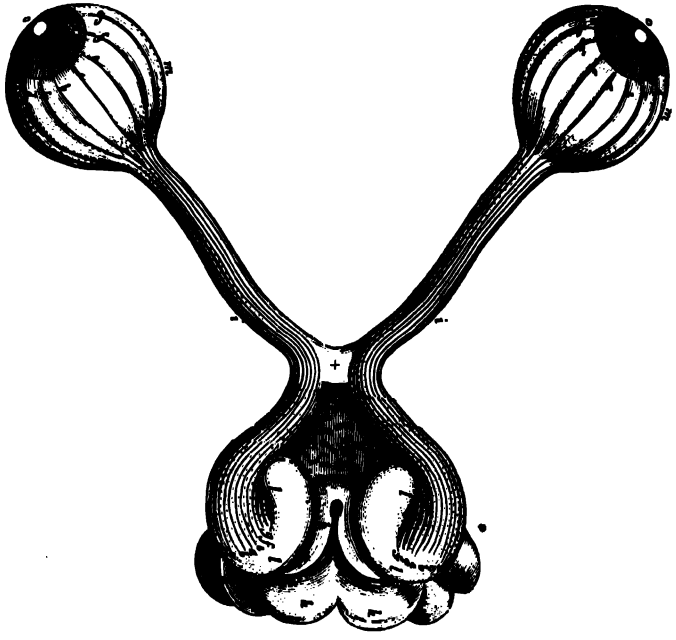

FIG. 74.—Visual system as represented by W. Briggs in his *Ophthalmo-graphia* (1685). The optic nerves (*i*, *i*) are composed of nerve fibers. Each fiber, or a small fiber bundle, was supposed to originate in a well-defined small area (*g*, *f*, *e*, *a*, *b*, *c*, *d*) of optic thalamus (*l*, *l*) and to terminate in a circumscribed area of the retina of the eye (*m*) marked by the same letter. The principle of a topographical projection of the retina upon the brain is similar to that of Des Cartes (*see* Fig. 71), except for the union of the homonymous "corresponding" fibers in the pineal gland. As in Des Cartes's figures, in Briggs's diagram also there is no interchange of fibers between the two optic nerves in the chiasma, each nerve remaining independent (Galen's doctrine). No optic fibers extend to the superior colliculi of the midbrain (*h*, *h*), and there is no mention made of a visual radiation to the cerebral cortex.

the lines of Des Cartes concerning the parallel course of the optic nerve fibers, placing their presumptive "origin," however, in the optic thalamus instead of in the cerebral ventricles (Fig. 74). Thus the idea of a topographical projection of the retinal surface upon the cerebrum profitable channels, produced no results for a long time. The reason was that most anatomists, physiologists, and clinical neurologists of the period were still submerged in the struggle with elementary anatomical problems ("origin" of optic nerves, structure of the chiasma), the

usual opinions expressed being taken literally from Vesalius and Galen.

The existence of a supranuclear division of the visual system remained, therefore, outside the sphere of immediate interest. The blame for this falls upon inadequate methods of investigation, among other factors, as pointed out by scientific interpretation of cerebral structures and functions. (*See* Wepfer 1658; Schneider 1660; Diemerbroeck 1683; Vieussens 1684; Morgagni 1719; Santorini 1724, 1775; Maitre-Jan 1725; A. Haller 1769, v. 4, p. 206; Zinn 1755; Winslow 1773, 1776; *see also* H. Heinrichs 1913; W. Sudhoff 1914.)

FIG. 75.—Raymond Vieussens (1641–1716), professor of anatomy in Montpellier, France. Author of *Neurographia Universalis* (1684), a voluminous treatise on the anatomy of the brain, spinal cord, and nerves. From W. Stirling, *Some Apostles of Physiology*, Waterlow & Sons, London, 1902.

Steno. Also, not until approximately the middle of the eighteenth century were the anatomy and physiology of the brain completely emancipated from Galen's idea of "animal" and "visual" spirits that had so far hampered a truly

3. Confusion concerning the structure and functional significance of the optic chiasma. One of the perennial problems of this period was the structure and function of the chiasma or junction of the optic nerves. In

regard to this, opinions differed and continued to do so until the end of the nineteenth century. Vesalius, Aquapendens, Valverda, Des Cartes, Briggs, Riolan, Diemerbroeck, Plemp, Vesling, and many others, joining Galen, maintained that there was no exchange of fibers in the chiasma, an opinion conveniently followed by the majority.

Bauhin, Lud. Mercatus, Sennertus, and their partisans, however, considered the chiasma not a simple contact but a complete mixing of substance of the two optic nerves. Its function, they believed, was not so much to improve the sight of one eye when the other was lost, as Galen thought, but "to enable the spirits to pass easily from one eye to the other." This view was, of course, only a variation of Galen's inconsequential thesis, defended previously by Porta.

Still a third group, adopting the opinion of Rhazes and Avicenna, advocated a complete decussation (Zinn).

Nor did the few pathological cases accidentally coming into the hands of the anatomist-surgeons help to clarify the issue. In one such case observed by Caesalpinus (1590) and reported by Diemerbroeck (1683, p. 375) the atrophy of the optic tract, coinciding with the site of the blind eye and of the atrophic optic nerve, was a duplication of a pertinent observation by Vesalius (sec. 8 [4], this chapter). (*See also* Porterfield 1759, v. 1, p. 190, and v. 2, p. 282; A. Haller 1769, v. 5, p. 346; Soemmerring 1778; Burdach 1819–26; S. A. W. Stein 1834.)

4. Earliest announcement of a partial decussation in the chiasma by Isaac Newton.—Closer to the truth in explaining the anatomy and functional significance of the optic chiasma was Isaac Newton (1642–1727), the celebrated English natural philosopher and mathematician (*see* Newton, *Opticks*, 1704, book 3, query 15; portrait Fig. 76).

Searching for an explanation of simple binocular vision, Newton assumed its cause to be the union in the chiasma of the nerve fibers which originate from the homonymous sides of both eyes. This information he, himself not an anatomist, may have obtained from one of the contemporary anatomists, as a hint in his note indicates (*cf.* pars. 1 and 2, this section; *see also* Fig. 71, where the fusion of homonymous "corresponding impressions" in the brain was clearly indicated by Des Cartes, although only in the pineal gland; for Ibn al-Haitham *see* sec. 6 [2], this chapter). Owing to this arrangement, the impressions from the homonymous halves of both retinae are transmitted either to the right or to the left half of the brain, the two cerebral impressions together producing one single mental experience. In modern times this idea assumed a concrete form in the concept of a "cyclopean eye" (Hering and Helmholtz). (*See* chap. XIII, 3.)

5. Earliest formulation of the "theory of identical or conjugate points."—The idea of a partial decussation in the optic chiasma serving as an anatomical arrangement that brings about a single impression in the binocular visual act, foreshadowed by Ibn al-Haitham, or Alhazen, during the eleventh century and later by Des Cartes and first clearly announced by Isaac Newton, was further taken up and elaborated upon by John Taylor (1727, 1750, portrait Fig. 77), a roving ophthalmic surgeon and adventurer.

According to Taylor's hypothesis, those fibers which are "akin," that is, similarly or syndynamically attuned, as are those which originate from the homonymous halves of both eyes, join in the central organ. In this way each point of the photoreceptive surface of one eye becomes anatomically and functionally correlated to a similar point of the contralateral eye. In Taylor's diagram (Fig. 78), fibers from the homonymous halves of both eyes are shown to join above the chiasma as two separate fascicles and to proceed together to their respective halves of the brain.

Taylor's hypothesis would be practically identical with the modern "theory of identical points" and "joining of homonymous fiber bundles" proposed by Johannes Müller and by Wilbrand (*Faszikelfeldermischung*, *see* chap. IV, 4 [5]), if it were not for the fact that the fibers from the ipsilateral and contralateral eye are depicted in his diagram as running parallel instead of being superimposed. On the other hand, far advanced though it was, Taylor's functional interpretation was inadequate, since it failed to recognize the true effect, which is stereoscopic

vision, as a functional consequence of the peculiar anatomical organization of the visual system. (For continuation of this subject, *see* sec. 12 [7], this chapter; chap. IV, 4 [5]; and chap. XIII, 3.)

6. FURTHER ELABORATION OF THE IDEA OF TOPOGRAPHICAL REPRESENTATION OF THE RETINAE IN THE VISUAL SYSTEM.—Of considerable interest also is Taylor's idea of the preservation of the relative positions of the optic nerve fibers along their course from the eye to the central organ or the topographical "projection" of the retina upon the brain. This idea, already suggested by Ibn al-Haitham (sec. 6 [2], this chapter), but first clearly expounded by Des Cartes

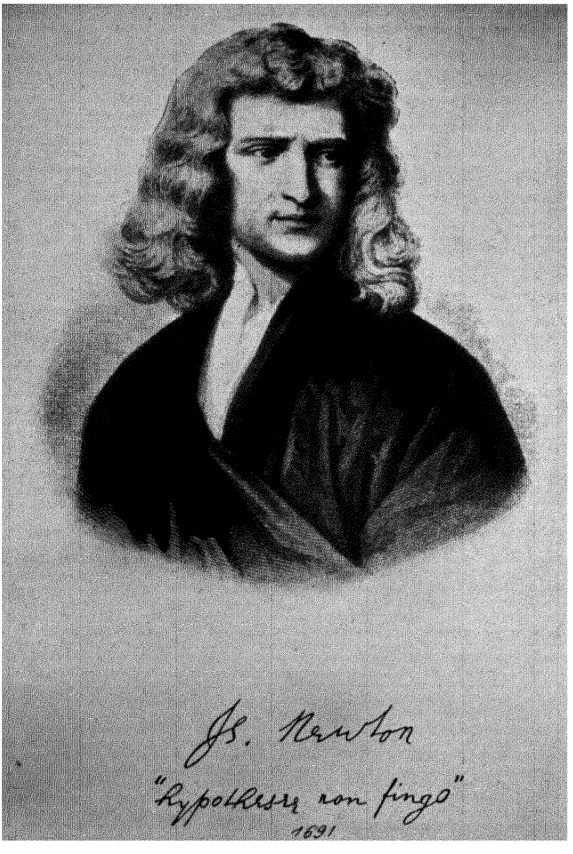

FIG. 76.—Isaac Newton (1642–1727), celebrated mathematician, physicist, and philosopher of Cambridge, England. Originator of the concept of "force of gravitation" as a basic factor in the universe. Student of the fundamental properties and nature of light ("corpuscular, emission, or emanation theory"). Showed white light to be a composite of homogeneous colored lights, together representing a visible "spectrum." Author of ***Principia Mathematica*, 1687**, and of "Opticks," 1704. First writer who clearly indicated the partial decussation of optic nerves in the chiasma to be a basis of the single subjective impressions in the binocular visual act, later expressed in the concept of a "cyclopean eye" by Hering and by Helmholtz. From E. Mach, *The Principles of Physical Optics*, Methuen & Co., London, 1925. (*Cf. also* Fig. 350.)

(sec. 10 [2, 3], this chapter), and again advocated by Briggs (par. 2, this section), as presented by Taylor, even though less explicit, appears closer to the modern viewpoint, since it is anatomically more correct. Its weakness was the lack of anatomical evidence. The earliest attempt to furnish such evidence was made by Zinn (1755, p. 193), who found that the number of fiber bundles in the optic nerve is constant and that they preserve the same relative order along the entire course of the nerve. (*Cf.* chap. IV, 4.)

QUI VISUM VITAM DAT.

FIG. 77.—John Taylor (1703–72). English ophthalmiatric "knight-errant" and, according to some historians, "the greatest charlatan among the oculists that ever lived." In spite of the adverse opinion of posterity about Taylor's character and professional accomplishments, it is only fair to admit that his view on the anatomical causes of single vision was remarkably modern: e.g., that the bundles composing the optic nerve, originating from the localities of both retinae used simultaneously in a binocular visual act, meet in one point in the brain and thus bring about a single subjective visual experience. Whether original or borrowed, this view was subsequently developed by Johannes Müller, H. Wilbrand, and others into the modern "theory of corresponding or syndynamical points" (*see* chap. II, 11, [5]). Frontispiece of Taylor's *Mechanismus*, 1750. (*Cf.* Fig. 78.)

7. SMALL INFLUENCE OF EARLY CLINICAL OBSERVATIONS UPON THE UNDERSTANDING OF THE VISUAL SYSTEM.—The divergence of opinions concerning the visual system during the seventeenth and eighteenth centuries is astonishing, in view of a considerable number of clinical and pathoanatomical observations. It seems, in fact, that as the number of observed cases increased, so did the disagreement, until, as A. Haller, a leading physiologist of his time, remarked, nothing but well-performed physiological experiments could clarify the issues (A. Haller 1769, v. 4, p. 206, portrait Fig. 80).

The only subject on which there seems to have been general agreement concerned the channel in the optic nerves. At last this fantasmagoria was eliminated. Originating in the days of Heróphilos and Erasístratos and cleverly propagated by Galen, it easily survived the credulous Middle Ages and managed even to linger on into the modern era of magnifying glasses and microscopes, all the while interfering with sober research and clear thinking. It was an illusion apparently caused by the central retinal blood vessels buried in the center of the optic nerve, which to an unaided eye may have simulated a collapsed channel (Zinn 1755). (*Cf.* Fig. 185.)

SEC. 12. INVESTIGATIONS OF THE VISUAL SYSTEM TOWARD THE END OF THE EIGHTEENTH AND DURING THE BEGINNING OF THE NINETEENTH CENTURIES

1. TRANSITION FROM GROSS ANATOMY TO MICROANATOMY.—During the first half of the eighteenth century little progress was made in the anatomy and physiology of the visual system. The reason was not so much the lack of interest as the fact that the crude dissection of fresh specimens, heretofore used almost exclusively, was obviously approaching its inherent limits. By this time, most of the gross features easily studied without magnifying glasses, such as the size, consistency, and fibrous composition of the optic nerves and related parts of the brain, had been described. The next task was to study finer details. This, however, had to wait until the beginning of the microscopic era. But just before this, during the second half of the eighteenth century, as if in preparation for the age of microscopy, gross anatomical investigation not only increased in volume but became more subtle in technique and in its concept.

During the early part of the nineteenth century the investigation of the visual pathway was the logical continuation of the preceding period, both in understanding the problems and in technical approach. The interest was still almost entirely confined to the surface features of the brain. So far as the deeper parts, especially the gray masses or nuclei and the various fiber tracts and sheets or laminae of the brain, were studied, the examination was done without the aid of optical apparatus. True, the microscope was now used more frequently than before, but only for the study of nervous tissue in general.

Even so, in the training of the anatomists, accumulated experience and maturity of scientific thinking advanced further in comparison with the past. In the investigation of the brain in general and of the visual system in particular, this led to a further refinement in analyzing the accessible structures. (On the influence of the perfection of microscope upon research *see* F. Merkel 1893; R. M. Allen; Clay & Court; *cf.* also chap. I, 7, and corresponding figures and references.)

2. CONFUSION CONCERNING THE "ORIGIN" OF OPTIC NERVES.—Among the numerous ques-

tions raised by gross anatomical investigation, some lacked adequate definition, since the general principles of organization of nervous tissues had not yet been formulated (*see* "neuron theory" chap. I, 8, and chap. IX). Only microscopy could have furnished these.

For the same reason, the various contradictory assertions relative to the "origin" of the "optic nerves" could have been neither confirmed nor refuted. In this respect almost every part of the brain not too distant from the optic nerves was claimed by someone as their presumptive origin. Among the parts so designated were the superior colliculi of the midbrain; the posterior colliculi and cerebellum; Vieussens' "oval center"; cerebral peduncles; tuber cinereum; the anterior portion of the corpus callosum and anterior commissure; the fornix; the corpus striatum; stria terminalis; thalamus and geniculate nuclei; lateral geniculate nucleus alone; the upper surface of the thalamus; the superior colliculi and lateral geniculate nucleus. Only those of the foregoing suggestions that could have been easily tested without the help of a microscope—for example, the hippocampal gyrus—could have been discarded as fallacious.

In summary, in the words of Soemmerring (1810), of all parts of the brain claimed to be related to visual function, this was certain only about the thalamus. But Burdach (1819–26), commenting on this, remarked that even this was doubtful. Hence, at the end of the first quarter of the nineteenth century, there was practically nothing known about the function of the great hemispheres of the brain, particularly about the gray superficial layer, the cortex. (*See* Soemmerring 1778; Gall & Spurzheim 1810–19; Burdach 1822; S. A. W. Stein 1834.)

3. THE PROBLEM OF THE CHIASMA.—The other of the two chief problems of the visual system during this period—the structure and functional significance of the optic chiasma—remained unsolved.

The majority still followed Galen's and Vesalius' opinion of a unilateral arrangement, some being in this respect even more radical, denying any relationship between the two nerves. A few advocated a complete decussation, an opinion expressed, according to Burdach, by some Greek anatomists before Galen; others a partial decussation; while still another group assumed an interlacement of fiber bundles without an actual crossing. In any case the evidence in favor of or against any of the foregoing views was inconclusive. This again served as a stimulus for many additional hypotheses, usually even less plausible (*see* Soemmerring 1778, p. 104).

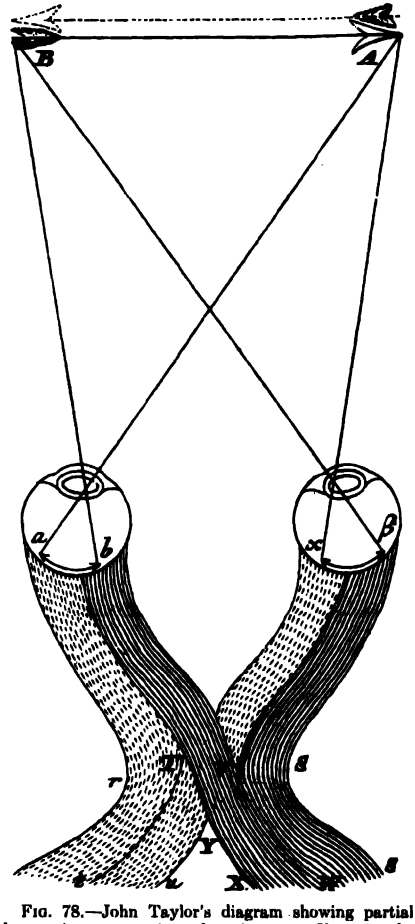

FIG. 78.—John Taylor's diagram showing partial decussation or crossing of optic nerve fibers in the chiasma as a basis of binocular single vision. From J. Taylor, *Mechanismus . . . des menschlichen Auges*, Fig. 5, Tab. V, published in Frankfurt a.M., 1750.

Only after the more careful anatomical studies by Michaelis (1790) and by the Wenzel brothers (1812) and after the observation of additional pathological cases, did the concept of a partial decussation become better substantiated. Such was a case reported by Rudolphi (1815), in which one eye was missing and where a strand was found to cross to the opposite tract

4. EARLIEST CORRECT INTERPRETATION OF HOMONYMOUS HEMIANOPIA. The first case of impaired vision in both eyes caused by a unilateral affection of the brain apparently the earliest recorded clinical observation of homonymous hemianopia or half-blindness of either the right or the left half of the fields of view — was described by Morgagni (1719, *Epist. Anat.*

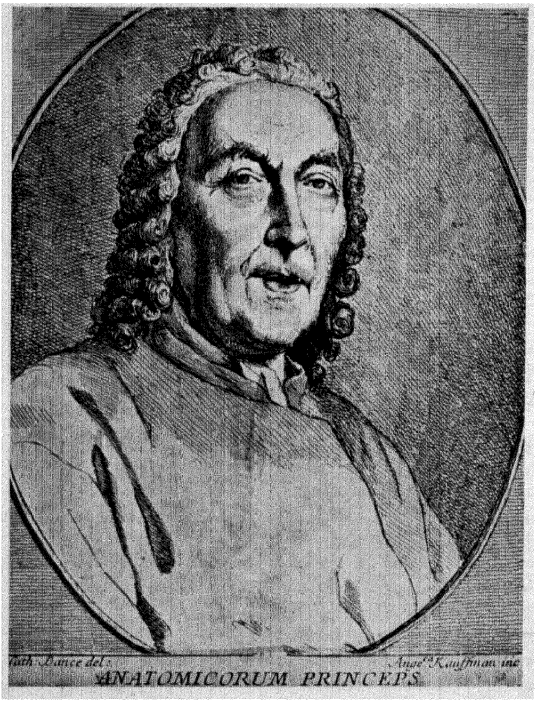

FIG. 79. —Giovanni Battista Morgagni (1682–1771), professor of anatomy in Bologna and Padua, in Italy. The "Prince of the Anatomists," and "Founder of Pathological Anatomy." In 1719 described a case, apparently the first on record, of impaired vision in both eyes caused by a unilateral lesion of the brain, or homonymous hemianopia (half-blindness). From C. G. Cumston, *Introduction to the History of Medicine*, K. Paul, Trench, Trubner & Co., London, 1926; A. A. Knopf, New York, 1926; and R. N. Wegner, *Das Anatomenbildnis*, 1939. According to a sketch by Angelica Kauffman, made from a drawing by Nathaniel Dance. (*See also* P. Capparoni, *Profili bio-bibliografici*, Ist. Naz. med. farm. "Serono," Roma, 1926.)

from the normal optic nerve. (*See* Burdach 1822, p. 392; Gall & Spurzheim 1810, p. 112; A. Haller 1769; Henle 1871, v. 3, part 2, p. 348; Meckel 1812–18, 1815–20; Soemmerring 1778; for doubts raised later, *see* chap. III, 9 [3–6].)

16, art. 13, portrait Fig. 79; *see also* Soemmerring 1778, p. 104). The first correct interpretation of this disturbance in connection with a partial decussation of fibers in the chiasma was given by Vater & Heinicke (1723). A few years later a similar view was expressed by J. Taylor

(1727, 1750, Figs. 77, 78). Weber (1805, p. 306), in analyzing a case observed by Ackermann, coined the term "partial decussation" instead of a less adequate "semidecussation."

A clearly formulated hypothesis of partial decussation in the chiasma as an anatomical condition of binocular vision and of homonymous hemianopia was given by W. H. Wollaston (1824), famous English chemist and physicist and himself a student of optics and optical phenomena. It was based on an analysis of hemianopic scotomas, from which he himself suffered, and also deduced from the observation of homonymous hemianopia, with which several of his acquaintances were afflicted. (*See also* G. B. Airy; Arago 1824; Testelin; and chap. III, 9 [3].)

5. DISCOVERY OF THE PULVINAR OF THE THALAMUS.—Vicq-d'Azyr (1786–90), Gordon (1815), and Meckel (1817), followed by Burdach (1822), first called attention to the overhanging posterior portion of the thalamus. Vicq-d'Azyr named this prominence *tuberculum posticum*, and Meckel, *tuberculum ganglii postici posterius* or *tuberculum ganglii postici posterius superius*. Burdach gave it the present name *pulvinar thalami optici*, or "cushion" or "cushioned seat" of the thalamus (Burdach 1822, p. 117).

6. DISCOVERY OF THE GENICULATE BODIES OR NUCLEI.—The internal or medial geniculate nucleus seems to have been first described by Willis (1664). Santorini (1724) and Reil (1809) named it *corpus geniculatum* or "geniculate body." By Santorini (1724, 1775), Girardi (*see* Santorini 1775), and Malacarne (1780) it was considered one of the sources of the optic nerve. Soemmerring (1778) called it *tuberculum thalami inferius*.

The external or lateral geniculate nucleus had already been seen by Santorini (1724) and later by Soemmerring (1778), Vicq-d'Azyr (1786–90), Reil (1809, 1812), Cuvier (1809–10), Gall & Spurzheim (1809), Carus (1814), Gordon (1815), Meckel (1817), Treviranus (1816–20), and Burdach (1822). The present name *corpus geniculatum externum*, or "external geniculate body," was given to it, apparently by Burdach, in contradistinction to the *corpus geniculatum internum*, or "internal geniculate body" (*see* Gall & Spurzheim 1809, p. 264; Burdach 1822, pp. 115, 118, 342). By Santorini, Reil, and Burdach it was considered to be a part of the thalamus.

Burdach found its core to be made up of a reddish-gray nucleus, covered on the outside by a layer of white substance belonging to the zonal stratum of the thalamus. "Sometimes both substances [that is, the gray and the white] interlace, like the tongues of a flame, almost as in the olives [that is, in the inferior olives]." The foregoing phrase definitely indicates that Burdach, for the first time, was describing the alternating layers which are characteristic of the structure of this nucleus, even though he did not recognize them clearly.

According to Burdach, the lateral geniculate connected with the superior colliculus by means of a brachium, inwardly adjoining the medial geniculate nucleus, its zonal stratum receiving one of the "roots" of the optic tract.

Gall & Spurzheim (1809, p. 264) observed both the lateral geniculate nucleus, their *corps articulé externe*, and the superior colliculus of the midbrain undergoing atrophy in a case where the optic nerve was damaged, and they correctly considered them, and not the thalamus proper, the true visual nuclei.

7. SEGREGATION OF THE OPTIC TRACTS FROM THE OPTIC NERVES.—The separation above the chiasma of the central portion of the optic nerve from the peripheral portion below had been made by Vieussens (1684). This was done more precisely by Vicq-d'Azyr (1786–89), who named the central portion *tractus opticus*, which was translated by Meckel and Burdach into the German *Sehstreifen*, or "optic stripe, band, or tract." They considered the optic tract a part of the brain itself, as distinct from the peripheral optic nerve.

8. MORE FACTS ABOUT THE "ORIGIN" OF THE OPTIC NERVES AND THE CHIASMA.—By the end of the first quarter of the nineteenth century, knowledge of the optic nerves and their relationship to the thalamus and adjoining parts of the brain stem reached the limit attainable by refined gross anatomical technique.

According to Burdach (1822, portrait Fig. 90), the fibers of the optic tract may, first, enter the tuber cinereum from the chiasma. Posteriorly the tract divides incompletely into two parts. The thinner medial portion passes underneath the medial geniculate nucleus to the midbrain tegmentum. The thicker outer or lateral portion enters into the lateral geniculate nucleus and into the pulvinar of the thalamus, where, in the superficial white medullary layer, the zonal stratum, it could be followed anteriorly. Other optic nerve fibers probably pass over to other parts of the brain stem—for example, the *substantia nigra* of the cerebral peduncles—and to the region adjacent to the quadrigeminal bodies.

While the precise origin—in the modern sense actually the termination—of the optic nerves was still uncertain, Burdach's analysis of the structure of the chiasma was remarkably clear. In it he found that the lateral or temporal fibers remained on the same side and that the medial or nasal fibers crossed to the opposite side. He further considered the possibility of the presence of commissural fibers, which, he thought, might connect the two optic nerves, or tracts, in the manner of loops (which he called *Hackenfasern*).

The idea of a commissural system was further developed by Johannes Müller (1826, portrait Fig. 355) in substantiation of his doctrine of "identical or conjugate points" of the two retinae in those species which possess binocular vision. At first, he assumed that each fiber divided, in the chiasma, into two branches, each branch passing to the identical or syndynamical point of one of the two retinae. Later on, however, Treviranus (1835, v. 2, p. 61), Volkmann (1836, v. 2, p. 10), Arnold (1839), and Johannes Müller himself (1837, p. xv) recognized a partial decussation in the chiasma, thereby moving the locus of the fusion of the two single retinal images farther into the brain. (*See* chap. III, 9 [3]; chap. VI, 4, 5, 6; and chap. XIII, 3.)

The final question as to whether or not the optic pathway continues beyond the brain stem to the cerebral cortex had not yet been raised. According to Burdach, the *corona radiata*, a fan-shaped system of nerve fibers connecting the various subcortical regions with the cerebral cortex, previously studied by Willis and by Vieussens and named by Reil (1809), had its center in the thalamus, whence it spread in all directions. Only Gall & Spurzheim (1810) hinted at the presence of a separate bundle or fiber tract from the lateral geniculate nucleus to the occipital lobe. The sagittal strata of the occipital lobe, the longitudinal and arcuate bundles, the forceps of the corpus callosum, and other fiber systems, through Burdach's studies, however, became recognized as definite anatomical entities. This marked the beginning of investigations of the fiber systems that make up the white subcortical mass of the cerebral hemispheres (*see* chap. III, 5 [2, 3]).

Chapter III

Investigation of the Visual Pathways and Centers during the Early Period of Modern Brain Research

SEC. 1. ANATOMY AND PHYSIOLOGY OF THE CEREBRAL CORTEX DURING THE SEVENTEENTH AND EIGHTEENTH CENTURIES

1. Late start in the investigation of the cerebral cortex and its causes.—It is a remarkable fact that during the first three hundred years of independent research in modern anatomy, from its revival by Vesalius (1543) until approximately the middle of the nineteenth century, only sporadic attempts were made to investigate the minute structure of the great cerebral hemispheres and to determine their probable function. This was especially true of the cerebral cortex and its connections with the rest of the nervous system. It almost seems as if there had been a tacit agreement among the scientists not to intrude into the sacred precinct of human anatomy—the repository of the soul, the seat of the reasoning mind. The few who considered the cortex a possible substratum of the psychic faculties and mental functions—the Swedish mystic E. Swedenborg (1738), the anatomists Francis Joseph Gall (1809–25) and Charles Bell (1811)—were long disregarded.

It may be argued that there were notable exceptions, for example, the microscopic investigations of Malpighi (1664), Leeuwenhoek (1674, 1677, 1685), Vieussens (1684), Ruysch (1691) and a few others (*see* sec. 5, this chapter). While this is true, it is also true that the efforts of early microscopists were, of necessity, aimed at the solution of general histological problems of the nervous system—for example, whether the primitive elements which make up the white and the gray substance of the brain are "fibers," "globules," or blood vessels or whether they are a pithy, structureless substance called "pulp." The investigation of specific architectural problems—for example, the kind and distribution of the nerve cells and fibers, their patterns of arrangement, relationships, and connections, and the local variations of cortical structure in general—had to wait for greater understanding of the basic problems of bodily organization, as well as for better technique.

2. Beliefs of the old anatomists concerning the functional significance of the cerebral cortex.—The almost total disregard by the pioneer microscopists of the minute structure of the cerebral cortex, which in Man represents the bulk of the gray matter of the central nervous system, which Swedenborg intuitively regarded as "the noblest substance of the brain," is not astonishing in view of the strange ideas current among them about its functional significance. Some of them (Malpighi, Vieussens, Bidloo, Le Cat, and Lamarck) considered it to be an excretory glandular tissue, reverting in this respect to the concept advocated by Aristotle two thousand years earlier. A similarly irrational view was expressed by no less an authority than the French Academy of Sciences, headed by the famous naturalist Cuvier (1808), in its dispute with Gall (1808). Ruysch also saw in the cortex nothing but a mesh of blood vessels. What probably was the lowest point in misconception of the cortex was reached when Bichat, "Pioneer of Scientific Histology" (1801–3), declared the nerve fibers in the brain to be hypothetical and artifacts. Burdach (1819) and Ehrenberg (1833, 1836), in turn, thought that the nerve fibers were made up of globules arranged in rows, even though Burdach noticed that the filaments appeared almost cylindrical when quite fresh and that

the globular appearance increased with the lapse of time.

Such notions, entertained by the foremost authorities of the time, were not of the kind to stimulate profound interest in the cerebral hemispheres, particularly in the cortex. Nor was the understanding of the cellular composition of the body advanced enough to provide a basis for further research. The cellular theory of Schwann (1838), Schleiden (1839), and Max Schultze (1861) had as yet not been formulated.

3. THE IDEA OF A HOMOGENEOUS, INDIVISIBLE "SOUL" A DETERRENT TO THE INVESTIGATION OF THE CORTEX.—The most important factor which prevented early investigation of the cerebral cortex seems to have been ideological and speculative. It was the idea of the unity and homogeneity of the *anima*, or transcendental "soul," and its identity with the two complementary principles, the *vis vitalis*, or "vital force," and the *mens*, or abstract "mind."

This concept, absolutely dominant at that time, accepted equally by philosophers and scientists, gave no incentive to anatomists and physiologists to look for some particular mechanism responsible for the well-defined nervous and psychic functions. Just as, in the macrocosm, the idea of creation of the World and Life by a supernatural power was unsuitable for stimulating any investigation into the origin and development of animate and inanimate Nature, so in the problem of Man's microcosm rational understanding was precluded by the concepts inherited from the irrational, mystical past. Since the "soul," albeit manifesting itself in various ways, was conceived as a single, homogeneous, and indivisible principle—the *anima* or *mens integra*—the only legitimate question to be dealt with by the investigators and philosophers was: In what part of the cerebrum does the integral, transcendental "soul" reside or stand in contact with, or by what means does it act upon, the bodily machine; or is it, perhaps, diffused over the entire brain or body—as various religious and philosophical systems postulated.

4. SPECULATIONS CONCERNING THE RELATION OF THE "SOUL" TO THE BRAIN.—In contrast to the scarcity of concrete information about the structure of the brain was the profusion of speculation on the relationship between the brain and the transcendental "soul" or "mind" (*see* Neuburger 1897; Révész 1917; Corner 1919). That there was some relationship was taken for granted upon purely speculative, "logical" grounds. In emulation of the Greek philosophers and naturalists, one or another of the numerous anatomical subdivisions of the cerebrum was claimed as the special "seat of the soul." Des Cartes considered the pineal gland lodged between the colliculi of the midbrain to be a link tying the soul to the body (*see* chap. II, 10 [2]; *cf.* Figs. 70, 71). Other investigators gave preference to other parts of the cerebral anatomy: to the corpus striatum and cerebellum (Willis), the corpus callosum (Bontekoe, Lancisi, La Peyronie, Chopart, Bonnet), the oval center (Vieussens), the pons (Molinetti, Haller, Wrisberg), the spinal cord (Crusius, Mieg), or the cerebellum (Drelincourt). Still others, on the contrary, averse to such crass materialism, believed the entire cerebrum (Haller, Zinn) or the entire bodily organism (R. Whytt) to be the habitat of the soul. (For the views of the Hindus, Greeks, Romans, and Hebrews on the material substratum of the "soul," *see* Neuburger 1897; Brunet & Mieli 1936, p. 1149; and Révész 1917.)

5. SPECULATIVE PSYCHOLOGY AND EARLY ATTEMPTS AT A FUNCTIONAL CEREBRAL LOCALIZATION.—The analysis or subdivision of the mental process into elemental components, when undertaken at all in these early attempts at a psychophysical correlation, was carried out along the lines of the "speculative rational psychology" of the time. The partial functions assigned to certain territories of the brain were more or less highly complex psychological abstractions, such as "memory," "imagination," "judgment," "reasoning," "religion," "knowledge," and the like. J. Ch. A. Mayer (1779), one of the pioneer writers on functional cerebral localization, trying to place various faculties in particular regions of the brain, conjectured that "memory" was stored in the cortex and "imagination" and "judgment" in the subcortical white matter, although both these substances, he thought, also collaborated in the perceptive and cogitative processes (*see* sec. 3 [1], this

chapter). "Apperception" and "will power," in his opinion, had their abode in the basal region of the cerebrum and close to the central termination of the nerves, while the role of the *corpus callosum* and of the *vermis* of the *cerebellum* was to integrate the impressions with the various particular functions.

6. LAST MANIFESTATION OF THE ANCIENT GREEK IDEA OF "PNEUMA" AS A PSYCHIC SUBSTRATUM.—As an example of the profundity of ignorance, the confusion of the principal issues, and the sophistry of the pseudo-scientific argumentation of that period in matters of cerebral physiology, S. Th. Soemmerring, one of the foremost authorities of his time, may be mentioned (portrait Fig. 37). As late as 1796 he proclaimed the cerebrospinal fluid that fills the ventricles of the brain to be a substratum of the "soul." His evidence in support of this fantasmagoria—the last manifestation of the Greek concept of *pneuma* or "spirit"—was the unity of the system of ventricular cavities and the apparent origin of the cranial nerves from these cavities. The underlying idea was that only a homogeneous substance, bringing into a common connection the origins of all cranial nerves, could possibly be a material substratum of the indivisible, homogeneous, transcendental "soul." (For a modified version of Soemmerring's hypothesis by Immanuel Kant, *see* Soemmerring's *Ueber das Organ der Seele*, p. 81; for Rolando's "galvanic or nervous fluid," *see* sec. 4 [1], this chapter; for similar ideas of Galen, expressed sixteen centuries earlier, *see* chap. II, 3, 5; *see also* Gall & Spurzheim 1810–19, v. 2, p. 214; Burdach, v. 2, p. 225; on Du Laurens, *see* chap. II, 9; on Des Cartes, *see* chap. II, 10.)

Ziehen 1902; Zinn 1755.

SEC. 2. THE DAWN OF MODERN BRAIN PHYSIOLOGY

1. PROBLEMS OF CEREBRAL PHYSIOLOGY AS FORMULATED BY A. HALLER.—Until the eighteenth century, interest in the visual pathway was almost wholly confined to the infranuclear division, from the eye to the "origin of the optic nerves," as pointed out in the preceding pages (chap. II, 11, 12). With the general advancement of the anatomy and physiology of the brain, this interest began to spread to the cerebral cortex. The chief reason seems to have been an increasing emphasis upon experimental physiology, as well as pathology. The rigid, preponderantly descriptive, anatomical treatment of the somatic sciences and the speculative "physiology" built upon them began to recede from their heretofore dominant position to a more proper place (*see* Neuburger). This advancement was due in no small measure to the great stimulus that the study of physiology received at that time, largely through the encyclopedic efforts of Albrecht von Haller (1769, portrait Fig. 80).

The questions about cerebral organization raised by Haller concerned the very foundations of the nervous system. The controversies which developed in the wake of his work stirred the minds of succeeding generations, and even now they are far from being allayed. These questions may be put into a single phrase: Is the brain an aggregation of many foci, each with a function of its own, or is this organ a common repository, wherein the impulses arriving from different peripheral sensory organs are transformed into a new composite, but homogeneous, process? (*See* A. Haller, *Elem. Physiol. Corp. Hum.*, 1769, v. 4, p. 396, par. XXVI, "An Diversae Diversarum Animae Functionum Provinciae"; for biography *see* Hübotter 1929–35.)

2. EVIDENCE FOR AND AGAINST FUNCTIONAL CEREBRAL LOCALIZATION.—Haller, to begin with, could not deny the obvious anatomical fact that the optic, olfactory, acoustic, and

other cranial nerves have their apparent "origin" in distinct parts of the brain. An a priori assumption could, therefore, be made that each of the various tubercles and eminences described in the brain by the anatomists was a storage place for particular "images," "shapes," "impressions," "sensations," or their vestiges, brought to them by a particular nerve—for example, the "optic thalami" for the visual "images." The region of the pons or "bridge" of Varolius and the *medulla oblongata*, where several nerves originate, would, accordingly, be the seat of a complex mechanism incorporating many motor and sensory functions. In the brain itself (evidently Haller here had in mind the cerebral cortex and the subjacent white substance), as suggested by numerous clinical and pathological-anatomical observations, certain regions may be concerned with one or another of several sensory functions, while still others may be related to motility. (Pourfour du Petit's experiments with dogs indicated the presence of such a motor center.) Also, by that time, a number of clinical observations of blindness became known, in which the pituitary gland or hypophysis, the pineal gland or epiphysis, or the optic nerve had been affected by a pathological process or in which the skull or the brain, meaning mainly the cerebral hemispheres, had suffered injury or the "optic thalamus" had

FIG. 80.—**Albrecht Haller** (Albrecht von Haller, 1708–77), a native of Switzerland and a noted poet and philosopher, professor of anatomy and botany in Göttingen, in Prussian Brunswick, Germany. Founder of modern physiology and leading authority of his time in this field. Protagonist of a unitarian concept of the nervous system, according to which the entire brain, including the cerebellum and spinal cord, were homogeneously organized and functioned in the same way in all parts. Author of *Elementa Physiologiae Corporis Humani* (1757–66), the first comprehensive modern treatise on physiology. Courtesy of Professor R. N. Wegner, University of Greifswald, Germany. According to a painting by Sigmund Freudenberger (1773, with addition of the order painted 1776), now in possession of Mr. Albert de Haller, of Lausanne, Switzerland. For other portraits *see* Arthur Weese, *Die Bildnisse Albrecht von Hallers*, Bern, 1909. *Cf.* J. Hirschberg, in Graefe & Saemisch, *Handb. d. ges. Augenh.*, 2d ed., v. 14, 1911.

been compressed. Of particular interest was a case of temporary blindness occurring after injury to one side of the head; and another case of blindness of long duration, which later cleared up, caused by an injury to the top of the head in the region of *bregma;* and, finally, a case of permanent blindness occurring after injury to the occiput.

Against this evidence, which pointed in the direction of functional localization, there were observations of other cases in which a single lesion had caused an impairment of several faculties. In one such case a tumor of the pineal gland was accompanied by headache, blindness, and deafness. These observations seemed to show that any major cerebral lesion may be followed by an impairment of several faculties.

3. HALLER'S VERDICT AGAINST FUNCTIONAL CEREBRAL LOCALIZATION.- After considering various clinical cases and other evidence known to him, Haller decided against the localization of special faculties in particular localities of the brain (for example, of vision in the region of the "origin" of the optic nerve or of hearing in the locality whence the acoustic nerve arises, and so forth). No nerve, he contended, has its own exclusive and limited territory in the brain stem or in the spinal cord, whence it emerges. Nor would it be proper, he thought, to express an opinion as to the purpose and the use of certain tubercles, for example, of the superior or inferior colliculi, of the midbrain, pons, striate bodies, cerebral hemispheres, or cerebellum, or to assign to any one of them a function which would differ from that of the brain as a whole. Haller declared the eminences and sulci of the brain to be the products of mechanical factors, such as pressure from the near-by pulsating arteries, or possibly to be caused by the weight of neighboring parts, and not an expression of specific functions.

According to Haller's definition of brain function, the concept of "equivalence" or "omnivalence" of all parts of the nervous centers reached an extreme. The entire brain, including the brain stem, cerebellum, and spinal cord, was to be regarded as a single great repository, into which various peripheral impulses pour and, as he seems to have implied, produce in it an entirely new psychophysical status identical with, or at any rate related to, and indispensable for, the action of the transcendental, indivisible "soul."

4. REASONS FOR HALLER'S FAVORING FUNCTIONAL CEREBRAL OMNIVALENCE.—The failure of such a mind as Haller's to adopt a more adequate view of cerebral organization is remarkable! He did not deny the too obvious anatomical diversity of the nervous organ but, instead, satisfied himself with a naïve mechanistic explanation. He recognized the peripheral nerves as independent conductors. Following Galen, Willis, and Whytt, he also admitted that the nerve fibers and fiber bundles which compose various nerve trunks retain their individuality all the way from their apparent central origin to their termination in the peripheral organs—all of which shows that he was well aware of the functional importance of such an arrangement. Haller admitted the validity of the principle of "localization" or the "somatotopic" principle in the peripheral nerves, the function of the individual fibers being, in modern parlance, to transmit specific impulses without interference and independently from those transmitted by all other filaments. But he failed to make the next logical step and admit the validity of the same rule in the central nervous organ. To him, apparently, this was too crude, too mechanistic, to be acceptable as an architectural pattern for the substratum of the "soul" or "mind."

After toying with the idea of "localization of cerebral functions," Haller performed a logical somersault by rejecting it, and seized upon the broad and comfortable theory of integral cerebral "equipotentialism"! The responsibility for this seems to lie not only with the insufficient scientific evidence at his disposal but even more with various nonscientific factors and considerations. Plainly, supernaturalism and transcendentalism, even among the scientists of that period, were still too strong to permit an unbiased study of the brain with the same scientific approach as that used for the investigation of less sacred parts of human anatomy.

References: Burdach 1819–22–26; A. Haller 1769, 1774–76; F. A. Lange 1908; Neuburger 1897; Puschmann *et al.* 1902–5; Révész 1917; Soury 1899; J. A. Unzer 1746, 1768, 1771; Willis 1664, 1682

SEC. 3. THE PLURALITY DOCTRINE OF THE FUNCTIONAL ORGANIZATION OF THE BRAIN

1. EARLY SPECULATIONS ON FUNCTIONAL LOCALIZATION IN THE BRAIN.—The idea of localization of distinct functions in particular regions of the brain is quite ancient. According to Burdach (1826, p. 270), Galen suggested three basic forces or properties as making up the "soul," for which his successors assumed three chambers in the brain, which they called *cellulae, specus, sinus* or *cavernae*. The anterior chamber served as a repository of "perception" (*φαντασία, phantasia, anima imaginativa, sensus communis*), the middle chamber for the faculty of thinking (*λόγος, διάνοια, νόος, νοῦς, φρόνησις, anima cogitativa*), and the posterior for memory (*μνήμη, anima memorativa*).

This concept, which was probably taken over by Galen from the older Greek philosophers, was accepted by the early Christian writers, Nemesius (4th century), St. Augustin (354–430), and others (*see* W. Sudhoff 1914). Subsequently it was entertained by Albertus Magnus (1206–80), Roger Bacon (1214–94), Hieronymo Manfredi (1430–93), and many other writers of the late Middle Ages and is well demonstrated in Figure 81. During the early period of modern anatomy and even for many years thereafter, numerous writers accepted it. Chanet (1649) considered the frontal portion of the brain to be the seat of imagination, made up of many small organs. Willis (1664), Molinetti (1669, 1675), and Bonnet (1759) also regarded the brain as a composite organ whose parts have different functions. Vieussens (1684) believed that the "animal spirit" from certain cerebral regions entered particular nerves.

The efforts of French brain surgeons and experimenters of the eighteenth century were of special importance in the development of the idea of diverse functions of different parts of the brain (*see* Neuburger 1897; Soury 1899). Among these, Lorry (1760), with the discovery of a respiratory center in the medulla oblongata, demonstrated for the first time the dependence of an important somatic function upon a definite locality of the brain. Saucerotte (1768) deduced from his experiments with dogs that the forelimbs and hind limbs had separate motor centers in the brain. Finally, Sabouraut (quoted by Soury 1899) postulated connections from every part of the body to a particular locality in the brain.

Dissatisfied with the dominant doctrine, which insisted that "the whole brain was a common sensorium" and that only "the extremities of the nerves were fitted to receive a peculiar impression; or that they were distinguished from each other only by delicacy of their structure, and by a corresponding delicacy of sensation" –and not at all by their diverse central connections and functional peculiarities— Charles Bell (1811), in England, and Magendie (1822–23), in France, initiated researches which led them to the discovery of the motor function of the anterior roots, and the sensory function of the posterior roots, of the spinal cord.

The following quotations from Charles Bell's writings show his opposition to the prevalent omnipotentialism: ". . . while the organ of sense is provided with a capacity of receiving certain changes to be played upon it, as it were, yet each utterly is incapable of receiving the impressions destined for another organ of sensation"; and ". . . properties of the nerves are derived from their connections with the parts of the brain . . . "; ". . . portions of the brain are distinct organs of different functions"; and "Through the nerves of sense, the sensorium receives impressions, but the will is expressed through the medium of the nerves of motion."

Such convictions, supported by experimental evidence, for a while helped save from oblivion the idea of functional cerebral localization, in spite of the great weight of adverse opinion resting upon such authority as Haller (1769) and J. G. von Herder (1784–91), a noted German philosopher and writer. Another exception in favor of cerebral functional localization was a pamphlet of J. Ch. A. Mayer (1779), an obscure Prussian writer.

2. GALL'S EVIDENCE IN FAVOR OF THE FUNCTIONAL DIVERSITY OF THE CEREBRUM.—The first systematic effort to give the idea of functional cerebral localization a scientific foundation and to bring it to the attention of the scientific world, was made by Francis Joseph Gall

(partly in company with Spurzheim, 1809, p. 288; 1810–19; 1825; portrait Figs. 83, 84).

Gall proclaimed an anatomical and functional diversity of the central organ, which was contrary to the idea of structural uniformity or homogeneity of the brain and oneness of cerebral processes generally accepted at the time. The brain, in his opinion, was composed of a number of particular systems differing from one another both in structure and in function. The cranial nerves—the olfactory, optic, oculomotor, and so forth—not only were related to different peripheral sensory and motor organs but also originated from different nuclei, and in other respects differed among themselves. Functional difference was the result not only of different peripheral connections but also of discrete central relationships. The brain was a composite

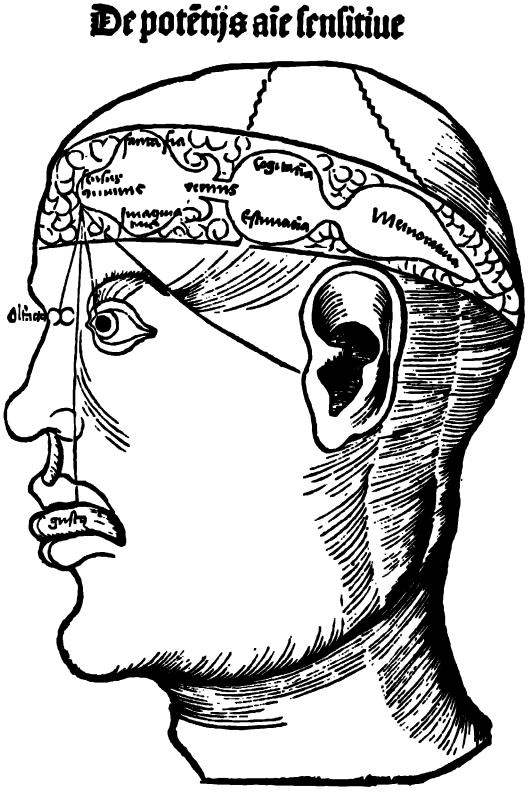

FIG. 81.—Medieval concept of the brain mechanisms serving higher or mental functions, according to a diagram from G. Reisch, *Margarita Philosophica*, printed in 1513. The brain was supposed, according to this, to contain three interconnected cavities or cells, each serving as a repository of a particular mental faculty. The frontal cell, a repository of common sense, fantasy, and imagination, alone would receive direct messages from the peripheral organs of sight, hearing, smell, and taste. The middle cell was the place of the thinking process and judgment, while the most posterior cell served the memory. The figure is one of the earliest Western pictorial presentations of the idea of localization of distinct faculties in definite localities of the brain, in which, according to the words of Hieronymo Manfredi (1490), "the soul performs its diverse operations, for which reason it is necessary that these parts be of different structure." From K. Sudhoff, Augenanatomiebilder, in Stud. z. Gesch. d. Med., Fasc. 1, 1907. (*Cf.* Fig. 62.)

organ made up of many systems, each with its own distinct function. The dispositions and properties of Man and animals were innate and were predetermined by organization.

3. Gall's system of intellectual and moral faculties and their localization. The various "intellectual and moral faculties" and traits of personal character, according to Gall, were stored in definite regions of the cerebrum and were not different manifestations of a single, uniformly organized substratum. Such faculties, according to Gall's classification, were: the instinct of procreation, love, sociability, courage, cleverness, property sense, pride, ruling instinct, ambition, vanity, circumspection, memory, educability, perfectibility, orientation in space or local sense, visual memory, auditory speech memory, philological talent, color sense, auditory tone sense, mathematical talent, temporal sense, mechanical and artistic talent, intellect, metaphysical sense, humor, causality, poetic talent, morality, compassion, honesty, conscience, goodness, avarice, irritability, religiosity, reason, and will power.

Fig. 82.—Pieter Camper (1722–89), Dutch anatomist whose ideas influenced F. J. Gall, originator of "cerebral organology" (*see* Figs. 83, 84). A frontispiece in Camper's *Discours, . . . sur le moyen de représenter d'une manière sûre les diverses passions qui se manifestent sur le visage*, Utrecht, 1792.

The more pronounced a trait was, the better developed was the corresponding cerebral territory. Outwardly this was manifested by the

prominences on the cranium (several decades later Panizza believed he had demonstrated this in experiments with animals). Turning his argument the other way, Gall claimed it was possible to determine what faculty, trait, or feature of the character was particularly developed in a given person from the prominences of the cranium. He also believed that a mental or moral faculty, since it is localized, could be impaired or lost by damage to a particular locality of the brain.

It is remarkable that, in the system devised by Gall, only a few of the faculties he listed correspond to the simple sensory or motor functions as conceived at the present time. This, without doubt, was because at that time the forebrain was universally accepted as the exclusive seat of the "psychic functions," whereas the "vital" somatosensory and motor functions were thought of as being regulated by the brain stem and cerebellum (*see* Neuburger 1897).

Gall's "doctrine of the plurality of cerebral organs" in contrast to the unitarian concept, with its practical corollary, "craniognomy," a branch of "physiognomy," subsequently (especially under Spurzheim's influence) degenerated into "phrenology," which lacked any factual foundation and is still a pseudo-science with some following among the unenlightened (*see* Macalister & X). On the other hand, Gall's basic idea, favorably looked upon by such a reserved anatomist and thinker as Burdach, was intriguing enough to stimulate numerous investigators to test it by scientific methods. From then on, the idea of the localization of distinct functions in special regions of the cere-

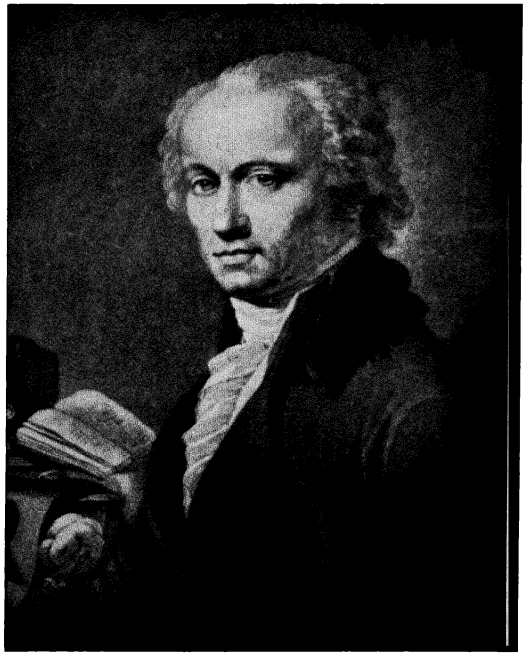

FIG. 83.—Franz Joseph Gall (1758–1828), brain anatomist and founder of the doctrine of functional cerebral localization. From G. Elliot Smith, *Essays on the Evolution of Man*, Oxford University Press, London, 1927. Courtesy Mrs. Grafton Elliot Smith. (*See* following figure.)

bral cortex or the concept of the brain as a composite organ made up of a number of territories with locally varying structure and function did not fail to influence neurological research, in spite of the determined opposition it met and the disrepute in which it was held by many. (*See* sec. 6, this chapter.)

SEC. 4. DOCTRINE OF FUNCTIONAL OMNIVALENCE OF THE CEREBRAL CORTEX

1. EARLY PHYSIOLOGICAL EXPERIMENTS AND THE PROBLEM OF THE FUNCTIONAL ORGANIZATION OF THE BRAIN.—The physiological experiments carried out during the eighteenth century by Pourfour du Petit, Haller, Zinn, Lorry, Fontana, and others, to determine the function of the brain, were continued with even greater zeal during the early part of the nineteenth century (*see* Neuburger 1897; Soury 1899). But the results of this early period of modern experimental physiology, in respect to the visual and other sensory and motor functions, were inconclusive. Pourfour du Petit (1710), experimenting upon dogs, observed contralateral paralysis when the corpus striatum was damaged, but only paresis or weakness if the lesion was limited to the cortex; vision, he thought, was impaired in the eye contralateral to the lesion. Lorry (1760), the discoverer of the respiratory center in the medulla oblongata, found that manipulations upon the brain did not elicit any reaction such as motion or sensation (for example, pain). Rolando (1809, 1828), in his numerous experiments upon the brains of various Mammals and other Vertebrates, either did not observe or ignored disturbance of vision, even when the thalamus and midbrain colliculi had been destroyed. His interest was wholly absorbed by the effects of his experiments on motor function. For him, as for many others among his contemporaries, the thalami were still the only visual centers. Rolando, opposing Gall's "doctrine of cranioscopy," as he called it, denied that the cortex of the cerebrum and cerebellum were composite structures or aggregations of organs with specific functions, as Gall contended, and considered these parts to be uniform, homogeneous masses. He was confirmed in this opinion by his observation of general convulsions which resulted from an application of galvanic current to the surface of the brain. The cortex, in Rolando's opinion, was the origin of an "electric or galvanic fluid," a kind of "nervous fluid," which was but a modern restatement of Galen's "vital or animal spirit" or *pneuma*. (*Cf.* chap. II, 3.)

2. FLOURENS' EXPERIMENTS ON THE BRAIN. – Of far greater significance to cerebral physiology were the experiments of P. J. M. Flourens (1824; portrait Fig. 85; for biography *see* Vulpian 1887). In these, because of their scope and completeness and because of Flourens' clear grasp of the essentials, the fundamental problem of cerebral organization seemed finally to have been solved. This problem—whether or not the various parts of the cerebrum that differed structurally had separate functions raised by Haller and others, especially after Gall's advocacy of the "plurality doctrine," again became acute (*cf.* secs. 2 and 3, this chapter). The negative answer that the cortex itself is not the seat of diverse functions which Flourens gave, expected and desired by most of the contemporary investigators, received almost universal acclaim.

A reward, the coveted membership in the French Académie des Sciences, was also bestowed upon Flourens, a mere youngster, in 1822, at a session presided over by Cuvier. This august body but fourteen years earlier, under Cuvier's influence, refused admission to a great man, Francis Joseph Gall, on the grounds that the cortex of the brain has nothing to do with the processes of thinking!

As a consequence, Flourens' concept of the

organization of the brain exerted a powerful influence upon the scientific and philosophical thinking of his time. It was the period following the French Revolution and its aftermath, Napoleon's ascent to power and his downfall. The heirs both to the French Revolution and to Napoleon, after an exhausting struggle and bent on reinstating the principles of conservatism, were ill disposed toward any tampering with the approved foundations of established order, least of all to a dismemberment of the supernatural, homogeneous soul.

3. Concrete results of Flourens' physiological experiments.—Flourens introduced a more adequate experimental technique than used by his predecessors. Instead of the crude, haphazard destruction practiced before, in which chance was the chief factor and where an effect upon the entire content of the cranial cavity was hard to avoid, he used a method of successive, careful ablations of circumscribed parts of the brain, with no damage to the others. Such a procedure could not fail to yield remarkable results. These, in summary, were: The two chief functions of the nervous system, sensation and motion, were distinctly localized. Only the peripheral nerves, spinal cord, medulla oblongata, and midbrain, when stimulated, produced immediate muscular contractions.

Fig. 84.—Franz Joseph Gall (1758–1828), originator of the "cerebral organology," in advanced age. Foremost student of the cerebral anatomy and physiology of his time. Proclaimed the cortex of the brain to be the seat of the psychic processes. Championed the idea of unequal structural organization and locally varying function of different parts of the brain, in opposition to the concept of functional equivalence of the entire brain defended by A. Haller (Fig. 80). Originator of the concept of localization of mental and moral faculties and traits in discrete parts of the brain, which, on the one hand, subsequently developed into modern teaching of cerebral functional localization and, on the other hand, degenerated into popular "phrenology." First indicated the seat of the faculty of speech to be in the frontal lobes, a suggestion further substantiated by Bouillaud (Fig. 94) and especially by Broca (Fig. 95). From a portrait by Félix Jean Marius Belliard, lithographed by F.-S. Delpech of Paris. For biography *see* Deutsch. med. Wchnschr., v. 35, p. 960, 1909; H. Head 1920; G. Elliot Smith 1923; P. J. A. Möbius 1905; B. Hollander 1928; and A. Froriep 1911. (*See* preceding figure.)

The cerebellum was an organ of co-ordination of movements initiated by the other parts. The cerebral hemispheres were the seat of the will. There were, accordingly, three principal nervous functions: (1) the will or perception, which is sensitivity; (2) the excitability which produces muscular contractions; and (3) the co-ordination of movements. The intellectual faculties, the "will," and the sensory performances or "perception" were localized in the cerebral hemispheres (i.e., cortex). In this way the functional subdivision of the central nervous system along anatomical lines into a forebrain, brain stem, cerebellum, and spinal cord was substantiated by experiment.

By distinguishing several functions and by localizing them in different parts of the central nervous organ, Flourens became one of the founders of the modern concept of functional cerebral localization. This appears substantially

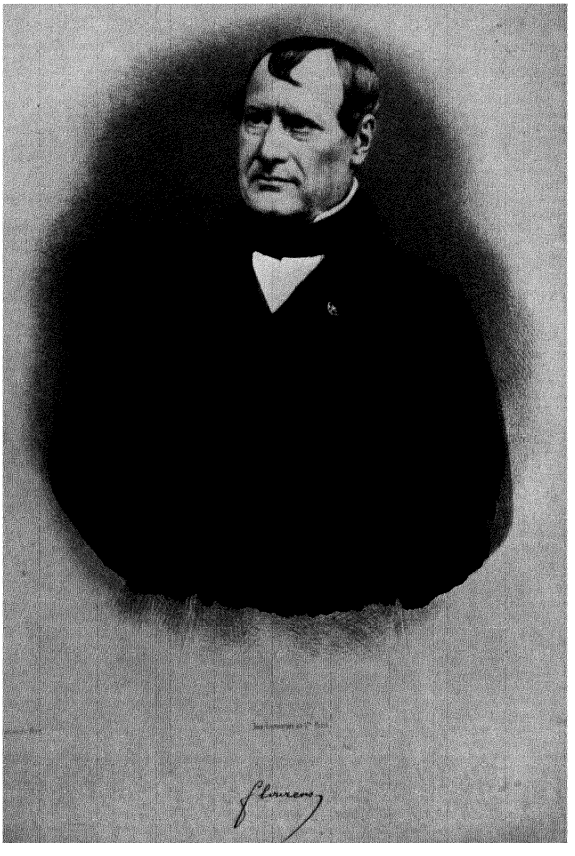

FIG. 85.—Marie Jean Pierre Flourens (1794–1867), professor of comparative anatomy in Paris. Initiator of modern experimental brain physiology. Champion of the doctrine of functional equivalence or homogeneity of the entire cerebral cortex, as distinct from Haller's homogeneous organization of the entire cerebrospinal system and from Gall's concept of cerebral diversity. From an engraving by Aug. Lemoine. Courtesy Crerar Library, Dr. Sonnenschein Collection, Chicago.

correct, even though he himself insisted upon the view that, owing to the multiple interconnections and the functional interdependence of its constituent parts, the brain represents but one single complex, or *un système unique*.

4. Restriction of the "omnivalence doctrine" to the cerebral cortex by Flourens.—In consequence of Flourens' experiments, Haller's concept of the functional omnivalence or equivalence of the entire central nervous system had to be recognized as an error. "The nervous system," in Flourens' words (1842, p. 56), "is not a homogeneous system. The function of the cerebral lobes is not the same as that of the cerebellum, nor of the cerebellum as that of the spinal cord, nor the latter's in any way like that of the nerves." The cerebral cortex, however, was a notable exception. Here, Flourens insisted, the principle of functional equivalence was valid: "The cerebral lobes are the exclusive seat of all sensations and intellectual faculties" (p. 97). Through his experiments he became convinced that the cerebral and cerebellar cortex—since seemingly unexcitable to direct stimulation—served exclusively higher sensory functions of sight, hearing, instinct, and probably intellectual faculties also. These functions, however, did not, in his opinion, depend upon distinct localities of the cortex. They were, in fact, all manifestations of one single basic function distributed over the whole cortex.

In support of his thesis Flourens brought up his observation that a limited portion of the cortex may be removed without appreciable impairment of any or all of the several sensory functions. Nor did it matter which portion of the cortex was destroyed. The only factor of importance was the quantity or amount of substance eliminated. Beyond a certain minimum of destruction, all faculties became impaired, and, after complete destruction, all were equally lost. From this experience Flourens concluded that the various sensory functions were not separately stored in particular regions but were uniformly represented in the entire cerebral cortex. The lost faculties might be recovered through a vicarious function of parts remaining normal, provided that the damage was not too extensive. The entire cortex, according to Flourens, functioned as a single, uniformly organized mass in which each part could substitute for any other part.

The only exception was sight, which in the case of unilateral destruction of the cortex was permanently lost in the contralateral eye. Flourens never recognized the hemianopic character of centrally caused visual disturbances, working as he did upon lower Vertebrates (Pigeons and Chickens), in which the optic nerves are completely or nearly decussated. (*Cf.* chap. VI, 5 [3].)

5. Doctrine of cortical omnivalence and the dogma of the unity of "soul" or "mind."—In the "doctrine of cortical equivalence or omnivalence" proclaimed by Flourens, the concept of the unity of "soul" or "mind," adhered to by the majority of anatomists, physiologists, and philosophers of the preceding periods, not only was fully preserved but seemed to have been experimentally substantiated. Its strong point, besides apparent solid experimental evidence, was its reasonableness when compared with the preceding attempts to confine the "soul" or "mind" to a particular, minute organ, such as the pineal gland, as, for example, Des Cartes did (*see* chap. II, 10 [2]).

According to Flourens' version, the Ancient Greek *hegemonikón*, or "dominant soul," was neither distributed over the whole organism nor restricted to a minute fraction of the bodily machine but was stored in the large mass of gray substance covering the cerebral hemispheres, the cortex. Within that relatively large container, however, the "intelligence" was nowhere tied to a particular, small locality to the exclusion of the remainder. (*Cf.* sec. 1 [4], this chapter.)

In practice, the difference between Flourens' and Haller's teachings was small. On the one hand, the cortex was anatomically and functionally connected to other subdivisions of the brain and spinal cord. On the other, the spirit of the time was attuned almost exclusively to the idea of unity of the entire central nervous system, to the disadvantage of any moderating qualification.

6. Flourens' discovery of the dependence of vision on the cerebral cortex.—

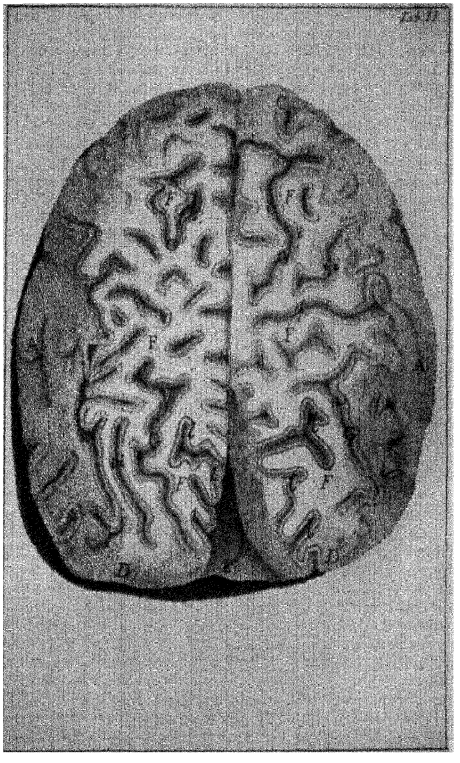

FIG. 86. Gennari's figure, where, for the first time, structural variation in the cerebral cortex was demonstrated. Horizontal section through human brain *in situ*, with upper portions of both hemispheres cut off to show the newly disclosed intracortical stripe *l, l*, named in honor of its discoverer "Gennari's stripe or line" (later also named "Gennari & Vicq-d'Azyr stripe"). *Labeling:* *A, A*, right and left hemispheres; *B, B*, longitudinal fissure; *C, C*, frontal lobes; *D, D*, occipital lobes; *E*, tentorium of cerebellum; *F, F*, white subcortical medullary substance; *G, G*, gray cortical substance; *h, h*, fissures or sulci; *i, i*, newly discovered white intracortical layer of frontal lobes, which in some localities appears double; *l, l*, pronounced white intracortical stripe of the occipital lobes, or Gennari and Vicq-d'Azyr's line (*lower part of figure*), which more than a century later was recognized as indicating the visual center, or "striate area" of G. Elliot Smith. From Francesco Gennari, *De peculiari structura cerebri*, published in 1782, Parma, Italy. (*Cf.* Figs. 226-29.)

inadvertently vindicated the substance of Gall's teaching and the opinion of Swedenborg (1738) and of Charles Bell (1811), according to which "the cineritious and superficial parts of the brain are the seat of the intellectual functions." From now on, in order to know the brain's organization, it became necessary to study not only the structure of the cortex itself but also its connections with the brain stem and the peripheral nerves.

The pioneer investigators of this period, whose chief interest was in the finer structure of the cortex, were Gennari (1782), Cazauvieilh (quoted by Baillarger 1840), Vicq-d'Azyr (1786 90), and Meckel (1815), followed later by Baillarger (1840), Hannover (1844), and Koelliker (1854). They furnished evidence of the nervous nature of the cortical substance and made a significant discovery of local variation in cortical architecture. Gennari first noticed the white medullary stripe of the occipital lobe in the cortex, which has been named for him (Fig. 86, *l*). This observation was subsequently confirmed by Vicq-d'Azyr, Rolando (1828), Soemmerring, and others. Only much later was it realized that this area was the visual center. (*See* chap. IV, 7 [3]; and chap. VIII, 3, 4.)

Most successful of the investigators of this period was Baillarger (1806 91), a pupil of Esquirol, "Creator of the Science of Psychiatry" (*see* Magnan 1902; *see* portrait Fig. 86*A*). By mounting thin sections upon glass and examining them against light, he found the cortex to be composed of no less than six parallel layers, alternating white and gray and differing in structure (Fig. 87, 88). The arrangement and number of layers varied from region to region; in some places there were only two. He found the fibers entering into the cortex from the subjacent white subcortical substance most numerous in the summit of the gyri, fewer along the walls of the sulci, and least numerous around the sulcal floor, where they were arranged obliquely. There was also a difference in termination: in some localities the fibers terminated in the lowermost layers, in others in the layers closer to the cortical surface. Baillarger also realized that the white cortical strata were made up partly of fibers penetrating from the white subcortical substance and partly of the autochthonous fibers arranged parallel to the surface. All these observations induced him to consider the cortex the most important and the most complicated substance of the brain. He was also the first to anticipate modern views: that the advanced stratification of the human cortex signified its "perfection" in comparison with those of other animals and that isolated damage to distinct layers is possible in various pathological processes.

Another group of anatomists, Rolando (1809), Gall & Spurzheim (1809, 1810 19, portrait Figs. 83, 84), Reil (1809, portrait Fig. 89), Burdach (1819 26, portrait Fig. 90), and Arnold (1839, portrait Fig. 91), were engaged in an effort to disentangle the various fiber systems which form the white medullary core of the cerebral hemispheres. Even so, all these initial attempts, especially in fiber anatomy, were no more than guides to future research. (*Cf.* chap. IV, 7 [1, 2].)

2. Discovery of the corona radiata of the cerebral hemispheres.- The relatively slow progress in cerebral anatomy was chiefly the result of the primitive techniques employed during that period. Fixation and hardening of specimens were occasionally practiced by most early modern anatomists, and regularly by Malpighi (boiling); Vieussens (boiling in water and oil, a suggestion given to Vieussens by his friend Baylé, professor in Toulouse); Ruysch (injecting and boiling; also embalming by a secret process, perhaps first using alcohol followed by diluted nitric acid); Monro (same as Ruysch); Vicq-d'Azyr (alcohol and hydrochloric acid); Niemeyer (corrosive sublimate followed by diluted nitric acid); and Gennari (freezing). But only after Reil, who used alcohol or turpentine followed by alcohol, was the preliminary fixation recognized as an essential requisite for the study of cerebral fiber systems. Until then, the customary procedure was to work with fresh, unfixed, and often decaying material, where many original structures and relationships were lost (*see* Burdach 1822, v. 2, p. 243). For this reason the fibrous constitution of the cerebral hemispheres was little known.

Among the systems first recognized was the *corona radiata*, a huge fiber fan radiating from the base of the cerebral hemisphere toward all

regions of the cerebral cortex. This system had already been observed by Thomas Willis (1664) and was subsequently described and depicted by Vieussens (1684, portrait Fig. 75). It was so named by Reil (1809, portrait Fig. 89), who considered it to be a continuation of the funiculi of the brain stem, spreading fanlike in the subcortical space. Reil described the apparent origin of the posterior portion of the *corona* in the yet undisclosed (*see* Reil 1809, p. 165; *see also* chap. II, 12 [8]).

3. Discovery of the principal cerebral fiber systems. A related problem much discussed at that time was the course and arrangement of fiber bundles, particularly whether all fibers terminate in the cortex, or whether some also originate in it, or whether they simply turn

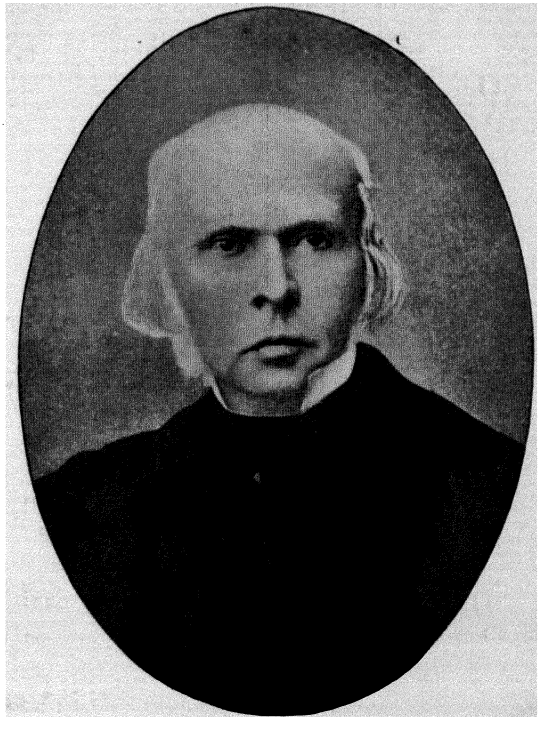

Fig. 86*A*.—Jules-Gabriel-François (J.-P.) Baillarger (1806–91), psychiatrist and pioneer investigator of the cerebral cortex. Author of the pamphlet *Recherches sur la structure de la couche corticale des circonvolutions du cerveau* (1840), which for the first time demonstrated the structural variation of different parts of the cortex. (*See* for biography Y. Magnan in France méd., v. 49, p. 173, and v. 50, p. 17; J. F. Fulton 1951; and Haymaker & Baer, *The Founders of Neurology*, 1953.)

thalamus and its termination in the occipital extremity of the hemisphere. This included the geniculo-calcarine fiber system, or visual radiation, the identity of which, except for a hint given by Gall & Spurzheim (1810), remained as around and pass back again to the brain stem. The many opinions expressed concerning this problem, mostly speculative, increased the existing confusion instead of clarifying matters (Burdach 1822, v. 2, p. 382). In spite of these

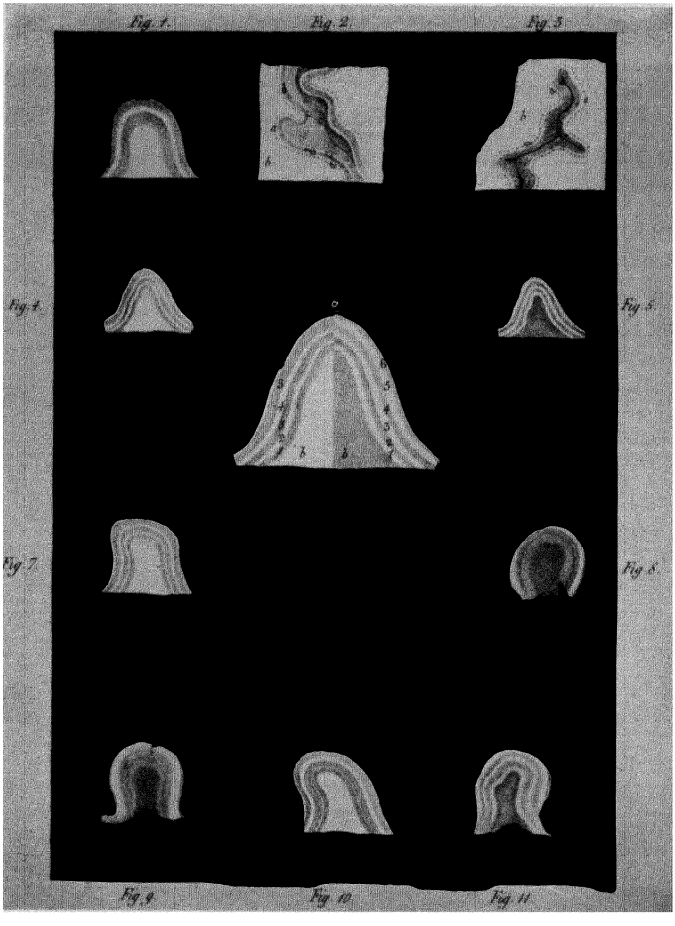

FIG. 87.— Baillarger's figure, which, together with the following figure, is the earliest presentation, after Gennari's, of a local structural variation of the cerebral cortex. *Labeling: 1*, white intracortical stripe of Gennari & Vicq-d'Azyr, indicating the visual center or striate area of G. Elliot Smith; *2*, Gennari's figure, exceptionally showing two white intracortical lines; *3*, another of Gennari's figures with usual single line; *4* and *5*, sheep cortex with six alternating gray and white layers, one in incident, the other in transmitted, light; *6*, same specimen slightly magnified, left half in incident, right half in transmitted, illumination (in the left half the myelinated layers *2*, *4*, and *6* appearing white, in the right half the same appearing gray, whereas layers *1*, *3*, and *5*, made up of nerve cells and only a few myelinated fibers, behave optically in an opposite way); *7*, human cortex in incident light with six alternating gray and white layers; *8*, local variation of human cortex in transillumination, with gray stripe, formed by closely packed lines *2*, *3*, and *4*, still showing a vestige of transparent line *3*; *9*, another variation showing subcortical white substance (*b*), inner zone of cortex composed of first four layers, of which *1* and *3* are poorly developed, and outer zone (*c*) chiefly made up of transparent gray matter containing little myelin; *10*, occipital cortex with a broad white intracortical stripe corresponding to fourth layer (in modern terminology "line of Gennari & Vicq-d'Azyr" or "Baillarger's outer layer"), and another much thinner white stripe corresponding to Baillarger's second layer (in modern terminology "Baillarger's inner layer"; *cf. 1* and *6* in this plate); *11*, cortex of a horse showing six layers in transmitted light. From J. G. F. Baillarger, *Recherches sur la structure de la couche corticale*, 1840. (*See* Fig. 88.)

difficulties, several distinct systems or "bundles" of fibers were identified in the core of the great hemispheres, some real, others artifacts. Such, according to Burdach, were the *tapetum, cingulum, fasciculus unciformis, f. longitudinalis inferior, f. arcuatus* or *f. longitudinalis superior,* and *f. baseos internus.* Later, when modern methods of making stained sections were developed, some of these systems, especially the *fasciculus longitudinalis inferior,* or the inferior longitudinal bundle, became of prime importance in the investigation of the visual pathway (*see* chap. IV, 2 [4], 3, 7 [4–10]). The callosal fiber system was also recognized as an independent anatomical entity. However, even the best authorities still remained silent about the connections of the cranial nerves with the cerebral cortex. (Burdach 1822, v. 2; Rolando 1828; F. Arnold 1838–42; *see also* chap. II, 12 [8].)

4. GRATIOLET'S INVESTIGATION OF THE FIBER SYSTEMS OF THE BRAIN.—During the beginning of the second half of the nineteenth century, the investigation of the brain was directed increasingly toward the cortex. Following the initial investigations of the fiber anatomy of the brain by Willis, Vieussens, Vicq-d'Azyr, Reil, Gall, Burdach, Arnold, and Foville, Gratiolet in a systematic study, chiefly of simian material, succeeded in bringing some degree of order into a subject which until then had been obscure (Gratiolet 1854, 1855; Leuret & Gratiolet 1857, v. 2, pp. 166, 179; portrait Fig. 92; for biography *see* Broca 1865). His technique consisted of "teasing" or careful dissecting of fixed and hardened specimens. By first removing the cortex and then gradually working deeper, he demonstrated the several layers or fiber systems which make up the subcortical white substance. These he found to be of several kinds: (1) the *fibres propres,* or short U-shaped association fibers connecting the adjoining gyri of the same hemisphere; (2) the anterior commissure; (3) the fibers originating from Reil's *corona radiata;* (4) callosal fibers; (5) radiations originating from the nerves related to special sensory functions; and (6) radiations from the "accessory ganglia," such as the quadrigeminal bodies, internal geniculate nucleus, and cerebellum.

5. DISCOVERY OF VISUAL RADIATION BY GRATIOLET.—Among these fiber systems passing to and from the cortex, that related to the optic nerve was of particular interest. It was believed in Gratiolet's time that this nerve had two chief "sources" or "roots": one in the quadrigeminal bodies, the other in the white medullary or zonal stratum that lines the dorsal face of the thalamus (*see* S. A. W. Stein 1834). In Mammals the second source was considered more important, and it was thought to be a direct continuation of the optic nerve. Beyond this, information did not go, and almost nothing was known about the pathway by which the visual impulses reach the cortex. Gratiolet's investigations seemed to indicate that the flat inner branch of the optic nerve or tract, after slipping beneath the medial geniculate nucleus, proceeded to the occipital pole of the cerebral hemisphere (Fig. 93). The thicker outer branch seemed to pass into the zonal stratum of the thalamus, where, after turning around the pulvinar, it continued in the oral direction. This root also surrounded the gray mass of the lateral geniculate nucleus. From it a small bundle passed directly to the superior colliculus. The bulk of its fibers, arranged in closely packed radii and rising from the outer edge of the lateral geniculate nucleus, was distributed along the entire superior margin of the hemisphere. The fibers of the optic tract, according to Gratiolet's interpretation, continued directly into the hemisphere, especially into the parietal and occipital lobes, where they spread in the form of a fan. The bundles of that fan, as they passed upward, gradually changed their position. Those from the outer division turned frontally, those from the inner division of the optic tract passed to the occipital lobe.

6. EFFECT OF GRATIOLET'S DISCOVERY ON VIEWS OF THE SIGNIFICANCE OF THE CEREBRAL CORTEX.—The visual pathway, as described by Gratiolet, offered several points worthy of attention. In the first place, the presence of a special sensory tract above the level of the brain stem was, for the first time, confirmed. This agreed with Flourens' experiments, which had demonstrated the importance of the cerebral cortex in the sensory functions, especially vision (*see* sec. 4 [4, 6], this chapter). Of equal

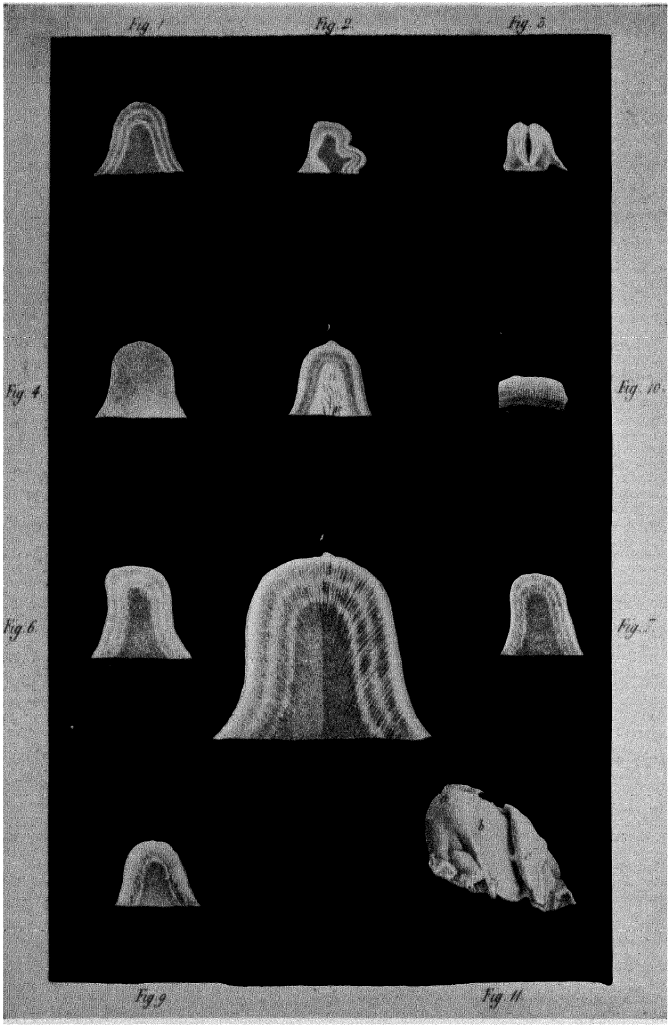

FIG. 88.—Another of Baillarger's plates showing local variation of structure in the cerebral cortex (*see* Fig. 87). ***Labeling:*** *1*, six alternating white and gray layers in Dog; *2*, same in **Cat**, partly visible; *3*, same in Rabbit, next to corpus callosum; *4*, homogeneous appearance of cortex of a newly born baby in incident light; *5*, same in transmitted light, with several opaque gray stripes and blood vessels at *v*; *6*, human cortex with two tiers of fibers in transmitted light; *7*, similar specimen of Pig with thicker and fewer fibers than in the preceding; *8*, composite and magnified figure, left half corresponding to *6*, right half to *7*; *9*, Dog cortex showing faint transverse or horizontal fibers, besides the radial; *10*, Rabbit cortex showing vertical fibers crossed at right angles by numerous transverse or horizontal fibers; *11*, convolution of human brain, with an outer layer *c* flapped over to the right side from the region *b*, leaving the region *a* intact.

significance was the fact that the visual pathway terminated in a distinct area of the cortex. Even though this area, as indicated by Gratiolet, was large, there remained a considerable portion of the cortex outside direct reach of these fibers. This was a significant advance over the theory, current until then, that the entire cerebral hemisphere was a uniformly organized substratum of homogeneous function (*see* Flourens versus Gall, in sec. 4, this chapter).

Gratiolet's discovery clarified the mystery that until then had enveloped the cerebral hemispheres, particularly the cortex. The fact that at least one of the principal sensory pathways, the visual, continued to the cortex lent substance to the idea of the paramount importance of the gray coat, of which many investigators in the past had been dimly aware (Willis 1664; Pourfour du Petit 1710; J. Ch. A. Mayer 1779; Gall 1809, 1810 19; Charles Bell 1811; Foville & Delaye 1820; Baillarger 1840).

The notion of the anatomists of preceding centuries that "the brain," by which they really meant the cerebral cortex, "neither sees, nor hears, nor feels" but in a way presides over these functions proved to be fallacious (*see* Du Laurens, chap. II, 9 [3]). Also, Gall's and Burdach's concept, generally adhered to during the first half of the nineteenth century, which grew out of Du Laurens' concept that the cerebral hemispheres were not directly related to the sense organs and hence were exclusively a substratum of the so-called "psychic functions" above the level of a mere sensory experience (Johannes Müller, Longet, Vulpian), had to yield to the force of contradictory anatomical evidence. In this way Flourens' experiments, which indicated the localization of vision in the cerebral cortex, were vindicated anatomically.

In the light of Gratiolet's observations, the cerebral cortex had to be recognized not as a kind of anatomical abstraction outside the somatic sphere but as the highest level of the nervous system, whose roots reach to the very confines of bodily organization.

SEC. 6. REVIVAL OF THE "DOCTRINE OF LOCALIZATION" OR FUNCTIONAL INEQUALITY OF THE CEREBRAL CORTEX

1. Discovery by Bouillaud of the cortical locality concerned with motor speech.—The idea of the functional omnivalence or equivalence of the entire cerebral cortex supported by the authority of Haller and Flourens reigned almost unchallenged throughout the greater part of the nineteenth century. Gall's premature and overly ambitious attempt to carry his "plurality doctrine" of cerebral functions to its logical consequence with insufficient means was not only no deterrent but lent positive support to the very idea he had tried to supplant. How firm and universal was the belief that the bulk of the brain, and especially the gray cortex, was structurally and functionally homogeneous is well illustrated by Gratiolet himself, who interpreted his anatomical discoveries in favor of Flourens, even though they pointed in the opposite direction (Leuret & Gratiolet 1857, p. 378).

The doctrine of cortical omnivalence, in spite of the high authority by which it was sustained, was, however, not accepted by all. In particular, certain observations accumulated by the clinicians disagreed with it. Flourens' teaching was first seriously questioned when Bouillaud (1825, 1839, portrait Fig. 94), leaving aside Gall's notion of the localization of "intellectual

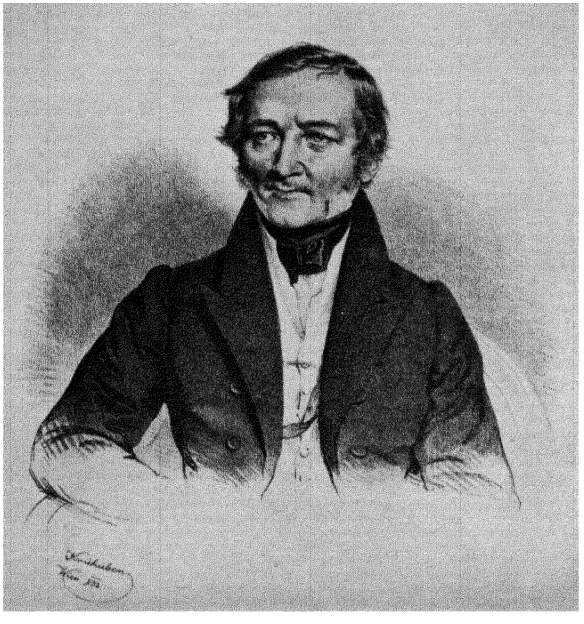

FIG. 90.—Karl Friedrich Burdach (1776–1847), professor of anatomy at Dorpat, Tártu or Yúryev, in Russian Estonia, and at Königsberg (now Kaliningrad), and Breslau (now Wrocław), both then in Prussia. Most encyclopedic writer of his time on the brain anatomy, physiology, and pathology and author of *Vom Baue und Leben des Gehirns*, in 3 vols., 1819–26. Pioneer investigator of the cerebral fiber systems: described the tapetum, cingulum, uncinate bundle, inferior longitudinal bundle, later recognized as the visual radiation, and the arcuate bundle, etc., of the brain, and the fasciculus cuneatus in the spinal cord and oblong medulla. Portrait and lithograph by Josef Kriehuber, 1832. From R. N. Wegner, *Das Anatomenbildnis*, 1939.

and moral faculties," applied his basic idea of functional plurality to the motor and sensory functions. Such a claim, in the first place, disputed the general aspect of Flourens' "equivalence doctrine." But, beyond this, Bouillaud's concept of the direct cortical influencing of the peripheral muscles was in outright opposition to Flourens, who, at most, admitted an indirect influence of the "will power."

A particular contention of Bouillaud was the dependence of the motor component of speech upon a definite locality of the cerebral cortex. He distinguished three components in spoken language. One was a specific function of coordination of auditory word images with the executive organs of speech, implying the presence of a cortical substratum of "motor word images," through which the act of speaking was brought about. This function of specific motor integration and its underlying mechanism differed both from the apperceptive or gnostic speech function (auditory word memory) and from the somatosensory and somatomotor mechanisms used in speech. In other words, Bouillaud assumed the presence of a cortical center for the co-ordination of the phonetic mechanism for the production of spoken words, a center of articulated language (a theory previously expressed by Gall). This "motor speech center" he, like Gall, localized in the frontal lobes (orbital surface). In support of his claim and against formidable opposition (Andral, Longet, Claude Bernard, Vulpian, *et al.*), Bouillaud was able to cite several cases from his own observation in which post mortem examination revealed a more or less extensive injury to the

FIG. 91.—Friedrich Arnold (1803–90), professor of anatomy in Zürich, Switzerland, and in Freiburg i.Br., Tübingen, and Heidelberg, Germany. Pioneer student of the human eye and nervous system, especially of fiber tracts of the brain. Described short or U-shaped association fibers, connecting adjoining gyri of the brain, and the "frontopontine tract of Arnold." According to a contemporary lithograph by M. Wieser, from R. N. Wegner, *Das Anatomenbildnis*, 1939. Courtesy Armed Forces Medical Library, Cleveland, Ohio.

frontal lobes, while the rest of the brain remained intact, and where other functions, with the exception of motor speech, had been unimpaired.

2. Bouillaud's concept of motor and sensory centers of the cerebral cortex.—Bouillaud's idea of the brain in general also appears surprisingly modern. In analogy with the motor speech center and based upon his experiments with various animals (1827), he postulated the presence of other motor and "intellectual"—now called sensory centers in the brain. There was, for example, a distinct center for vision, the destruction of which caused either impairment of sight or blindness, and a similar

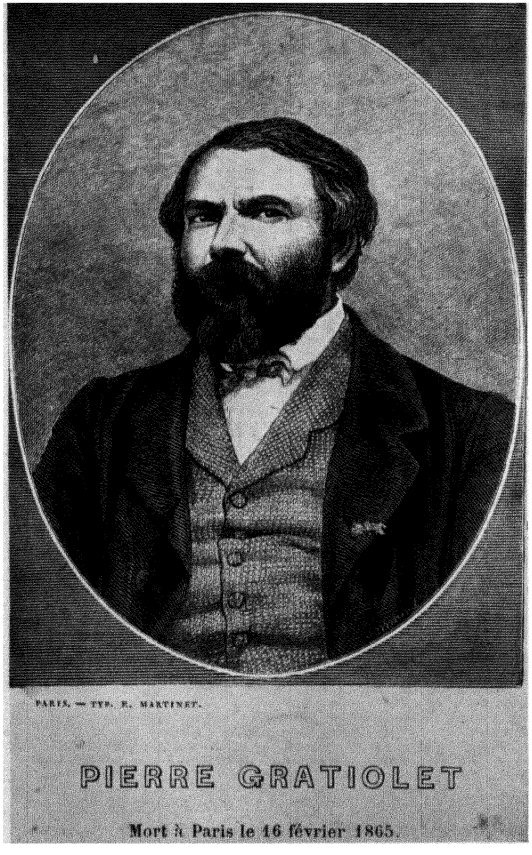

Fig. 92.—Louis-Pierre Gratiolet (1815–65), anatomist and physiologist of Paris. Prominent student of comparative anatomy of the brain. Systematically investigated fibrous core of the brain and described its principal constituent fiber systems. First disclosed the fibers of visual or "Gratiolet's radiation," along which the impulses pass from the eyes to the cortex of the brain. Frontispiece in Mém. Soc. Anthropol., Paris, v. 2. For biography *see* Broca in same vol., p. cxii. (*Cf.* Fig. 93.) For other biographies *see* J. de conn. méd., Paris, 1865, v. 32, p. 95; Bull. Soc. méd. de l'Yvonne, Auxère, 1866, pp. 33–54, and 1868, pp. 17–37; Gaz. hebd. de méd., Paris, 1865, 2d ser., v. 2, pp. 161, 177; Union méd., Paris, 1865, 2d ser., v. 25, pp. 353–62; Wien. med. Wchnschr., 1865, v. 15, p. 345; and Gaz. d. Hôp., Paris, prob. 1865.

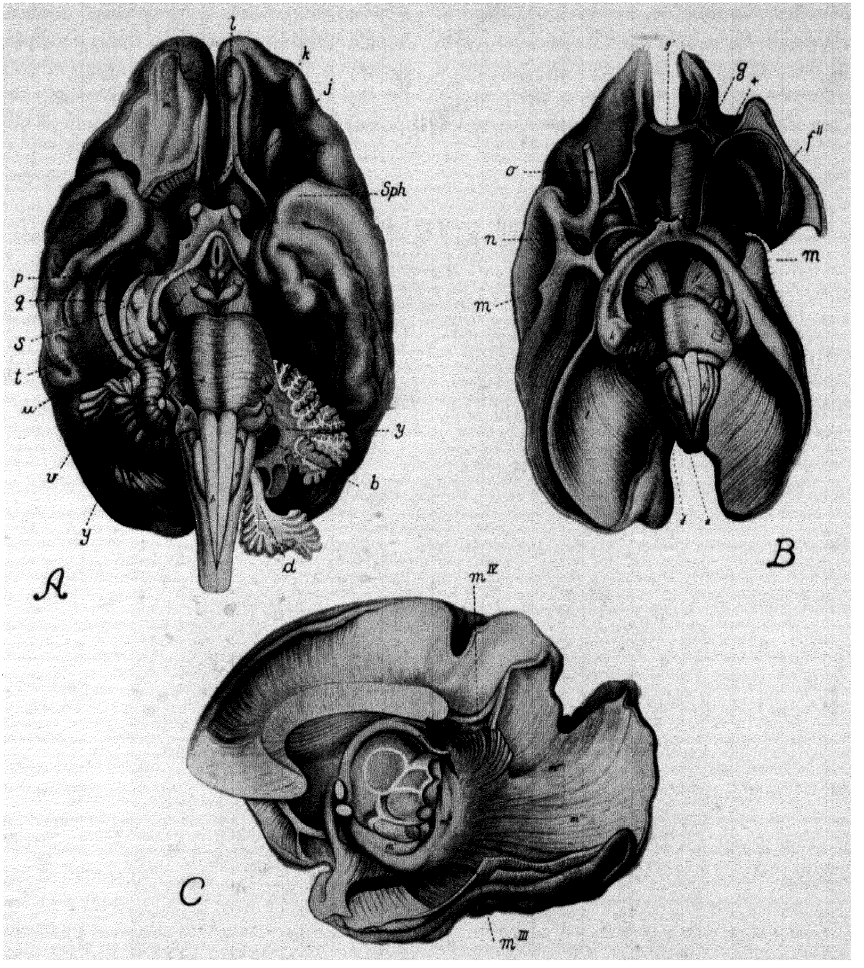

FIG. 93.—Visual pathway of Baboon *Papio* and of Capuchin Monkey, dissected by Gratiolet (1857). In this work, for the first time, a connection was shown between subcortical visual centers and cerebral cortex, the so-called "visual or optic radiation of Gratiolet"; and the importance of the cortex as the uppermost level in the cerebral hierarchy was anatomically demonstrated.

Labeling: *A*, view of the brain from below, with a part of the right temporal lobe removed to show the entry of optic tract *o* into subcortical visual centers: lateral geniculate nucleus (*s*) and pulvinar of thalamus (*t*); *B*, basal view of the dissected visual system of both hemispheres showing junction of optic nerves in the chiasma (*h*), external and internal "roots" of optic nerve (*i*, *j*), external or lateral geniculate nucleus (*k*), and the apparent continuation of optic nerve as a "visual radiation" (*l*) to the occipital lobe; *C*, medial view of right hemisphere showing visual pathway after removal of obstructing parts: the optic tract (*m*), inner and outer root of the same (m^I, m^{II}), the latter enveloping the external geniculate nucleus, with fiber fan of visual radiation (m^{III}) streaming toward the occipital lobe at right; m^{IV}, anterior fibers of radiation mingling with callosal fibers. From a specimen "teased" or dissected with needles, after a preliminary maceration. From Leuret & Gratiolet, *Anatomie comparée du système nerveux* (*atlas*), 1857, Pls. 26 and 27.

auditory center. The makeup of the somesthetic system, he believed, was more complicated. Here each nerve, related to a particular region in the periphery of the body, terminated in a discrete portion of the brain, a lesion in the area of termination causing impairment of sensation in the corresponding territory. The concept of functional cerebral localization, as formulated by Bouillaud, was first extended to each of the several "primary" or "elemental" functions, such as the motor, somesthetic, visual, and auditory. Furthermore, Bouillaud assumed the principle of "projection," or somatotopic representation of the peripheral receptor surfaces in the cerebrum, so far postulated only for the visual system (Ibn al-Haitham, Des Cartes, Briggs, Taylor; *see* chap. II, 6 [2], 10 [2], 11 [2, 6], and Figs. 71, 74), to be valid also for the somesthetic system, long before Meynert gave it a more concrete definition and Munk proved it experimentally. In this way the problem of cerebral functional localization,

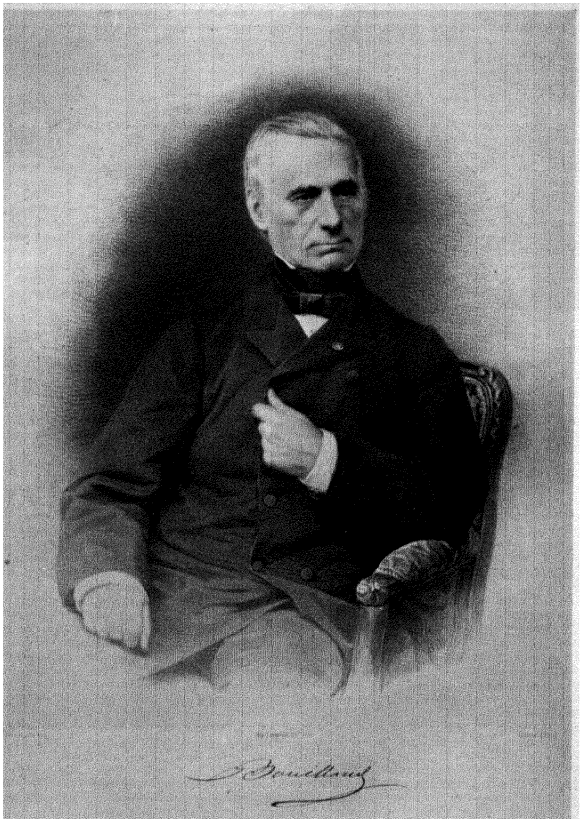

FIG. 94.—Jean Bouillaud (1796–1881), professor of medicine in Paris. Follower of Gall and a precursor of Broca in the cerebral functional localization. From an engraving by Bornemann. initiated by Gall's fantastic system, assumed for the first time a concrete form suitable for further research along modern scientific lines.

3. FURTHER ATTEMPTS TO LOCALIZE MOTILITY, VISION, AND SPEECH IN THE BRAIN.—Bouillaud was not alone in claiming the functional diversity of the cerebral cortex. A few other pioneers of that period, in France and elsewhere, accepted the idea of cerebral functional localization, which to them seemed to promise more fruitful results than could be expected from an essentially negative concept of "cortical functional omnivalence." Foville & Pinel-Grandchamp (1825), for example, noticed distinct impairment of motor, or somesthetic, functions in cases of cerebral lesions. Paralysis of a single limb meant to them that each had a separate center in the brain. The arm center, they believed, was in the thalamus, the leg center in the corpus striatum. Subsequent investigations showed this to be an error, but the idea of functional diversity of the cerebrum was kept alive through their efforts during a period which otherwise was mostly ill disposed toward it.

About the middle of the nineteenth century, Panizza (1855–56), in Italy, clearly under the influence of Gall's ideas, made a series of experiments with the visual system and studied cases of impaired sight in cerebral lesions. His work convinced him that the faculty of vision depended upon the posterior portion of the hemisphere and that the bilateral destruction of this locality produced complete blindness without affecting other cerebral functions. Unfortunately, Panizza's work failed to impress contemporary scientific thought, which was still almost entirely dominated by Flourens' doctrine of cortical functional omnivalence (*see* sec. 4, par. 2, this chapter, and chap. IV, 1).

Bouillaud's idea of cerebral organization received powerful support in Broca's discovery of a "motor speech center" (1861 and later, portrait Fig. 95; for biography *see* Broca 1880). Instead of localizing it in the orbital surface, as Gall and Bouillaud did, however, Broca placed this particular "center" in the posterior third of the left inferior frontal gyrus (Fig. 274). When this locality suffered damage, it resulted in "aphemia," now known as motor aphasia (Trousseau) or apractic aphasia (Nielsen), a kinetic apraxia of speech in Liepmann's sense, that is, an inability to pronounce words, with understanding of spoken or written language more or less preserved and with other functions of the mouth, tongue, and throat, such as mastication and deglutition, remaining normal; (in left-handed persons the motor speech center is commonly assumed to be in the right frontal lobe; for references *see* Moutier 1908; Monakow 1914; Nielsen 1946). The idea of functional cortical localization gained further support in the obvious structural diversity of the brain in general, and in particular in the structural variation of the cerebral cortex noticed by Gennari (1782), Baillarger (1840), Meynert (1866, 1868, 1869), Charcot (1876–80), and others, until it was considered a firmly established fact (*see* chap. IV, 7). In retrospect, powerful support of the same concept was derived from the numerous clinical and pathoanatomical observations of J. Hughlings Jackson (1861–88, portrait Fig. 106), the noted English neurologist.

4. DISCOVERY OF SOMATOMOTOR AREA BY HITZIG.—The efforts of Bouillaud, Panizza, Broca, Meynert, and Hughlings Jackson, forming a continuous chain of evidence, did little at the time to dislodge the firmly intrenched "doctrine of cortical functional omnivalence." Most contemporary investigators, especially physiologists, unable to elicit movements of the limbs or any other visible manifestation by stimulation of the cortex in living animals or at most observing generalized, unco-ordinated convulsions and seeing no definite impairment or loss of well-defined function in cases of a partial destruction of the cortex, persisted as before in favoring Flourens' doctrine of the unexcitability and functional equivalence of the entire cortex. (Longet, Claude Bernard, Vulpian, Schiff *et al.*)

This situation changed radically when Hitzig (1870, portrait Fig. 96), in collaboration with Fritsch, in experiments on dogs showed that motor response of the contralateral limbs may be elicited by electrical stimulation of a certain cortical area of the frontal portion of the brain. In the Monkey, as he later found (1873), this area corresponded to the precentral gyrus (Fig. 280). Hitzig's observation that when a liminal stimulus was applied, the response was restrict-

ed to one or to a few muscles was significant in contrast to the generalized convulsions regularly obtained by Rolando (*see* sec. 4 [1], this chapter). The discovery of the presence of small excitable motor foci was further amplified by Hitzig's observation that the limb whose excitable cortical focus was destroyed became paralyzed (duplication of Pourfour du Petit's observation made in 1710).

Hitzig's discovery was subsequently confirmed and variously augmented by numerous experimenters and observers of human pathological cases. In this way not only the presence of the cortical motor and somesthetic areas was demonstrated but also their composition of minute foci. In the motor area such foci represent individual muscles and muscular groups or, more correctly, particular detailed motions; in the somesthetic area the foci represent restricted portions or segments and parts of seg-

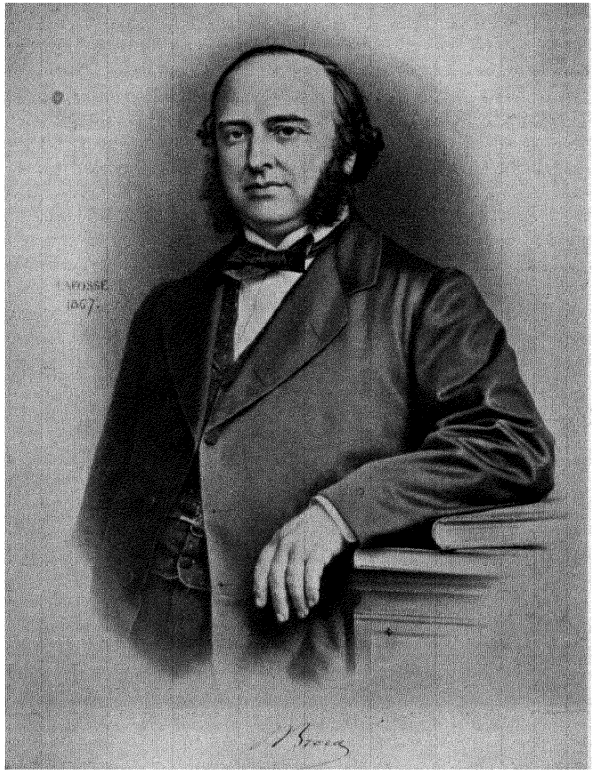

FIG. 95. Paul Broca (1824-80), professor of pathology at the University of Paris, at the age of forty-three. Famous as a brain anatomist and exponent of the idea of functional cerebral localization. First indicated the area in the lower portion of the left frontal lobe of brain on which the faculty to pronounce words, or "motor speech," in the normal right-handed persons, depended: "Broca's area" or "Broca's speech center." A pioneer anthropologist and craniologist. From an engraving by I. Lafosse, 1867. Courtesy Crerar Library, Dr. Sonnenschein Collection, Chicago. Biography by G. Cordier, in Dumesnil & Bonnet-Roy, v. 3, 1947; and Haymaker & Baer, *The Founders of Neurology*, 1953.

ments of the surface and of the deeper parts of the body. In this way, albeit belatedly, the essential ideas which Bouillaud had championed several decades earlier were ultimately vindicated. (For modern investigations of cortical representation of somaesthetic and motor functions *see* Ph. Bard; Bartholow; Bechterew; Leyton & Sherrington; Luciani; Luciani & Seppilli; Luciani & Tamburini; Mankowski; Marshall & Bard; Marshall, Woolsey & Bard; Mott, Schuster & Sherrington; Munk; Penfield; Penfield & Boldrey; Penfield & Erickson; Scarff; Schäfer; Sciamanna; C. & O. Vogt; Woolsey; Woolsey & Bard; Woolsey & Walzl.)

FIG. 96.—Julius Eduard Hitzig (1838–1907), professor of psychiatry at Halle a.S., Germany. His discovery, made 1870 conjointly with G. Fritsch, of electrically excitable foci in the cerebral cortex whose stimulation produces movements of various groups of muscles, limbs, etc., opened up the era of modern brain research. 5. OVERTHROW OF THE "OMNIVALENCE DOCTRINE" AND ITS REPLACEMENT BY THE "THEORY OF FUNCTIONAL CEREBRAL LOCALIZATION."—The discovery of the "motor area" in the cerebral cortex by Fritsch & Hitzig disposed of the hitherto dominant thesis of the unexcitability

of the cerebral cortex (Wepfer, Lorry, A. Haller, Rolando, Magendie, Flourens, Longet, Claude Bernard, Vulpian, Schiff, Brown-Séquard, *et al.*). Most important, however, Hitzig's work demonstrated an unequal physiological or functional significance of different localities of the cerebral surface, in opposition to the doctrine of functional equivalence.

In consequence of Hitzig's discovery and against formidable opposition (Schiff, Brown-Séquard, Goltz, *et al.*) numerous investigations were undertaken during the following decades, in Man and other Vertebrates, through which the principal "centers" in the cerebral cortex—somesthetic, visual, auditory, and others—were discovered. Also, certain localities concerned with definite "psychic" functions, such as memory for spoken or written language, music, and visual objects and the ability to execute skilled movements, such as writing or instrument playing, and many others, were more or less accurately plotted (*cf.* chap. VIII, 1 [4], and Figs. 274, 275).

These discoveries brought about a great change in the entire concept of the minute organization and function of the brain and of the nervous system in general. It became understood that "mind" or "intellect" was not a single, total, indivisible function of the entire cerebrum but a composite of numerous partial functions, many and perhaps all of which were bound to distinct localities of the cerebral cortex and subcortical regions and variously interlinked among themselves.

The discovery of excitable foci by Hitzig was, in a sense, the first experimental vindication of the principle of functional localization in the cerebral cortex, propounded by Gall and adhered to by a few advanced thinkers. But not all tenets of the "doctrine of cerebral functional plurality" were substantiated. The idea of the cortex as an exclusive repository of functions and faculties usually termed "higher" or "psychic" had to go.

In the light of Hitzig's disclosures, it became apparent that the huge mass of the gray substance which is the cortex of the cerebral hemispheres was as much an anatomical substratum of the "simple," "primitive," or "elemental" nervous functions, such as sensation and motility, and therefore an integral part of the bodily machine, as it was an instrument of those elusive phenomena and subjective experiences called "psychic" or "mental," to which ordinary terms and measures used in anatomy and physiology are not applicable.

SEC. 7. EARLY ATTEMPTS TO LOCALIZE THE SENSE OF VISION IN THE CEREBRAL CORTEX

1. VAGUENESS CONCERNING PROBABLE LOCATION AND BOUNDARIES OF THE CORTICAL AREA RELATED TO VISION.—The initial efforts to identify the locality and to delimit the area of the cerebral cortex related to sight produced, at best, only vague results. For this the blame lay with the anatomists of the preceding period. The terminal area of visual radiation indicated by Gratiolet (1854; *see also* Leuret & Gratiolet 1857), including, as it did, the entire occipital and part of the parietal lobes, was too large to be of great value to an experimenter (*see* sec. 5 [5, 6], this chapter, and Fig. 93). On the other hand, Meynert (1869), while emphasizing the termination of the radiation in the occipital lobe and disclaiming such in the parietal, unfortunately maintained that almost the entire temporal lobe was also related to the visual pathway. This may in part explain the varied and often quite opposite views expressed during the subsequent period concerning the precise locality and extent of the cortical visual center.

First among the modern localists, Bouillaud (1827), while obtaining evidence of functional cerebral localization in general, failed to indicate the seat of the visual or any other sensory center (*see* sec. 6 [2], this chapter). Andral (1840), although not opposed to the principle of localization, had not found any evidence of a visual center in the pathological cases he had collected.

B. Panizza (1855–56) seems to have been the first to notice an impairment of sight in localized experimental brain lesions. Both in his experiments with dogs and in human pathological cases where the "parietal" lobe was destroyed, he noticed blindness in the contralateral eye, as he interpreted it, which, in fact, must have been homonymous hemianopia (*see* sec. 9 [4, 6], this chapter). Significantly, this was precisely the locality where, according to him, the fibers of the optic nerve "originate" (whether this anatomical knowledge was the fruit of Panizza's own effort or was obtained from Gratiolet is not clear). When both the "parietal" (really the occipital) lobes were damaged, the result was complete blindness (*see also* sec. 6 [3], this chapter, and chap. IV, 1 [1]).

Next to consider the problem of visual localization was F. H. Chaillou (1863). In one case of homonymous hemianopia observed by him the lesion involved the occipital lobe (for details, *see* chap. IV, 1 [1]). These observations of Panizza and Chaillou, few as they were and made by relatively obscure investigators, carried no weight against the general trend of the time, which, supported by the authority of Flourens, opposed localization. (*See also* chap. IV, 1 [1].)

2. LOCALIZATION OF VISION IN THE ANGULAR GYRUS BY FERRIER.—Of greater consequence, closely following, as they did, the striking discovery of Fritsch & Hitzig (*see* preceding section), were the experiments of David Ferrier (1873 and later, portrait Fig. 97). Having observed that when the angular gyrus of the Monkey is stimulated by electricity, conjugate movements of the eyes to the contralateral side result, he declared it to be the visual center. Later, finding that a bilateral destruction of the angular gyrus alone was not sufficient to cause complete and permanent blindness, for which it was necessary to destroy the occipital lobes also, Ferrier thought that the area concerned with the visual function included both. He thought the angular gyrus to be more important, since in his opinion this locality was related to the centers of the visual fields, or "maculae." The occipital lobes, Ferrier contended, may be injured, or "cut off bodily, almost to the parieto-occipital sulcus, on one or on both sides simultaneously, without the slightest appreciable impairment of vision."

3. PROBABLE CAUSES OF FERRIER'S MISTAKE.—Examined in the light of present knowledge, Ferrier's experiments appear crude and their post mortem anatomical control inadequate. The most likely factor to have caused the impairment of visual function following injury to the angular gyrus was an interference with the branches of the middle cerebral artery which supply the underlying visual radiation, as had been pointed out previously by Starr (1884) and by Schäfer (1888; *see* chap. VII, 3, 8, and

chap. X, 4). Another misleading factor was the absence of a noticeable impairment of vision in the Monkey after a bilateral destruction of the occipital lobes. This may be explained by the relatively small size of the central scotomas caused by the removal of the "macular" cortex over the occipital operecula (a similar observation was made in Klüver's experiments, private communication; *see also* chap. IV, 7 [3]).

connection (*see* Ferrier's scheme, 1886, and compare with Figs. 400 and 401 in this book). According to his hypothesis, not all fibers related to the temporal halves of the retinae, which we now know remain uncrossed in the chiasma, pass in the midbrain to the opposite hemisphere, as was assumed by Landolt (1875) and Charcot (1876–80), but only those related to the "areae of clear vision," that is, to the foveae

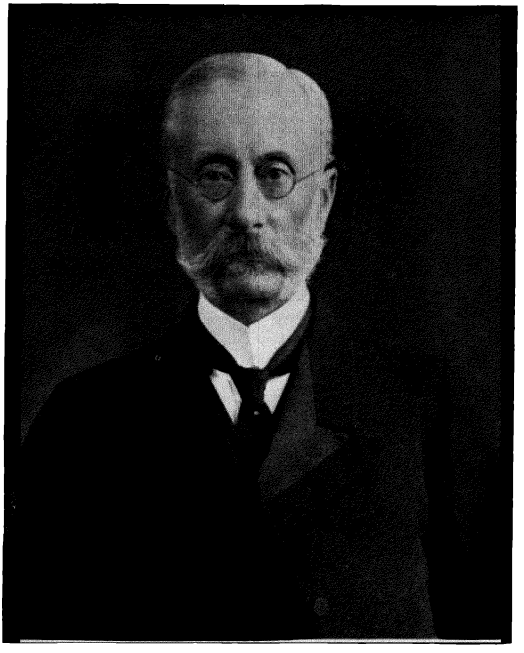

FIG. 97. David Ferrier (1843–1928), pioneer of modern experimental brain research. Photo by Maull & Fox, 187 Piccadilly, London, W., received from Professor J. F. Fulton, of Yale University, New Haven, Conn. For biography *see* Haymaker & Baer, *The Founders of Neurology*, 1953.

4. FERRIER'S EXPLANATION OF "CENTRAL SPARING" IN HEMIANOPIA.- Ferrier missed, at first, the hemianopic character of the visual disturbance after a unilateral lesion of the brain. Subsequently (1881), under the pressure of contrary evidence furnished by Luciani & Tamburini (1879) and others, he acknowledged that in such cases both eyes were affected. His interpretation of "central or macular sparing" in homonymous hemianopia is interesting in this

or "maculae" of the two retinae (*cf.* sec. 9 [6], this chapter).

This view, illogical and contrary to the facts, has never been substantiated by any unequivocal anatomical and clinical evidence. In spite of this, however, the idea of a partial crossing or recrossing of the visual fibers at the level above the midbrain in the corpus callosum, for example, was later taken over by Wilbrand, Heine, Niessl von Mayendorf, R. A. Pfeifer,

O. Foerster, and others in their search for an explanation of "central sparing" in hemianopia. For this purpose they devised a hypothesis of bilateral total representation of each central fovea in both cerebral hemispheres, to be discussed elsewhere in this book (*see* chap. IV, 1; chap. VI, 4, 5, 11; and chap. XI, 8, 9).

5. The significance of Ferrier's investigations for functional cerebral localization.– For one point—his firm conviction of the existence of a well-defined cortical region concerned with the visual function and in spite of his mistakes, Ferrier is entitled to unreserved praise. Also noteworthy was the general conclusion to which he was led through his researches: "that a functional equivalence or indifferentism of the various regions of the cortex and the theory of one region compensating for the loss of another are assumptions which involve anatomical impossibilities." In this way Ferrier boldly attacked the "doctrine of functional equivalence" of the entire cerebrum.

6. Revival of the cortical "equivalence doctrine" by Goltz and the hypothesis of "vicarious function."—Ferrier's claim to have discovered the principal centers in the cerebral cortex (motor, somesthetic, acoustic, visual, olfactory, gustatory, and others) precipitated a series of investigations whose purpose was to test and possibly to correct, or to refute, his observations.

Goltz (1875 and later), repeating Ferrier's experiments, arrived at different conclusions. For, irrespective of the part of the brain operated upon, the consequent disturbance, he claimed, was the same, always concerning more or less all functions, sensory as well as motor. The only difference was in degree, which in turn depended upon the quantity or amount of the substance destroyed. The reality of the cortical "centers," both sensory and motor, Goltz denied altogether, insisting that each cortical locality was related to all motor and sensory nerves of the body. Small lesions or even large ones, such as the removal of one-fourth of the brain, in Goltz's opinion, produced little impairment of either the motor or the sensory functions. This he interpreted as resulting from a "substitution" or "vicarious function" of the remaining portions of the brain (*cf.* Flourens, in sec. 4 [4], this chapter). Hitzig's and Ferrier's discoveries, through which functional localization in the cerebral cortex seemed to have been placed upon a solid basis, were again questioned in the light of Goltz's experiments, and the old doctrine of "functional equivalence" of Haller and Flourens was revived.

It is noteworthy that Goltz's exposition found a responsive audience. The prejudice against the novel idea of functional cerebral localization was obviously still deeply ingrained and was strong enough to influence many to disregard the glaring inadequacies of Goltz's technique, as well as his argumentation. And his technique was extremely crude: washing out parts of the brain with the help of a stream of tap water forcibly introduced into the cranial cavity, with no regard for the structures intended to be removed or those to be left intact or with any consideration of such factors of general pathology as infection. Even after Goltz had improved his technique, it would have been nothing short of a miracle, had his badly conceived and ineptly performed experiments resulted in anything but interference with the working of the entire brain.

SEC. 8. LOCALIZATION OF VISION IN THE OCCIPITAL LOBE

CORTICAL AND MENTAL BLINDNESS

1. Munk's critique of Goltz's experiments.—The challenge to the emergent modern concept of functional cerebral localization, which, in spite of a slight concession to it, the views of Goltz and other advocates of the "omnivalence doctrine" represented, was ably taken

up by Munk (1876, 1877 and later; portrait Fig. 98). The objections to Goltz's work were directed both against the substance of his doctrine and against his technique. To Munk it seemed inconceivable that "whereas in the lower centers the best harmony rules, on the upper levels there should be a complete confusion." Also, it was obvious that, with his opponent's experimental technique, no localized lesions were possible, since, because of increased intracranial pressure and infection, all parts of the brain were necessarily interfered with. Goltz's experiments were, according to Munk, of no value as evidence against the concept of functional localization in the cerebral cortex.

FIG. 98. Hermann Munk (1839–1912), professor of physiology at the Veterinary Hochschule in Berlin. Pioneer in experimental investigation of the cerebral functional localization. First furnished the evidence in favor of localization of visual function in the occipital lobe of the brain and of auditory function in the temporal lobe. Defined mental or psychic blindness as distinct from cortical blindness. First proved experimentally the retinotopical or "point-to-point" organization of visual centers in the cerebral cortex. From Deutsch. med. Wchnschr., v. 35, p. 258, 1909. For obituary *see* Neurol. Centralbl., v. 31, p. 1343, 1912. (*Cf. also* Figs. 99, 100.)

2. DISCOVERY OF MENTAL OR PSYCHIC BLINDNESS BY MUNK. From his own experiments Munk found that the anterior half of the cerebral hemisphere serves the motor functions and the posterior half the sensory functions. In particular, when in the posterior sensory sphere the occipital lobe was superficially damaged close to its pole, a locality which he labeled A_1, or the "visual area" (Figs. 99, 100), the result was a remarkable psychic disturbance of a transient character, which within four, five, or six weeks disappeared completely: *Seelenblindheit* or "mental or psychic blindness," subsequently renamed "visual agnosia."

This defect manifested itself in an inability to understand the meaning or significance of visual objects which were familiar before the operation, although the same objects were recognized by means of other senses, e.g., hearing or smell. The behavior of the animal was the

more remarkable, since signs of true blindness were absent: the animal apparently saw objects and was able to avoid running into obstacles, their symbolic meaning alone having been lost. In the course of time, however, the animal gradually relearned the significance of objects and persons seen, passing through a process of learning similar to that of young animals, although requiring less time. This visual disturbance Munk interpreted as caused by the loss of traces of past visual impressions or experiences, or mnemonic engrams (*Erinnerungsbilder*). (For human pathology *see* chaps. XI, XII.)

3. Definition of cortical blindness.— The same area A_1 on the lateral face of the occipital lobe in the Dog, Munk assumed, represented also the locus of distinct or direct vision

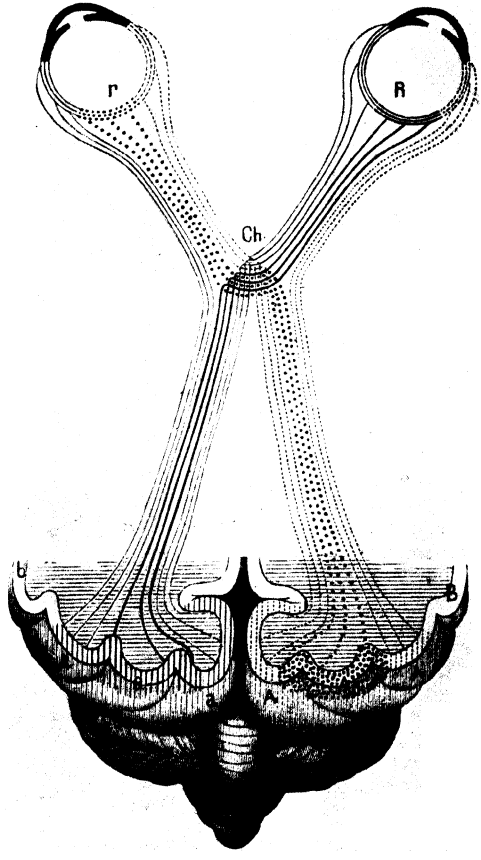

Fig. 99.—The representation of the retinae in the visual pathways and centers of the cerebral cortex in Dog, according to Munk (1879). *Labeling: AA*, right visual area; *aa*, left visual area; A_1 and a_1, centers of visual areae whose destruction supposedly produces "mental or psychic blindness"; *B* and *b*, auditory areae; *Ch*, chiasma of optic nerves; *R*, *r*, right and left retinae. Note that according to this scheme the ipsilateral and contralateral homonymous or "identical" portions of both retinae do not coincide, as now accepted, but are distinctly represented in the same area. (*Cf.* Fig. 100.)

in the field of view, homologous with foveal or "macular" vision in Man. When the occipital lobe was more extensively damaged or removed bodily, the result was not only loss of visual memory but true blindness. Munk thought at first that in the Dog the blindness concerned only the contralateral eye, thus repeating the erroneous interpretation of Pourfour du Petit, Flourens, Panizza, and Ferrier. In the further course of his work (1878, 1879), in both the Dog and the Monkey, because of a partial crossing in the chiasma found by Gudden, Munk recognized the defect to be homonymous hemianopia (this symptom was first, but less clearly, produced experimentally by Luciani & Tamburini 1877). When both occipital lobes were destroyed, the result was complete and permanent blindness. The blindness caused by destruction of the visual area of the cerebral cortex Munk named *Rindenblindheit*, or "cortical blindness," in contrast to the "mental or psychic blindness" described above.

4. RETINOTOPICAL ORGANIZATION OF THE CORTICAL VISUAL AREA.—Concerning the detailed relationship of the visual receptor organ —the retina—to the visual cortical area, Munk concluded that "the central elements of the visual area, where the optic pathway terminates and where perception takes place, are arranged in an orderly manner and continuously, as are the receptors in the retina where the fibers arise, viz., that the adjoining retinal units remain close to the same units in the cortex." With this, the problem of the cerebral representation of the retina was formulated, and a basis was given for subsequent investigations of the visual pathway (*see* chap. II, 10, 11 [2 & 6], and chap. IV, 4).

5. OCCIPITAL LOCATION OF THE VISUAL AREA. —In opposition to Ferrier (*see* sec. 7 [2], this chapter), Munk found the visual center in the Monkey to be limited to the occipital lobe. Destruction of the occipital lobe produces a visual disturbance—contralateral homonymous hemianopia if the lesion is unilateral; complete and permanent blindness if it is bilateral. Munk found the angular gyrus, where, according to Ferrier, the most distinct vision corresponding to the fovea or "macula" was represented, to be a sensory-motor center for contralateral conjugate eye movements and for the winking reflex (*see* Munk & Obregia 1890).

6. EFFECT OF MUNK'S WORK ON SUBSEQUENT BRAIN RESEARCH.—Munk's discoveries and his interpretation had a profound effect upon contemporary students of cerebral anatomy, physiology, and pathology, as well as psychology. In summary, they demonstrated, first, the localization of the distinct motor, somesthetic, visual, and auditory functions in particular regions of the cerebral cortex and, second, that both the "higher" or "psychic" and the "elemental" receptor and motor functions were located in the cortex.

Enthusiastically accepted by most, Munk's observations encountered an equally skeptical attitude in others. The errors in detail, e.g., Munk's assumption of separate representation of the ipsilateral and contralateral homonymous halves of the two retinae in the cortex, both in the Dog and in the Monkey, and the localization of the visual center on the lateral face of the occipital lobe in the Dog, however, in no way diminished the effect of his researches as a powerful stimulus to the further investigation of the brain in general and of the visual system in particular (*see* chap. IV, 4, 5).

Sachs 1895; E. A. Schäfer 1887, 1888, 1889; Siemerling 1890; Soury 1899; Vitzou 1888, 1893; Weigandt 1900, 1901; Wilbrand 1887.

SEC. 9. EARLY MODERN INVESTIGATION OF THE INFRANUCLEAR DIVISION OF THE VISUAL SYSTEM

1. BEGINNINGS OF MODERN OPHTHALMONEUROLOGY.—The modern period of investigation of the visual system, like that of modern ophthalmology in general, began with the discovery of the ophthalmoscope by Helmholtz (1851, Figs. 101, 102), the introduction of the plotting

of fields of vision by Albrecht von Graefe (1856, portrait Fig. 103), and the invention of the perimeter by R. Förster (1867, portrait Fig. 104). The ophthalmoscope furnished the means of examination of the intraocular structures in the living—an advantage which inaugurated a new epoch in ophthalmology: in Graefe's own words, "Helmholtz has revealed to us a new world!" Perimetry made possible an accurate quantitative measurement of the visual functions and in pathological conditions, conjointly with anatomical considerations, the diagnosing of the seat of the lesion along the intra- and extracranial portions of the visual pathway.

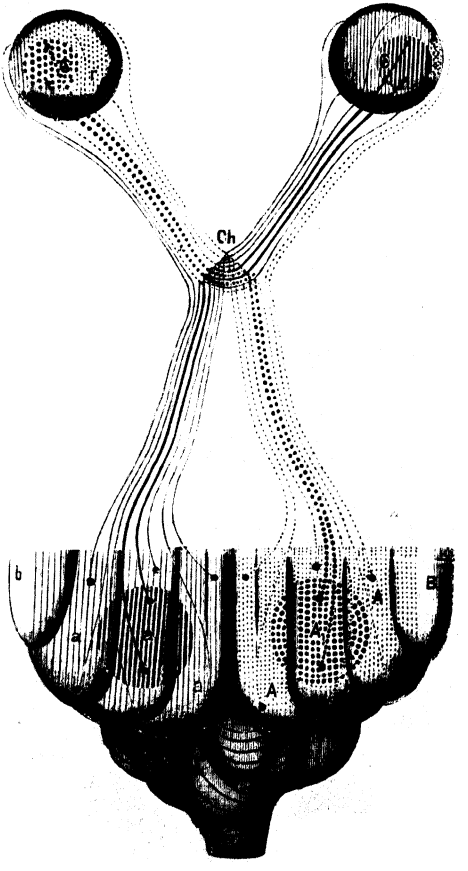

FIG. 100.—Representation of the two retinae in the visual pathways and cortical areae of Dog, according to Munk (1879). *Labeling: AA*, right visual area; *aa*, left visual area; A_1 and a_1, centers of visual areae whose destruction supposedly produces "mental or psychic blindness"; *B* and *b*, auditory areae; *C* and *c*, centers of the retinae, or central foveae ("maculae"); *Ch*, chiasma of optic nerves; *R* and *r*, right and left retinae. Note separate representation in each visual cortical center of the right and left homonymous or "identical" retinal halves, instead of in a coextensive territory, as now accepted. Each fovea or "macula," according to this diagram, is represented in the contralateral hemisphere only. (*Cf.* Fig. 99.)

These modern clinical methods of examination of the visual organs and their functions, combined with anatomy, physiology, and pathology, offered the means for a detailed analysis of the intrinsic organization of the visual system. (For biographies *see* F. Hübotter 1929 35; L. Königsberger; E. Michaelis 1877; J. Hirschberg; W. Schwagmeyer; for additional information on perimetry *see* J. Bjerrum 1884, Cushing *et al.*; H. Rønne 1911, 1917, 1921, 1924, 1927; C. W. Rucker 1946; Rucker & Keys 1950; Traquair 1946; C. B. Walker 1913, 1917, 1921, 1929; W. P. C. Zeeman 1925.)

2. THE SEARCH FOR THE SUBCORTICAL VISUAL CENTERS. Until long after the middle of the nineteenth century, no great progress was made toward solving the perennial problem of the "origin" of the optic nerves, beyond what Gall, Burdach, Stein, Gratiolet, and those who preceded them had known. According to the pres-

FIG. 101.—Hermann Ludwig Ferdinand Helmholtz (1821–94) in his younger years. Professor of physiology at Königsberg (now Kaliningrad), Bonn, and Heidelberg, and professor of physics at Berlin, Germany. Inventor of the ophthalmoscope (*see* Fig. 102). Authority on physiological optics, acoustics, electrophysics, etc. One of the most brilliant personalities in modern science. Portrait from his biography by L. Koenigsberger, 1902–3. (*See also* Fig. 356 and legend.)

entation of Panizza (1855–56), Meynert (1869, 1872), Gudden (1869, 1870, 1874, 1875, 1879, portrait Fig. 105), Forel (1872), Huguenin (1875, 1878), Tartuferi (1878, 1880, 1882), Henle (1879), J. Stilling (1880, 1882), Wilbrand (1881), Ganser (1882), Monakow (1889 and

later), Bernheimer (1889, 1891), and others, there are three principal subcortical stations related to the optic nerves: the lateral geniculate nucleus, the pulvinar of the thalamus, and the superior colliculus of the midbrain. There was, however, some uncertainty as to whether the medial geniculate nucleus, the thalamus proper, Luys's body, the inferior collicus, the pons, and the tuber cinereum of the hypothalamus should not also be included. Flechsig (1896), employing a more efficient technique, expressed doubts that any optic nerve fibers reached the thalamus proper (*see* chap. IV, 2 [3]). Dimmer (1899), applying the Marchi method to a human specimen, also found that most optic fibers terminated in the lateral geniculate nucleus; only a few in the superior colliculus; and hardly any in the pulvinar of the thalamus.

At this time little was known of the finer

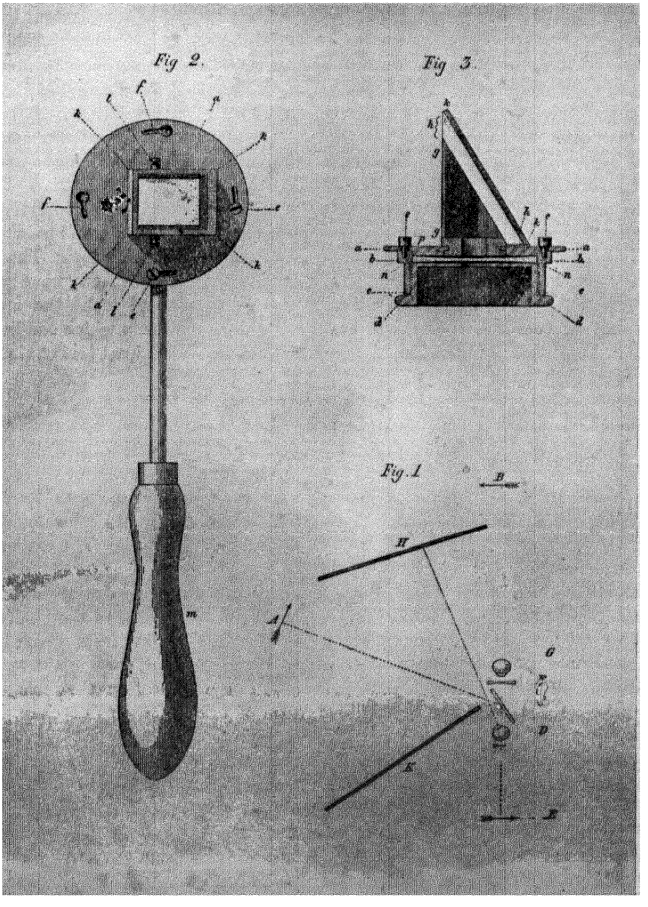

FIG. 102.—Original ophthalmoscope or "eye mirror" invented by Helmholtz (1851), an instrument that laid the foundation for modern ophthalmology. *1*, explanation of its principle; *2*, instrument assembled for use; *3*, horizontal section of the ophthalmoscope. (*See* W. Schwagmeyer 1952, and preceding figure.)

structure of the subcortical visual centers. The peculiar alternating cell and fiber layers or laminae of the lateral geniculate nucleus were first hinted at by Burdach (1822; *see* chap. II, 12 [6]). Burdach's casual remark, however, was forgotten until the laminar structure of this nucleus was more accurately described by Meynert and by Henle. Meynert's interpretation was that, of each two medullary laminae, one belonged to the tract and the other to the visual radiation, with one cellular lamina between them (*cf.* chap. VI, 6 [6]).

3. PARTIAL VERSUS COMPLETE DECUSSATION IN THE CHIASMA OF THE OPTIC NERVES. The other vexing problem—the structure and the functional significance of the optic chiasma—remained, as before, in a state of confusion, in spite of the greatly increased interest in this problem (*cf.* chap. II, 11 [3]; 12 [3, 4]). The majority of early modern anatomists, physiologists, and clinicians—beginning with Treviranus (1835) and ending with Cramer (1898) and others—accepted "semidecussation," or, rather, partial crossing, proposed by Isaac Newton, Vater & Heinicke, Taylor, Wollaston, Arago, and Johannes Müller (*see* chap. II, 12 [3, 4]). This view was accepted by Alison (1836), Cruveilhier (1838, 1852), Arnold (1839, 1851), Longet (1842), Foville (1844), Hannover (1852), Sahmen (1854), A. Graefe (1856), J. Hughlings Jackson (1863, 1875), Testelin (1866), Alexander (1867), Hjort (1867), Zagórski (1867), Keen & Thomson (1871), Gudden (1874–79), Reich (1875), Hirschberg (1875, 1876), Schweigger (1876), Plenk (1876), R. Förster (1877), Pooley (1877), Munk (1877 and later), Hosch (1878), Nicati (1878), Gowers (1878), Baumgarten (1878, 1881), Henle (1879), Nieden (1879), Adamük (1880), Purscher (1880), Mauthner (1881), Tartuferi (1881), Féré (1882), Stilling (1882), Ganser (1882), Bechterew (1883), Gnauck (1883), Noyes (1884), Starr (1884), Jatzow (1885), Singer & Münzer (1888), Siemerling (1888), Bernheimer (1889, 1900), Hebold (1891), Hüfler (1895), L. Jacobsohn (1896), and Hellendall (1897).

The opposition, however, represented by Biesiadecki (1861), Pawlowski (1869), Brown-Séquard (1872), Mandelstamm (1873, 1875), Michel (1873 and later), Cohn (1874), Scheel (1874), Schwalbe (1874), *et al.*, all of whom advocated the idea of a complete crossing of the optic nerve fibers in all Vertebrates, including Man, was hardly less formidable, especially in view of the fact that, in spite of Gudden's perfectly clear evidence to the contrary, it was backed by the authority of Koelliker (1896, 1899, 1900) and other histologists of note. As to Johannes Müller, his earlier assumption of division of each optic nerve fiber, with branches passing to the opposite halves of the brain, was later vindicated to some extent by S. Ramón y Cajal (1899) and Koelliker (1899). The former saw such bifurcating fibers in small numbers in the chiasma of the Rabbit and Rat, the latter in the Cat, Ox, and Dog (*see* chap. II, 12 [8]).

The refusal to acknowledge a partial decussation in the human chiasma and in that of higher Mammals was strange, in view of an increasing number of clinical cases of homonymous hemianopia caused by unilateral lesions of the visual pathway above the chiasma. The principal reason for this reluctance may have been the crudeness of anatomical technique and the use of vertebrate species in which conditions were different from, or at least less obvious than, those in Man.

4. EARLY MODERN INVESTIGATIONS OF VARIOUS TYPES OF HEMIANOPIA.—More successful in the functional analysis of the visual pathway than the anatomists were the clinical ophthalmologists and neurologists who relied upon human material. The earlier observations of Morgagni and of Vater & Heinicke but especially the lucid description and interpretation by Wollaston (1824) of the "half-blindness" or rather "half-vision" from which he and several of his friends suffered again revived interest among the clinical ophthalmologists in the nature of this affliction (*see* chap. II, 12 [4]; *see also* Testelin 1866). A. Graefe (1856), "founder of modern ophthalmology," found the right answer when he interpreted homonymous hemianopia—in his opinion a rather frequent disturbance—as caused by a unilateral cerebral lesion of the visual pathway above the place of partial decussation in the chiasma. Incidentally, the term with which this disturbance was first designated was "hemiopia," meaning "half-vision" or "half-sight"; the present terms "he-

mianopia" and "hemianopsia," meaning "half-blindness," were subsequently introduced by Hirschberg (1875).

Graefe's work, well presented by Engelhardt (1865), was rapidly followed by numerous clinical and pathological studies of cases showing various types of defects in the fields of view. D. E. Müller (1861), Saemisch (1865), and Williams (1875) explained bitemporal hemianopia as caused by compression of decussating fibers in the chiasma, which leaves the nondecussating fibers intact, while Knapp (1875) interpreted binasal hemianopia as a consequence of interference with uncrossed fibers in the same locality, in his particular case through pressure exerted by atheromatous blood vessels.

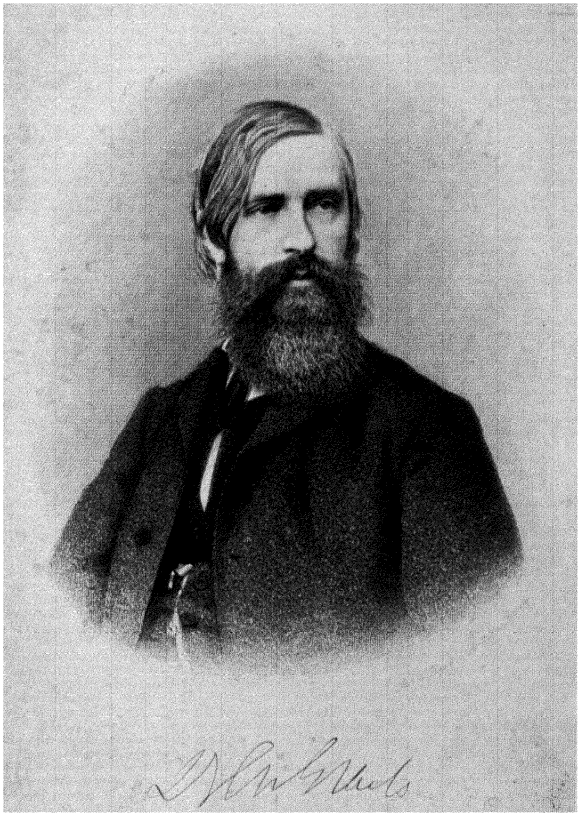

FIG. 103.—**Albrecht von Graefe (1828–70)**, professor of ophthalmology in Berlin, Germany. Man most deserving the title "Founder of Ophthalmology." Pupil of Johannes Müller (Fig. 355) and of Arlt, and a friend and collaborator of Heinrich Müller (Fig. 46), Du Bois-Reymond, Donders (Fig. 358), and Helmholtz (Fig. 101). First to use in clinical practice the ophthalmoscope invented by Helmholtz (Fig. 102); in Graefe's words, "Helmholtz gave us a new world!" First began systematic plotting of the fields of view in cases of defective vision. Brought about recognition of ophthalmology as an independent branch of medical science. Introduced numerous important practices into clinical ophthalmology. Founder of the Arch. f. Ophth., in 1854. Frontispiece in E. Michaelis, *A. v. Graefe, sein Leben und sein Wirken*, 1877. *See also* E. Michaelis 1877; and J. Hirschberg in Graefe & Saemisch, *Handb. d. ges. Augenh.*, 2d ed., v. 1 (1), 1910.

5. Solution of the problem of the chiasma.—The evidence from numerous clinical observations, verified by careful post mortem examinations accumulating toward the end of the nineteenth century and from physiological experiments, overwhelmingly favored the concept of "semidecussation" in the chiasma, a term introduced by Wollaston, which Alison later replaced by the more correct term "partial decussation" (*see* Hughlings Jackson 1875; Wilbrand 1881; Bernheimer 1889, 1896; Delbrück 1890; Darkschewitsch 1891; Hebold 1891; Bechterew 1898; Cramer 1898; Dimmer 1899; S. Ramón y Cajal 1899; Siegrist 1899; Wilbrand & Saenger; A. Pichler 1900).

Fig. 104.—Richard Förster (1825–1902), professor of ophthalmology in Breslau (now Wroclaw), then Prussian Silesia. Inventor of the arc perimeter, an instrument with which to plot the normal fields of view and to study the various defects, such as hemianopias and scotomas. First suggested multiple blood supply of the occipital pole as the cause of the so-called central or "macular" sparing frequently found in homonymous hemianopia. From J. Hirschberg, in Graefe & Saemisch, *Handb. d. ges. Augenh.*, 2d ed., v. 15 (1), p. 160, 1918.

According to this view, now generally accepted, in Man and other Primates the central portion of the chiasma is made up of fibers, originating in the nasal halves of both retinae, which cross the mid-line from the respective optic nerves to enter the contralateral optic tract. The fibers from the temporal halves of the retinae do not decussate but, forming the lateral bundles of the chiasma, proceed to the optic tracts of the same side. The suprachiasmal portion of the visual pathway of each side (the optic tracts, lateral geniculate nuclei, visual radiations, and visual cortical centers) contains, accordingly, two sets of fibers, the crossed, which are somewhat more numerous, and the uncrossed, corresponding to the right or left homonymous halves of both retinae.

In lower Vertebrates (Fishes, Amphibians, Reptiles, Birds, and possibly also in the most

primitive Mammals [*Echidna*, *Platypus*]), whose monocular fields are largely or entirely separated and whose vision is therefore preponderantly or entirely panoramic, decussation seems to be complete (Gudden 1874–79; Stilling 1882; Michel 1887; Singer & Münzer 1889; Sölder 1898; S. Ramón y Cajal 1899, 1909–11; Harris 1904; Lubsen 1921; C. J. Herrick 1944, *et al.*). In the infraprimate Mammals, beginning with Marsupials and Rodents, the relative number of homolateral nondecussating fibers increases with the increase of overlap of the two monocular fields of vision or with the perfection of binocular stereoscopic vision, which is the same

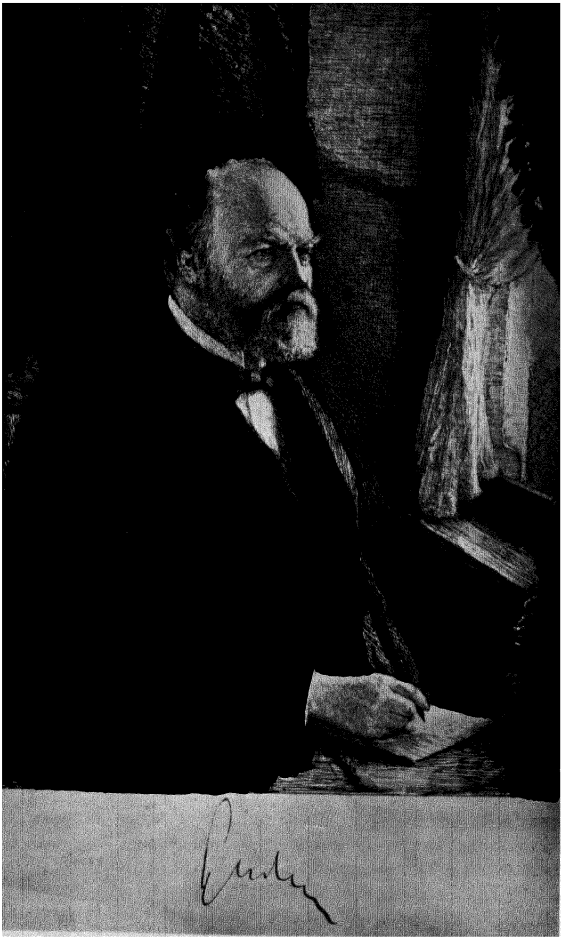

FIG. 105.—Bernhard von Gudden (1824–86), professor of psychiatry in Munich, Bavaria, Germany. Pioneer investigator in experimental neuroanatomy, in particular of the vertebrate visual system. Frontispiece from Gudden's *Gesammelte und hinterlassene Abhandlungen*, 1889. For biography *see* T. Meynert, in Wien. med. Bl., 1886; in Arch. f. Psychiat. u. Nervenk., v. 18; and in Haymaker & Baer, *The Founders of Neurology*, 1953.

thing. In the Mouse, Rat, and Rabbit the nondecussating fibers are believed to be few; in the Opossum and the Horse they amount approximately to one-fifth; in the Cat almost to one-third; in the Monkey and in Man almost to one-half (*see* Dexler 1897; S. Ramón y Cajal 1899; Minkowski; Brouwer; Brouwer & Zeeman; Barris, Ingram & Ranson; Bodian; for further details on the comparative structure of the chiasma *see* chap. VI, 4, 5, 6).

The fact of partial decussation in Mammals has been further confirmed by physiological experiment. (Nicati 1878; Bechterew 1883; my own observation in Cat and Monkey). Anatomical experimental evidence of semidecussation of the foveal or "macular" fibers was furnished in the 1930's by Le Gros Clark & Penman (*see* chap. IV, 6 [5]; for the evidence presented in this book *see* chaps. VI, XI, XII).

6. LANDOLT'S AND CHARCOT'S HYPOTHESIS OF THE DECUSSATION OF OPTIC NERVE FIBERS IN THE MIDBRAIN. A hypothesis proposed by Landolt (1875) and supported by Charcot (1876–80) may be mentioned in connection with the question of the chiasma and homonymous hemianopia. An increasing number of the observed cases of half-blindness caused by verified unilateral suprachiasmal cerebral lesions had induced Charcot to accept partial crossing in the chiasma and, consequently, homonymous hemianopia in unilateral lesions of the optic tract. Such, for example, was a case reported by Gowers (1878) of softening of the posterior portion of the thalamus and another by Hirschberg (1875), where one optic tract was compressed by a gliosarcoma. However, in order to explain the "amaurosis of the contralateral eye," which many at that time, following Flourens and Panizza, still believed to be caused by unilateral suprachiasmal brain lesions (*see* secs. 4 [4], 7 [1], this chapter, and chap. IV, 1 [1]), Charcot assumed an additional crossing in the region of the quadrigeminal bodies of the midbrain of those fibers which remain uncrossed in the chiasma (some of the older anatomists, e.g., Willis 1664, and Rolando 1809, believed the two optic nerves were united in the posterior commissure at the place of their apparent origin). The total effect of this arrangement in Man would be an amaurosis of the opposite eye in the case of a unilateral lesion of the visual pathway at the levels above the midbrain, the same as in the Lower Vertebrates, where decussation in the chiasma is considered to be complete (*cf.* chap. VI, 5). Such an arrangement would also agree with the early experiments of Pourfour du Petit, Ferrier, and Munk, who at first believed the unilateral destruction of the cortical visual center caused blindness only of the contralateral eye (*see* secs. 7 [4], 8 [3], this chapter). Even though this speculation was subsequently proved to be fallacious (*see* Starr 1884), the idea of a partial crossing or of a recrossing of the visual pathway above the midbrain level persists in the hypothesis of bilateral cortical representation of the fovea or "macula" (*see* chap. VII, 3 [4], 6; and chap. XI, 8).

7. EARLY MODERN ATTEMPTS TO DISCOVER THE RETINOTOPICAL ORGANIZATION OF THE INFRANUCLEAR DIVISION OF THE VISUAL SYSTEM. From the intensive study of clinical cases showing various forms of disturbance of the fields of view there gradually evolved the conviction that the intrinsic disposition or arrangement of its constituent fiber bundles was the core of the problem of the visual system and that through its study the dimensional relationship of the retinal surface to the brain and its functional and pathophysiological significance might be disclosed.

Most of the interest centered around the identity and course of the foveal fibers, usually termed "macular bundle," or the continuation of the "papillomacular fascicle" of the retina. The investigations of D. E. Müller (1861), Purtscher (1880), Samelsohn (1880, 1882), Uhthoff (1880, 1884. 1887), Vossius (1882), Bunge (1884), Jatzow (1885), Thomsen (1888), Schmidt-Rimpler (1889), Widmark (1897), and Dalén (1906) showed that this bundle is located in the center or axis of the optic nerves, chiasma, and optic tracts. The exception is the portion of the optic nerve close to the eyeball, where, to approximately the point of entry of the central blood vessels, the "macular bundle" holds a peripheral position at the lateral or temporal margin of the nerve. On cross-section, this area has the shape of a wedge lodged between the peripheral or "extramacular" fiber segments. Some uncertainty remained as to its

position in the chiasma, the evidence pointing toward a dorsoposterior location immediately underneath the optic recess. The question of the ipsilateral uncrossed fibers was also much discussed; most authors favored a dorsolateral position in the chiasma and in the optic tracts.

The problem of quadrantic representation, among other topics, was discussed by Marchand (1882), who, anticipating Brouwer & Zeeman's modern work (chap. IV, 6 [4]), found the lateral segment of the optic tract related to the inferior portion of the retina. Whether the crossed and the uncrossed fibers in the chiasma and in the tracts are present as compact, separate bundles (Gudden) or whether they intermingle (Kellermann, Delbrück, Dimmer 1899) remained an open question, which was answered only in recent times (chap. VI, 6).

8. HENSCHEN'S SCHEME OF RETINOTOPICAL ORGANIZATION OF INFRANUCLEAR DIVISION OF THE VISUAL SYSTEM.—The effort of the preceding investigators, especially of Samelsohn and Jatzow, to find the arrangement of the retinal segments on a cross-section through the various levels of the infranuclear portion of the visual pathway was taken up and systematically carried on by S. E. Henschen (1890–92 and later; *see also* chap. IV, 4 [4–7]).

According to his scheme, "macular" or foveal fibers in the optic nerves, chiasma, and tracts form a separate bundle. Immediately behind the eyeball this bundle has the shape of a wedge located in the lateral or temporal half of the nerve. Farther up, above the portion containing the central blood vessels, the foveal bundle assumes a central position, being surrounded on all sides by fibers related to the extrafoveal portions of the retina. The four foveal quadrants are also arranged in a definite order. Close to the eyeball the two nasal quadrants are in the center and are flanked above and below by the upper and lower temporal quadrantic foveal fibers. The two bundles corresponding with the upper and lower extrafoveal temporal quadrants are in the same temporal half of the optic nerve but are kept apart by the foveal bundle. The two nasal extrafoveal quadrantic bundles are in the nasal half of the nerve and are contiguous. As the foveal bundle above the point of entry of the central vessels becomes axial, the upper and lower temporal extrafoveal quadrantic fibers gradually merge along the temporal periphery of the nerve. In the chiasma, only the center is made up of crossed fibers, the lateral portions containing both crossed and uncrossed fibers intertwining in complicated loops and layers. In this locality the foveal bundle is located either centrally or in the dorsal portion of the chiasma. In the optic tracts the foveal-macular bundle preserves a central location in the same way as in the optic nerves, being flanked above by the temporal and below by the nasal extrafoveal quadrantic fibers. Henschen believed a similar arrangement to be present also in the lateral geniculate nuclei.

9. CRITIQUE OF HENSCHEN'S VIEWS.—Henschen's scheme, as shown by investigations of Wilbrand & Saenger (1904), Rønne (1914), Minkowski (1920), and later Brouwer & Zeeman (1925, 1926), Brody (1934), Le Gros Clark & Penman (1934), and those presented in this book, was at fault in several respects (*see* chap. VI, 4–7). His first mistake was to assume that the ipsilateral and contralateral fibers took a separate course above the chiasma: he supposed the ipsilateral remained chiefly in the lateral, and the contralateral chiefly in the medial, portion of the tracts. He also assumed that each set terminated separately, by quadrants, in the lateral geniculate nuclei. Henschen's presentation of the foveal or "macular" fibers in the optic tracts as surrounded on all sides by the extrafoveal or "peripheral" fibers, was likewise an error. Nor was the arrangement of the upper and lower quadrants, either in the tracts or in the lateral geniculate nuclei, as given in Henschen's scheme, correct. Finally, Henschen failed to notice discrete terminations of ipsilateral and contralateral fibers in the alternating cell laminae of the lateral geniculate nuclei, discovered by Minkowski, and thus misunderstood the essential functional role of these internodes of the visual pathway (*see* chap. VI, 6). In spite of these errors, Henschen's work was of great merit, since it showed the road that subsequent investigators had to follow. (*Cf.* chap. VI, 4, 5, 6, 7.)

Chapter IV

Modern Anatomical, Experimental, Clinical, and Pathological Investigation of the Visual Pathways and Centers

SEC. 1. EARLY MODERN ATTEMPTS TO LOCALIZE VISUAL FUNCTION IN THE HUMAN CEREBRAL CORTEX

1. EARLIEST CLINICAL CASES OF VISUAL DISTURBANCES VERIFIED BY POST MORTEM EXAMINATION. —The observations of impaired sight, hearing, sensation, and motor function caused by the cerebral lesions that were occasionally recorded during the seventeenth, eighteenth, and first half of the nineteenth centuries produced no convincing evidence in favor of localization of the specific functions in particular territories of the cerebral cortex. Indeed, as Flourens' experiments indicated, such an intimate relationship was not to be expected (*see* chap. III, 4).

Concerning vision, the first breach in this, on the whole, negative situation was made by the experiments and the clinical and pathoanatomical investigations of Panizza (1855, 1856). In a case seen by him, a right-sided hemiparesis and hemianesthesia caused by a hemorrhage in the left thalamus was associated with "blindness of the right eye" (this was, of course, an erroneous interpretation of homonymous hemianopia accepted at that time, originating with Pourfour du Petit's and Flourens' experiments; *see* chap. III, 9 [6]). In another similar case there was a lesion in the thalamus and one in the posterior region of one cerebral hemisphere. Panizza also described a fiber tract originating in the posterior portion of the thalamus and terminating in the posterior superior gyri of the hemisphere —obviously the visual radiation of Gratiolet or a part of it (*see* chap. III, 5 [5]). Its interruption regularly produced, in Panizza's experience, "blindness of the opposite eye." In the case of a bilateral lesion the blindness was complete, with no impairment of other functions.

Another pioneer of that period, Chaillou (1863), reported a case apparently of right-sided homonymous hemianopia, with other symptoms, in an elderly person. It was caused by foci of softening, partly on the inner face of the left occipital lobe and partly in the posterior portion of the left thalamus.

Since in both Panizza's and Chaillou's cases cortical lesions were complicated by lesions in the thalamus, they in no way changed the trend of opinion, which, under Flourens' influence, was, in general, antilocalist (*see also* chap. III, 6).

2. INTRODUCTION OF PERIMETRY AND ITS EFFECT UPON NEURO-OPHTHALMOLOGY.—An important factor which made possible modern investigation of the visual pathway was the introduction of systematic testing of the fields of vision in disturbances caused by cerebral pathology by A. von Graefe (1856, portrait Fig. 103). The plotting of the fields, made popular by J. Hughlings Jackson (1863, portrait Fig. 106), became a routine procedure after the introduction of the perimeter into clinical practice by R. Förster (1867, portrait Fig. 104). Interest was at first quite naturally restricted to the infranuclear division of the visual system. Before long, however, the supranuclear division came to the fore. During this period the principal characteristics of visual field disturbances were discovered, and their various types classified. In apoplexy, for example, Graefe (1865) noticed a frequent occurrence of hemianopic symptoms, often with "sparing" of the central portions of the fields around the fixation points. In other cases the division line between the normal and the blind halves of the fields was

straight, passing through the fixation points. The relative frequency of the hemianopic defects of vision in cerebral disease was emphasized by J. Hughlings Jackson (1875), Schweigger (1876), R. Förster (1877), and other clinicians. (For biographies *see* J. Hirschberg 1911; F. Hübotter 1929 35; E. Michaelis 1877.)

cus of the occipital lobes. The optic nerve, according to him, terminates both in the lateral and medial geniculate nuclei and also in the pulvinar of the thalamus. From these three localities, he thought, fibers arise that terminate partly in the ensiform and lingual gyri and partly in the hippocampal sulcus (the posterior

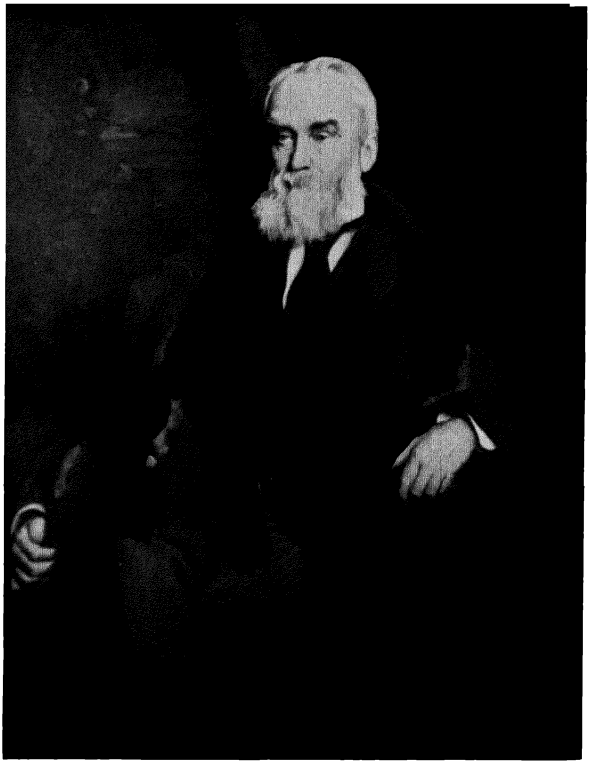

FIG. 106. John Hughlings Jackson (1835–1911), physician at the National Hospital for Paralysed and Epileptic, Queen Square, London, England. Pioneer clinical neurologist and neuropathologist. Among the first to emphasize the importance of the ophthalmoscope and of the plotting of fields of view in clinical neurology. An early student of the cerebral functional localization in relation to clinical neurology. A unique observer and interpreter of the clinical manifestations of nervous disease. Courtesy Dr. F. M. R. Walshe, of London. For biography and writings *see* J. Taylor *et al.*, in Jackson's *Neurological Fragments*, 1925; *cf. also* his *Selected Writings*, 1931, and Haymaker & Baer, *The Founders of Neurology*, 1953.

3. EARLY ANATOMICAL SUGGESTION OF AN OCCIPITAL LOCALIZATION OF VISUAL FUNCTION.—Meynert (1869) was apparently the first to express an opinion concerning the location of the cortical visual center around the calcarine sulportion of that sulcus is identical with what is now called the "calcarine sulcus or fissure"; *cf.* Figs. 271, 273). Subsequently, this view was accepted by Huguenin (1878) and by Wilbrand (1881). It is also possible that Meynert's opin-

ion was the source of Munk's idea of locating the visual center in the posterior region of the cerebral hemisphere (*see* chap. III, 8 [5]; on Meynert *see* J. Fritsch 1892; Jolly 1892; Anton 1930; De Crinis 1939; O. Vogt 1943).

4. First verified clinical cases suggesting the occipital seat of visual center.—The clinical cases of visual field defects observed with increasing frequency during this period were of far greater importance to the localization of visual function in the cerebral cortex than were the anatomical investigations. Most of these cases definitely indicated the presence of a center of sight in the occipital lobes. The observations reported by Levick (1866), Keen & Thomson (1871), Pooley (1877), Baumgarten (1878), Hosch (1878), Huguenin (1878), Curschmann (1879, 1881), Nothnagel (1879), and Westphal (1879, 1880, 1881) supported this theory. Unfortunately, evidence from human pathology was inconclusive. In almost all cases the pathological changes found in the brain were not confined to the occipital lobe, much less to a small portion of its cortex or subcortical fibers. Usually the destruction extended to the adjoining territories, mostly to the parietal or temporal lobes, occasionally as far as the insula, central region, frontal lobe, thalamus, and other parts. This insufficient evidence may, then, explain why some prominent investigators of that period (e.g., Goltz and Hitzig) remained faithful to the ancient thesis of a preponderance of the subcortical nuclei in the visual function. (*Cf.* chap. III, 4 [6]), 5 [6].)

Notwithstanding the afore-mentioned difficulties, Wilbrand (1881, portrait Fig. 107), after reviewing all known clinical observations, decided in favor of occipital localization of vision. This, of course, agreed with Munk's physiological experiments (*see* chap. III, 8 [5]), and with the occipital termination of visual radiation described in the Monkey by Gratiolet (1854–57), Huguenin (1878), and Wernicke (1881). The field defects found in homonymous hemianopia may, according to Wilbrand, be caused not only by lesions of the optic tract, thalamus, and adjoining structures but also by cortical and subcortical lesions affecting only a portion of the occipital lobe. An incomplete hemianopia, for example, may be caused by a focus close to or in the cortex, where the incoming visual fibers spread over a wide area, in analogy with the somatomotor monoplegias caused by a similar location of small lesions in the motor cortex or in the outgoing motor fibers. (On Wilbrand *see also* sec. 4, this chapter.)

5. Earliest suggestion of the striate area as a visual center.—Wilbrand's deductions were soon corroborated by Giovanardi (1881), who described the brain specimen of an *anophthalmos* or a baby with congenital absence of eyes and other parts of the visual system, where he found marked atrophy of the occipital lobes (Fig. 108). Even more to the point were two cases of homonymous hemianopia (Fig. 109) reported by Haab & Huguenin (1882). In one, a solitary tubercle and, in the other, a single embolic encephalomalacic focus in the contralateral calcarine region were found. It was logical, then, for Huguenin to suggest that the cortical area in the occipital lobe, distinguished by the presence of Gennari's and Vicq-d'Azyr's stripe, may be concerned with the visual function.

6. Starr's pathophysiological analysis of visual pathways.—Another clinical observer of that period, M. A. Starr (1884, portrait Fig. 110), after discussing more than two dozen cases of visual disturbances known at that time, became convinced that the visual center was located in the occipital lobes. The symptoms of homonymous hemianopia, according to him, may be produced not only by unilateral lesions of the optic tract but also by those of the pulvinar of the thalamus, of the posterior portion of the internal capsule, of fiber radiation to the occipital lobe, of the medullary portion of that lobe, and of its cortex. Each occipital lobe was anatomically and functionally related to the homonymous halves of both retinae. A unilateral lesion of the suprachiasmal portion of the visual pathway, therefore, did not make, according to Starr, the contralateral eye blind, as Flourens, Panizza, Charcot, and many others believed at that time, but instead it destroyed the function of the contralateral halves of both fields of vision. (*Cf.* chap. III, 4 [4], 9 [6], and par. 1, this section.)

Starr's analysis of the visual mechanism of

the brain was a far cry from the uncertainty which had existed only a few years earlier. Nevertheless, more well-observed clinical cases documented by careful post mortem examination, were needed to duplicate Munk's animal experiments in Man by a detailed correlation of parts of the fields of vision with definite localities of the occipital cortex. (*See* chap. III, 8 [4].)

7. CLINICAL OBSERVATIONS POINTING TO THE CALCARINE FISSURE AS A LOCALITY CONCERNED IN VISUAL FUNCTION; EVIDENCE OF A QUADRANTIC REPRESENTATION OF HEMIRETINAE. During this period, additional clinical observations made the localization of the visual center in the occipital lobe practically certain (Schweigger 1876, 1891; Wilbrand 1881, 1885, 1887, 1890, 1892; Haab & Huguenin 1882; Jany 1882; Marchand 1882; Noyes 1884; Féré 1885; Monakow 1885; Richter 1885, 1889; Gruening 1886; Reinhard 1886 87; Séguin 1886; Nothnagel 1887). Among these, a classical case observed

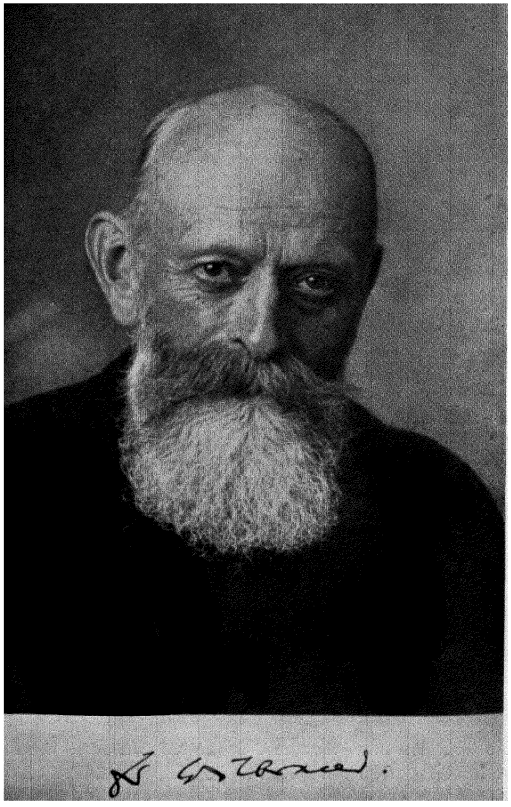

FIG. 107.—Hermann Wilbrand (1851–1935), professor of ophthalmology at Hamburg, Germany, at the age of seventy. Encyclopedic neuro-ophthalmologist and co-author, with A. Saenger and C. Behr, of *Die Neurologie des Auges* published in ten volumes, 1899–1927. Suggested bilateral representation of each complete fovea in the cerebral cortex as an explanation of central or so-called "macular" sparing in cases of homonymous hemianopia. Author of the hypothesis of syndynamical homonymous conductor units in the suprachiasmal portion of the visual pathway as the anatomical basis of the functional congruity of both monocular fields of view in the normal binocular visual act. From Klin. Monatsbl. f. Augenh., v. 66, p. 769, 1921.

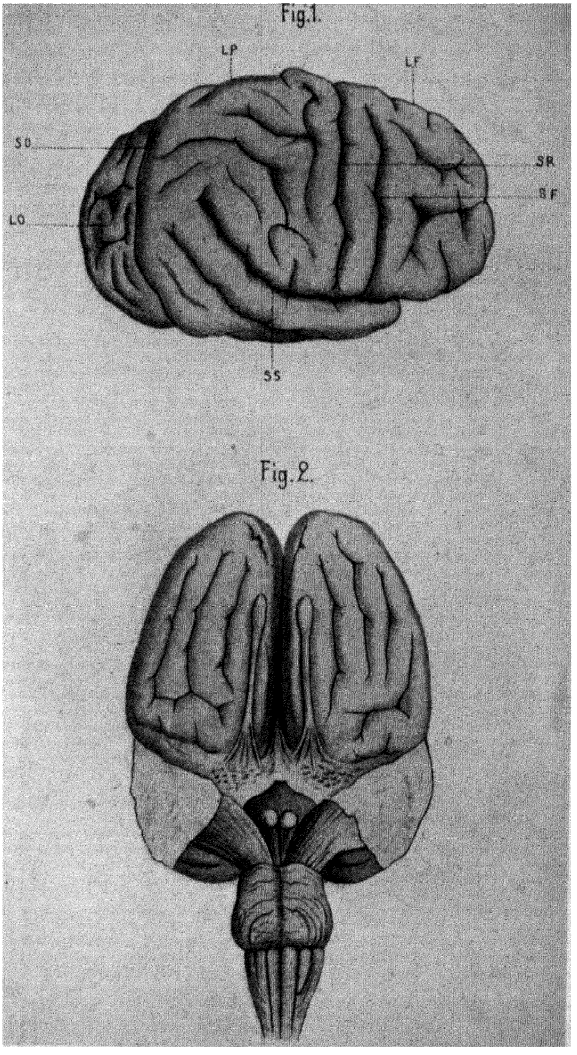

Fig. 108.—Brain of a fourteen-month-old child with a congenital anophthalmia, first of its kind, reported by Giovanardi as evidence of localization of vision in the occipital lobes of the brain. All parts making up the visual system were absent: the eyes, optic nerves, chiasma, tracts, and lateral geniculate nuclei, while the occipital lobes were underdeveloped. Upper figure shows the lateral view of the right cerebral hemisphere with the atrophic occipital lobe (*LO*), separated from the rest by a deep and long external parieto-occipital sulcus (*SO*) resembling simian sulcus (*cf. l* in Figs. 280, 282, 284). Lower figure shows the basal view of the brain. From E. Giovanardi in Riv. sper. di freniat., v. 7, p. 244, 1881.

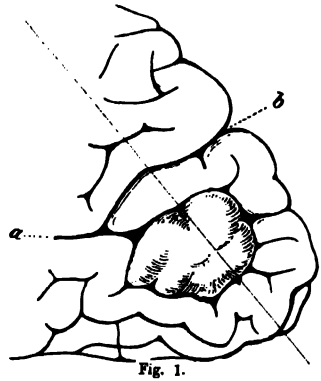

Fig. 1.

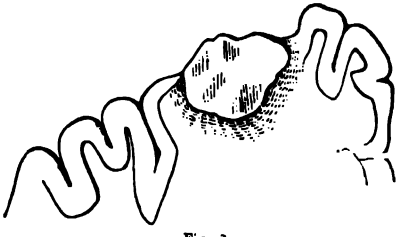

Fig. 2.

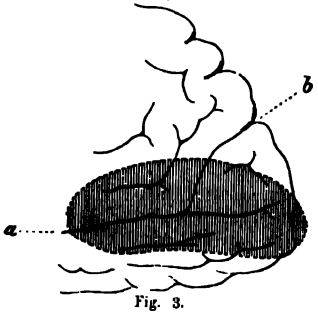

Fig. 3.

FIG. 109.—First verified cases of visual disturbance caused by localized lesions of the calcarine region of the occipital lobes, reported by Haab (& Huguenin). Upper sketch shows the inner face of the right occipital lobe with a solitary tubercle located in the calcarine fissure (*a*). Middle sketch shows same specimen cut along the indicated line. During life a left homonymous hemianopia was found. Lower sketch also shows the inner face of the right occipital lobe with the calcarine fissure (*a*) and parieto-occipital sulcus (*b*), the shaded area indicating the approximate extent of encephalomalacic region caused by embolism. Here, too, a left-sided homonymous hemianopia was present during life. From O. Haab (& Huguenin), in Klin. Monatsbl. f. Augenh., v. 20, p. 141, 1882.

by Henry Hun (1887), Professor of Diseases of the Nervous System at the Albany Medical College, was noteworthy (portrait Fig. 111; for biography *see* La Salle d'Archambault 1924). The plotting of the fields of view revealed a blindness confined to the left inferior homonymous quadrants of both sides (Fig. 112). A post mortem examination showed a single encephalomalacic lesion in the right occipital lobe, limited to the inferior margin of the cuneus, that is, to the upper lip of the calcarine fissure (*A* in same figure). This rather uncomplicated case was the next after Haab & Huguenin's to furnish evidence of localization of the visual center on the inner face of the occipital lobe (Huguenin, 1878, claimed that most fibers of the visual radiation terminate around the calcarine fissure).

But beyond this, Hun's case was also the first to demonstrate a quadrantic representation of the homonymous hemiretinae in the cerebral cortex: the upper quadrants above, the lower quadrants below, the calcarine fissure (in the fields, owing to the dark-chamber effect of the eyes, the arrangement of the quadrants is inverted). It also lent substance to the view, later expounded in detail by Flechsig, that only a relatively small portion of the occipital cortex, precisely where the visual radiation terminated, was the "gateway" for incoming visual impulses and therefore a substratum of "simple visual sensation." The remaining and larger territory of the occipital lobe, especially its lateral face, was the substratum of "higher," gnostic, mnemonic, and other "psychic" visual functions. (*See* chap. III, 8, and sec. 2, this chapter.)

With these observations, the presence of a "visual area" or "visual center" in each occipital lobe, located along the "calcarine sulcus," was established for those few who were qualified and willing to evaluate the available data objectively; (the term "calcarine sulcus" originated with Th. Huxley 1861; *see* chap. VIII, 1 [4]). A representation of the homonymous halves of the retinae by quadrants was also demonstrated. In this way the two principal points insisted upon by Munk, but as yet based only upon animal experiments, became substantiated for the human visual system also: the presence of a definite center of vision in the

occipital cortex and a topographical representation of the retina in this center.

The next task was to determine more exactly the limits of the visual cortical area in the human brain, especially its identity with a definite cytoarchitectural territory; the precise representation of the various parts of the hemiretinae in it, primarily of the central fovea or "macula"; the microscopic study of its minute structure; its various fiber connections; and the clinical and psychophysiological analysis of its many functional manifestations.

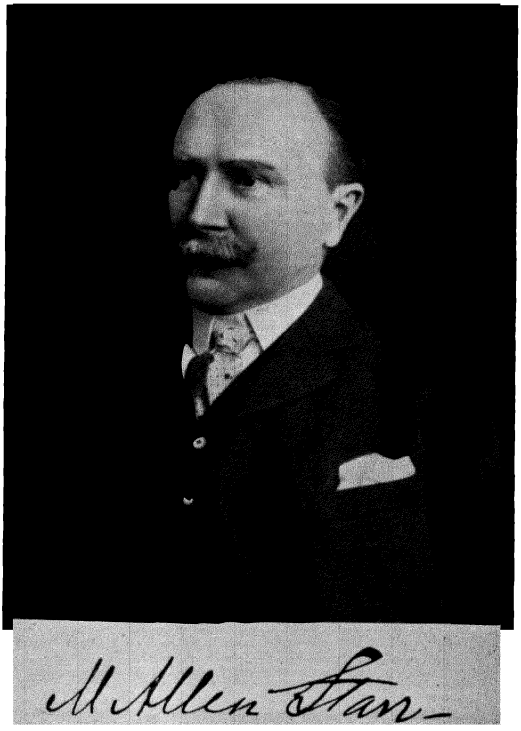

FIG. 110.—M. Allen Starr (1854–1932), professor of neurology at Columbia University, New York. An illustrious pioneer of American neurology. One of the early writers who successfully analyzed visual disturbances of central origin and correctly interpreted their pathoanatomical basis. For portrait and obituary *see* F. Tilney, in J. Nerv. & Ment. Dis., v. 77, p. 226, 1933; *see also* Haymaker & Baer, *The Founders of Neurology*, 1953.

SEC. 2. DOCTRINE OF THE "PROJECTION CENTERS" AS DISTINCT FROM "ASSOCIATION AREAS" OF THE CEREBRAL CORTEX

1. Improvement of laboratory technique and the advancement of brain research.— The investigations of the cortical visual centers and their connections received a powerful stimulus toward the close of the nineteenth century from the anatomical investigations of normal brain structures, especially of the fiber systems and tracts. This, in turn, became possible because of a general improvement in histological laboratory technique introduced by Reil, Hannover, B. Stilling, Türck, H. Müller, J. Gerlach, Beneke, Waldeyer, Böttcher, Meynert, Blum, and others. The improvements consisted in the hardening of brain specimens in various chemical solutions, such as alcohol, chromic acid, and chromic salts, which permitted the making of thin sections, to which stains could be applied. It now became possible to study, in serial sections, the normal and degenerated fiber tracts of which the brain is largely made. The normal relationships of the various structural elements were much better preserved in such preparations than in the torn-off bits of tissue obtained by the maceration and "teasing" procedures in use until then.

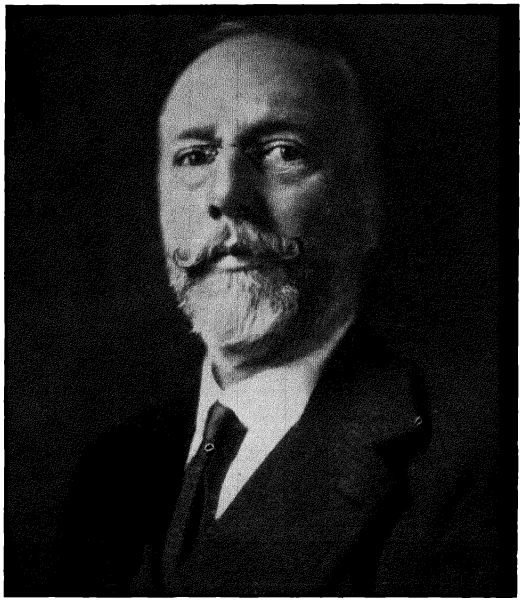

FIG. 111.— **Henry Hun** (1854–1924), professor of diseases of the nervous system at the Albany Medical College, Albany, New York. Described one of the earliest clinical cases of quadrantic homonymous hemianopia, where post mortem examination revealed a single lesion limited to the upper lip of the calcarine fissure of the contralateral occipital lobe. This observation showed, first, the location of the visual center along the calcarine fissure and, second, the representation of homonymous hemiretinae, by quadrants, in the cerebral cortex. From Arch. Neurol. & Psychiat., v. 11, p. 711, 1924. For biography *see* La Salle d'Archambault in same volume. (*Cf.* following figure.)

With this technique, by following serial sections, the origin, course, relationships, and termination of discrete fiber bundles could be determined. Also, through the application of such dyes as carmine or cochineal and of hematoxylin or logwood dye, the thin, transparent sections were made more useful for the micro-

scopic study of fine details, such as the nerve cells in the cerebral cortex, in the various nuclei of the brain, and in the spinal cord. When, as a further development of this trend, a number of special staining procedures were devised by Golgi (1873, 1878), Weigert (1882), Ehrlich (1885, 1886), Marchi (1886–87), Nissl (1894, 1895), S. Ramón y Cajal (1903, 1904), Bielschowsky (1904), and others, efficient techniques had been found which made possible detailed structural analysis of the nervous organs. (For historical reviews *see* Burdach 1822, p. 243; Flechsig 1876, 1927; J. Stilling 1882; Gierke 1884–86; Stieda 1899; Neuburger 1910; Edinger 1911; Wallenberg 1926; R. Krause 1926–27; Polyak 1941–48; F. T. Lewis 1942; Rasmussen 1943; Conn 1948; *cf.* also chap. III, 5 [2].)

2. Initiation of modern brain research; Meynert.—Among the first to apply the improved techniques to the brain in a systematic way was Theodor Meynert (1867–68, 1869, 1872), Professor of Psychiatry in Vienna (portrait Figs. 113, 311; *see also* sec. 7 [2], this chapter). His fundamental investigations threw new light upon the complex organization of the brain and opened new vistas to subsequent investigators. One idea of the many which were to influence the coming generation was his concept of "projection," or topical representation in the cerebral cortex of the receptor surfaces of the

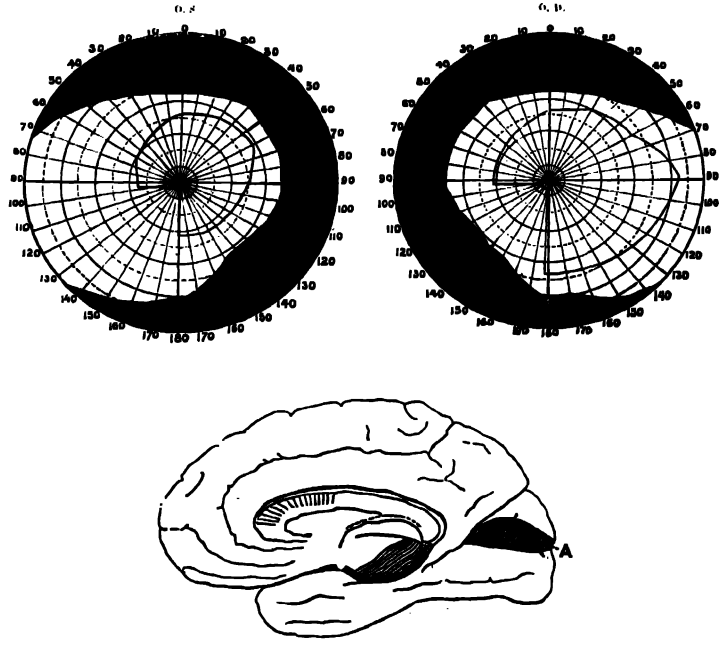

Fig. 112.—First recorded case of a quadrantic homonymous hemianopia caused by a limited cortical lesion along the calcarine fissure, verified by a post mortem examination, reported by Hun (Fig. 111). The fields of view of both eyes showed a complete loss of function in the left lower quadrants between the horizontal and vertical meridians, extending as far as the fixation points, the loss also extending into upper quadrants, including here an area larger than the monocular temporal crescent. A single lesion (*A*) was found on the inner face of the right occipital lobe, which destroyed the lower portion of the cuneus or the upper lip of the calcarine fissure. From H. Hun, Am. J. M. Sc., N.S., v. 93, p. 140, 1887.

sense organs, such as the retina, cochlea, skin, etc. (it is possible that Meynert, in turn, was influenced by similar ideas expressed previously by E. H. Weber, 1852, originator of the compass test for two-point discrimination of the tactile sense; for biography *see* Anton 1930 and De Crinis 1939).

3. DISCOVERY OF MYELOGENESIS; FLECHSIG. —The new ideas and the application of a new technique proved exceptionally successful in the hands of Paul Flechsig, Professor of Psychiatry in Leipzig (dates of publications 1872–1927, especially from 1894 on; portrait Fig. 114; for biography *see* Quensel 1917; Flechsig 1927; R. A. Pfeifer 1930). Early in his career Flechsig noticed that in the fresh unstained brain and spinal cord of newborn babies and fetuses only a few parts were myelinized, while the rest was without myelin. Even more distinct was the contrast between the myelinized and unmyelinized fiber tracts in the sections stained with

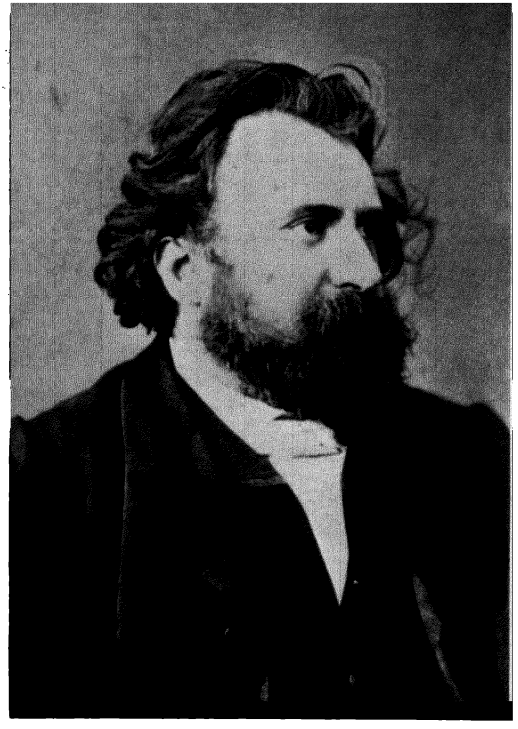

FIG. 113.—Theodor Hermann Meynert (1833–92), professor of psychiatry at the University of Vienna, Austria. Pioneer of modern investigation of the minute structure of the brain. He first systematically studied the cerebral cortex and showed its structure to vary in different localities. As early as 1867–68 he described the peculiar structure of the visual cortex, later called "striate area" by G. Elliot Smith, with its eight layers and "solitary cells," since then known as "Meynert cells." He created the concept of the "projection" of body surface and of the sense organs upon the cerebral cortex and named the principal fiber tracts, connecting body periphery and sense organs with the cerebral cortex, "projection systems," in contrast with short "association fibers," by means of which various parts of the cerebral cortex are interconnected. Portrait received from Frau Dora von Stockert-Meynert, Meynert's daughter, in 1946. (*See also* Fig. 311.) For biography *see* P. Jolly, in Arch. f. Psychiat., v. 24, p. iii, 1892; J. Fritsch, in Jahrb. f. Psychiat., v. 11, p. 1, 1892; G. Anton, in J. f. Psychol. u. Neurol., v. 40, p. 256, 1930; M. de Crinis, in Ztschr. f. d. ges. Neurol. u. Psychiat., v. 165, p. 17, 1939; O. Vogt, in Anat. Anz., v. 94, p. 49, 1943, and Haymaker & Baer, *The Founders of Neurology*, 1953.

carmine or, better yet, with Weigert's recently developed special hematoxylin method for staining myelin. Obviously, different tracts and systems of fibers in the central nervous organ develop their myelin sheaths at different periods of pre- and postnatal life. Those fibers, Flechsig found, which belong to the same system mature at approximately the same time, while those of

4. FLECHSIG'S MYELOGENETICAL INVESTIGATION OF PROJECTION AND ASSOCIATION FIBER TRACTS OF THE BRAIN. Flechsig, realizing the

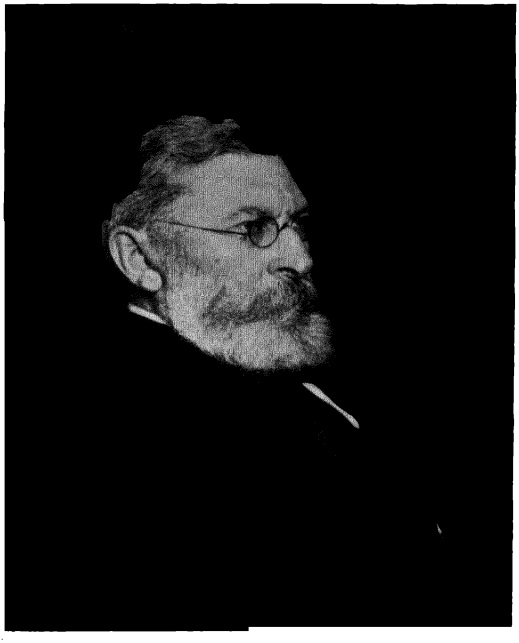

FIG. 114.—Paul Emil Flechsig (1847–1929), professor of psychiatry at Leipzig, Saxony, Germany. One of the foremost students of the brain as an organ of the mind. Creator of the concept of the "projection centers" of the cortex, where the principal nerve tracts either terminate (olfactory, gustatory, somesthetic, visual, auditory) or originate (motor), as distinct from the much more extensive regions, the "association centers," where the impulses from "projection centers" meet and where they are integrated into composite processes. From Arch. f. Psychiat. u. Nervenkr., v. 91, 1930. (*Cf.* following figure; for biography *see* Quensel 1917; Flechsig 1927; R. A. Pfeifer 1930; and Haymaker & Baer, *The Founders of Neurology*, 1953.)

anatomically and functionally different tracts do so at different periods. The order or sequence of myelinization of particular fiber systems during individual development apparently repeats the phylogenetic appearance, the earliest being

importance of his discovery to cerebral anatomy, began systematically to investigate all the fiber tracts of the human brain and spinal cord. His labor, carried on for more than fifty years, had far-reaching consequences in understanding

branching off from the principal afferent tracts). Because he believed these intervening regions to be provided with association fibers only and also because of the intermediate location of some of them between the sensory spheres, Flechsig named these parts of the cortex "association centers" or "association areas" (*Assoziationszentren*) and considered them to be a substratum of the "psychic functions" (*geistige Zentren, Cogitationszentren*, meaning psychic or thinking centers). The association regions, because of their relatively large size in the human brain when compared with the infrahuman species, Flechsig looked on as a "specific human

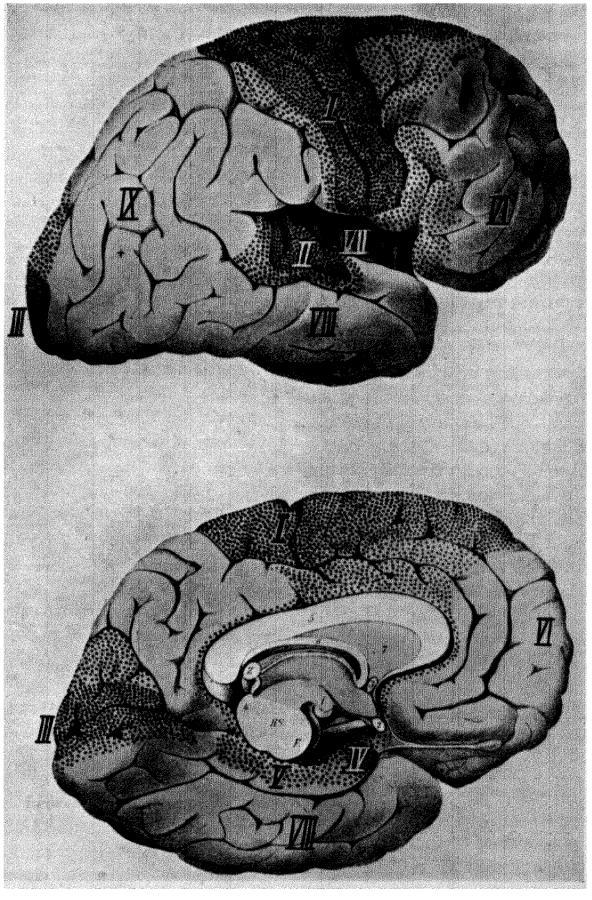

FIG. 115.—Lateral (*above*) and medial (*below*) views of human brain, showing Flechsig's sensory or receptor areas (*densely stippled*) surrounded by marginal zones (*less dense stippling*), with association areae in between (*without stippling*). *I*, somesthetic and somatomotor area; *II*, auditory sphere; *III*, visual sphere; *IV*, olfactory sphere; *V*, gustatory sphere; *VI*, frontal association area; *VII*, insula; *VIII*, temporal association area; *IX*, parieto-occipital association area; *1*, mammillary body; *2*, optic chiasma; *3*, anterior commissure; *4*, superior colliculus of midbrain; *5*, corpus callosum; *6*, fornix; *7*, pellucid septum; *Z*, pineal gland; *HS*, midbrain tegmentum; *F*, *pes* or foot of the cerebral peduncle. acquisition" (*cf.* Figs. 274, 275). Phylogenetically, they are the latest to appear and are the material foundation of "Man's mastery over other creatures."

7. FUNCTION OF THE ASSOCIATION REGIONS OF THE BRAIN.—Flechsig believed that the function of the extensive cortical association areas filling the space between the sensory spheres was, in general, to serve as repositories of past impressions arriving through the afferent channels via the sensory spheres or, in his definition, to serve essentially as a substratum of "memory" and its integration or building of complex processes. The posterior association area, comprising a large portion of the parietal, occipital, and temporal lobes, would be concerned with the integration of the visual, somesthetic, and auditory impulses. Its task would be retaining visual, auditory, and somesthetic experiences and integrating them and also performing certain complex acts of the order of Liepmann's "praxias"—for example, reading and visual understanding of written language, understanding spoken words or auditory language, and the like. The function of the insular association area, hidden in the Sylvian fossa or pit, as yet little understood, may also in some way be related to language. The function of the largest association area comprising most of the frontal lobe would be uppermost in the hierarchy of cerebromental functions and faculties: consciousness of one's own personality, or *Ego*, conscious and purposeful planning and acting, will power, "character," logical thinking, and judgment. In a word, the frontal lobes would be the anatomical substratum of a "unified person, conscious of itself, and capable of free and independent action."

8. PROJECTION AND ASSOCIATION AREAS AND FUNCTIONAL SIGNIFICANCE OF THE CEREBRAL CORTEX.—The subdivision of the cerebral cortex into two fundamentally different categories of "centers"—one, the sensory and motor spheres or "projection centers," whose essential function was reception of incoming, and emission or discharge of outgoing, impulses; the other, the association areas or intellectual centers proper—at once threw light upon the most vexing and obscure problem of modern neurology: the functional significance of the cerebral cortex. Flechsig showed this cortex, which in early times was looked upon as an inert mass, possibly a gland (Hippocrates, Aristotle, Malpighi, Vieussens, Cuvier, Lamarck), or at best as an organ where, in some unaccountable way, the "soul," "psyche," or "mind" was linked to the "body," to be an ingeniously constructed mechanism whose constituent parts have a reason and purpose: to conduct to, and to receive the various impulses arriving from, the peripheral sense organs; to integrate these impulses into compound processes and to store up their traces or "engrams"; and to make use of such relatively stable engrams by initiating and carrying out the various motor and secretory acts. In the light of Flechsig's interpretation, the many mental and sensory faculties, including those which are specifically human, e.g., language, not only were linked to the various structures of the same territory, such as particular groups of cells and fibers, as Munk supposed, but were a functional expression of an elaborate topographical differentiation and organization of the same cortex. The first prerequisite to an understanding of the intimate processes of which "mind" or "intellect" was a supreme manifestation was, then, to investigate the complex structure of the brain, especially of the cortex, and its connections.

9. MODIFIED CONCEPT OF FLECHSIG'S PROJECTION AND ASSOCIATION AREAS OF THE BRAIN.—Flechsig's concept of the subdivision of the human cortex into sensory and association areas, in spite of much opposition (e.g., from Sachs, Monakow, Niessl von Mayendorf, Hitzig, Siemerling, Weygandt, O. & C. Vogt, *et al.*), in the main remains valid. The idea of a fundamental difference between the functions of sensory spheres and association areas has since been corroborated by numerous clinical, pathoanatomical, and experimental observations. The primitive, elemental character of functional disturbances which accompany lesions of the sensory and motor spheres is, by now, fairly well established, especially when compared with more complex subjective and objective phenomena observed in the pathology of, or in experiments upon, the "association areas" (in-

cluding those with conscious human subjects). (*See* O. Foerster 1923, 1926, 1929, 1931, 1934, 1936; Foerster & Penfield 1930; Löwenstein & Borchardt 1918; Mankowski 1929; Penfield 1937–38, 1938; Penfield & Boldrey 1937; Penfield & Erickson 1941; Penfield & Evans 1935; Penfield & Gage 1934; Penfield & Rasmussen 1950; Klüver & Bucy 1937, 1938, 1939; Scarff 1940.)

Flechsig's subdivision appears valid though his idea of cerebral organization must be qualified. Most of the association areas, except, perhaps, parts of the temporal lobe, are not without connections with the subcortical regions, as Flechsig thought, but are related, e.g., to the thalamus, through afferent fibers of their own (Monakow; Siemerling 1898; Probst 1900; d'Hollander 1922; Minkowski 1923–24; Polyak 1932; Le Gros Clark 1936; A. E. Walker 1938, 1940; Walker & Fulton 1938; Freeman & Watts). Also, fiber tracts such as the frontopontine system of Arnold, temporopontine system of Türck, frontonigral, occipitotectal, and other systems originate in some of them (Polyak 1932; P. M. Levin 1936; Levin & Bradford 1938; A. E. Walker 1938; Papez 1939; Peele 1942; *et al.*). The afferent connections of the association regions, however, seem to be of a different order, less direct, originating in thalamic nuclei which are not the terminals of the great afferent sensory tracts of the brain stem and which, therefore, apparently transmit impulses of a complex nature, devoid of the character of concrete conscious objectivity.

SEC. 3. MYELOGENETIC INVESTIGATION OF VISUAL RADIATION

1. ORIGIN OF VISUAL RADIATION IN THE LATERAL GENICULATE NUCLEUS. Flechsig's investigation of the visual system (1874, 1876, 1881, 1883, 1889, 1894, 1895, and later) proved to be no less fruitful than that of the other systems. Visual radiation, discovered by Gratiolet (*see* chap. III, 5 [5]), had been, until then, little known. Meynert (1869; 1872, p. 721) described and illustrated it in the Monkey, though in a rather sketchy way (*see* sec. 1 [3], this chapter). In addition, he erred when he assumed that a portion of it terminated in the temporal lobe. Nor did Munk, in his notable experiments, indicate the exact location of the visual center (*see* chap. III, 8 [5]).

According to Flechsig, the afferent fiber tract, by which impulses from the eyes reach the cortex, is the first of the several fiber systems of the occipital lobe to develop myelin sheaths. Because of this, he termed it *primäre Sehstrahlung*, "primary visual radiation." He at first assumed that its origin was in the lateral geniculate nucleus, in the pulvinar of the thalamus, and in the superior colliculus of the midbrain. Later, however, in contrast with his forerunners, he found that it originated in the lateral geniculate nucleus only (*see* chap. III, 9 [2]). The thalamus, in Flechsig's opinion, was not an internode of the visual pathway. The initial portion of the visual radiation, close to its origin, was the first to become myelinized, followed somewhat later by the section close to the cor-

tex. This process of maturing was interpreted by Flechsig as an expression of the ascending or corticopetal character of this fiber system. Another system, a descending or corticofugal tract, arising in the occipitotemporal cortex and terminating in the midbrain, remained distinct from the first, even though it was close to it. Since that fiber tract, the occipitotemporal efferent corticotectal system, becomes myelinized at a later period, Flechsig named it *secundäre Sehstrahlung*, or "secondary visual radiation."

2. THE COURSE OF THE VISUAL RADIATION, ACCORDING TO FLECHSIG.—Flechsig (1896), describing the visual radiation in the human brain, first called attention to the peculiar course of the ventral fibers. These fibers, from their origin in the lateral geniculate nucleus, first go forward and downward in the temporal lobe. In the anterior portion of that lobe they turn under and around the inferior horn of the lateral ventricle and continue toward the occipital lobe, where they terminate. This sharp turn made by the visual radiation is known as Flechsig's "temporal knee" "temporal detour," or "temporal loop" (*see* Figs. 235, 236).

The "temporal loop" was subsequently studied by Niessl von Mayendorf, Hösel, Stauffenberg, Archambault, Löwenstein, A. Meyer, Zingerle, Monakow, Traquair, R. A. Pfeifer, Elze, L. L. Mayer, and Rasmussen (*see also* chap. VII, 3 [6]). Its discovery was erroneously attributed by some writers to A. Meyer and to H. Cushing (for Meyer's admission of Flechsig's priority, *see* Fox & German 1936, discussion).

In the occipital lobe the fibers of the visual radiation are arranged in a thick lamina, one of several deep fiber layers of the white medullary core concentrically enveloping the posterior horn of the lateral ventricle; Sachs (1892, 1893) described them as an "external" and "internal sagittal stratum" and a "tapetum" or "medial sagittal stratum" lining the ventricle.

The visual radiation, identical with the "inferior longitudinal fascicle" of Burdach (*see* chap. III, 5 [3]), was, according to Flechsig (1896), not a system of association fibers connecting the visual center in the occipital lobe with the auditory speech center in the temporal lobe, as it was considered to be by Wernicke, Sachs, Edinger, Monakow, Dejerine, and many others, but a constituent of Reil's *corona radiata*. (*Cf.* sec. 7 [4], this chapter.)

3. TERMINATION OF THE VISUAL RADIATION IN THE STRIATE AREA, ACCORDING TO FLECHSIG.—Visual radiation, Flechsig found, terminates in the brains of babies up to one month old in the part of the cortex of the occipital lobe around the calcarine fissure or sulcus, characterized by the intracortical stripe of Gennari & Vicq-d'Azyr, to which the term "striate area" was later given by G. Elliot Smith (1904; *see also* chap. VIII, 3 [5]). Here, according to Flechsig (1895), the main axis cylinders terminate. Soon, however, beginning with the end of the first postnatal month, the radiation fibers, probably collaterals, Flechsig thought, spread over a larger territory, which included the entire cuneus, lingual gyrus, and lateral face of the occipital lobe as far as, but not including, the angular gyrus that belonged to the parietal association region (1895, 1896). This whole extensive region belonged to the visual sphere in the wider sense. The larger part, that is, all but the striate area, was, however, a "marginal zone of the visual sphere," which Flechsig considered to be a substratum of the higher visual functions.

4. EFFECT OF FLECHSIG'S INVESTIGATIONS UPON THE MODERN CONCEPT OF CEREBRAL ORGANIZATION.—Flechsig's anatomical investigations and his interpretation of cerebral organization made a deep impression upon those of his contemporaries interested in the problem of brain and mind, both adherents and opponents. Through his efforts, the pioneer work of Gratiolet and Meynert was splendidly developed and brought to a preliminary conclusion. From that time on, knowledge of the visual pathway, of the cortical visual center, and of the remainder of the brain rested on a solid anatomical foundation.

Especially valuable was Flechsig's indication of the calcarine region as the visual center. Even so, much remained uncertain. Both the precise origin of the radiation and its terminal area in the cortex, in Flechsig's description, were left somewhat vague. Nor was it quite cer-

tain from his presentation which of the constituents of the radiation were afferent and which efferent. Also, he made no attempt to analyze the functional makeup of the visual pathway from which any useful indication could be gleaned for the topographical representation, or "projection," of the retina in the cerebral cortex. But the reality of a specific pathway involved in vision, stretching from the lateral geniculate nucleus of the betweenbrain to the inner face of the occipital lobe along the calcarine fissure and to its pole, was now beyond reasonable doubt.

SEC. 4. THEORY OF TOPOGRAPHICAL REPRESENTATION OF THE RETINA IN THE CEREBRAL CORTEX

1. Definition of the problem. The problem of the relation of the eye, or, more correctly, of the retina, to the brain in general and to the cerebral cortex in particular may be divided into two parts. The first concerns the identity of the visual pathway or the fiber system along which the impulses from the eyes pass to the various subcortical centers and finally to the cortex. This also includes the precise locality, boundaries, and extent of the terminal areas of the visual pathway. How the solution of this question was foreshadowed by Des Cartes, Briggs, and J. Taylor, and how it was advanced by others, especially by Gratiolet and by Flechsig, have been dealt with in the preceding pages (*see* chap. II, 10 [2], 11 [2, 5, 6]; chap. III, 5 [5]; chap. IV, 3).

The other particular problem may be formulated as follows. The photosensitive retinal membrane represents roughly a surface of somewhat more than half of a hollow spheroid, each point of which has a definite functional value in two-dimensional space in relation to the central fovea or "fixation point" as a common point of reference. The problem, then, was to determine whether, and to what extent, the original spatial or dimensional relationships of the retina are preserved in the visual pathways and centers; and, if they are, how and where the various distinct localities of the retina, such as the fovea ("macula"), the extrafoveal periphery, the upper and lower quadrants, the monocular crescent, the vertical and horizontal meridians, and so forth, were represented on the various levels of the visual pathway and in the cerebral cortex.

The particular question of topographical representation of the retina in the brain is part of a wider problem concerning the relationship of the peripheral receptor surfaces to the cerebrum, clearly formulated and correctly interpreted by E. H. Weber (1852), "Originator of the Science of Psychophysics," and later more clearly defined by Meynert (1869, 1872).

2. Early experiments to determine the topographical relationship of the retina to the cerebral cortex.— The necessity for a stable dimensional relationship of the photosensitive receptor surface of the eye to the brain had been clearly foreseen by Ibn al-Haitham centuries earlier (*see* chap. II, 6 [2]). Des Cartes, Briggs, J. Taylor, Zinn, Hun, and others had accepted this idea as self-evident (*see* chap. II, 10 [2], 11 [2, 5, 6]). With most of them, however, this was no more than speculation based upon logical postulation, unsupported by factual evidence. Only modern experiment could have furnished this evidence.

Munk (1879, 1881) was the first to make an experimental attempt to solve the problem of the topographical representation of the retinal surface in the cerebral cortex, in pursuance of Weber's, Graefe's, and Meynert's ideas of "projection." From his experiments on dogs and monkeys he mistakenly concluded that the temporal portion of the retina was represented in the lateral portion of the ipsilateral visual

area, and the much larger nasal portion of the retina in the larger medial portion of the contralateral visual area. He also found that in the Dog the upper half of the retina was related to the anterior portion, the lower half to the posterior portion, of the visual area (more than a quarter of a century later, this observation was confirmed by Minkowski; *see* sec. 7 [3], this chapter). On much firmer ground was E. A. Schäfer (Sharpey-Schäfer 1888, 1889, portrait Fig. 116), who was in fact the first to demonstrate a regular topographical distribution of oculomotor centers in the cortex of the occipital lobes, whence he postulated a similar organization of the adjacent visual area.

3. OPPOSITION TO STABLE REPRESENTATION OF THE RETINA IN THE CORTEX. Munk's and Schäfer's concept, while favorably received by most clinicians, met with strenuous opposition from contemporary physiologists and experimenters—Goltz (1881), J. Loeb (1884), Luciani

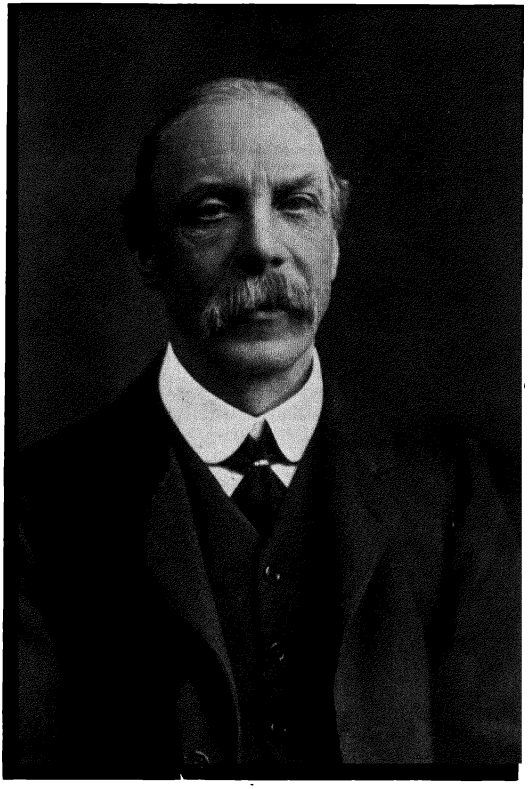

FIG. 116. Edward Albert Schäfer (Sharpey-Schäfer, 1850–1935), professor of physiology at the University College of London, and at the University of Edinburgh, Scotland. One of the leading British physiologists. First experimentally disclosed the topographic arrangement of stimulable points in the occipital lobe of the Monkey from which distinct conjugate eye movements could be elicited, in agreement with Munk's hypothesis of cortical projection of the retina. Also, he first produced experimentally, in the Monkey, "psychic blindness" and "change of character" after a bilateral removal of temporal lobes, which has recently become of interest in the light of experiments by Klüver & Bucy. Portrait courtesy of Dr. F. M. R. Walshe, of London. Obituary and portrait in Quart. J. Exper. Physiol., v. 25, p. 99, 1935.

(1885), Ferrier (1886), Brown-Séquard (1889, 1890, 1892), Monakow (1892, 1902–4, 1905, 1914), H. Sachs (1895), and, remarkably, also Hitzig (1901–3, 1905). While, by and large, they accepted the hemianopic character of visual disturbances following a unilateral lesion of the posterior portion of the cerebral hemisphere, the opponents questioned any detailed and stable relationship between the restricted portions of the retina and the well-defined segments of the cerebral cortex. The profit from their profuse criticism was, on the whole, rather modest: the discovery that, in the Dog, the visual area was located in the posteriormost portion of the hemisphere, instead of on the lateral surface of the occipitoparietal region, where Munk localized it, and that the ipsilateral and contralateral homonymous halves of the retinae had a common representation in the same cortical area, instead of being represented in separate areas placed side by side, as Munk originally assumed.

4. Wilbrand's and Henschen's attempt to reveal the functional organization of the visual pathway.—The dispute between Munk and his adversaries about a detailed and stable projection of the retina in the brain was taken up by numerous investigators of the following generation.

First to substantiate the topographical organization of the visual cortical area by experiments with monkeys was A. E. Schäfer (Sharpey-Schäfer 1888, 1889, portrait Fig. 116), a London physiologist. A regular, topographical arrangement of the points at and close to the occipital lobe, from which synergic ocular movements could be elicited, was to him suggestive of a similar topographical organization of the cortical visual center.

Among the clinicians siding with Munk, the most notable were H. Wilbrand (pub. 1881–1929, portrait Fig. 107), of Hamburg, Germany, and S. E. Henschen (pub. 1892–1931, portrait Fig. 117), of Uppsala and Stockholm, Sweden. During their activity, spreading over almost half a century, these two indefatigable researchers systematically investigated all parts of the visual pathway, beginning with the optic nerves, subcortical visual stations, and visual radiation, and including the visual cortical centers. The way in which Wilbrand and Henschen attempted to solve the problem was partly through normal anatomy, but more especially through the study of visual disturbances in clinical cases, followed by a careful pathoanatomical analysis of brain specimens. The result of their efforts may be summarized, first, in their conviction of cortical preponderance in vision, in this respect breaking from the older school of Goltz, Hitzig, and others, who, still adhering to the former views, ascribed the principal role to the subcortical centers; the other important result of their work was the substantiation of a stable topographical representation of the retina in the brain, which they elaborated and documented in detail.

5. Wilbrand's hypothesis of syndynamical conductors in the suprachiasmal division of the visual system.—Early in his career, Wilbrand (1890) was induced by his clinical campimetric work to accept Munk's "retinotopical principle," with, however, one notable qualification. From observations of congruous scotomas of central origin, he concluded that the two homonymous retinal halves were represented in a common cortical area, instead of independently, side by side, as Munk insisted. Out of this Wilbrand developed a hypothesis, according to which the two sets of optic nerve fibers arising from the "identical or conjugate points" of the homonymous halves of both retinae come to lie very close together in the visual pathway above the chiasma. The visual radiation, for example, he imagined to be made up of pairs of bundles, one corresponding to the ipsilateral, and the other to the contralateral, "identical point," each bundle terminating in a minute territory of the visual cortex. He also thought of the functional cortical units as each made up of two minute areas, an ipsilateral and a contralateral. The visual cortical center, as conceived by Wilbrand, was a mosaic of such double units, each representing a point in the ipsilateral and a point in the contralateral homonymous halves of the two retinae, the points which, in the normal binocular visual act, function syndynamically: the "hypothesis of associated or syndynamical homonymous conductor units" in the visual pathway (*Hypothese der Faszikelfeldermischung*).

Such complete, uniform, and accurate commingling of the syndynamical receptor, conductor, and perceptive units of both sides — which otherwise preserve their relative topographical position in the entire visual pathway from the retina to the visual cortex — was, in Wilbrand's opinion, the anatomical basis of the congruity of visual field defects of homonymous character, that is, of similarity in shape, size, and location of the blind areas in both monocular fields of view regularly found in the unilateral lesions of the brain which involve the suprachiasmal portion of the visual pathway. (*See* Wilbrand 1907, 1925, 1925–26, 1926, 1930; Wilbrand & Saenger 1917, 1918; for the forerunners of Wilbrand's hypothesis, Des Cartes, Isaac Newton, John Taylor, and Johannes Müller, *see* chap. II, 10 [2], 11 [4, 5]; for Monakow, *see* sec. 5 [5], this chapter; *cf. also* chap. XIII, 3.)

6. HENSCHEN'S VIEW OF THE VISUAL SYSTEM'S INTRINSIC ORGANIZATION. — Henschen, through his study of brain specimens of numerous cases in which various types of visual field defects had been found during life, also became convinced that there was a stable projec-

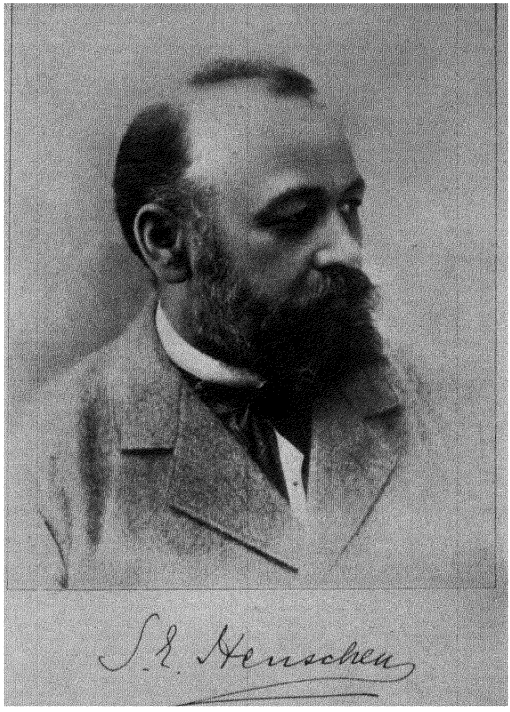

FIG. 117. — Salomon Eberhard Henschen (1847–1930), professor of medicine in Upsala and Stockholm, Sweden. One of the foremost modern students of the pathology of the brain and its clinical manifestations. An indefatigable champion of the idea of functional cerebral localization. A great figure in the field of neurology of his time and an opponent of the "diffuse" or "pliable" concept of cerebral organization championed by C. Monakow (*see* following figure). From Henschen's autobiography in L. R. Grote, *Die Medizin der Gegenwart in Selbstdarstellung*, v. 5, F. Meiner Verlag, Hamburg, 1925. *See also* Krabbe in Acta Psychiat. & Neurol., v. 6, 1931; Pötzl 1926; Minkowski 1932; Haymaker's *Guide*, 1948; and Haymaker & Baer, *The Founders of Neurology*, 1953.

tion of the retina onto the subsequent links of the visual pathway, including the cerebral cortex; his dictum that the visual cortical center was a "replica of the retina" or, in fact, a "cortical retina" became famous and much disputed. (*Cf.* Monakow's *Abklatsch*-hypothesis in subsec. 4, following section.)

The following, in brief, is the internal organization of the visual system as outlined by Henschen. Within the optic nerve the fiber segments originating from particular quadrants of the retina have a definite position. The foveal or "macular bundle" is located approximately in the center of the nerve. In the lateral geniculate nucleus, the upper retinal quadrants were located in the upper, the lower quadrants in the lower, and the "macula" in the intermediate, segments (for the actual relationships *cf.* sec. 6 [4], this chapter, and chap. VI, 7). Of the three sagittal fiber layers of the occipital lobe described by Sachs, it is the external stratum that is the visual radiation, and not the internal, which is an efferent system. The dorsal bundles of the radiation terminate in the upper lip of the calcarine fissure; these represent the upper retinal quadrants or lower quadrants in the fields of view. The ventral bundles of the radiation, representing the lower retinal quadrants, or upper field quadrants, enter the lower lip of the fissure. The floor of the fissure receives fibers from both the upper and the lower bundles of the radiation. Functionally, it corresponds to the horizontal meridians of the retina (thus in Henschen's case *Eggert*, 1911; *see* Fig. 396, this book). However, Henschen was not able to indicate where the "macular" or foveal bundle was located in the radiation. On one occasion he suggested the possibility of "macular fibers" being spread in a thin layer on the inner, ventricular face of the radiation, with the "extramacular fibers" on the outside.

7. Location and functional organization of the cortical visual center. The cortical visual center, Henschen was certain, was confined to the calcarine fissure. For a long time, however, he (1903, p. 93) was not sure whether it was identical with the striate area or whether the tip of the occipital lobe belonged to it. He was equally uncertain in locating the cortical fovea, or "macula." For a number of years he believed it to be in the anterior portion of the calcarine region, at the point of junction of the calcarine fissure and parieto-occipital sulcus, and the extramacular retinal periphery to be in the occipital pole. He obstinately clung to this view, in spite of good evidence to the contrary (1890–96, 1900, 1907, 1911, 1917). Such was a notable case clinically investigated by R. Förster (1890) and anatomically studied by Sachs (1895), the first wherein Munk's "cortical blindness" was carefully tested. In this case both fields of view were blind, with the exception of central portions around the points of fixation; the pathological cause was symmetrical encephalomalacic foci in the territories of both posterior cerebral arteries, which spared both occipital poles (on the vascular mechanism by which such polar sparing may be explained *see* chap. X, 6 [3], 8 [4], and chap. XI, 8, 9).

Even more convincing was another similar case reported by Laqueur & Schmidt (1899; *see also* Laqueur 1899, 1904): a bilateral homonymous hemianopia with a minute central field "rest" of less than two degrees caused by a thrombotic encephalomalacia spreading over the medial face of both occipital lobes and sparing only the poles. In spite of this demonstration showing the "macula" or central fovea to be represented in the occipital pole and the retinal periphery in the anterior portion of the striate area, as advocated by Dejerine (1895–1901), Christiansen (1902), Beevor & Collier (1904), Laqueur (1904), Niessl von Mayendorf (1905), and especially Lenz (1909, 1910, 1914, 1924, 1926, 1927), Henschen refused to accept such an arrangement and did so only much later upon overwhelming evidence, especially of war injuries made known through Inouye (1909), Cantonnet (1915), Uhthoff (1915, 1916, 1922), Holmes & Lister (1916), Marie & Chatelin (1916), Monbrun (1917, 1919, 1924), Souques (1917), Souques & Odier (1917), Holmes (1918, 1919), Moreau (1918), Morax (1919), Morax, Moreau & Castelain (1919), Monbrun & Gautrand (1920), and other investigators (*see* sec. 7 [7], this chapter; *cf. also* chaps. XI, XII).

Summarizing the work of Wilbrand and of Henschen, it is fair to say that, even though they were not able to avoid all pitfalls—Wil-

brand & Saenger, as late as 1918, localized the so-called "monocular crescent" in the occipital pole—progress in the knowledge of the visual system achieved during the following years was in no small degree the result of their labors and of the interest they kept alive.

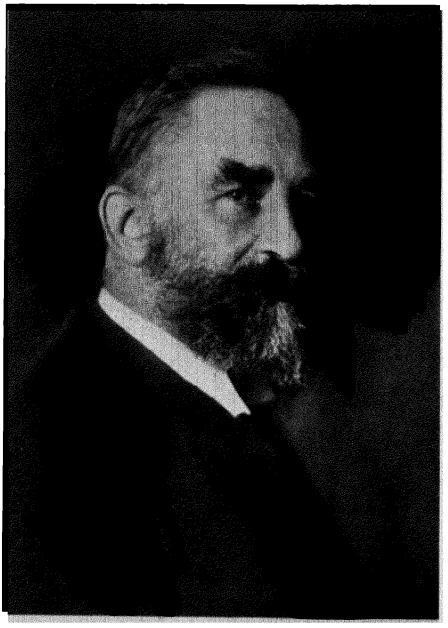
SEC. 5. HYPOTHESIS OF "DIFFUSE" OR "PLASTIC" ORGANIZATION OF THE VISUAL CENTERS

1. Objections of decentralists to stable functional localization of vision. The modern doctrine of detailed and fixed representation of the retinal surface in the brain, especially in the cerebral cortex, promulgated by Munk and further developed by Wilbrand and Henschen (*see* preceding section), was not unopposed. In fact, for several decades most of the nonclinical investigators disclaimed it. Hitzig, pioneer of functional cerebral localization, rejected it. Subsequently it was vigorously disputed by many, including some of the foremost authorities of the time (Brown-Séquard, Goltz, Loeb, Luciani, Gudden, Vialet, Bernheimer, Wehrli, Stauffenberg, S. I. Franz, Kalberlah, P. Marie, H. Sachs, *et al.*).

For a number of years, the recognized leader of this "decentralist school" in neurology was Constantin Monakow, Professor of Neurology in Zürich (portrait Fig. 118, pub. 1881–1928; for biography *see* Minkowski 1931, 1936, 1953; Winkler 1923; and R. A. Pfeifer 1925). To him, the basic concept of cerebral organization and of the visual system in particular, championed by Munk, Wilbrand, and Henschen, seemed too crudely mechanistic to be acceptable or even probable. It is true that Monakow never went to the extreme of denying altogether the idea that particular functions may be more closely related to certain localities of the cerebral cortex. In fact, the title of his last great contribution, *The Localization in the Forebrain*, would disclaim such an allegation. In this respect he contrasted favorably with the extremist leaders of the antilocalist trend of former days, A. Haller, Flourens, Goltz, Brown-Séquard, and others (*see* chap. III, 2, 4). What Monakow and his followers were opposed to was the insistence of the localists on a "rigid," "exclusive," and "insoluble" dependency of a certain function upon a definite cortical locality. The paramount importance of vision and the "enormous complexity" of the visual function, in Monakow's opinion, excluded the possibility of its dependence upon a single limited area of the brain, such as the "calcarine region," as claimed by the localists.

2. The concept of diffuse or multiple cortical representation of the retina as proposed by Monakow. The starting point of Monakow's argumentation—and the source of his errors—was his assumption of three subcortical visual centers: the lateral geniculate nucleus, where, according to him, 80 per cent of the optic nerve fibers terminate; the pulvinar of the thalamus; and the superior colliculus of the midbrain (*cf.* chap. III, 9 [2]). His experiments and pathological studies suggested to him that each of the three stations might be related through its own fiber system to a particular locality of the cortex.

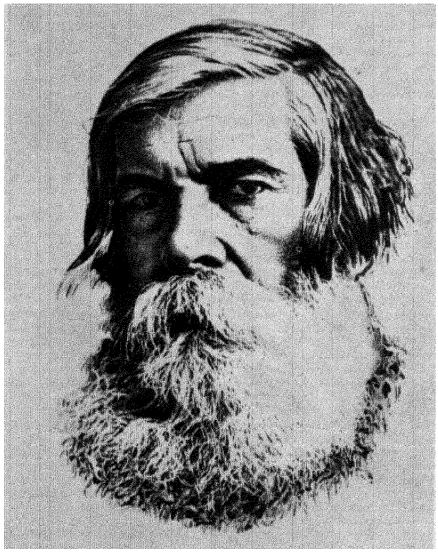


The representation of the lateral geniculate nucleus, which, according to him, was obviously the most important of the three stations, was almost identical with, or possibly somewhat larger than, the striate area, the latter being the most important part of the entire visual cortical sphere, its "nuclear zone." The pulvinar and the superior colliculus project upon parts

of the cortex, apparently outside the striate area (here Monakow undoubtedly misinterpreted the corticofugal or motor character of the occipitotectal fiber system). There are, accordingly, three, and in any case no less than two, distinct "visual spheres" in the cerebral cortex. In each of these, possibly widely separated, visual centers the pattern or plan of retinal representation was possibly different. Again, apart from its principal terminal area, the fiber tract from each of the three subcortical stations of sight might spread over the adjoining cortex, the "accessory or subsidiary zone." There might even be a third extensive representation, a "conjoint visual sphere," common to all three subcortical stations.

The anatomical visual sphere of the cortex, according to Monakow, was neither so restricted nor so sharply outlined as advocated by the radicals of cerebral localization (e.g., Wilbrand, Henschen). In fact, it included not only the cuneus and the lingual and descending gyri but also the lateral face of the occipital lobe and, in addition, probably parts of the parietal lobe (*cf.* Figs. 271, 272, 273). The precise boundaries of this "wider visual sphere" whose bilateral destruction produces permanent cortical blindness were, according to Monakow, not yet known.

This view of the organization of the visual centers was maintained by Monakow even after Bechterew (1906), Kurzveil (1909), and, remarkably, also his own pupil Minkowski (1911) furnished adequate experimental evidence in favor of the striate area as the "physiological center of vision" (*see* sec. 7 [3], this chapter). (*See* Monakow 1914, pp. 373, 374, 379, 386, 394, footnote.)



3. MONAKOW'S OPPOSITION TO THE CONCEPT OF "THE CORTICAL RETINA." Monakow was especially averse to the concept of a stable, detailed retinotopical arrangement, either in the visual pathway or in the visual cortex, such as was claimed by Wilbrand and by Henschen (*see* sec. 4 [4–7], this chapter). He refused to accept the "point-to-point" or "one-to-one" representation as an organizational principle in the visual system and in the nervous system in general. But, unlike Hitzig, who fanatically persisted in denying all retinotopical relationships whatsoever, Monakow, at any rate, admitted a rough quadrantic representation. He believed that in the visual radiation the upper retinal quadrants are represented in the upper, the

C. v. Monakow

FIG. 118.—Constantin v. Monakow (orig. Monáchov, in Russian, 1853–1930), professor of neurology in Zürich, Switzerland. An encyclopedic investigator of normal brain structure and its changes in pathological conditions and in experiment. First demonstrated experimentally the occipital location of visual functions. One of the leading figures of his time in neurology, and a champion of the "diffuse" or "pliable" concept of cerebral functional localization (as against a rigid concept, insisted upon by S. E. Henschen, *see* preceding figure). Author of *Die Gehirnpathologie*, 1905, and of *Die Lokalisation im Grosshirn*, 1914. From Schweiz. Arch. f. Neurol. u. Psychiat., v. 13, 1923. For biography *see* M. Minkowski in the same journal, v. 27, 1931, and Arch. internat. de neurol. v. 55, p. 531, 1936; *also* C. Winkler in Schweiz. Arch. f. Neurol. u. Psychiat., v. 13, p. 11, 1923; Haymaker's *Guide*, 1948; Haymaker & Baer, *The Founders of Neurology*, 1953; and Katzenstein, Neue Zürch. Zeitung, December 9, 1953.

lower quadrants in the lower, segments, agreeing in this point with Henschen. In the cortex he advocated representation of the upper retinal quadrants in the anterior, and of the lower quadrants in the posterior, parts of the occipital cortex, constantly confusing this view with Henschen's scheme, according to which the upper retinal quadrants are projected upon the upper lip, and the lower quadrants upon the lower lip, of the calcarine fissure.

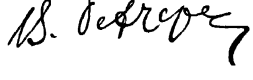


FIG. 119. Vladímir Mihâilovich Béhterev (Békhteryev, 1857–1927), together with I. P. Pávlov, the most assiduous Russian investigator of the structure and function of the nervous system, studied conducting pathways of the spinal cord and brain. Of importance were Béhterev's physiological experiments on localization of particular functions in distinct parts of the cerebral cortex, such as taste (in operculum), cutaneous and muscular sensibility (in parietal region), vision (in occipital lobe), and complex motor acts (in motor area). Especially revealing was his disclosure of the dependence upon the cerebral cortex of the function of the heart, of the numerous visceral organs and organs of generation, of respiration, of regulation of blood pressure and of temperature. Author of several books on anatomy and physiology of the nervous system and on clinical neurology, including *The Functions of the Nerve Centers* (*Die Funktionen der Nervencentra*, in German), 1908–11, in three volumes. Portrait from his anniversary book (Sbornik) published by Government Psychoneurological Academy and by Reflexological Government Institute for Brain Research, Leningrad, 1926. For biography *see* W. Haymaker's *Guide*, 1948; and Haymaker & Baer, *The Founders of Neurology*, 1953.

4. MONAKOW'S REJECTION OF DISCRETE CORTICAL REPRESENTATION OF THE FOVEA OR "MACULA." Monakow was even less prepared to accept a representation of the fovea or "macula" in a restricted "island-like" portion of the cortex, such as was insisted upon by his principal opponents, Wilbrand and Henschen, and subsequently by Lenz. Instead, for several reasons, he advocated the concept of "diffuse representation" of the "macula" in a wide area.

To begin with, the "macular fibers" of the optic nerve and tract, he maintained, spread diffusely in the entire lateral geniculate nucleus. In this way, he believed all original retinal spatial, dimensional, or topographical relationships became obliterated. Furthermore, he assumed that the terminals of the "macular" fibers were not directly related to the nerve cells whose axons form the visual radiation, but to a special category of small nerve cells, which he called *Schaltzellen*, meaning "intercalated cells," the neurons belonging to Golgi's second type with a short axis cylinder. These intercalated cells, in turn, Monakow claimed, were related to the larger elements, his *Hauptzellen* or "principal cells," whence the fibers of the visual radiation originate.

Since all these contacts were "diffuse," that is, widespread and irregular, even if a part of the visual pathway were blocked off by a lesion, the "macular" influences could still spread to all parts of the lateral geniculate nucleus and could thus gain access to an extensive area of the cortex. A diffuse arrangement of this kind, furthermore, would facilitate a process which he termed *Umschaltung*, a "rearrangement," or "regrouping," of the original retinal relationships. A continuous isolated conduction in the visual pathway would, accordingly, not exist.

Nor was there a distinct and compact "macular bundle" in the visual radiation, according to Monakow. The representation of the "macula" in the cortex would be only "indirect," perhaps multiple, and spread over a wide area. It probably extended beyond the "anatomical visual

sphere" proper (which in Monakow's jargon was apparently synonymous with the striate area) to the lateral face of the occipital lobe, possibly as far as the posterior portion of the angular gyrus, a reminder of a similar claim made decades earlier by Ferrier (*see* chap. III, 7 [2]).

Such an arrangement would, of course, preclude any fixed, "geometrical" retinotopical representation of the retina and "macula" in the visual system. An *Abklatsch*, meaning an accurate replica or a copy of the retina in the cerebral cortex, a "cortical retina," claimed by Wilbrand, Henschen, and other localists, was not present, and a transmission of unaltered retinal "figures" to the cerebral cortex did not take place. Logically, Monakow also doubted whether any strictly "macular" hemianopic scotomas of purely cortical origin were possible and whether they ever occur (for contrary observations, *see* chaps. XI, XII).

Monakow, on the other hand, rejected the hypothesis of bilateral representation of each total "macula," proposed by Wilbrand, correctly pointing out its inconsistency with the basic views of his opponents, who, according to him, "invented it" (*see* chap. VII, 6, 8; chap. XI, 8, 9).

5. INADEQUACY OF THE "DECENTRALIST" CONCEPT OF THE VISUAL SYSTEM.—The essential idea of cerebral organization held by Monakow was "plastic," nonmechanical. It was incompatible with the concept of a visual pathway composed of numerous, nearly equivalent, and largely independently functioning conductor units made up of cells and fibers arranged in such a way as to preserve topographical relationships between the retina and the cortex. The congruity and the precise linear outlines of homonymous hemianopic field defects, neatly explained by Wilbrand's hypothesis of "commingling of syndynamical ipsi- and contralateral conductor units," in terms of Monakow's doctrine, would remain a puzzle (*see* sec. 4 [5], this chapter). Such fundamentally "dimensional" functions as visual acuity and visual space perception were equally inexplicable.

The only symptom to which his doctrine could be applied with some profit was "macular sparing" in homonymous hemianopia (*see* chap. XI, 8 [esp. 5], 9). If there were partial damage to the lateral geniculate nucleus, for example, the impulses from the "macula" could still pass over to portions remaining normal and thus attain the cortical level, since, according to Monakow, the "macular fibers" spread diffusely over the entire nucleus. Similar interpretations would also be applicable to cases with partial destruction of the visual cortical area. For here, too, because of widely scattered and possibly multiple representation, "macular" impulses could still find a sufficient cortical substratum, even though the calcarine cortex were largely destroyed. Functionally, this again would manifest itself by "sparing" the "macula," that is, the central or foveal portion of the otherwise blind fields of view (*cf.* chap. XI, 8).

6. CRITIQUE OF THE "DECENTRALIST" CONCEPT OF THE CEREBRAL ORGANIZATION OF VISION.—The deductions of Monakow, Hitzig, Bernheimer, and other decentralists concerning the functional organization of the visual pathway and centers suffered from two fatal weaknesses.

The first was the inadequacy of their investigative technique when measured not only by modern standards but also by those of their own time. Goltz's technique, for example, was inexcusable, even at the time at which it was practiced (*see* chap. III, 7 [6]). The experimental technique of other decentralists, not excluding Hitzig and Monakow himself, was also rather "sloppy." It did not permit accurate gauging of restricted functional defects, such as small scotomas.

Their laboratory procedures were also rather primitive and sometimes quite faulty. But the greatest weakness was their method of study and interpretation, which may be characterized as slack, undisciplined, and often illogical: thus when Monakow consistently used the terms "origin" and "termination" of the fiber systems vicariously, leaving in confusion the question of their functional character, whether sensory-afferent or motor-efferent, or when, while admitting a functional-anatomical organization of the visual radiation, he nevertheless refused to accept the unavoidable pathophysiological consequences of it. Nor could such defects, with glaring prejudices and intransigence, be covered by a profusion of questionable evidence, by additional gratuitous hypotheses, and by an

endless torrent of persuasive, but empty, verbiage found in too many of the voluminous treatises of this school (*see* especially Hitzig 1900–1903, Weygandt, Monakow 1914, and Goldstein).

Small wonder, therefore, that the "decentralist" views held but little appeal for those used to disciplined and strictly causal anatomical and physiological thinking. The decentralists found, on the contrary, and still occasionally find sympathetic response among those, usually little acquainted with anatomy and biology in general, who habitually seek satisfaction in such nebulous concepts as are expressed by the terms "cerebral plasticity," "vicarious function," "total action," "diaschisis," "reorganization of functions," "dynamic factors," "pseudo-fovea," and the like and among those who generally favor the "dynamic" and "functional" viewpoint, as against the "anatomical" and "mechanical."

SEC. 6. RECENT INVESTIGATIONS OF THE INFRANUCLEAR DIVISION OF THE VISUAL SYSTEM

1. Improved standards in neuroanatomy and their effect upon the investigation of the visual system.—With the advent of the twentieth century, the demands upon the anatomy, physiology, and pathology of brain research increased, in harmony with the higher standards in other branches of natural science and medicine. The guessing and speculation characteristic of much clinical medical thinking of the preceding decades, with its self-bestowed freedom to create plausible hypotheses of anatomical structures whenever needed in order to explain away a difficult diagnostic situation, gradually became recognized as unsatisfactory. Clearly, only evidence which could be observed, verified, tested, and measured was acceptable as a criterion fit for the solution of pending problems.

The substantial achievements of Munk, Flechsig, Wilbrand, Henschen, and a host of other investigators in furthering knowledge of the brain under normal and pathological conditions, great as they were in comparison with the preceding period, did not seem binding in the opinion of many. There was too much left to the liberty of individual interpretation and to personal preference, to have the value of permanence and finality.

In the visual pathway the important question of the subcortical nuclei, undoubtedly related to the optic tracts, still had to be answered. Another problem was the exact projection of the extrafoveal retinal quadrants and of the fovea or "macula" upon the subcortical visual stations. Even less certain was the exact origin, course, and arrangement of the bundles of the visual radiation and the way they reached their respective terminal areas in the cerebral cortex. The basic question—whether or not the terminal cortex of the visual radiation was identical with the striate area still remained to be answered. This uncertainty may have been responsible for the prolonged influence that the ideas of Monakow and other "decentralists" had upon their time. It became obvious, then, that the only way to clarify the internal organization of the visual pathway was through well-planned, systematic experimentation, supplemented by the study of selected pathological cases.

2. Identity, course, and termination of the foveal or "macular" fibers in the human optic nerve and lateral geniculate nucleus.—The first decisive move in the anal-

ysis of the fascicular composition of the infranuclear division of the visual system, in continuation of the pioneer work of D. E. Müller, Samelsohn, Purtscher, Uhthoff, Vossius, Bunge, Jatzow, Thomsen, Schmidt-Rimpler, Widmark, Dalén, Wilbrand, and Henschen (*see* chap. III, 9 [7–9]), was made by H. Rønne (Roenne 1914, portrait Fig. 120). Contrary to the claim of Monakow, Bernheimer, and other "decentralists," in several cases of central neuritis of the optic nerve caused by diabetes, alcohol, and tobacco, he found the "papillomacular bundle" to be a definite anatomical entity, terminating in a sharply outlined locality, corresponding approximately with the intermediate segment of the lateral geniculate nucleus.

3. Early experimental evidence in favor of retinotopical organization of the visual system. The experimental approach to the problem of the fascicular composition of the optic nerves and tracts was first used by Pick (1894), Pick & Herrenheiser (1895), Usher & Dean (1896), and H. Parsons (1902). In their experiments, in which they made small lesions in the retina, they studied the infranuclear section of the visual system. The method used was that of Marchi's secondary degeneration, by which the course of fibers was determined. Even though in some of these experiments monkeys were used, as well as rabbits and cats, the results were of limited value, since the lateral geniculate nuclei were not examined.

Fig. 120.—Hennig Kristian Trappand Rønne (Roenne, 1878), professor of ophthalmology at Copenhagen, Denmark. Eminent investigator of the visual organs and a "chief exponent of quantitative perimetry" in modern time (according to Traquair). First correctly indicated the location of "macular representation" in the intermediate segment of the lateral geniculate nucleus and of the "macular fiber bundle" in the intermediate portion of visual radiation of the occipital lobe of the brain. Courtesy Professor H. Rønne.

Lubsen (1921), following Ariëns Kappers' suggestion, carried out similar experiments upon a fish, *Leuciscus rutilus*, and found detailed retinotopical representation in the midbrain tectum. Similar evidence of detailed retinal representation was obtained by Brouwer (1923, 1926), Brouwer & Zeeman (1925, 1926), Zeeman (1925), and Overbosch (1927), in the optic nerves, chiasma, and lateral geniculate nuclei of the Rabbit and Cat and in the contralateral superior colliculus of the midbrain in the Rabbit. A like situation was also found by Lashley (1934) in the Rat and by Bodian in the Opossum (1937).

4. BROUWER & ZEEMAN'S EXPERIMENTS CONCERNING THE RETINOTOPICAL ORGANIZATION OF THE INFRANUCLEAR DIVISION OF THE SIMIAN VISUAL SYSTEM.—Far more fundamental and certainly more spectacular, because of the obvious human implications, were the experiments performed by Brouwer & Zeeman upon monkeys (1925, 1926, portrait Fig. 121). They found that in the optic nerve the "macular" fibers are gathered into a thick bundle. Close to the eyeball this bundle hugs the temporal margin of the nerve. Near the chiasma the macular bundle gradually shifts toward the center. In the chiasma its position is central, leaving the upper and lower margins to the fibers from the upper and lower extramacular nasal quadrants. In the optic tracts the crossed and the uncrossed fibers were not separated but were intermingled. They were, however, arranged retinotopically, with the upper quadrants in the dorsomedial, the lower quadrants in the lateroventral, and the "macula" in the intermediate segment of the tract. (*Cf.* chap. VI, 7.)

Brouwer & Zeeman recognized the lateral geniculate nucleus, the gray pregeniculate nucleus, and the superior colliculus of the midbrain as the subcortical terminal stations of the optic nerve. In none of the species (Rabbit, Cat, Monkey) was the pulvinar of the thalamus connected directly with the eye. In the Monkey there is no *fasciculus accessorius optici anterior* and no *tractus peduncularis transversus* of Gudden, found in the Rabbit and the Guinea Pig (*see also* Overbosch).

The most important result of Brouwer & Zeeman's fundamental work concerned the lateral geniculate nucleus. In the Monkey, the bulk of the optic nerve fibers terminates here. Relatively few fibers pass over to the superior colliculus by way of the brachium, fewer in the Monkey than in the Cat and the Rabbit. On the contralateral side, these optotectal fibers are more numerous, apparently all originating in the extramacular parts of the retina. There is a slight suggestion of retinotopical projection in the colliculus also, the fibers from the upper retinal quadrants entering the posterior, those from the lower quadrants entering the anterior, segments.

In the lateral geniculate nuclei the upper extramacular quadrants are projected upon the inner or medial, the lower quadrants upon the outer or lateral, segments (the nasal quadrants in the contralateral, the temporal quadrants in the ipsilateral, nucleus). The much-disputed "macula," more correctly called the central fovea, sends fibers to the intermediate segment of the nucleus lodged between the two extramacular segments. The size of the "macular" representation is larger than that of the extramacular segments. Altogether, Brouwer & Zeeman were able experimentally to substantiate Rønne's observation of retinal representation in the human lateral geniculate nucleus, and in this point corrected Henschen's error (*see* chap. III, 9 [8, 9], and sec. 4 [6], this chapter).

Concerning the controversy between Henschen, who advocated a restricted and sharply localized projection of the "macula," and Monakow, who favored a diffuse spreading of the "macular" influences over most of the lateral geniculate nucleus, Brouwer & Zeeman were less explicit. Since, according to their observations, "macular" fibers appeared scattered over a larger portion of the nucleus and since there seemed to be partial overlapping of the "macular" and "extramacular" segments, "macular" impulses could, in their opinion, reach the entire nucleus and thus spread over an extensive portion of the visual cortical area, an obvious concession to Monakow's viewpoint. On the other hand, since only the "macular" fibers terminate in the intermediate segment, there was no doubt about a certain amount of localization of the "macula" also (a guarded compromise with Henschen's viewpoint). (*Cf.* secs. 4 [6] and 5 [4], this chapter; for detailed com-

parison with results presented in this book *see* chap. VI, 7.)

5. Le Gros Clark & Penman's and Brody's experiments on retinotopical projection in the lateral geniculate nucleus.—Brouwer & Zeeman's observations have been further amplified, and in several important points corrected, by the experiments, also made upon monkeys, of Le Gros Clark & Penman (1934, portrait Fig. 310), and by Brody (1934). In these, small lesions were made in different parts of the retina. The method by which the location and size of degenerated zones in the lateral geniculate nuclei were determined was "transsynaptic" or "transneuronal" atrophy-degeneration, which permits greater precision than the Marchi method. In various parts of

FIG. 121.—Bernardus Brouwer (1881-1949), professor of neurology at Amsterdam, Netherlands. An illustrious investigator of the visual pathways and centers. In association with W. P. C. Zeeman, first furnished experimental evidence in the Monkey of a quadrantic representation of the retina in the lateral geniculate nucleus. Courtesy Professor B. Brouwer, 1946. For obituary and portrait *see* Nederl. tijdschr. v. geneesk., v. 93 (4), p. 3866, 1949.

the nuclei a sharp projection was found, with no overlapping of the "macular" segment by the "extramacular."

The extent of the "macular" projection was also less, being restricted to approximately the posterior two-thirds of the lateral geniculate nucleus. Anteriorly it begins as a narrow segment, gradually expanding, until, close to the posterior extremity, almost the entire nucleus belongs to the "macula." The central fovea is apparently confined to the posterior third of the nucleus. Of the six cell layers, all belong in part to the macula-fovea, with separate layers representing the ipsi- and contralateral homonymous halves of the two maculae-foveae. "Macular" representation follows the same pattern as that found in the "extramacular" parts of the nucleus. Finally, the "fibers from the nasal half of the 'macula' undergo complete decussation in the chiasma, while those from the temporal half remain uncrossed."

6. THE DISCOVERY OF SEPARATE TERMINATION OF CROSSED AND UNCROSSED OPTIC NERVE FIBERS BY MINKOWSKI.—Cramer (1898) and S. Ramón y Cajal (1899) already anticipated that the two sets of optic nerve fibers—the nondecussating ipsilateral and the contralateral which decussate in the chiasma—terminate discretely. The question, however, was positively answered when Minkowski (1913, 1920, portrait Fig. 122) made the notable discovery that the two categories of fibers do not terminate in the same layer, but in different layers of the laminated lateral geniculate nucleus. In the Monkey, for example, if the left eye is removed, the cell laminae *1*, *4*, and *6* of the contralateral right geniculate nucleus—counting from the lowermost superficial layer at the hilum—degenerate, indicating a termination of the decussating fibers; in the nucleus of the left side, where the nondecussating ipsilateral fibers terminate, laminae *2*, *3*, and *5* are affected (for designation and terms *see* chap. VI, 8 [3]; *see also* Le Gros Clark 1941; Le Gros Clark & Penman 1934). In other words, the cell layers or laminae in the lateral geniculate nucleus represent two sets, one related to the ipsilateral, the other to the contralateral, homonymous retinal half.

In Man the arrangement is essentially the same, as was first found by Minkowski and subsequently confirmed by Schroeder (1929), Balado & Franke (1930), Lenz (1930), Le Gros Clark (1932), Sántha (1932), Hechst (1933), Juba (1933), Orlando (1933), and Barris (1935). (*See also* chap. VI, 6 [5], 8 [3].)

The effect of this peculiar mechanism, according to Minkowski, is a simultaneous transmission of impulses from the "corresponding or conjugate points" of the two homonymous retinal halves which work together in a normal binocular visual act, along two sets of fibers, to two sets of minute segments of two adjoining cell layers of the lateral geniculate nucleus. In this nucleus and also in the visual radiation, the two monocular channels still remain separate, although they are close together. The locality where the final union or fusion of the monocular impressions—if it is to be achieved—may take place seems, accordingly, to be the striate cortex of the occipital lobes of the brain.

Minkowski's discovery raised two problems. The first of them concerns the functional significance of the two or three layers which, in the Primate lateral geniculates, are assigned to each set of fibers (ipsilateral and contralateral). The other is the probable functional effect, or "purpose," of the double or triple supply of each point of the striate cortex by the fibers arising from the adjoining points of the two or three layers of both sets. (*See* chap. VI, 6 [6].)

7. THE DISCOVERY OF ACCESSORY SUBCORTICAL VISUAL CENTERS.—In addition to the principal large stratified or laminated portion which, in Primates, makes up the bulk of the lateral geniculate nucleus, Minkowski found a smaller, caplike portion, the *griseum praegeniculatum* or *substantia grisea praegeniculata*, that is, the pregeniculate gray nucleus, attached to the former along the dorsomedial aspect in approximately the anterior half. This particular gray nucleus is also a terminal station for the optic nerve fibers, mostly decussated, as Minkowski believed. This small nucleus, first described by Nissl and Koelliker (*corpus geniculatum laterale ventrale*, *see* Koelliker 1896, pp. 542, 543), seen by Dejerine (1895–1901), and described by C. Vogt (1909) and by Friedemann (1911), must therefore also be considered one of the several subcortical visual centers. It partly degenerates

if one eye is destroyed, but it remains normal when the visual radiation or the occipital lobe is damaged. (*See* chap. VI, 1 [4], 4 [4], 5 [4, 5, 6, 7], 7 [5], 10.)

Later Barris, Ingram, and Ranson (1935) added, in the Cat, to the three stations of the optic nerves already known: the dorsal portion of the lateral geniculate nucleus, the superior colliculus of the midbrain (dorsal part of the lus. The number of crossed and direct fibers is about equal.

The ventral nucleus, the nucleus of the optic tract (*n. lentiformis mesencephali*), the pulvinar, the *pars posterior* of the pulvinar, and the nucleus of the posterior commissure receive no optic nerve fibers. No optic fibers cross the midline in the posterior commissure or between the superior colliculi. The anterior and posterior ac-

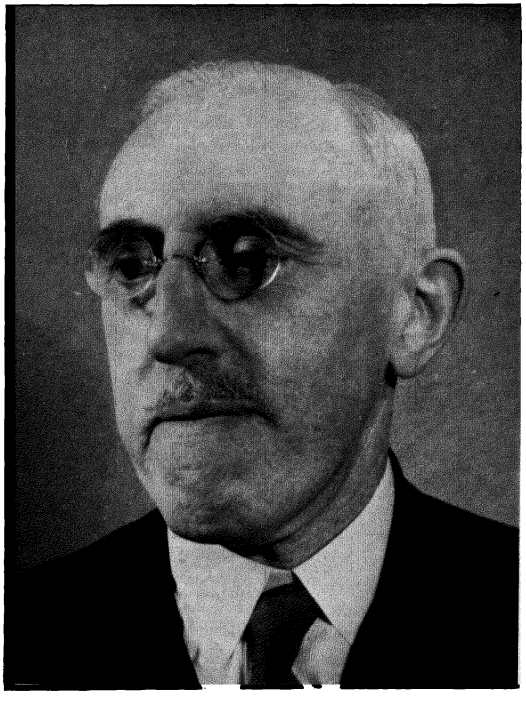

Fig. 122. Mieczyslaw Minkowski (1884), director of the Institute for Brain Research in Zürich, Switzerland. An eminent modern experimental neuroanatomist. First produced experimental evidence of the identity of the striate area of G. Elliot Smith and of the visual cortical center. First disclosed a topographical or point-to-point representation of the striate area in the lateral geniculate nucleus. Also first demonstrated the termination of ipsilateral and contralateral homonymous retinal optic nerve fibers in distinct layers of the lateral geniculate nucleus in the Monkey. Courtesy Professor M. Minkowski, 1946.

stratum opticum), and the pregeniculate nucleus, also the rostral part of the pretectal area (the center for the constrictor of the pupil). The avenues to the superior midbrain colliculus and the pretectum are the zonal strata of the thalamus and the brachium of the superior colliculus. The number of crossed and direct fibers is about equal.

The ventral nucleus, the nucleus of the optic tract (*n. lentiformis mesencephali*), the pulvinar, the *pars posterior* of the pulvinar, and the nucleus of the posterior commissure receive no optic nerve fibers. No optic fibers cross the midline in the posterior commissure or between the superior colliculi. The anterior and posterior accessory optic tracts or fascicles are apparently absent in the Cat and in all Mammals above the Rodents. The same experimenters found that "fibers, the cell bodies of which lie within the dorsal nucleus of the lateral geniculate body, pass exclusively to the cerebral cortex."

They did not find evidence in favor of a geniculopulvinarian or geniculothalamic connection.

8. FUNCTIONAL ORGANIZATION OF THE INFRANUCLEAR DIVISION OF THE VISUAL SYSTEM IN PRIMITIVE MAMMALS.—Because of the low taxonomic status of the investigated animal, the experiments on the visual system of the Opossum by Bodian (1937) are of no small interest. Here, too, the subcortical stations are the dorsal portion of the lateral geniculate nucleus, the superior colliculus, and the optic tegmental nucleus (where the posterior accessory optic tract, which is completely crossed, terminates). It is less certain whether a few fibers also terminate in the ventral portion of the lateral geniculate nucleus, in the pretectal nucleus, and in the accessory nucleus of the optic tract (the *noyau accessoire de la voie optique bigéminale* of S. Ramón y Cajal). No fibers of retinal origin, however, cross in any of the supraoptic commissures. The retinotectal fibers are preponderantly crossed. A remarkably detailed retinotopic projection is present both in the dorsal portion of the lateral geniculate nuclei and in the superior colliculi. In the latter, the binocular portion of the ipsilateral retina is represented in a way similar to that found in the lateral geniculates. (On cortical projection in the Opossum, *see* sec. 7 [10], this chapter.)

9. INVESTIGATION OF THE MINUTE STRUCTURE OF THE SUBCORTICAL VISUAL CENTERS.—With the problem of the terminal nuclei of the optic nerves and their fiber connections with other regions of the brain, the problem of their minute structure, development, and comparative anatomy and the functional interpretation of their structures have absorbed a great deal of attention in modern times. The question of the homology of the dorsal and ventral portions of the lateral geniculate nucleus—first identified in this way by Koelliker (1896)—in various classes of Vertebrates and their gradual change during the process of evolution was ably presented by Le Gros Clark (1932). The structural analysis of the lateral geniculate nucleus, superior colliculus, and adjoining parts of the between- and midbrain, with the help of the Golgi method, was attempted by S. Ramón y Cajal (1899, 1909–11, 1923) and by his co-workers Tello (1904) and Taboada (1927–28), and further by Balado & Franke (1931, 1937), O'Leary (1938, 1940), and other investigators (*see* chap. VI, 9). A similar series of investigations was carried out in inframammalian Vertebrates by P. Ramón y Cajal (1890, 1891, 1894, 1896, 1897, 1898, 1899, 1917, 1922, 1943) and by Ch. J. Herrick (1917, 1925, 1933, 1934, 1935, 1936, 1938, 1939, 1941, 1942, 1943, 1944, 1948).

SEC. 7. RECENT INVESTIGATIONS OF THE SUPRANUCLEAR DIVISION OF THE VISUAL SYSTEM

1. Probable causes of the long delay in the histoanalysis of the cerebral cortex. The reasons why it took so long to answer such an apparently elemental question as the presence and location of the visual center in the cerebral cortex were many. Among the most potent negative psychological factors were the beliefs, concepts, and prejudices inherited from earlier times. Another factor was the irrepressible inclination of the human mind to accept only those bits of information which fit into certain preconceived schemes (*cf.* sec. 5, this chapter). These and occasionally other even less excusable features of human character were apparently responsible for the fact that the perfectly valid evidence presented by Hun, Laqueur, and Flechsig in favor of a single visual center in the occipital lobe was declared insufficient or simply brushed aside.

Other reasons, undoubtedly of an objective nature, also contributed their share to the general retardation. The most important was the lack of proper orientation in the cerebral cortex. The sulci and gyri were structures too crude, which varied too much from species to species and from individual to individual, to serve as reliable landmarks. The attempts of early modern experimenters to determine the functions of the various cortical localities were quite vague. If an important discovery was made, such as that of Fritsch & Hitzig (*see* chap. III, 6 [4]), it was more an accident than a logical consequence of planned investigation.

There is nothing surprising, therefore, in the fact that in the early phases of modern brain research some of the brighter minds keenly felt the necessity of learning more about the minute structure of the cortex. And very little progress had been made in this field since Gennari (1782) and Vicq-d'Azyr (1786–90) first noticed the white stripe in the occipital cortex named after them, except the little information added by Baillarger (1840) and by a few other pioneer neurohistologists (*see* chap. III, 5 [1]). Theirs was, however, only preliminary work, carried out with primitive technique and concerned only with broad aspects of the problem.

2. Modern investigation of the minute structure of the cerebral cortex.—The modern period of microscopic investigation of the minute structure of the cerebral cortex was initiated by Berlin (1858) and taken up by Arndt (1867–68) and in a more systematic way by Meynert (1865, 1867–68, 1869, 1872, and later; portrait Figs. 113, 311; for biography *see* Anton 1930; De Crinis 1939; *see also* sec. 2 [2], this chapter). Among other parts of the cortex, Meynert studied the striate cortex of the occipital lobes (*cf.* chap. VIII, 4 [1]). Soon thereafter, Betz (1874, 1881) discovered giant ganglion cells in the precentral motor cortex.

In the course of the following decades the minute structure of the cerebral cortex became an object of increasing interest. As a result of the persistent efforts of numerous investigators, more or less complete charts have been plotted of the cerebral hemispheres of Man and of numerous other vertebrate species, especially of Primates and other Mammals, and, in addition, some work has been done on the structural analysis of the cortex with the Golgi method.

Of these contributions, the important ones are given below, the first contribution of each author being used as a chronological key: B. Lewis (1878); Lewis & Clarke (1878); Henschen (1892); Hammarberg (1893); Kaes (1893, 1907); S. Ramón y Cajal (1893, 1899–1904, 1900–1906, 1909–11, 1921, 1922, 1923, 1924, 1926); Nissl (1897); Schlapp (1898, 1902–3); Bolton (1900, 1901, 1903, 1911, 1933); G. Mann (1900); O. Vogt (1900, 1902, 1903–4, 1906, 1943); Hermanides & Köppen (1903); Brodmann (1903–18); A. W. Campbell (1904, 1905); C. & O. Vogt (1904, 1919, 1926); Köppen & Löwenstein (1905); Mott (1905, 1907); O. & C. Vogt (1906); G. Elliot Smith (1907, 1919, 1927, 1930); Marburg (1907); Watson (1907); Mauss (1908, 1911); Mott & Halliburton (1908, 1910); Mott & Kelley (1908); Ariëns Kappers (1909, 1911, 1928); Mott, Schuster & Halliburton (1910); Marinesco (1911); Mott, Schuster & Sherrington (1911); Flores (1911); Roncoroni (1911, 1927); Rose (1912, 1929, 1930, 1935); Lorente de Nó (1922, 1933, 1934, 1935, 1943);

Gray (1924); Economo & Koskinas (1925); Woollard (1925); Economo (1927, 1928, 1928–29, 1929, 1930, 1931); Filimonoff (1929, 1931–33); Le Gros Clark (1931, 1932, 1942); Hines (1934); Filimonoff & Sarkisoff (1935); Ariëns Kappers, Huber & Crosby (1936); Bonin (1938, 1939, 1942, 1945, 1947, 1950); Sarkisoff & Filimonoff (1938); Bailey & Bonin (1946); Krieg (1946, 1949); Lashley & Clark (1946); Bailey, Bonin & McCulloch (1950). (As standard reference works, Campbell, Brodmann, Economo & Koskinas, and Ariëns Kappers *et al.* 1936, may be most useful; for localization *see* chap. III, 6 [4].)

Before the first reliable cyto- and myeloarchitectural charts of the brain were available as guides, there were few places to look for indications of special functions. The most diligent experimental students of the visual system in the later part of the nineteenth century—Ferrier, Munk, and Monakow did not have sufficient cytoarchitectural data to rely upon in their work. This may explain why the two former localized the visual center in the wrong place, while Monakow—except for having demonstrated, generally, that there was some sort of topographical relationship—became lost in a maze of learned "decentralistic" potentialities, assumptions, and hypotheses (*see* chap. III, 8; and sec. 5, this chapter).

3. Minkowski's demonstration of the identity of the striate area and the cortical visual center and of the stable representation of the retina in it.—The early experimental attempts to locate the cortical visual area resulted in an approximation, at best. Ferrier's "macular center" in the angular gyrus and Munk's "visual sphere" A_1 on the lateral face of the parieto-occipital region, none of them precisely outlined, were, as evidenced by subsequent research, obviously illusions caused by experimental interference with the visual radiation coursing underneath that locality on its way to the striate cortex. Monakow (1882 and later) and Bernheimer (1900) were able, from their own experiments, to indicate only generally the location of the visual center in the posterior portion of the hemispheres. The results obtained by Bechterew (1901, 1906), Agadschanianz (1906), and Kurzveil (1909) were only a little more positive.

The turning point in the long-lasting dispute between the "localists" and the "decentralists" in this quest finally arrived when Minkowski (1910, 1911, portrait Fig. 122) experimentally produced complete and permanent blindness in the Dog by removing the striate area of both occipital lobes. Through his crucial experiments the question, first asked by Huguenin (1882), of whether or not the striate area was identical with the "physiological visual center," as it was believed to be by Flechsig (1895), H. Sachs (1895), and others, was positively answered (*see* secs. 2 [5], 3 [3], this chapter). Furthermore, in other experiments with partial removal of the striate area, Minkowski (1912, 1913, 1914) found the upper halves of the retinae to be related to the anterior half and the lower halves to be related to the posterior half of the striate area—in this point confirming Munk's earlier observations. And, beyond this, by making small lesions in the Cat, variously placed in the striate area, each lesion causing a corresponding small segment in the lateral geniculate nucleus to degenerate, Minkowski was able to reveal the topographical organization of the supranuclear division of the visual system.

In this way, Minkowski proved experimentally that the striate area was the cortical visual center and that the retina was represented in it in a detailed and stable manner. His work was the more noteworthy, since it was carried out in Monakow's own institute. And although Minkowski, in drawing his conclusions, exercised due deference toward his chief, the deleterious effect of his experiments upon Monakow's decentralist doctrine was unavoidable.

4. Identity of the visual radiation and the inferior longitudinal bundle of Burdach.—Another step in the right direction were the anatomical investigations of Niessl von Mayendorf (1903, 1905, 1907), Hösel (1905), La Salle d'Archambault (1905, 1906, 1909), Redlich (1905), Probst (1906), K. Löwenstein (1911), Zingerle (1911), Stauffenberg (1914), Venderovich (Wenderówič 1915, 1916). Traquair (1922, 1931), R. A. Pfeifer (1925, 1930), Putnam (1926), Papez (1942), and Rasmussen (1943). In agreement with Flechsig's earlier ob-

servations (*see* sec. 3 [2], this chapter), they showed the "inferior longitudinal bundle" of Burdach—the "external sagittal stratum" of Sachs—to be identical with Gratiolet's "visual radiation," originating in the lateral geniculate nucleus and terminating in the calcarine cortex, rather than a long association system which it had been, until then, considered to be (*see* chap. III, 5 [3]). The "internal sagittal stratum" of Sachs, which Monakow and others mistook for the visual radiation, on the contrary, was revealed to be principally made up of efferent, corticofugal nerve fibers, arising in the posterior regions of the cortex and terminating in the superior colliculus of the midbrain and elsewhere.

5. REMAINING UNCERTAINTIES ABOUT THE VISUAL RADIATION. In spite of these disclosures, there was still no general agreement on a number of important issues. One such was the precise origin of the visual radiation—whether it was in the lateral geniculate nucleus alone, as the localists following Flechsig believed, or also in the pulvinar of the thalamus and possibly in the superior colliculus of the midbrain, as Monakow and his followers claimed. Nor were the exact course, arrangement, and termination of fiber bundles as yet well known, in spite of numerous studies in this direction. (*See* Vialet 1893, 1894; Niessl von Mayendorf 1903, 1905, 1907, 1920, 1921, 1930; La Salle d'Archambault 1905, 1906, 1909; Weber 1905; Quensel 1906; A. Meyer 1907, 1912; Tsuchida 1907; Henschen 1910; Zingerle 1911; Winkler 1913; E. De Vries 1913; Monakow 1914; Stauffenberg 1914; Brouwer 1917; Holmes 1919; Rønne 1919; Minkowski 1923–24; Pfeifer 1925; Putnam 1926; and others.)

6. THE PROBLEM OF THE FUNCTIONAL ORGANIZATION OF THE VISUAL RADIATION AND THE IDENTITY OF THE FOVEAL OR "MACULAR" BUNDLE. The arrangement of the various segments of the visual radiation related to particular quadrants of the fields of view, assuming that there was a regular arrangement, puzzled investigators for a long time. Even after World War I, one of the best-informed authorities could only express a guess, without offering specific indications. Thus G. Holmes (1918, portrait Fig. 123) wrote:

> We are consequently forced to the conclusion that the fibres of the radiations are arranged regularly in laminae or series according to the origin of the impulses they carry. The defects in the fields are so frequently quadrantic, despite the gross nature of the injuries, that it is tempting to assume that even in the main mass of the radiations, those indirectly connected with the upper and the lower halves of the retinae are contained in distinct bundles, separated from each other by an anatomical interval; but this hypothesis seems *a priori* so improbable that it cannot be accepted without further evidence, and unless an anatomical basis for it can be discovered.

A similar view was also expressed by Monbrun (1919).

Least certain was the identity and arrangement of the "macular bundle," functionally related to the central foveae. Monakow, in conformity with his antimechanistic concept, assumed an intimate mingling of "macular" fibers with the extrafoveal or peripheral fibers in the entire visual radiation (*cf.* sec. 5, this chapter). Niessl von Mayendorf considered it possible that the macular fibers were contained either in the dorsal or in the ventral segment of the visual radiation, or in both. According to Henschen's opinion, macular fibers were spread out in a thin layer either on the inner or on the outer face of the visual radiation (*cf.* sec. 4 [6], this chapter).

A fourth possibility, that of the macular fibers filling in the "anatomical interval" of Gordon Holmes and of Monbrun and thus keeping apart the upper and the lower extramacular segments of the radiation related to the lower and upper extrafoveal field quadrants, suggested by H. Rønne (Roenne 1919, portrait Fig. 120), seemed too artificial to have wide appeal.

It was equally uncertain whether the striate area alone or a portion of it or perhaps, in addition, portions of the adjacent occipital and parietal cortex receive fibers of the visual radiation. Nor did R. A. Pfeifer's effort (1925, 1930) materially help to clarify the issue. As late as 1927, Lenz was justified in calling the internal organization of the visual radiation "exceedingly complicated and not yet in every respect clarified." (*Cf.* chap. VII.)

7. WAR INJURIES AND THE INTERNAL MAKE-UP OF THE VISUAL SYSTEM.—The influence which experience with war injuries had upon

the localization of vision in the brain, and especially upon the understanding of the structure of the visual pathway and the organization of the visual centers was, contrary to what could be expected, relatively slight. During the enormous and confusing conflicts of modern war, there was apparently little disposition or opportunity for systematic study of a problem and microscopic experience, cases of injuries to the occiput of the head, accompanied by disturbed visual function, were only rarely mentioned. The first report of twenty-three cases of hemianopias and central scotomas was made by Inouye (1909) from the Russo-Japanese War (1904).

In contrast with this scarcity was a fairly

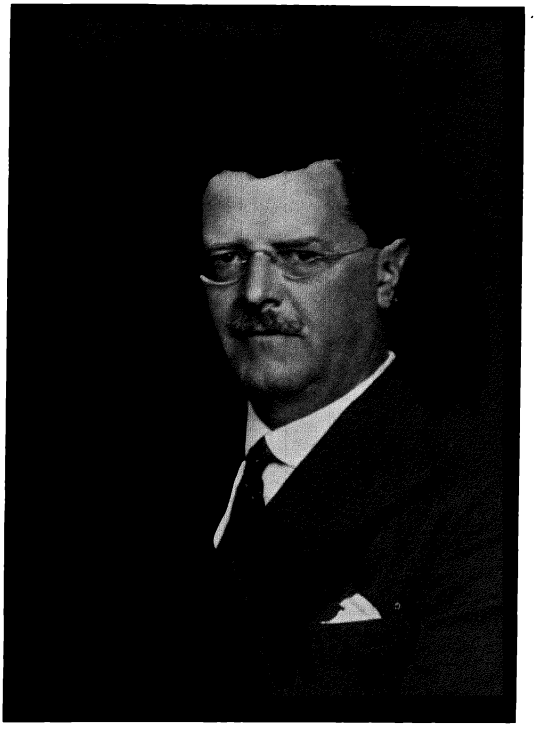

FIG. 123.—Gordon Morgan Holmes (1876), of National Hospital for Paralysed and Epileptic, Queen Square, London, England. One of the most productive investigators of visual brain mechanisms, in particular of the cortical representation of the retina and of the pathology of vision. Courtesy G. Holmes, 1948. (*Cf.* following figure.)

whose utilitarian value seemed remote. In such adverse circumstances, few important cases of cranial injuries were carefully examined by competent neurologists, and fewer specimens of such cases ever came to be properly studied with modern histological techniques.

During the Franco-Prussian War (1870–71), because of insufficient theoretical knowledge large number of cranial injuries observed during World War I (1914–18) and thereafter, which showed defects in the fields of vision. Prominent among these were the contributions by Axenfeld (1915), Bolton, Bramwell & Robinson (1915), Dimmer (1915), Marie & Chatelin (1914–15, 1915, 1916), Terrien & Vinsonneau (1915, 1916), Uhthoff (1915, 1916, 1922), Beau-

vieux (1916–17), Cérise (1916–17), B. Fleischer (1916), Holmes & Lister (1916), Morax (1916, 1917), Best (1917, 1919, 1920), Fuchs & Pötzl (1917), Souques (1917), Souques & Odier (1917), G. Holmes (1918, 1919, 1931, 1934), F. Morcau (1918), Szily (1918), Wilbrand & Saenger (1918), G. Jefferson (1919), Fleischer & Ensinger (1920), Lenz (1922, 1924, 1926, 1927), Balado, Adrogue & Franke (1928), R. A. Pfeifer (1930), Brouwer (1930, 1932), Balado & Malbrán (1932), *et al.* (*see* subsec. 10, this section). This abundant evidence, in the light of subsequent experience, unanimously supported the localist the evidence mentioned above, G. Holmes and Wilbrand & Saenger, as early as 1918, were able to devise sketches of the arrangement of the retinal quadrants and of the fovea in the cortex of the calcarine region (Fig. 124). According to them, the upper extramacular quadrants are represented in the upper lip, the lower quadrants in the lower lip, of the calcarine fissure; the "macula" in the posterior extremity at the occipital pole; and the monocular crescent in the most anterior zone of the striate area, with the intermediate belts arranged in an orderly sequence between these localities. The vertical

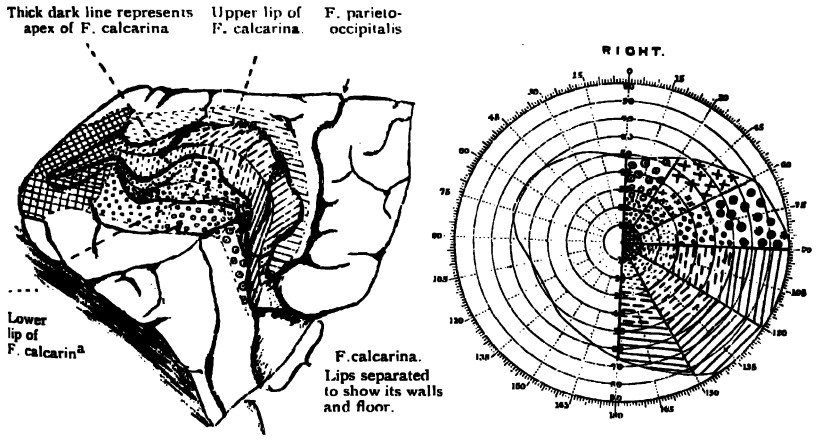

FIG. 124.—"A diagram of the probable representation of the different portions of the visual fields in the calcarine cortex. On the left is a drawing of the mesial surface of the left occipital lobe with the lips of the calcarine fissure separated so that its walls and floor are visible. The markings on the various portions of the visual cortex which is thus exposed correspond with those shown on the chart of the right half of the field of vision. This diagram does not claim to be in any respect accurate; it is merely a scheme." From G. Holmes, in Brit. J. Ophth., v. 2, p. 353, 1918.

concept. Unfortunately, only a small number of these cases were autopsied, and even fewer were competently examined with the help of modern histopathological techniques. The situation being what it was, it was possible for Klüver (1927), in his critical review, to venture a statement to the effect that it would not be difficult to compile as imposing a list of modern contributions in favor of a decentralist viewpoint and against Henschen's localist concept.

8. SKETCH OF A "CORTICAL RETINA" IN THE HUMAN BRAIN.—In spite of the shortcomings of

meridians or division lines between the heteronymous halves of the retinae would, according to these maps, run along the upper and lower boundaries of the striate area, with the horizontal meridians extending along the floor of the calcarine fissure from the anterior to the posterior extremity of the striate area.

9. EXPERIMENTAL-ANATOMICAL EVIDENCE OF THE RETINOTOPICAL ORGANIZATION OF THE CORTICAL VISUAL CENTERS.—Experimental evidence showing the retinotopical organization of the visual radiation and the striate area of the

cortex in Primates was first produced by Minkowski (1920). According to him, the upper segment of the visual radiation and the striate area was related to the medial half, the lower segment to the lateral half, of the lateral geniculate nucleus. Van Heuven (1929) and also Brouwer, Van Heuven & Biemond (1929), continuing earlier experiments by Brouwer and his co-workers upon the infranuclear division of the visual pathway (*see* sec. 6 [4], this chapter), were able to confirm and amplify the essential points obtained from the study of human pathological cases.

This was further substantiated and elaborated by a series of experiments performed by the author (1932, 1933) in Monkeys, although with a different technique. Some discrepancy in detail was found, which, however, could be easily explained by a somewhat different configuration and development of human and simian brains. Whereas in Man, because of a tremendous expansion of the parieto-occipitotemporal association region, almost the entire striate area is pushed onto the medial face of the occipital lobe (Fig. 290), in lower Monkeys about half of it is still found on the lateral face, covering practically the entire occipital lobe or the "occipital operculum" (Fig. 280). The posterior limit of the striate area where the central fovea or "macula" is represented, which in Man usually just covers the tip of the occipital lobe, in the Monkey is a homologue of the portion of striate area close to its anterior boundary on the lateral face of the hemisphere, stretching along the simian sulcus. The representation of the monocular nasal portion of the retina that appears to be phylogenetically a more stable portion of the visual center, is located, both in Man and in the Monkey, at the anterior limit of the striate area on the medial face of the hemisphere (*see* chap. VIII, 2). The visual radiation, these experiments disclosed, is made of functional segments, with an axial segment belonging to the "fovea-macula" in the middle, filling the "anatomical interval" of Gordon Holmes and of Monbrun, and with the two "extramacular" segments flanking it above and below, representing the "extramacular" periphery. A fascicle of the visual radiation supposed to decussate in the corpus callosum, which, according to Heine, Niessl von Mayendorf, Lenz, O. Foerster, R. A. Pfeifer, and others, was responsible for the "central sparing" frequently observed in homonymous hemianopia, was not found in these experiments (*cf.* chap. VII, 3 [4], and chap. XI, 8, 9).

10. Further evidence of the detailed functional organization of the striate area.—While these experiments did away with the last possible doubt which could reasonably be entertained against a rough quadrantic representation of the retina in the cerebral cortex, the problem of a more detailed, or one-to-one, representation required further investigation. For, in their experiments, Brouwer & Zeeman, and their co-workers observed quadrantic changes, no matter what the size of the retinal lesion was and no matter where in the quadrant it was located. There was still some doubt, therefore, whether Monakow's decentralist concept and Pierre Marie's idea of "global quadrantic representation" – as against Wilbrand's and Henschen's concept of a "cortical retina" – may not have been correct after all.

In order to clarify this particular problem, the author made small, variously placed lesions in the striate area of Monkeys, some measuring 1 mm. or less in size (1932, 1933). By studying minute zones of degeneration caused by these cortical lesions in the lateral geniculate nucleus, clear evidence was obtained in favor of detailed retinotopical organization of the supranuclear division of the visual pathway. In still other experiments where lesions in the striate area were arranged to represent various "figures," the zones of degeneration in the lateral geniculate nucleus agreed rather accurately in shape and location with the lesions (for details, *see* chap. VII, 5 [3], and Figs. 248, 252, 256). A well-differentiated retinotopical organization of the striate area, though much below that found in Monkeys, had also been revealed in preponderantly nocturnal Rats by Lashley (1934) and in the Opossum by Bodian (1935, 1937).

Subsequent experiments and carefully studied pathological cases reported by Brouwer (1930, 1932), Pfeifer (1930), G. Holmes (1931, 1934), Juba (1933), Mackenzie, Meighan & Pollock (1933), Polyak & Hayashi (1936), Walker & Fulton (1938), and Polyak (1942), the noteworthy experiments of Foerster (1929)

with electrical stimulation of the occipital lobe in conscious human subjects in which subjective photomas and hallucinations in various parts of the visual field were evoked, and the "plotting" of changes in the action potential over the striate areas in Monkeys whose retinas were stimulated with minute beams of light (*see* O'Leary & Bishop 1938; Talbot 1941; Talbot & Marshall 1941; Marshall & Talbot 1942) leave no doubt as to the essential retinotopical organization of the entire visual system. The cortical representation of the retina – with certain qualifications – may indeed be considered what Meynert, Munk, Flechsig, Wilbrand, Henschen, and most clinical neurologists and ophthalmologists have for many decades believed it to be: a "cortical retina."

It was a strange fate that the most solid support that Henschen's thesis was to receive should have come from experimental anatomy and physiology, precisely where he expected it least. (For complete experimental evidence, *see* chaps. VI, VII.)

In summary, we may now venture to say that the visual system of Man and his Primate relatives, the Monkeys and Apes, may safely be considered explored, in spite of a few belated doubts such as those expressed by Foerster (1929), according to which not only the "macula" but the entire retina were represented globally in both hemispheres, and by Hyndman (1939) and Balado & Malbrán (1932), according to which the macula had a second representation outside the occipital lobe.

SEC. 8 RECAPITULATION OF PAST EFFORTS TO EXPLAIN THE PHENOMENON OF VISION IN TERMS OF PHYSICAL FACTORS AND ANATOMICAL STRUCTURES

The effort to explain vision in terms of natural factors had its origin in Ancient Greece. This was not accidental. The inquisitive spirit of that gifted people, the relative peace and prosperity of the country, the religion which chiefly represented personified forces of nature relatively free from magic, the democratic organization of the political units, the resulting relative freedom of thought and speech, and the many contacts of a seafaring people with foreign countries - all contributed to conditions favorable to the rise of science. Nor is it an accident that the logically thinking Greek naturalists, taking the first step before proceeding further, began the investigation of the visual system with the eye (Aristotle, Herόphilos, Rûfos). However, impatient as they were to satisfy their thirst for knowledge, they invented the mysterious "visual spirit" and a channel in the optic nerve through which this spirit could reach the brain (Alkmâion, Heróphilos, Galen).

The Arabs and other Arabic scholars of the Middle Ages, hampered by the restrictive laws of Allah's prophet, added little to what they learned from their Greek teachers. Their merit was in having preserved the most important part of Greek intellectual heritage, which otherwise would probably have perished (Ḥunain ibn Isḥāḳ, ʿAlī ibn ʿĪsā, Ibn al-Haitham, Ibn Sīnā).

Another fortunate circumstance was a gradual improvement of living conditions in southwestern Europe during the second half of the Middle Ages, so that time and thought could again be given to the germs of learning coming from Arab lands, chiefly through the activity of Gerard of Cremona and the translator academy of Toledo in Spain. From then on, in many a secluded chamber of a monastery, away from the intrigues of the capitals and castles and from the battlefields, lights began to burn over the new Latin translations of the ancient Arabic manuscripts, and, as always, enlightenment followed study (Vitello, Roger Bacon, John Peckham, Albertus Magnus).

When, through this preparatory work, the Renaissance began, eagerness to learn more about Man and Nature became universal among the educated. Astronomy, physics, and medicine, for the first time since the collapse of the Classical World, began to make real progress. From obscure beginnings the glass industry emerged, producing eyeglasses for the comfort of the aged (A. Spina, Murano, near Venice). This put optical lenses into the hands of clever men, to experiment with and to lay the foundation of the modern science of optics (Maurolycus, Daniello Barbaro, Giambattista della Porta). Augmented by the *camera obscura*, or "dark chamber," such lenses finally helped to explain the true function of the eye's structures, especially light refraction in the dioptrical media and the formation of the retinal image (Plater, Kepler, Scheiner). With the discovery of the telescope (Kepler, G. Galilei), modern astronomy, which the genius of Copernicus had already foreshadowed, was born; and with the invention of the microscope, the all-important science of microscopy began its course (Malpighi, Leeuwenhoek).

The next step, after finding a correct functional interpretation of the eye's structures, was to discover just how the light stimuli, impinging upon the eye, elicit reactions in the brain which enable us to see. Whether it was with the help of some transcendental, immaterial medium or a palpable "visual spirit," it was obvious that special arrangements and connections in the nervous mechanism were at work. Early, crude anatomy could do little to reveal these, except to indicate in a rough way the optic nerves and their apparent origin (Leonardo da Vinci, Vesalius, Willis). Later on, even though anatomical knowledge had advanced but little, the first attempts were made to interpret the visual sense of space and binocular vision by means of a specific intrinsic organization of the visual pathway (Des Cartes, Newton).

But only in modern times, with the general development of natural science and medicine, were the principal features of the visual system, from the eye to the visual centers in the cerebral cortex, discovered.

To achieve this, the lives of many gifted men, and infinite labor and patience were expended. Nor was the road which led to our present considerable knowledge always smooth. It was diffi-

cult, rough, and often devious. There were many blind alleys, and much time and effort were wasted in retracing steps (Haller, Gall, Flourens). It was not all the fault of some and all the virtue of others. Most investigators erred in something and were right in other ways (Munk, Monakow, Wilbrand, Henschen).

Final success, then, is the result of the combined efforts of many, each contributing something, much or little, positive or negative, according to his character, ability, and material facilities (Bouillaud, Broca, Gratiolet, Hitzig, Munk, Flechsig, Monakow, Wilbrand, Henschen, Rønne, Minkowski, Brouwer & Zeeman, Holmes, Marie, S. Ramón y Cajal).

The remaining problems, inasmuch as they can now be formulated, are of two categories: first, a complete morphological, biochemical, and biophysical analysis of the minute structures which make up the visual system; and, second, a detailed correlation of these structures with the known visual functions. To know which particular sets of neurons and other associated structures serve, why and how, as the instruments of achromatic sensations and of color vision, of acuity, of visual form and space perception, of the intensities of subjective photic experiences, of contrasts and like phenomena, of binocular stereoscopic vision, of the various reflex actions, and, lastly, of the many higher or psychic functions of vision - this appears as the final purpose of the investigation of the visual system.

If, in addition, through greater knowledge of the mechanics of vision and its operation under normal conditions, and of the many factors underlying pathological disturbances, better methods are found to prevent or retard ailments of sight or to restore failing vision, the labor invested will be well repaid.

PART II

Anatomy and Histology of the Retina and of the Visual Pathways and Centers of the Brain

Chapter V

Structure of the Vertebrate Retina

SEC. 1. STRUCTURE AND FUNCTION OF THE EYE

1. STRUCTURAL PLAN OF THE VERTEBRATE EYE AND ITS WORKINGS.—The eye of all Vertebrates, including the human eye, is a peripheral sense organ by means of which the individual reacts to the physical radiant energy called "visible light." The first task of the eye is physical: to refract those rays of light falling into it in such a manner as to produce real images of the external objects from which the light rays emanate or are reflected—images that are symmetrically accurate, although reduced in size and inverted.

The other, and no less important, task of the eye is the sorting of nervous impulses, generated in the eye by the action of light, and the transmitting of them to the brain. In the brain the corresponding subjective reactions of "seeing" and of "visual appreciation" of seen objects take place, as a result of which the individual makes the necessary adjustments to his changing environment.

The first task the formation of a physical image on the retina is accomplished because of the eye's organization as a dioptrical apparatus. In this sense the vertebrate chamber eye may be looked upon as a living photographic motion-picture camera. How the dioptrical principles of the *camera obscura*, or "dark chamber," upon which the eye is built were discovered in the past is related in chapter I, 5 (*see also* Figs. 31, 33). The subject of the physical optics and dioptrics of the eye is exhaustively dealt with in a number of treatises, such as those of Gullstrand (1902), Helmholtz (1924 25), Preston (1928), A. König (1929), R. W. Wood (1934), Rohr (1937), Southall (1937), Emsley (1939), Tschermak-Seysenegg (1942), Le Grand (1946), Linksz (1950), Pascal (1952), Rüchard (1952), and others; whereas a discussion of the structure of the eye is to be found in the books of Salzmann (1912), Ovio (1927), Duke-Elder (1932), Kolmer & Lauber (1936), Walls (1942), Detwiler (1943), Kronfeld *et al.* (1943), Rochon-Duvigneaud (1943), and E. Wolff (1948). For details concerning the retinal structures *see* the subsequent sections of this chapter and the monograph *The Retina* (1941, 1948) by this author.

The other, and much more complicated, function of the eye and of the central visual pathway connected with it is to generate and conduct nervous impulses to the brain—impulses varying in a great many ways: in quality, in intensity, in spatial and temporal distribution, etc. This role of the eye and of the remainder of the visual apparatus still remains largely obscure. The structures instrumental in this complex function and the role that each performs in the total process of vision are the principal themes of Part II of this book. (*Cf.* Helmholtz 1924–25; Piéron 1936, 1945; Bartley 1941; P. J. Bouma 1947; Granit 1947; Wright & Martin 1947; Pirenne 1948; Davson 1949.)

The eye, like other useful organs of the body, is adapted, in all the details of its intrinsic organization, to its physiological task (Fig. 125). Its shape is more or less spheroidal, the shape best suited for preventing distortion—a factor essential in a dioptrical apparatus. Its outer membrane is a tough fibrous tunic, which, together with the fluids filling its cavities and the intraocular pressure maintained by the heart's action, helps preserve the shape of the eye. Most of that outer tunic, the sclera (*scl*), is opaque, the opaqueness being made complete by the pigmented chorioid membrane (*chor*) and by the pigment epithelium of the retina (layer *1* in Figs. 127, 128, 129). The anterior segment, the cornea (*cor*), which faces the out-

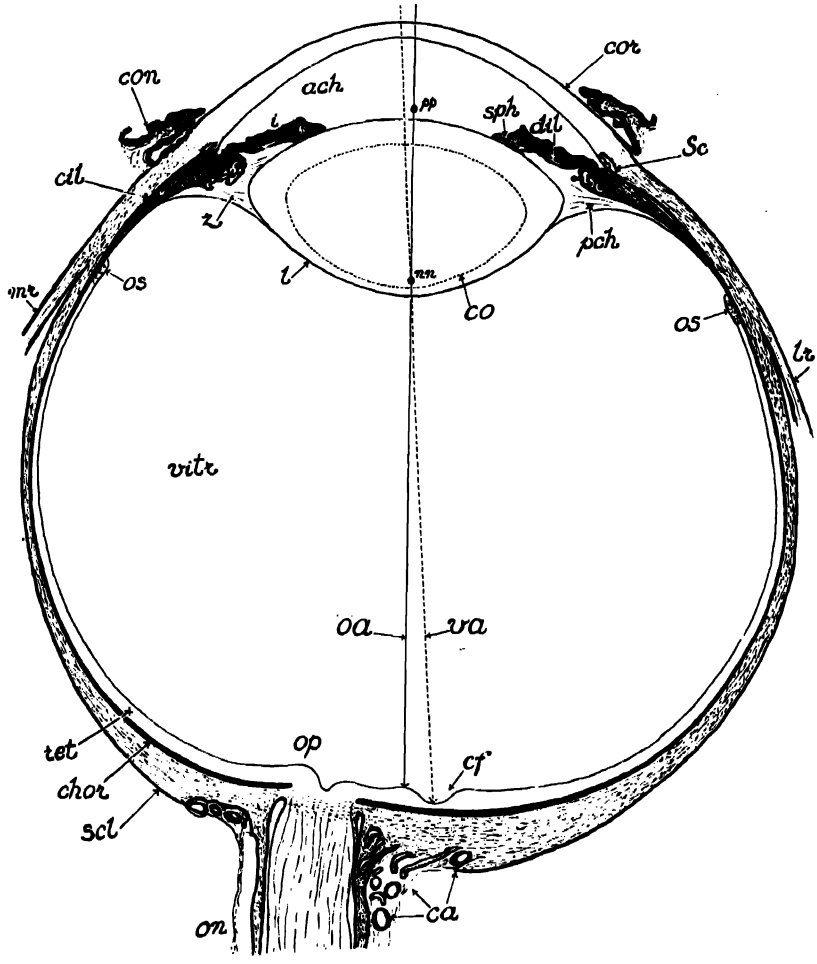

FIG. 125.—Horizontal section through the fully developed human eye drawn with the help of camera lucida, magnified approximately 6×. Right side temporal, left side nasal. *Labeling: ach*, anterior chamber; *ca*, ciliary arteries; *cf*, central pit or fovea; *chor*, chorioid membrane; *cil*, ciliary body; *con*, conjunctiva; *cor*, cornea; *dil*, dilator muscle of pupil; *i*, iris membrane; *l*, crystalline lens; *lr*, lateral rectus or straight muscle (tendon); *mr*, medial rectus or straight muscle (tendon); *nn*, double nodal point of eye; *oa*, optical axis; *on*, optic nerve; *op*, optic papilla, disk, or head of optic nerve; *os*, ora serrata, serrated margin of retina; *pch*, posterior chamber; *pp*, double principal point; *ret*, retina; *Sc*, venous scleral sinus or canal of Schlemm or Lauth; *scl*, sclera; *sph*, sphincter or constrictor muscle or pupil; *z*, ciliary zonule of Zinn or suspensory ligament of lens; *va*, visual axis; *vitr*, vitreal chamber and vitreal body. Actual length of visual axis, from anterior surface of cornea to posterior surface of retina, 21 mm.; length of transverse diameter, from retina to retina, 21.5 mm. Note varying thickness of all three coats, their thickest parts being in posterior portion; the thinnest locality of sclera is along nasal equator; of chorioid, along equator all around; of retina, at ora serrata; cornea is thinnest along its vertex; scleral radius of curvature varies considerably from point to point, being also different on nasal side from that on temporal, making the shape of eyeball asymmetrical. (*Cf.* Fig. 365.)

side world, is transparent, as are also the fluid and semisolid media within the eyeball itself, permitting free passage of light into the eye's interior—into the aqueous humor in the anterior and posterior chambers (*ach, pch*), the vitreous humor (*vitr*) in the large vitreal chamber, and the elastic lens (*l*) placed in between.

The light that enters the eye, however, cannot spread within it in a haphazard way but is forced to follow the laws of refraction. First, not all the light rays that enter through the transparent front window—the cornea—gain free entrance into the interior but only those that pass through the opening in the iris (*i*), the pupil. Here they are further compelled, by the refractive power of the lens, to change their direction until they are concentrated into the smallest possible dimension, or focused, on the photosensitive screen that coats the inside of the eye—the retina (*ret*). Changed in this way, the rays of light that are distributed over the expanse of the retina, like the rays from a motion-picture projector on a screen, reproduce in succession a variety of pictures of external objects, much reduced in size from the objects seen and in an inverted position.

The next step—the last in the eye, although first in the long chain of the neurodynamical changes and reactions of the visual apparatus—involves the minute structures of the retinal membrane and concerns their working. These structures, because of their chemical composition, number, histological peculiarities, special distribution, and connections with one another or isolation from one another, are capable of reacting specifically to the stimulation of physical light and of transmitting, combining, selecting, or otherwise modifying their reactions, which are then sent to the brain. Suffice it to say that, in general, the more the retinal structures are capable of reacting in detail to the locally and dynamically varying light stimuli, which, in the aggregate, form the physical ocular image, the more complete and accurate are the messages sent to the central arbiter, the brain, about the things and events in the world of light in which we live.

Briefly, the eyeball, complicated though its structure is, is no more than an elaborate container for the true peripheral photoreceptor the retina—which alone, by virtue of its photosensitivity and specific organization, is capable of bringing the organism into photodioptrical relationship with the surrounding world.

2. Dimensions and dioptrical landmarks of the eyeball.—The normal human eye of an adult measures 24 or 25 mm., or approximately 1 inch, in diameter (Fig. 125). The approximate diameter of the eye of a Gorilla is the same; of a Chimpanzee, 21 mm.; of a Rhesus Macaque, 19 mm. (Fig. 126).

Several convenient landmarks and dioptrical lines and planes are customarily distinguished in the eyeball. The straight line (solid in the figure) connecting the anterior pole, or vertex, of the cornea with the farthest point at the posterior end of the eyeball is the *anatomical axis*. This line almost coincides with the *geometrical axis*, which, in turn, is practically identical with the *optical axis* (*oa*), or the sagittal line passing through the centers of rotation of the refractive optical media of the eye, the cornea, and the lens.

The *visual axis* (*va*), or the line of vision or gaze (indicated by an interrupted line in our figure), in the fundus deviates from the optical axis by 4°–7° laterally or temporally and is about 3°.5 below the horizontal meridian, as it passes through the center of the central fovea (*cf*).

A plane vertical to the visual axis, where this axis passes through the largest circumference of the eyeball, is called the *equator*. Other planes that pass through the visual axis of the eyeball are known as the *meridians*. Of the latter, the most important are the vertical meridian, oriented anteroposteriorly or sagittally, and the horizontal meridian. The first divides the eyeball into a nasal and a temporal half; the second into an upper and a lower half. Both divide the eyeball and its membranes into four *quadrants:* an upper and a lower nasal and an upper and a lower temporal.

3. Outer tunic of the eye: sclera and cornea.—The outermost of the three eye membranes is a tough, fibrous tunic. Its larger posterior portion, the sclera (*scl*), is opaque. The smaller, and more sharply curved, anterior portion—the cornea (*cor*)—is transparent under normal conditions of life. The cornea is made up

of several regularly arranged layers. Normally it is devoid of blood vessels, but it contains numerous nonmedullated nerves and their terminals.

4. UVEAL TUNIC AND CILIARY MUSCLE.—The middle, vascular tunic, the *uvea* (black in Fig. 125; white in Fig. 126), is a nutritive organ, especially of the retina. The larger posterior portion of the uvea, called the *choroid membrane* (*chor*), consists chiefly of blood vessels. by approximately sixty to seventy minute, radially arranged folds, varying in length and in thickness and consisting largely of smooth muscle fibers and blood vessels.

The action of the ciliary organ—by relaxing the fibers of the *suspensory ligament*, or *Zinn's zonule* (*z*), one end of which is attached to the chorioid and the other end to the lens—increases the bulge or curvature of the lens and thus, by increasing the refractive power of the crystalline lens (*l*), serves to accommodate vi-

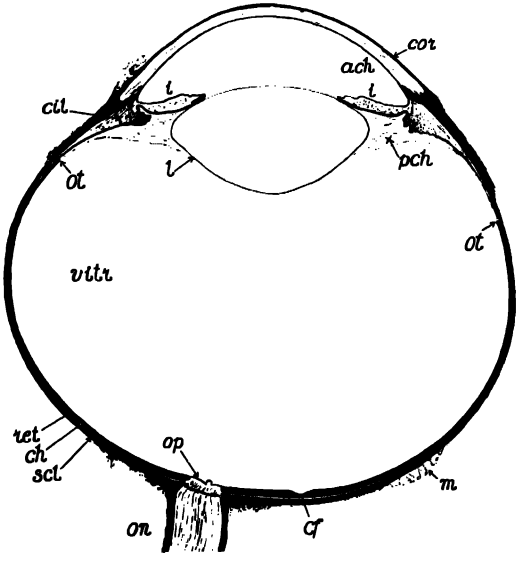

FIG. 126.—Horizontal section of a right eyeball of a Rhesus Macaque (*Macaca rhesa, M. mulatta*), magnified 4½ ×. Right side temporal, left side nasal. Actual length both of the optical axis (from anterior surface of cornea to posterior surface of retina) and of the transverse axis approximately 19 mm. *Labeling: ach*, anterior chamber; *ch*, chorioid membrane; *cf*, central fovea; *cil*, ciliary body; *cor*, cornea; *i*, iris; *l*, lens; *m*, portion of an extrinsic muscle; *on*, optic nerve; *op*, optic papilla; *ot*, ora terminalis or retinal margin; *ret*, retina; *scl*, scleral coat.

The uvea also is composed of numerous chromatophore cells containing dark pigment, which make it an opaque screen, lining the interior of the ocular cavities, which are filled with transparent media—the posterior chamber (*pch*) and the vitreal cavity (*vitr*).

The anterior portion of the uveal tunic, where it is firmly attached to the outer fibrous coat at the line where the opaque sclera passes into a diaphanous cornea, is transformed into a special organ, the *ciliary body* (*cil*), represented sion for close range. Conversely, the relaxation of the ciliary muscle fibers increases the tension of the suspensory ligament, which in turn, by flattening the lens, decreases its refractive power, thereby adjusting the eye for distant vision. (*See* par. 8, this section.)

5. IRIS AND PUPIL.—The anterior portion of the uveal tunic, the *iris* (*i*), is a thin, circular membrane placed curtain-fashion in front of the lens. In the living, it is visible through the

transparent cornea. Its individually varying color is caused by the different quantity of pigment stored in the cells of its tissue.

The nearly circular opening, the pupil, placed almost centrally in the iris, permits light from outside to pass through the lens into the inner, vitreal chamber of the eye (*vitr*). The black color of the pupil is caused by the very small quantity of light reflected from the interior of the eye, in comparison with the intense outside light.

The size of the pupil is determined by the action of two minute, antagonistically functioning, muscles contained in the iris tissue. One muscle, consisting of circular fibers near the pupillary margin, is called the *sphincter*, or *constrictor*, of the pupil (*sph*). This muscle, as well as the *ciliary accommodation muscle* (*cil*), responds to the stimuli of parasympathetic oculomotor nerves and nuclei of the midbrain (by way of the ciliary ganglion). The activation of the iris sphincter decreases the size of the pupil and thus cuts down the amount of light falling into the eye. This reflex action results from the stimulation of the retina by light.

The other muscle of the iris, composed of delicate fibers arranged radially, is the *dilator* of the pupil (*dil*). It is under the influence of the sympathetic ciliospinal center of Budge (which is located in the lowermost cervical and uppermost thoracic segments of the spinal cord) by way of the cervical sympathetic trunk, its superior ganglion, and its postganglionic fibers.

The iris membrane, which is lined on its inner side and up to its pupillary margin with a heavily pigmented, nonnervous extension of the retina, functions as an opaque curtain, preventing light from entering the vitreal cavity except through the pupil.

6. RETINA.—The innermost membrane or tunic of the eye is the *retina* (*ret*). In contrast with the cornea, sclera, and uvea, the retina is an organ made up entirely of nervous tissue and blood vessels. It is the actual photoreceptor organ, or the structure which, stimulated by physical light entering the eye, elicits nervous reactions, which, transmitted to the brain, are manifested in the subjective experience of vision.

The retinal membrane develops as an outpocketing of the frontal end of the brain, one protuberance on each side, during the early period of embryonic life (*cf.* chap. XIII, 2, and Figs. 434, 435). The primary optic vesicle first formed contains a space which communicates freely with the ventricular cavities of the brain by means of a hollow optic stalk—the future optic nerve. During further development the anterior wall of the primary optic vesicle gradually caves in until it touches the back wall, whereupon the original ventricular space disappears. In this way the two sheets of the embryonic retina—the inner and the outer—join, forming the secondary optic vesicle, or optic cup. In this vesicle the outer sheet becomes the pigment layer, and the inner sheet the nervous retina proper. In the anterior nonnervous ciliary and iridial portion of the retina lining the ciliary body and the back face of the iris, both sheets retain the character of a simple epithelium loaded with pigment.

The larger, posterior nervous portion—the retina in the proper sense—is a highly transparent membrane, with the exception of the pigment layer. In the living, in those vertebrate species where this membrane contains blood vessels—as, for example, in Man, Monkeys, and Apes—the color of the retina is determined by the blood contained in its vessels. After death, with the emptying of most blood from the vessels, the retina appears as a glassy, colorless membrane. Within a short time after death, however, the tissue of the retina assumes a dull whitish coloring and loses its transparency, owing to the process of coagulation. (For details on the retinal structures, *see* subsequent sections in this chapter, and Polyak, *The Retina.*)

7. CHAMBERS AND HUMORS OF THE EYE.—The inner space of the eye is filled with transparent fluid and transparent bodies and is subdivided, by partitions, into three cavities or chambers.

The *anterior chamber* (*ach*), inclosed by the cornea, the iris, and as much of the anterior surface of the lens as is left exposed by the varying size of the pupil, is filled by a thin, watery fluid, the *aqueous humor.*

The *posterior chamber* (*pch*), which is limited by the posterior surface of the iris, by that part of the anterior surface of the lens which is not

included in the pupil and is not covered by the iris, by the equatorial margin and the adjoining portion of the posterior surface of the lens, and also by a portion of the vitreal membrane, is a minute, meniscoidal space encircling the lens equator in a ringlike fashion. It is also filled with aqueous humor, which is here being secreted from the epithelium of the ciliary ridges containing blood vessels and capillaries.

The largest and most posterior chamber, the *vitreal cavity* (*vitr*), which is inclosed by the retina, zonular ligament (*z*), the posterior surface of the lens (*l*), and the hyaloid membrane, is filled with a viscous and somewhat gelatinous fluid, the *vitreous humor*.

8. Crystalline lens.—In Man and his primate relatives the crystalline lens (*l*) is an elastic body, resembling a lentil. It is characterized by a regular shape, smooth surfaces, high transparency, and a considerable index of refraction.

Anteroposteriorly the lens is somewhat flattened, with the curvature of its anterior surface less than that of its posterior surface. The lens is inclosed in a delicate, structureless envelope, whose two leaves - the anterior and posterior lens capsules - form a pillow-like casing, to whose equatorial edge the fibers of the suspensory ligament, or zonule, are attached. The tissue of the lens consists of numerous cells elongated into thin, long, elastic, fiber-like structures, the *lens fibers*, arranged in an intricate, but very regular, pattern.

Owing to its structure, the lens is endowed with an elastic property, permitting the lengthening of its sagittal axis and the shortening of the radii of curvature of its anterior and posterior surfaces. In a relaxed condition, relieved from the tension of the suspensory ligament (which, in turn, is sustained by intraocular pressure) an effect normally brought about by the action of the ciliary muscle during the process of accommodation the lens increases its refractive power and thus adjusts the dioptrical apparatus of the eye for close vision. Conversely, the pull of the suspensory ligament in the unaccommodated eye causes the two sheets to compress the lens, thereby counteracting the elastic tendency of the lens, and, by increasing the radii of curvature of its surfaces, causes the refractive power of the lens to decrease and in this way adjusts it for distant vision. The pull of the suspensory ligament is made possible by the relaxation of the ciliary muscle. (*Cf.* par. 4.)

9. The eye as a dioptrical apparatus. As stated earlier, the eye may be compared to a dark chamber, *camera obscura*, provided with a dioptrical apparatus and a photosensitive back screen. The parts of the dioptrical apparatus of the eye are the cornea, which is stable, and the lens, which is changeable. The back screen in the eye is represented by the photosensitive retina. On it the light rays, when properly focused by the accommodation apparatus, are united in such a way as to form a sharp, inverted, and much diminished image of visible external objects toward which the visual axis is directed. In Man and other terrestrial Vertebrates most refraction takes place in the cornea; in the aquatic Vertebrates mostly, or only, in the lens.

The nervous reactions elicited in the retinal tissue, varying in many ways from point to point on the retinal surface, especially in intensity and quality, are further propagated to the brain, where they are subjectively interpreted as variously illuminated and colored objects of many shapes, sizes, and numbers, still or in motion, near or distant, and so forth. In the further course of the visual process, the seen objects are compared with those seen before and are either recognized as known, and identified with these, or as unknown; they are additionally evaluated as to their meaning and other properties trains of subjective experiences designated as "higher," "psychic," or "mental" visual functions.

10. Accessory organs of the eye. The eyes are also equipped with extrinsic muscles, nerves, glands, and blood vessels. With these, the eyes are lodged in the bony orbits of the skull, which are filled with a fatty tissue. In addition, the eyes are protected by the lids, lashes, and brows. Together with the oculomotor centers of the brain and spinal cord, all these structures form an ingeniously devised apparatus serving binocular stereoscopic vision.

SEC. 2. GENERAL FEATURES OF THE MINUTE STRUCTURE OF THE RETINA

1. Introductory remarks.—The histological elements which make up the tissue of the nervous or functioning portion of the retinal membrane, from the optic papilla to the *ora serrata*, resemble those found in the brain, whence this membrane derives, both phylogenetically and ontogenetically. The nervous parenchyma is represented here by nerve cells in the proper sense and by their expansions, both carriers of the specific retinal function. Another important constituent is the neuroglia, which forms the framework in which the nervous parenchyma is lodged. The third constituent is the pigment epithelium, a derivative of the outer sheet of the secondary optic vesicle of the early embryo (*see* chap. XIII, 1, 2). These

three constituents, with the possible exception of microglia, are of ectodermal origin (*see* sec. 9 [3], this chapter). Numerous blood vessels, branches of the central artery and vein, penetrate the retinal membrane and form a dense capillary network in its vitreal half. These are of mesodermal origin. (*See* chap. X, 2 [3].)

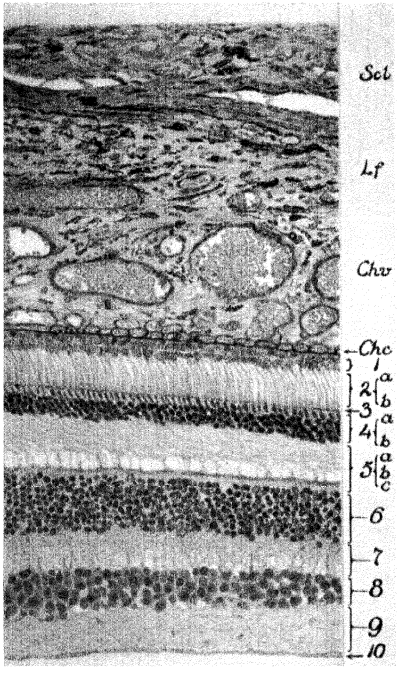

FIG. 127.—Vertical section through the tunics of human eyeball in the region of central area stained with haematoxylin and eosin. Upper half of figure shows portion of fibrous sclera containing pigment-bearing chromatophore cells and some blood vessels, more numerous in the chorioid membrane, which is principally vascular, containing also some chromatophores, and terminating next to the retina in a choriocapillary layer composed of minute vessels. Lower half of figure shows retinal membrane made up of cellular and fibrous elements arranged in regular, parallel layers. *Labeling: Chc*, choriocapillary layer; *Chv*, vascular layer of chroioid membrane; *Lf*, lamina fusca; *Scl*, less pigmented portion of scleral membrane; *1*, pigmented epithelium of retina; *2*, bacillary layer; *3*, outer limiting membrane; *4*, outer nuclear layer; *5*, outer plexiform layer; *6*, inner nuclear layer; *7*, inner plexiform layer; *8*, ganglion cell layer; *9*, layer of optic nerve fibers; *10*, inner limiting membrane of retina. Magnified approximately 150×.

The nerve cells and fibers and the elements of the supporting tissue are arranged in several distinct layers and zones parallel to the surface of the retina and to one another. These layers are noteworthy because of their regularity. In the human and simian retina, ten layers and sublayers, or zones, may be distinguished, beginning with the layer closest to the chorioid membrane (Figs. 127, 128), and are described below.

2. PIGMENT EPITHELIUM (1).—This is the outermost layer of the retina, immediately adjoining the chorioid. It was first well described by Th. Wharton Jones (1833). It is represented by a single layer of cuboidal cells, which, from the surface, appear pentagonal or hexagonal in shape. From the vitreal end of the cell body containing a nucleus, ragged, fringe-like protoplasmic expansions spread between the photoreceptors. These expansions and the near-by vitreal part of the body are filled with the granules and needles of a dark-brown pigment—the fuscin.

In numerous Vertebrates, such as Fishes, Amphibians, and Birds, the pigment changes its position according to the intensity of illumination. In strong daylight in the bright-adapted eye, the pigment migrates into protoplasmic expansions, closer to the external limiting membrane, reducing or preventing a lateral diffusion of light. In dim light in the dark-adapted eye, on the contrary, the pigment migration is the reverse, from the fringes into the cell bodies, thus exposing the photoreceptors to the full action of light of low intensity. There are indications that similar, although apparently less extensive, movements of the pigment may occur also in the Mammals, including the Primates. (*See* Genderen Stort 1886, 1887; Chiarini 1904–6; Garten 1907; Arey 1915, 1916, 1919, 1928, 1932; Detwiler 1916, 1923, 1943, 1944, 1945; Laurens & Williams 1917; Laurens & Detwiler 1921; Detwiler & Lewis 1926; Zikulenko 1926; Walls 1928, 1942; E. Scharrer 1929; Luppino 1930; Wigger 1937–38, 1939; Arey & Mundt 1941; Sverdlick 1942; Arey & Jennings 1944.)

3. BACILLARY LAYER (2).—Immediately vitrealad to, and partly enveloped by, the pig-

ment epithelium is the second layer, composed of more or less rodlike or flasklike scleral ends of the visual cells or photoreceptors—the rods (*a*) and the cones (*b*).

In sections vertical to the surface of the retinal membrane, the bacillary layer, when well preserved, appears vertically striated, with the extensions of the lines directed toward the pupil of the eye.

In the human and simian retina there are two varieties of elements in the bacillary layer: the thinner, but somewhat longer and more numerous, rods and the thicker, shorter, and less numerous cones. Since each rod and each cone is, in turn, made up of an outer and an inner segment, with a short intermediary zone between, the bacillary layer may be further subdivided into two zones: *2-a*, represented by the outer segments, and *2-b*, represented by the inner segments. Because the boundary line between the outer and the inner segments is slightly closer to the sclera in the rods than in the cones, the division line between *2-a* and *2-b*, even though distinct, is not sharp but appears somewhat fuzzy (*cf.* Fig. 130).

The function of the bacillary layer is "photoreception," a specific reaction to physical "light." In this process probably all three constituents of the rods and cones—the outer and the inner segments, as well as the intermediary zone—participate, even though it seems probable that the initial reaction takes place in the outer segments. (*Cf.* sec. 3 [5], this chapter.)

Formerly, the bacillary layer was termed "Jacob's membrane," or "Jacob's tunic"; and, together with the retinal pigment epithelium, the capillary layer of the chorioid membrane, and Bruch's glassy membrane, it was known as the "membrane of Ruysch or Doellinger."

4. Outer limiting membrane (3).—This term is applied to a structure that appears as a sharp line separating the bacillary layer from the layers below. The line, visible in both stained and unstained preparations, represents a membrane-like structure produced by the joining of the top ends of the supporting neuroglial "radial fibers" of Müller. In the flat view the outer limiting membrane appears perforated by countless openings, somewhat pentagonal and hexagonal in shape, for which reason it was also called the "reticular membrane." The smaller and more numerous of these openings serve for the passage of rods; the fewer larger ones, for the passage of cones.

The function of the outer limiting membrane seems to be that of providing stable support for the lower ends of the rods and cones proper, by which they are firmly kept in place. This membrane was first described and named by M. Schultze (1866), even though it had been seen by others earlier.

5. Outer nuclear layer (4).—The relatively thick fourth layer is formed by closely packed bodies of photoreceptor cells containing the nuclei of the rods and cones. The larger nuclei, which in stained preparations are paler and fewer in number, are the cone nuclei. These are oriented with their longer axes more or less vertical. Their position, spacing, and number closely agree with those of the cones proper of the bacillary layer in each particular locality of the retina.

With the exception of the foveal center, the cone nuclei are found in a single row immediately below the outer limiting membrane, where they form zone *4-a*. In the center of the central fovea they are at some distance from this membrane and are present in several tiers (Figs. 129, *I*, and 161). The smaller, darker, and, in Primates, far more numerous rod nuclei, filling the fourth layer as far as its vitreal boundary, form zone *4-b*. Their number also closely corresponds with that of the rods in the bacillary layer, in a given locality of the retina. In the foveal center both the rods and the rod nuclei are absent (*see* above-mentioned figures).

6. Outer plexiform layer (5).—The fifth layer is located between the outer and the inner nuclear layers. In most regions of the retina it is relatively thin (Fig. 129, *IV*, *V*, *VI*). In the region of the axis, corresponding to the central area, however, the outer plexiform layer attains considerable thickness (Figs. 127, 128, 129, *II*, *III*). Here, also, it is further differentiated into three sublayers.

The outer zone, *5-a*, composed of the inner rod and cone fibers, shows a parallel striation. Outside the central area this striation is more or less vertical (Fig. 129, *V*). In the periphery

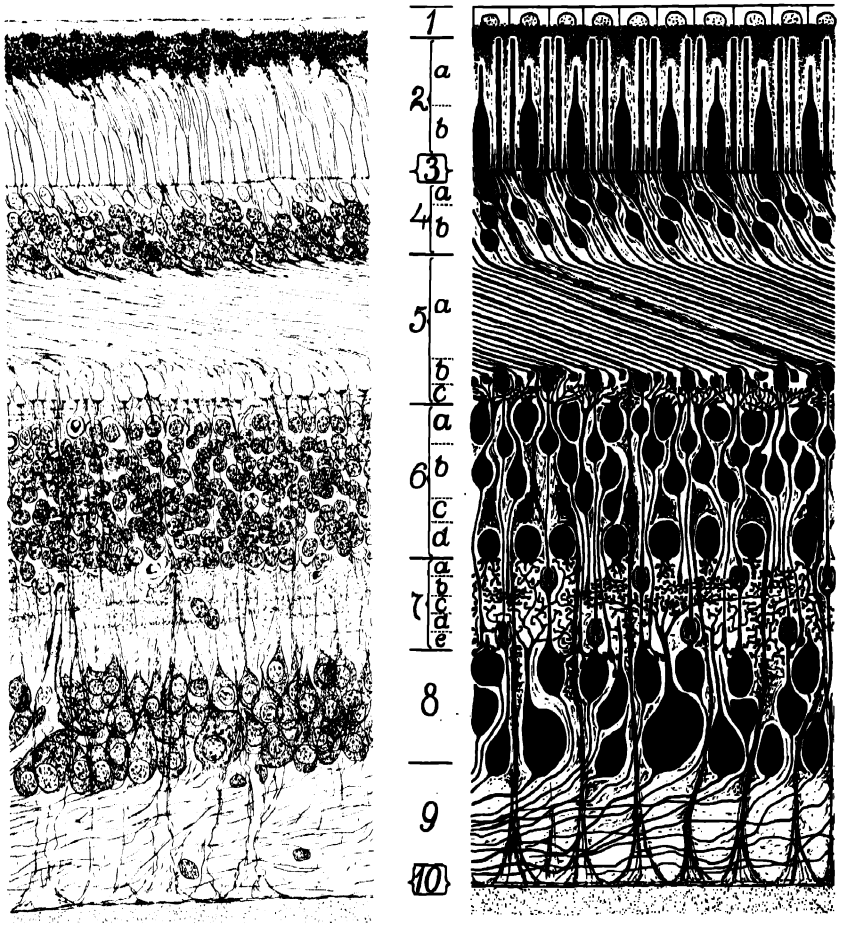

FIG. 128.—Structure of human retina as it appears in sections vertical to its surface, from central area midway between areal periphery and central fovea. Left half of figure shows the appearance of a preparation stained with haematoxylin and eosin, right half showing constituent cellular and fibrous elements of retinal tissue disclosed with the help of "analytical" methods of staining such as Golgi (silver dichromate) and Ehrlich (vital methylene blue stain). Layers: *1*, pigment epithelium; *2*, bacillary layer; *3*, outer limiting membrane; *4*, outer nuclear layer; *5*, outer plexiform layer; *6*, inner nuclear layer; *7*, inner plexiform layer; *8*, ganglion cell layer; *9*, layer of optic nerve fibers; *10*, inner limiting membrane. Note that zone *2-a* of bacillary layer is made up of outer segments, zone *2-b* of inner segments of thinner rods and thicker cones; *3*, outer limiting membrane resulting from joining of top-ends of supporting radial fibers; zone *4-a* formed of larger and paler cone nuclei, zone *4-b* of smaller, darker, and more numerous rod nuclei; *5-a*, outer fiber layer of Henle representing inner fibrous expansions of rod and cone cells, *5-b*, terminal swellings of same (smaller rod spherules and larger cone pedicles), *5-c*, outer expansions of bipolars and all expansions of horizontal cells, the last two zones representing the first synaptical field in the retina and in the visual system; *6*, inner nuclear layer, comprising bodies and nuclei of horizontal cells, bipolars, amacrines, a few displaced ganglion cells, and most radial fibers; *7*, inner plexiform layer formed by expansions of sixth and eighth layers, such as bipolars, amacrines, and ganglion cells; layer *10* or inner limiting membrane formed by joining of lower expanded ends of supporting radial fibers, a boundary toward vitreous fluid. *Cf.* Figs. 127, 129.

of the central area the striation is oblique (Figs. 127, 128). Close to and within the central fovea the obliquity of the striation increases so as to become almost horizontal, owing to a peculiar slant of the much elongated inner rod and cone fibers of the central pit, the "outer fiber layer" of Henle (Fig. 129, *I*, *II*, *III*).

The intermediate zone, *5-b*, is also present throughout the whole of the retina, being most distinct in the central area (Figs. 127, 128, 129, *II*, *III*). It is composed of swollen vitreal ends of the inner fibers of photoreceptors, smaller and more round in the rods—the rod spherules; larger and somewhat conical in the cones—the cone pedicles.

In the slope of the central fovea, in a belt where the inner fibers of the centralmost rodless foveal territory terminate, zone *5-b* is made up of a single row of regularly arranged, cuboidal cone pedicles (visible in Fig. 129, at the right

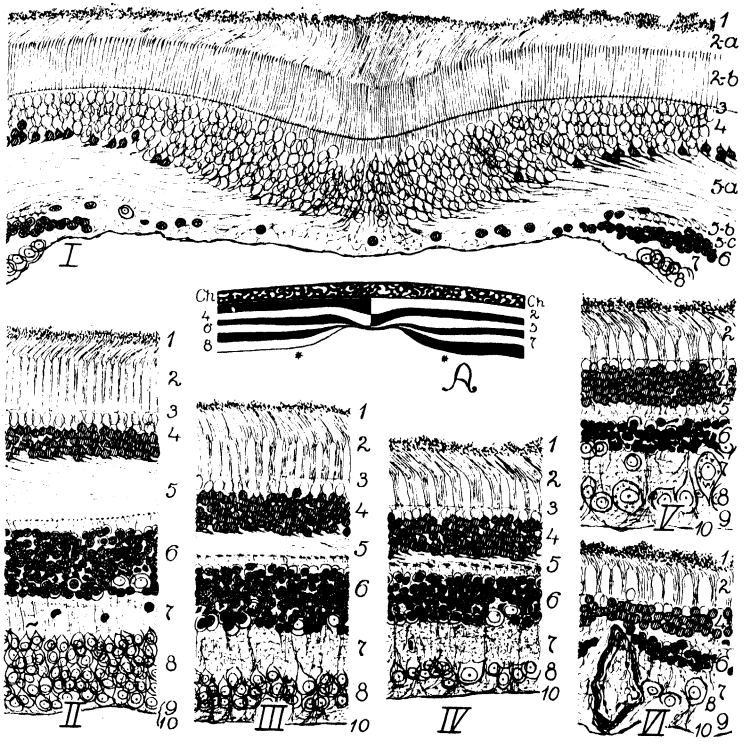

FIG. 129.—Regional variation of retinal structure in Rhesus Macaque. *I*, center of central fovea showing greatly lengthened, much thinner, and more numerous central cones (slightly disarrayed), which, together with their nuclei in the fourth layer, are alone present in the central "rodless area"; at some distance from center, smaller and darker rod nuclei in *4* begin to appear singly and in groups (*cf.* Figs. 127, 128, 161); lower layers below *4*, in the center, are much reduced, fibrous zone *5-a* greatly so, while zones *5-b* and *5-c* are entirely absent, as are also layers *6–9*; *A*, sketch at lower magnification of central fovea and its immediate vicinity of central area, ** marking the limits of the foveal pit; note a well-developed chorioid membrane, *Ch*; *II*, perifoveal region with five tiers of ganglion cells; *III*, perifoveal region in the periphery of central area, with ganglion cell layer reduced to three tiers; *IV*, near periphery, with ganglion layer represented by a single continuous cell row; *V*, middle periphery with a partly discontinuous layer of much larger ganglion cells; *VI*, far periphery of retina along ora serrata or ora terminalis; *VII* (not represented), where ganglion cell layer is disrupted by more or less considerable intercellular intervals.

and left ends of sketch *1*). Outside this foveal belt, in most of the central area and in the entire extra-areal periphery, zone *5-b* contains both the cone pedicles and the rod spherules (Fig. 128).

In number and spacing, these two structures —the pedicles and spherules—closely correspond to the number and spacing of the two varieties of photoreceptors in the *2-b* zone of the bacillary layer. In the foveal center the *5-b* zone is absent (Figs. 129, *1*, and 161).

The inner zone, *5-c*, is made up of external or scleral expansions of the nerve cells of the inner nuclear layer (Fig. 128). Together with *5-b*, this zone corresponds to the classical "outer plexiform" or "outer reticular layer" of earlier writers.

Zones *5-b* and *5-c* are the place of a synaptical contact of photoreceptors or neurons of the first order and of the bipolars and horizontal cells or neurons of the second order in the visual system. The fifth layer, particularly zones *5-b* and *5-c*, represents, accordingly, the first "synaptical field" in the retina and in the visual system.

7. INNER NUCLEAR LAYER (6).— The sixth layer, apparently most voluminous in the primate retina except in the foveal center, is formed by closely packed cell bodies and nuclei that belong to the various categories of the nerve cells. Some of the nuclei are somewhat larger than those in the fourth layer, while others are about equal in size; but all are smaller than the nuclei of the eighth layer. Also they vary considerably in size among themselves.

This layer may be further subdivided into four ill-defined zones (Fig. 128). The uppermost zone, *6-a*, predominantly represents the "horizontal" cells (*c*). Zone *6-b* is made up of the nuclei of bipolar cells (*d*, *e*, *f*, *g*, *h*). Zone *6-c* contains, in Man, in addition to the bipolar nuclei, most of the nuclei of the supporting "radial fibers" of Müller (*u*). The lowermost zone, *6-d*, contains chiefly the bodies and nuclei of the "amacrine cells" (*i*, *k*, *l*) and of a few displaced ganglion cells ("Dogiel's cells") and an occasional bipolar nucleus. The position of the nuclei of Müller's "radial fibers" varies in different species (closer to, or farther away from, layer *7*).

The inner nuclear layer has been named by Henle the "outer ganglion layer," and by W. Müller the "ganglion of the retina." This layer and the layers below contain blood vessels belonging to the system of the central retinal artery and vein, whereas the layers above contain no blood vessels (*see* chap. X, **2**). In the center of the foveal pit the sixth layer and the layers below it are practically absent (*see* Figs. 129, *1*, and 161; *cf.* sec. 10 [6], this chapter, and Fig. 512).

8. INNER PLEXIFORM LAYER (7). —The thick seventh layer, which has a fine granulated appearance, is almost entirely fibrous. In it are found, here and there, only a few nuclei belonging to the nerve and neuroglial cells and also to the endothelial cells of capillaries, besides those of an occasional larger blood vessel.

A closer study reveals an indistinct vertical, as well as horizontal, striation. The coarser vertical striping, more pronounced close to the ganglion layer, is chiefly caused by the thick trunklike main pillars of Müller's radial fibers, which may be continuously followed in the extra-areal periphery as far as the tenth layer. The finer vertical striation, where discernible, is due to the ascending and descending protoplasmic and axonal expansions of the nerve cells of the adjoining layers, *6* and *8*. The horizontal stripes, Ramón y Cajal's "granular lines," are caused by the evenly arranged terminal and preterminal dendritic and teledendric expansions of the nerve cells (compare left and right sides in Fig. 128).

Since these expansions vary from level to level in number, thickness, and other details, the texture of the meshwork of the inner plexiform layer also varies somewhat, being finer or coarser or otherwise differing from level to level. Using these criteria, five zones—*7-a*, *7-b*, *7-c*, *7-d*, and *7-e*—may sometimes be distinguished in this layer, at least in the central area and close to it.

Analytical studies show the inner plexiform layer to be the place of synaptical contacts between the bipolars and amacrines, or neurons of the second order, and the ganglion cells, or neurons of the third order (right half in Fig. 128). This layer, accordingly, is the second "synaptical field" in the retina and in the visual system.

9. GANGLION CELL LAYER (8).—The ganglion layer consists of larger elements more closely resembling the typical nerve cells of the brain or spinal cord than those found in the two nuclear layers (for this reason, some have called it "layer of brain cells"). In well-stained preparations, not only the nuclei of these cells, but their bodies as well, may easily be seen (Fig. 127 and left half in Fig. 128).

There are not less than five, and possibly more, varieties of ganglion cells in the primate retina (*m*, *n*, *o*, *p*, *r*, *s*). The size of the cell bodies and nuclei varies more than in the other two cellular layers, *4* and *6*. The total number of the ganglion cells, however, is less than the number of cells in either the outer or the inner nuclear layers.

In most of the retinal expanse there is only one, often a discontinuous, row of cells in the ganglion layer (Fig. 129, *IV*, *V*, *VI*). In the human and simian retina, in the central area alone, except in the foveal pit, the ganglions are found in more than one tier; close to the central fovea, there are as many as six to eight tiers (Figs. 127, 128, 129, *II*, *III*).

By far the greater majority of the nuclei of the ganglion layer are those of nerve cells proper, with only a few belonging to the neuroglial cells. The latter are typical small astrocytes and microglia and a few displaced nuclei of the radial fibers of Müller. There are also some nuclei of blood vessels.

The ganglion layer has been named by Henle the "inner ganglion layer," and by W. Müller the "ganglion of the optic nerve."

10. LAYER OF OPTIC NERVE FIBERS (9).—The ninth or optic fiber layer is composed of axis cylinders, probably mostly of ganglion cells, both of those whose bodies are in the eighth layer and of those of the few displaced ganglions in the inner zones, *6-c* and *6-d*, of the sixth layer. Possibly some fibers belong to the "exogenous axons" of extraretinal origin.

Because of their varying course, the nerve fibers in customary vertical sections, depending upon the locality and orientation of the plane of cutting, are seen arranged either horizontally or assembled into bundles, cut across. The more or less vertically arranged striation of this layer is caused by the inner, conically swollen ends of the thick pillars of Müller's radial fibers which form the supporting frame of the retina.

The ninth layer has been termed by Henle "inner fiber layer." Its nerve fibers, as soon as they leave the eyeball, form a thick nervelike trunk known as the "optic nerve." They continue as the optic tracts and terminate in the subcortical or primary visual centers of the midbrain and betweenbrain (chap. VI, 4 [3, 4, 5]).

Normally, in the human and simian retina, the optic nerve fibers do not possess myelin sheaths; and, because of their transparency and lack of color, they therefore remain invisible in routine ophthalmoscopic examination. Occasionally, as an anomaly, streaks and patches of myelinated fibers are found. Myelin investments are provided in the extraocular portions of fibers beyond the cribriform or sievelike lamina, in the optic nerves and tracts. In some animals, e.g., the Rabbit, the intraocular sections of fibers are also myelinated in certain places. (On the arrangement and course of bundles of optic nerve fibers in the human and simian retina, *see* chap. VI, 2.)

11. INNER LIMITING MEMBRANE (10).—The tenth and innermost layer of the retina appears as a sharp, thin line bounding the retinal tissue toward the vitreous (Figs. 127, 128). It is composed of flattened vitreal ends of Müller's radial fibers, which are joined to one another. It is not, therefore, a detachable membrane but a part of the retinal supporting or neuroglial tissue. This membrane-like structure is not identical with the hyaloid membrane which adjoins it from underneath and which belongs to the vitreous. The inner limiting membrane was first described by Pacini (1845).

Throughout the retinal tissue, beginning with zone *2-b* and continuing as far as the inner limiting membrane, there are supporting elements—important and indispensable structural and functional constituents. (*see* sec. 9, this chapter). In the primate retina, blood vessels are present only in the inner layers, from *5-c* to *9*, inclusive. The outer layers, from *1* to *5-b*, inclusive, rely for their nutrition upon the choroid membrane. (*See* chap. X, 2 [3].)

The stratification of the retina in sections vertical to its surface shows important variations in certain regions, depending upon the

function of a particular locality. Most markedly, this stratification deviates from the type just described in the central area and fovea, in the papilla or disk of the optic nerve and in the region of the *ora serrata* (*see* secs. 10, 11, this chapter).

SEC. 3. VISUAL CELLS OR PHOTORECEPTORS

1. General features of rods (*a*) and cones (*b*).- The photoreceptors are nerve cells or neurons of the retina, specially adapted in structure and in physiological, chemical, and probably also physical properties to react to the physical form of energy called "light" (Fig. 130).

They are considered "neuroepithelial cells" by some authorities. Such a distinction, as far as it denies the nervous status or nature of the photoreceptors, appears to have little justification and is otherwise meaningless; for both histogenetically and in adult form the photoreceptors possess certain features characteristic of typical nerve cells. In the cones these are a large vesicular nucleus containing a nucleolus, a typical teledendron at the end of the inner cone fiber, and synaptical junctions with undoubted nerve cells of the retina.

Other characteristics of nerve cells, however, are absent. There are no chromophile granules of Nissl and probably no neurofibrils. Instead, the photoreceptors have special features of their own, the rod- and conelike scleral ends of the bacillary layer, which are present in this form nowhere else in the organism.

Each photoreceptor cell has a "body," with a "nucleus" in the outer nuclear layer; in the cone cells, this body has a typical spherical "nucleolus." The nucleus is sometimes, but rarely, displaced into the rod or cone proper, in zone *2-b*, above the outer limiting membrane. When this occurs, it is called an ectopic nucleus.

From the scleral end of the body an expansion usually arises, the "outer fiber," much thinner in the rods than in the cones. This outer fiber, as it slips through one of the openings in the outer limiting membrane, *3*, becomes either a rod or a cone proper of the bacillary layer, *2*. When the nucleus is close to, or immediately underneath, the outer limiting membrane, as is the case in almost all cones except those in the center of the central fovea (Figs. 129, 161), the outer fiber is short and thick or is absent altogether, and the body continues directly into a rod or cone proper.

Ordinarily, just before passing through the outer limiting membrane, the outer rod or cone fiber increases to the thickness of its rod or cone proper. At the point of passage through that membrane, there is usually a slight dent, indicating a groove where the ring of the opening of the limiting membrane is fitted. Above the dent there is often a slight flaring of the base of the rod or cone proper.

2. Outer bacillary expansions, or rods and cones proper.—The part of the photoreceptor cell which is in the bacillary layer is a peculiar structure composed of an "inner segment" and a slightly shorter "outer segment" kept together by a narrow zone, the "intermediate link."

In the rods, both segments have straight

sides, and the difference between the outer and the slightly thicker inner segment is small. This gives the rods their characteristic slender form (*a*, in Fig. 130).

In the cones, the inner segment is also only a little thicker in the central fovea (Fig. 161); outside the fovea the swollen inner segment, however, is considerably thicker than the outer segment and has somewhat curved, bulging sides (*b*, in Fig. 130).

The outer cone segment is much more delicate than the inner and is much longer in the fovea. Outside the fovea the outer segment is almost the same length as the inner. It has a slender conical shape, a narrow tip, and a somewhat widened base, where it is continuous with the intermediate link. This gives the central foveal cones a rodlike appearance and the extrafoveal cones a flasklike appearance and thus accounts for the name "bulbs" formerly given the latter.

In the central fovea the cones are thinner and longer, and the longest and most attenuated are found in the very center of the central fovea (Fig. 161). Here the inner segment is but little thicker than the outer segment, which is also much longer than the inner.

The rodlike appearance of the cones in the foveal center, however, in no way changes their true cone character, as shown by the typical cone nuclei, thick inner fibers, and relatively large spheroidal or cuboidal pedicles, or swollen lower ends, which are very different in shape and size from the much smaller rod spherules. The slenderness of the central foveal cones, therefore, is not evidence that would permit confusing—much less identifying—them with genuine rod photoreceptors (discussed in par. 4, this section). The staining properties of the central cones also differ from those of the adjoining rods. (*Cf.* also Figs. 157, 158, 159; *cf.*, however, Fig. 512.)

The regular, even appearance of the rod- and conelike parts of the photoreceptors is found only in preparations expertly made from perfectly fresh specimens. In routine material the regular form is usually lost and is replaced by various artifacts, such as bulbous swellings and

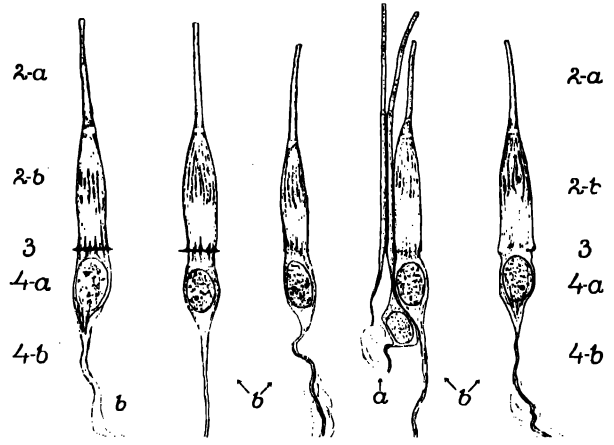

FIG. 130.—Elements of bacillary and outer nuclear layers from a "teased," unstained preparation of the retina of an adult Rhesus Macaque freshly fixed in osmium vapors (preparation of Professor G. W. Bartelmez). Region of central area. Thinner structures represent rods (*a*); thicker structures, cones (*b*). In rods note uniformly cylindrical shape, inner segments in *2-b* only slightly thicker than outer segments in *2-a* and separated from latter by a very narrow intermediate zone. In cones outer segments slightly cylindrical and much thinner than the flask-shaped inner segments, both segments separated by a clear intermediate zone consisting of a highly refringent substance. In two cones the neuroglial outer limiting membrane (*3*) with its "fiber baskets" is still attached. Larger cone nuclei include typical spherical nucleoli. Both rod and cone bodies continue inward as "inner fibers," a few still surrounded by their neuroglial sheath. Camera lucida drawing, approximate magnification 550×.

other deformities. These artifacts are most often found in the outer segments, which is indicative of their extreme fragility.

The rods and cones proper, that is, their inner and outer segments, where the initial process of photoreception takes place, form a solid, continuous "mosaic" or "pavement" throughout the entire retinal membrane (*see also* sec. 10 [5], this chapter). With the exception of a minute rodless area in the center of the central fovea or pit (Figs. 150–56), corresponding to direct vision in the axis of the visual field, and a transitional circular belt around the central fovea, where the rods are few (Figs. 157–60), the rods and cones are mixed in almost even numbers in each particular territory, forming the double photoreceptor apparatus of the retina. The exact gradient in various meridians, however, is yet to be determined.

The anatomical fact of the presence of both kinds of photoreceptors suggested to Max Schultze (1866) the idea of functional difference in the rods and cones. This idea was subsequently elaborated by Parinaud, Kries, and others into the "theory of the duplex retina." This theory considered the retina to be made up of a double photoreceptor-conductor mechanism, one a cone apparatus active during daylight or photopic conditions of illumination and characterized by high acuity, responsiveness to colors, and other peculiarities; and the other a rod mechanism functioning in dim light and much more responsive to low intensities but not reacting specifically to different wave lengths of light.

The photoreceptor mosaic, while fairly homogeneous in each particular small retinal territory, exhibits considerable variation in the relative numerical composition of the constituent rods and cones. This is demonstrated by sections cut through the retina parallel to the surface or by well-made whole-mounts of the retina. Such preparations show the gradual appearance of the rods, singly and in groups (Figs. 157–59), from the rodless center of the fovea, where only cones of minute size are present (Figs. 150–56), through the extrafoveal belt of the central area, where each cone is surrounded by a row of rods (Fig. 160), to the extra-areal territory, where there are three or more rods between each two adjacent cones, with a corresponding wider spacing of the cones. (*See* sec. 10, this chapter, for a discussion of the photoreceptors of the central fovea and area.)

3. PHOTOSENSITIVE SUBSTANCES OF THE RODS AND CONES.—The outer segments of the rods and, to a lesser extent, those of the cones stretch into the pigment epithelium (layer *1*) and are imbedded between its pigment-filled protoplasmic fringes (Figs. 127, 128, 129). In the living eye, especially in one which is dark-adapted, the outer rod segments contain a peculiar photosensitive chemical substance of an extremely unstable nature, which acts as a mediator in the process of photoreception. This photomediator has been variously named "rhodopsin," "erythropsin," or "visual purple," and it may be partly responsible for the pink color which the retinal membrane has in life. (In the Fish retina a similar substance with slightly different spectral properties is known as "porphyropsin" or "visual violet"; and there are other substances, such as "visual yellow," "visual red," and "visual blue," as well as others not yet identified, according to Dartnall 1950.)

Visual purple has lately been identified as a complex "color protein" or "chromoprotein," that is, a conjugate protein containing vitamin A or carotene and probably other compounds as well, which are its indispensable constituents (Wald 1936, 1938, 1939, 1942, 1943, 1944, 1945, 1945–46, 1948, 1950; Broda, Goodeve & Lythgoe 1940; Godding 1945). Vitamin B_2 has also been shown to be concerned in the synthesis of photochemical substances (R. A. Morton 1944).

Visual purple and the pink color of the retina may be preserved for some time in a freshly dissected retina or in an extract solution, if the specimen is kept in darkness at a low temperature (between pH 5.2 and 10). Visual purple is believed to be produced by the outer rod segments without the aid of pigment epithelium (Tansley 1933).

Soon after it is subjected to the action of light, visual purple disintegrates into "transient orange," "indicator yellow" (formerly called "visual yellow" and "retinene"), and finally into a colorless substance, "leucopsin" or "visual white," the end-product being vitamin A_1, or visual violet vitamin A_2 (Wald).

Through the process of bleaching, probably

by initiating a change in the electrical potential, visual purple acts as a nerve stimulus and hence brings about the sensation of "light" (Dartnall 1948; Tansley 1950).

The presence of visual purple in the retina can be demonstrated by partly exposing a freshly enucleated eye to light. When this is done, the rhodopsin partly disintegrates, leaving on the retina figures of various shapes that may be rendered permanent by the action of an appropriate fixative (Kühne's "optograms").

Under normal conditions visual purple is in a constant state of regeneration, a process that is still not completely understood (Tansley 1950). It is always present in quantities sufficient for the activation of the retina, especially so in the scotopic or dark-adapted eye.

Since the discovery of visual purple by Boll (1877, 1881), its chemical and physiological properties have been much studied by W. Kühne (1877, 1878, 1882), Ewald & Kühne (1877), and others, and again in modern times by Hecht (1921, 1924, 1931, 1937, 1938, 1940, 1944), Tansley (1931, 1933, 1950), A. C. Krause (1934, 1942), Lythgoe (1937), Wald (1938, 1942, 1944), Wald & Clark (1938), and others (*see also* Granit 1950).

Visual purple is considered to be a substance indispensable for the light reaction of the rods. It is extremely light-sensitive. Its absorption curve, approximately determined by Trendelenburg (1904), was first accurately plotted by Lythgoe (1937). Its maximum absorption has been found to be about the wave length of 0.5 micron, or the greenish-blue part of the visible spectrum, corresponding to a quantum yield of 1 (by which one quantum of light destroys one molecule of visual purple; Dartnall, Goodeve & Lythgoe 1938).

The photosensitivity or absorption curve of visual purple agrees with the human dark-adapted, or scotopic, luminosity curve, illustrating the distribution of brightness for a dark-adapted eye to a spectrum of low intensity (Schneider, Goodeve & Lythgoe 1939; *et al.*). All evidence, accordingly, indicates that "visual purple mediates scotopic vision by virtue of the photochemical changes it undergoes on exposure to light" (Dartnall 1948).

It has been claimed that a similar, but colorless, chemical photomediator, the "cone substance" or "iodopsin," is contained in the cones (Studnitz 1936–37, 1937–38, 1940, 1941; Wald 1937, 1938, and later publications). Its absorption curve is supposed to correspond to the distribution of sensitivity or luminosity of radiation in a photopically adapted human eye or to the daylight luminosity curve for cone vision. The maximum of this photopic luminosity curve in a daylight-adapted eye, with the cones dominating or even suppressing the scotopic rod–visual purple mechanism, is at the wave length of light of 0.56 micron, that is, in the greenish-yellow segment of the visible spectrum. It is, accordingly, considerably shifted toward the long end of the spectrum in comparison with the scotopic maximum, which is at the wave length 0.5 micron, corresponding to the greenish-blue part of the spectrum ("Purkinje shift" or "Purkinje phenomenon"; *see* Helmholtz' *Treatise on Physiol. Opt.*, v. 2, Pl. II).

The chemical composition of "iodopsin" is not known, but indirect evidence indicates that it is a carotenoid protein, closely related to the rod photopigments, rhodopsin and porphyropsin (Wald 1945–46). Another hypothesis, however, claims that the photomediator both in scotopic rod vision and in photopic cone vision is visual purple (Dartnall 1948). This hypothesis has been questioned by Granit (1950).

The basic question whether the photopic photomediator of the cones is a single, homogeneous substance responsive to all color hues of the visible spectrum that can be distinguished or whether there are several chemical photomediators in the cones more or less structurally closely interrelated has not been answered. It is the belief of the author that this problem is infinitely complex, beyond the capacity of an exclusively anatomical, physiological, biochemical, or electrophysiological analysis.

The photoreceptor role of the outer rod segments is supported by the following evidence: the presence of visual purple in the outer rod segments, the insulation of these segments by the pigment in the bright-adapted eye, and their exposure to full action of light in the dark-adapted eye, which is also assisted by the movement of the outer rod segments closer to, or farther from, the outer limiting membrane through the action of the myoid component

of the inner rod segments observed especially in Lower Vertebrates, the reverse of the movement of the photopic cones (the so-called photokinetics of the retina).

The intermediate links, largely refractory to dyes in stained preparations and therefore improperly called "vacuoles," are found in freshly prepared specimens of retinae of Birds and some Lizards to be red, orange, or green in color. These "colored globules" have, therefore, been interpreted as "filters," by means of which the spectral composition of physical light passing through them to the photoreceptor outer segments is variously modified (Walls & Judd 1933; Walls 1942). This interpretation has been disputed by Studnitz (1940).

4. Differential characteristics of primate rods and cones.— Ever since the formulation of the duplexity theory of the retina, the problem of the structural and functional similarity or dissimilarity of rods and cones has been periodically discussed. Especially alluring was the concept of the identity of the rods and cones in the foveal center. The rodlike appearance of the slender cones in the very center of the fovea, when examined superficially, encouraged such an interpretation.

Nothing could be more erroneous and misleading than to insist upon the identical nature, and hence identical function, of the central cones and rods proper. Whatever their common phylogenetical and ontogenetical origin, the two varieties of photoreceptors are as different in the fully differentiated state found in the mature human and simian retina as any closely allied histological elements could be. Additional evidence of this difference is found in their different synaptical relations with other neurons of the retina, discussed elsewhere. (*Cf.* secs. 8, 10, 11, this chapter, and chap. IX.)

Following are the principal characteristics by which the rods and the cones may be differentiated in the primate retina.

The rod nuclei residing in the outer nuclear layer are considerably smaller in size, angular in shape, and have a crude inner framework with larger meshes and several crude nodules or granules in it. In hematoxylin and eosin or phloxin preparations they stain more sharply than the cone nuclei and in a darker, decidedly blue-black hue. The cytoplasm enveloping the nucleus and forming the body of the rods is scanty. From it, a thin, filamentous inner fiber descends to the outer plexiform layer, where it terminates in the shape of a minute, more or less oval, "spherule."

The cone nuclei are larger, smoother in outline, and less frequently angular in shape. In the retinal periphery they are oval or elliptical; in the fovea they are spherical. The inner framework is composed of much finer and more numerous meshes and trabecules and is much more delicate and regular in appearance. The cone nuclei stain in a characteristic, decidedly pink or purplish hue, in contrast to the sharp, dark, "steel-engraving" hue of the rod nuclei. They are enveloped by a relatively thick layer of cytoplasm, which forms the body, from which a stout fiber descends to the outer plexiform layer, where it terminates in the form of a sizable "pedicle," more or less conical or bulbous in shape.

In the primate retina these features are present in all regions, including the central fovea. By means of them, two categories of photoreceptors may be easily distinguished. There is little doubt that these morphological and tinctorial characteristics indicate a profound difference in the chemical, and therefore physiological, properties of the two varieties of photoreceptors. (Cf. E. Wolff 1941.)

Another important and easily ascertained fact is the identity of appearance, and hence identity of function, of all cones in any given small territory of the retina. In the very center of the fovea, for example, all cones are of much the same diameter, shape, and hue and hence must possess identical functional properties. Slight differences in the shape and size and in the saturation of staining, observable in many cones, do not follow any pattern of distribution that could reasonably be expected from a homogeneously organized photoreceptor mosaic. (*Cf.* cones in Figs. 157–59.)

The histological and cytological characteristics just discussed are easily discerned in any good microscopic preparation of a human or simian retina. They all indicate that the properties of the cones are essentially identical in the entire retina and are different from the properties possessed by the rods. This defini-

tion in no way precludes functional differences among the cones of different retinal regions, as, for example, different spectral responsiveness between the central cones compared with the cones in the periphery of the retina.

5. REFLECTIONS ON THE INTERPLAY OF PHYSICAL AND STRUCTURAL FACTORS IN THE INITIAL PROCESS OF PHOTORECEPTION.—Since H. Müller (1853) presented the evidence which demonstrated the photoreceptor role of the bacillary layer and Boll (1877) announced the discovery of visual purple, the question of the mechanics and location of the initial process of photoreception has been considered. By what interplay of various essential factors is it made possible, and in precisely which structures does it occur? Although much knowledge has been accumulated since then, we are still far from able to give a fully satisfactory answer. For this a deeper knowledge of basic photophysics and biochemistry will be necessary.

The first step in photoreception seems to take place in the outer segments. The location of these segments as the ultimate parts of the rod and cone cells still freely entered by light, before light is impeded by the optical barriers of retinal and chorioidal pigment, and the continuity of the outer segments with the inner segments, the cell bodies, and inner fibers indicate this. The intermediary links between the outer and the inner segments must also be essential. The disproportionately small size of the outer cone segments, representing but a fraction of the volume of the inner segments in the entire retina except the outer fovea, is not necessarily contrary to this interpretation. In a sense, the outer segments may act as triggers whose action discharges the more bulky inner segments (Fig. 130).

In the very center of the outer fovea, where the outer cone segments exceed the inner segments in length, the disproportion may be much smaller and may, in fact, be reversed in favor of the outer segments, in spite of their extreme thinness (Fig. 161).

The difference in bulk of the outer and inner segments of the rods is much smaller in all regions of the retina. This and the presence of visual purple seem to confirm the role of the outer segments as primary photoreceptors.

The slender conical shape of the outer segment in the majority of cones may be indicative of their function as collectors of rays of light, by which the intensity of the stimulus, transferred to the inner segment, is increased. The great lengthening of the outer segments in the very center of the outer fovea, with a slight shortening and a striking thinning of the inner segments, is additional evidence in favor of the outer segments being the principal photoreceptors in this particular locality.

Next to be considered is the distribution of the photosensitive substances. This is a problem to be solved by microphysics and microchemistry conjointly with histological methods, and no reliable solution is to be expected by hypothesizing. There are many questions concerning this matter. Is the photosensitive substance uniformly spread through the entire photoreceptor? Or is it preponderantly, or entirely, accumulated in part of it? Is this part its core, its surface, the inside, or the outside of its surface, or both, forming a sort of two-faced membrane? Or is the photosensitive substance accumulated in some special way, perhaps in seriated layers, fibrils, a network, or micelles? The separation of the outer rod segments into a great number of thin plates resembling a roll of coins has been interpreted as indicating preformed structures. No comparable separation has been observed in the outer cone segments, which seem to have, when fresh, a uniformly plastic constitution, which would indicate a rather uniform, homogeneous distribution of the photosensitive substance.

There is still another question. Since the light entering the layer of photoreceptors must first pass through the inner segments and intermediate links, it is logical to suppose that the process of photoreception may begin here but can be consummated only in the outer segments. Is this initial phase a purely physical, optical one, in which the inner segment "guides" and "collects," hence intensifies, the rays of light before they enter the outer segment? Or is it a chemical process, or a combination of both? In any case, the inner segment does not seem to be a mere vehicle for the light rays passing through it to the outer segment, nor merely a conductor of impulses passing back from the outer segment, but probably is

also a contributing generator to these impulses.

The thesis which postulates active participation of the inner segments in the process of photoreception is further supported by the essential role which their diameter plays in the perception of space, or visual acuity. This is evidenced by the following considerations.

The structural arrangement postulates that light must pass through the inner segment and intermediate link, no matter what it does in these two parts, before it enters the outer segment. Since the inner segments are several times as thick as the outer segments, in the entire retina except in the very center of the outer fovea, the sensitive points in the visual space must be separated by blind intervals, corresponding to the intervening spaces. It should, then, be possible to determine experimentally whether or not the smallest stimulable points correspond to the diameter of the outer, or to the diameter of the inner, cone segments.

Since the inner cone segments outside the very center of the outer fovea have a respectable diameter, ranging from roughly 2 to 3 microns in the foveal periphery to 6 or 8 microns in the far periphery of the retina, each cone could accommodate more than one ray, including the rays of the long waves, for example, orange and red (from 650 to 700 millimicrons in diameter). This would indicate that more parallel rays can enter the thicker cones of the retinal periphery than can enter the cones close to and in the central fovea.

This raises a further question as to whether or not the thicker cones are capable of responding discretely to more than one ray. This aspect of the cone function touches the fundamental problem of the nervous system dealt with in detail in chapter IX. In the light of what is said there, it appears that each individual "neuron" or nerve cell is capable of responding to one or more simultaneous stimuli always in a rather global way, as a unit (even though varieties of synaptical contacts found in most neurons indicate a modulation of such global response).

Each cone, accordingly, may always react as a single, indivisible unit, no matter how thick it is or how many elemental rays of light may stimulate it. Each cone may, at any given short period of time, respond in one way only.

The way to increase the number of stimulable points on the receptor surface of the retina is to increase the number of individual cones per surface unit, which occurs in the central fovea, maximally so in the center of the outer fovea. Here the cone thickness, in Man and Monkey, is reduced roughly to 1 micron and may be even a little less in individual cones. The diameter of central cones, then, is just large enough comfortably to accommodate precisely one ray of light of any wave length of the visible spectrum (Figs. 154, 155). The reduction of cone diameter in the very center, in turn, is compensated for by greater length, obviously to increase the bulk or volume of the outer segments which contain the photosensitive substance.

In the eyes of certain species believed to possess extremely high visual acuity, for example, the Golden Eagle (Fig. 171), the thinnest cones are much thinner than the thinnest foveal cones in Man or Monkey, approximating $\frac{1}{4}$ micron. This gives pertinence to the question of whether the usual concept, adhered to by physicists, of the "ray" of light as the ultimate physical entity is correct, or whether there are perhaps other properties of light that would allow a use of angular values much smaller than those corresponding to the diameter of the thinnest cones in the human and simian retina (1 · 1.5 microns, or 12 18 seconds of arc), as indicated by the "aligning power of the eye" or the Nonius or Vernier methods of measuring. In order to remain within accepted concepts, we may consider the possibility that in the case of keen-sighted species, such as the Eagle, light of short wave lengths can still be comfortably accommodated within cones measuring not much more in thickness than $\frac{1}{3}$ micron (corresponding to a visual angle of 4 seconds of arc) and is preponderantly or exclusively utilized.

6. Inner expansions or fibers of rods and cones.—The vitreal ends of the bodies of photoreceptor cells are thinned out into inner fibers, filamentous in the rods and of considerable thickness in the cones. These "inner fibers" enter in the outer plexiform layer, forming zone *5-a* (Figs. 140, 145, 146, 147, and colored schemes in 177, 178, 179).

In the peripheral extra-areal regions of the retina the inner rod and cone fibers are short

and arranged vertically to the surface of the retina; in the rods and cones, whose bodies adjoin the fifth layer, these fibers are practically nonexistent.

In the central area the inner photoreceptor fibers are of considerable length, the longest being in the cones and in the few rods of the central fovea (*see* sec. 10, this chapter). Here they are arranged obliquely and stretch for hundreds of microns in Henle's outer fiber layer to reach their related bipolars in the sixth layer, which is displaced laterally by the formation of the foveal depression (*see* Fig. 161; also 512).

7. Inner terminations of photoreceptors; rod spherules and cone pedicles. The inner photoreceptor fibers terminate with enlarged, swollen ends. The "cone pedicles" are larger and somewhat conical or bulbous, the "rod spherules" are smaller and spherical, oval, or pyriform in shape. Both these terminal swellings form, in the aggregate, the intermediate zone, *5-b*, of the outer plexiform layer (Figs. 128 and 140; and also 146, 147, and colored schemes in 177, 178, 179).

The lower ends or bases of the cone pedicles are all strung along a line which corresponds exactly with the boundary line between zones *5-b* and *5-c*. In the extrafoveal regions, half-a-dozen or so short, barbel-like "basal filaments" spread from each pedicle in zone *5-c*, some of them carrying minute swellings at their ends (*b* in Fig. 141). In the central fovea the basal filaments are mostly absent.

The rod spherules, filling the gaps between the cone pedicles in several closely packed rows are not all in direct contact with zone *5-c*, the majority remaining at some distance from it. This difference in arrangement has some bearing upon the kind of synapses which the two varieties of photoreceptors undergo with the bipolars and horizontal cells (*see* secs. 4, 6, and 8, this chapter).

I, 6 [3], 7 [2]; for central fovea and yellow spot *see* secs. 10, 11, this chapter.)

SEC. 4. BIPOLAR CELLS OF THE RETINA

1. General features of retinal bipolar cells. –These neurons have received their name because of their bipolar appearance. The "bodies" of the bipolar cells (*d*, *e*, *f*, *h*), with their "nuclei" wrapped in scanty protoplasm, are closely packed in the inner nuclear layer, *6* (Figs. 132, 133, 134, 143, 144, 146, 147 and colored schemes in 177, 178, 179). Only exceptionally is one or the other bipolar nucleus found displaced in the outer plexiform layer. The bodies are usually irregularly spherical, oval, or somewhat like a short spindle.

Usually, from each body two processes arise which are oriented vertically. The shorter "scleral process" extends into the outer plexiform layer (*5*), and the "vitreal process" stretches into the inner plexiform layer (*7*). The former may be considered a dendritic expansion, the latter an axis cylinder of the differentiated, functionally polarized neurons (*cf.* chap. I, 8 [5], and chap. IX). In the two plexiform layers, both processes divide into secondary, tertiary, etc., branches, different in morphological appearance and synaptical relationships.

Several distinct varieties of bipolar cells may be distinguished in the primate retina according to their appearance, anatomical contacts, and probable functional role. These represent two groups: "common," "polysynaptic rod and cone bipolars" (*d*, *e*, *f*, possibly also *g*), which are in synaptical contact with both kinds of photoreceptors, and "monosynaptic bipolar" (*h*), which is related only to the cones.

2. Mop bipolar (*d*).—This bipolar variety is morphologically clearly characterized. Usually, from the upper end of the "body" a single, relatively thick, main "dendritic or scleral process" extends in the scleral direction. In the inner zone of the outer plexiform layer (*5-c*) this process divides repeatedly until a small mop of delicate, filamentous terminal branches is formed (thus in Fig. 134, lower center). Occasionally, a single, somewhat stouter, filament extends as far as the outer nuclear layer, resembling the "club of Landolt" found in the Lower Vertebrates (left end of middle sketch, in Fig. 133).

The fine filaments of the mop spread out in zone *5-b*, where they cling to the sides of the cone pedicles and rod spherules. Both the rod spherules close to zone *5-c* and those that remain at some distance from it are in contact (Fig. 140). In this way, each mop bipolar becomes synaptically related to a compact group of photoreceptors, rods as well as cones. This is the multiple and common axodendritic type of synapse.

Another noteworthy feature is the reciprocal partial overlapping of the dendritic mops of the adjoining mop bipolars (thus at left end in middle sketch, in Fig. 133, and in lower center in Fig. 134). Because of this, a group of photoreceptors related to a single mop bipolar is also partly related to the adjoining mop bipolars; that is, the separation of a functional group of photoreceptors related to a single mop bipolar from the similar functional groups of the adjoining mop bipolars is not abrupt, but gradual.

The third feature is the overlapping or mingling of the dendritic expansions of the mop bipolars with those of the other bipolar varieties and of the horizontal cells.

In other words, a group of the rods (*a*) and cones (*b*) synaptically related to a single mop bipolar (*d*) is simultaneously related not only to the adjoining mop bipolars (*d*) but also to a few cells of the other bipolar varieties (*e*, *f*, *h*) and to the horizontal cells (*c*).

3. Synapses of the mop bipolar with photoreceptors.—The synaptical relationships described above indicate a potential influencing of the mop bipolars (*d*) both by the rods (*a*) and by the cones (*b*), which may take place either simultaneously or successively. This influencing

is, of necessity, diffuse, that is, less precisely limited in space than in the *h*-bipolar, involving, as it always does, a group of mop bipolars.

The influencing of a single mop bipolar either by a single cone or by a minute group of rods and cones seems to be ruled out on morphological grounds, because of dendritic overlapping and multiple contact with the photoreceptors.

Nor does it seem probable that an influence arising either in the rods or in the cones, or in both, could be restricted to the mop variety of

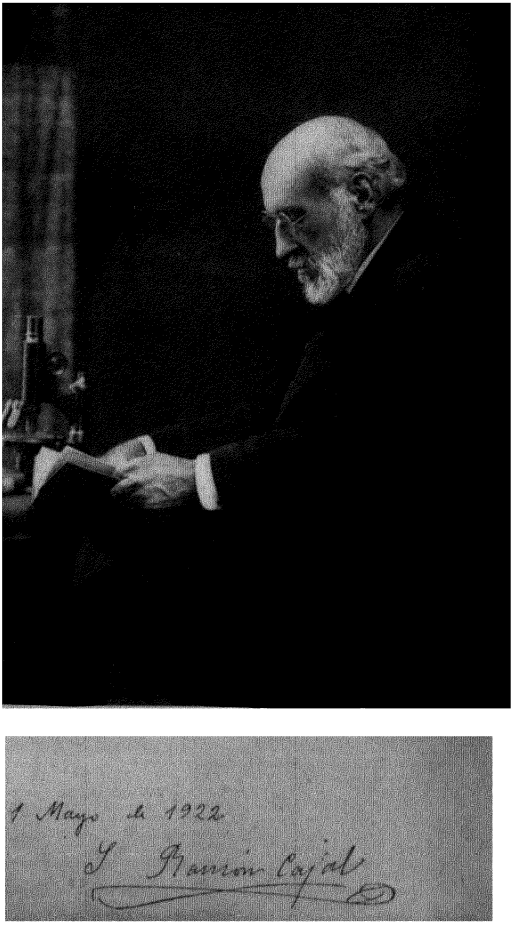

FIG. 131.—**Santiago Ramón y Cajal** (1852–1934) at the age of seventy. One of the most brilliant investigators of the structure of nervous system and sensory organs, in particular of the retina, and an ingenious interpreter of their functions. From *Libro en honor de D. S. Ramón y Cajal*, Madrid, 1922, v. 1, Frontispiece. Courtesy Instituto Cajal, Madrid. (*See also* Figs. 52, 317.)

bipolars, except, perhaps, by a raised threshold of responsiveness in the remaining bipolar varieties (*e–f, h*).

Finally, a restriction of the mop bipolar to the influences of either the rods or the cones, on grounds of synaptical relationship, appears possible only in situations where either the one or the other category of photoreceptors ceases to be responsive to the stimulus of physical light.

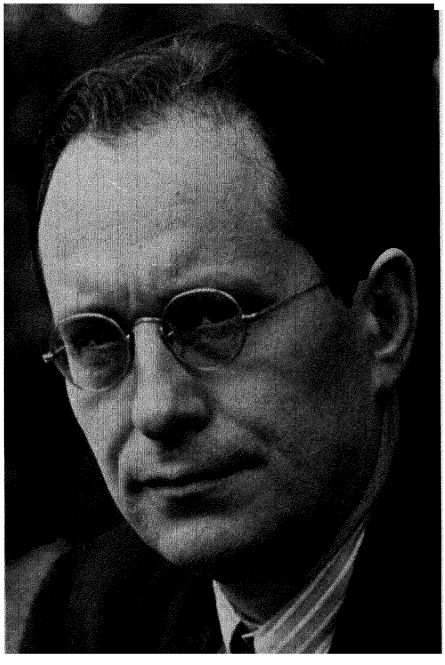

FIG. 131*A*.—Stephen Polyak (1889–1955), author of the present book, at the time of completion of the manuscript of *The Retina*. A snapshot taken during the summer of 1939 by Professor Friedrich Wassermann, of the University of Chicago.

This could possibly take place in a system maximally adjusted either for scotopic or photopic vision.

4. SYNAPSES OF THE MOP BIPOLAR WITH GANGLION CELLS.—The "vitreal process," "axis cylinder," or "axon" of the mop bipolar, usually much thinner and provided with spindle-shaped varicosities characteristic of nerve fibers elsewhere, descends to the lowermost part of the inner plexiform layer (*7-e*). Here it divides into two or three short, thick, swollen branches terminating with crude, irregularly spherical varicosities. The nodular varicosities of this simple teledendron adhere directly to the surface of the bodies of the ganglion cells of the eighth layer adjoining the seventh layer. This is the axosomatic type of synapse.

There are usually also one or two short twigs branching off from the axon higher up, in the third or fourth zone of the seventh layer, whose terminal swellings touch one or another of the thick main ascending dendrites of the ganglion cells. This is the axodendritic synapse.

Since the teledendric axonal arborizations of the mop bipolars do not penetrate into the deeper parts of the ganglion layer, it is probable that the synapses of the ganglion cells whose bodies are buried deeper in the thick ganglion layer found in the central area are accomplished through the above-mentioned short collateral twigs of the mop bipolars somewhere in the vitreal half of the inner plexiform layer.

The number of ganglion cells related to a single mop bipolar is two, three, or at most four. There is apparently no selection of ganglion cell varieties to which the mop bipolars are related, while, on the other hand, the ganglion cells related to the mop bipolars are simultaneously also related to other bipolar varieties. A ganglion cell may be related to two or more of the adjoining mop bipolars, as well as to other bipolar varieties. The functional interpretation of these anatomical arrangements indicates a diffusion of influences, passing through the mop bipolars upon all ganglion cell varieties, and a relatively small localizing value.

5. DISTRIBUTION AND HISTORY OF MOP BIPOLAR.—The mop variety of bipolars, in Primates, is present in great numbers in all regions of the retina. It is present in the central area and fovea to the limit of the rodless area, that is, to the edge of the foveal floor. Only in the rodless area of the central fovea, corresponding to the minute centralmost territory, where the photoreceptor layer is represented exclusively by the cones, has the presence of the mop bipolar not been ascertained.

The mop bipolar may have been seen by Tartuferi (1887) and by other investigators and was named "rod bipolar" by S. Ramón y Cajal (1892–93, 1909–11).

6. Brush and flat-top bipolars (*e, f, g*).—The bipolar cells of these two or three varieties usually also have a single main "dendritic expansion," which may be either slender or fairly stout, ascending to the fifth layer, and a thin "axonal process," descending to the seventh layer.

When the body adjoins the fifth layer, several thin dendritic branches arise directly from it. The dendritic ramifications of one type resemble a brush with the tips of its thin, bristle-like filaments cut off straight (*e*, right lower corner in Fig. 134). The other type has undulating branches which sweep laterally (*f*, upper center, in same figure). In both they differ from the branches of mop bipolars, in that they are strictly confined to the inner zone of the outer plexiform layer, *5-c*. Except for an occasional larger or smaller varicosity, frequently found in flat-top bipolars, all dendritic branches in both varieties just reach the division line separating zone *5-b* from zone *5-c*. The strict adherence to this boundary is remarkable because of the minute dimensions of the structures involved.

Careful study reveals that the filamentous dendrites, in both brush and flat-top bipolars, just touch the vitreal faces of the cone pedicles (that largely determine the boundary line between *5-b* and *5-c*) and the lowermost of the rod spherules (Fig. 140). The lateral faces of the cone pedicles and those rod spherules situated farther up in the intermediate zone, *5-b*, which are in contact with the dendritic filaments of mop bipolars, remain out of reach of brush and flat-top bipolars.

7. Synapses of brush and flat-top bipolars with photoreceptors.—The peculiar synaptical relationships of brush and flat-top bipolars with the photoreceptors, different from those found in mop bipolars, are undoubtedly an indication of their specific function.

The feature common to all three "diffuse" bipolar varieties so far considered (*d, e, f*, and the freakish form *g*) is their relationship to both the cones and the rods, even though many, perhaps the majority, of the rods are in no contact with brush and flat-top varieties.

Another resemblance is the overlapping of their adjoining dendritic tops both by those of the same variety (thus *d* by *d*, *e* by *e*, *f* by *f*), and by those of other varieties (*d* by *e* and *f*, *e* by *d* and *f*, *f* by *d* and *e*). A minute group of photoreceptors, both rods (*a*) and cones (*b*), related to a single brush bipolar, accordingly, also influences the adjoining brush bipolars, even though to a lesser degree. The same group of rods and cones simultaneously influences the adjoining flat-top bipolars (*f*), as it also does the mop bipolars (*d*), and the midget bipolars (*h*); the cones also influence the horizontal cells (*c*). From the synaptical contacts it appears that the emphasis in brush and flat-top bipolars is less upon influences arising in the rods than is the case in mop bipolars.

Finally, the fact that a part of the synaptical surface of the cone pedicle, its lateral sides, is used by the mop variety (*d*), while the other part, the vitreal face of the same pedicle, is in contact with the brush, flat-top, and midget varieties (*e, f, h*), as illustrated in detail in Figure 140, indicates a separation or sorting of influences originating from the common source—the cones—and their direction into several channels, each serving as a passage for a specific influence.

In other words, the peculiar and specific synaptical arrangements of each diffuse bipolar variety with the rods and cones are indicative of their specific responsiveness to influences arising from a common source, the photoreceptors.

8. Synapses of brush and flat-top bipolars with ganglion cells. The terminal axonal ramifications and synapses of brush and flat-top bipolars in the inner plexiform layer (*7*) differ even more from those of mop bipolars than do their dendritic synapses in the outer plexiform layer (*5*). They are, in general, more delicate, consisting of a small clump of thin, short twigs, swollen in places into varicosities and with minute buttons at the ends, occasionally all twisted into a fine meshwork.

They are, furthermore, conspicuous because of the locality in which they are found. Whereas the teledendrons of mop bipolars (*d*) are always located in the lowermost zones of the seventh

layer (zones 7-*d* and 7-*e*), those of brush (*e*) and flat-top bipolars (*f*) spread exclusively in approximately the scleral half of the same layer (zones 7-*a*, 7-*b*, and 7-*c*).

The synapses they undergo with the ganglion cells likewise differ. In brush and flat-top bipolars the contact is either with the twigs or with the main trunk of the dendritic processes, and never with the bodies of the ganglion cells (axodendritic synapses), whereas the principal contact of mop bipolars is with the ganglion cell bodies.

In one respect, all diffuse bipolar varieties are alike: there is apparently no selection of the ganglion varieties to which they are synaptically related, all ganglions (*m*, *n*, *o*, *p*, *r*, *s*) being

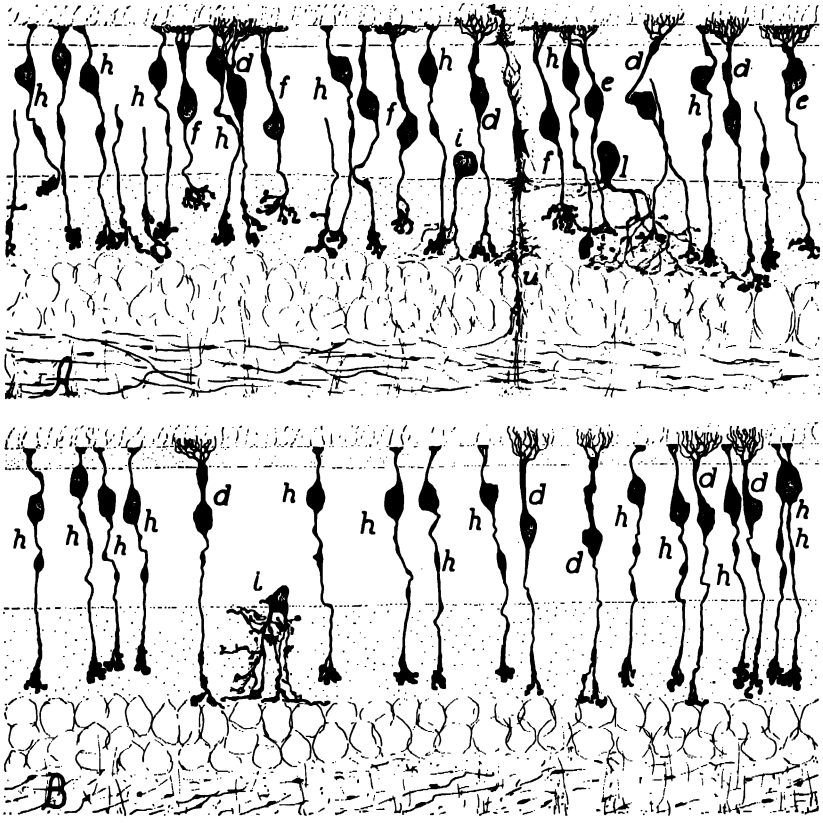

FIG. 132.—Bipolar cells of different varieties of the retina of a Rhesus Macaque stained with the Golgi method. Selection from the periphery of a single section, from central area not far from the papilla of the optic nerve. Individual bipolars or groups of bipolars drawn as found in the preparation, either singly or in groups, to show synaptic relationships with lower ends of photoreceptors (given in outlines in the upper tier of each sketch) and with ganglion cells (their bodies outlined in the lower tier). *Labeling: d*, mop bipolars; *e*, brush bipolars; *f*, flat-top bipolars, which all represent diffuse or common rod and cone bipolars; *h*, midget bipolars, which are the individualized cone bipolars; *i*, *l*, so-called amacrine cells; *u*, radial fiber of Müller belonging to supporting structures of the retina. Note the individual contact of *h* bipolars with cone pedicles and the absence of overlapping with other *h* bipolars; presence of overlapping in diffuse *d*, *e*, and *f* bipolars among themselves and with *h* bipolars. Only a small number of the cells were stained in this preparation, making it possible to study various details. (*Cf.* Figs. 143, 144.)

related to both brush and flat-top bipolars, as they are to mop bipolars. These relationships are multiple, less restricted in space, several bipolars of diffuse varieties being related to each ganglion cell, especially of the larger varieties (*m*, *n*, *p*), few in the central area, and many in the extra-areal periphery.

In still another way a multiple synaptical relation is assured, since several ganglions, especially of the midget variety (*s*) in the central area, are related to each brush or flat-top bipolar. Moreover, each brush and flat-top bipolar may be related to several ganglion cells of different varieties.

Finally, neither the territories of brush and flat-top bipolars nor those of their related ganglion cells are completely separated from one another but overlap, and more so in the extra-areal periphery than in the central area of the retina.

9. DISTRIBUTION AND HISTORY OF BRUSH AND FLAT-TOP BIPOLARS. Both brush and flat-top bipolars are present in great numbers in the entire retina, including the central fovea. They have been found alone in the centralmost area of the fovea, where the rods are missing. Whether or not this is an accident of the Golgi stain used in this work, future investigation alone can determine.

Whether brush and flat-top bipolars are one or two distinct varieties also remains uncertain. The similarity of their synaptical contacts, in spite of their somewhat different appearance, suggests that both may be but slight variations of the same type. This seems to be even more true of the *g*-variety, which is probably a freak. A more detailed investigation in various vertebrate species may solve this problem.

Brush and flat-top bipolars were first seen by Tartuferi (1887), who called them *cellula a pennachio*, and were described by S. Ramón y Cajal (1892–93, 1909–11) as "cone bipolars."

10. MIDGET BIPOLAR (*h*).—This variety, because of its appearance and its synaptical connections, is the most conspicuous bipolar neuron of the human and simian retina (Figs. 132, 133, 134, 140, 146, 147, and colored schemes in 177, 178, 179). Its small body is usually in one or both of the scleral zones of the inner nuclear layer (*6-a* and *6-b*).

The "dendritic expansion" in most cases is a short, thin fiber passing straight into the outer plexiform layer. The division into a ramification ordinarily takes place quite close to the boundary line separating zone *5-b* from *5-c*. This terminal dendritic ramification is quite peculiar and is found almost nowhere else in the nervous system. It consists of a dozen or so thin and very short branchlets, all of about the same length and all remaining close together (*see* lower sketches in Fig. 133, and right-hand sketches in Fig. 134, and especially Fig. 140). Each minute twig carries at its end a tiny spherical or globular swelling, all the globules about the same size and arranged in approximately the same plane.

The terminal dendritic "bouquet" or "rosette" resembles a minute basket, cup, or tray, whose shallow floor is formed of closely packed terminal globules. Seen in profile and at low magnification, the entire structure appears as a single, solid, cup-shaped, or funnel-like expansion (thus some in Fig. 132) and has been described as a minute "plaque" in the fovea of Birds (S. Ramón y Cajal 1892–93, 1909–11) and as a "meniscus" in the simian retina (Fortin 1925). However, the employment of appropriate oil-immersion lenses of high magnification (Leitz's Ultropak and other objectives that have a long working distance) reveals its composite structure.

11. SYNAPSES OF MIDGET BIPOLAR WITH PHOTORECEPTORS. An attentive study of the relationships of the dendritic bouquets of midget bipolars shows them all strung along a line just beneath the intermediate zone of the outer plexiform layer, *5-b* (Figs. 128, 129, 161).

The bouquets are separated from one another by intervals. These intervals vary in length, depending on the region. In the central area, especially in the fovea, the midget bipolar bouquets are short and very closely spaced, the separating intervals between them measuring not more than about one-third the length of a single bouquet. Farther away, the spread or size of the bouquets, as well as the separating intervals, rapidly increases until in the extra-

areal periphery the intervals are several times the length of a single bouquet.

The most centrally located midget bipolars have the smallest bouquets. They are in the fovea, where they are found as far as the margin of the foveal floor or foveola; that is, as far as cone pedicles are present in zone *5-b* (*cf.* middle sketch in Fig. 161). In routinely stained preparations the dendritic bouquets of midget bipolars appear at low magnification as a broken line of short and somewhat more intensively stained segments (Fig. 127). On closer scrutiny, each of these segments is revealed to be made up of a number of minute granules (they have, therefore, been named "granular clods" by Dogiel 1884). Their spacing corresponds exactly to that of the cone pedicles in zone *5-b*. In hematoxylin and eosin- or phloxin-stained preparations the pedicles appear pale and, because of this, have been erroneously interpreted by Balbuena as "vacuoles." It is not difficult to notice, in fact, that to each cone pedicle there

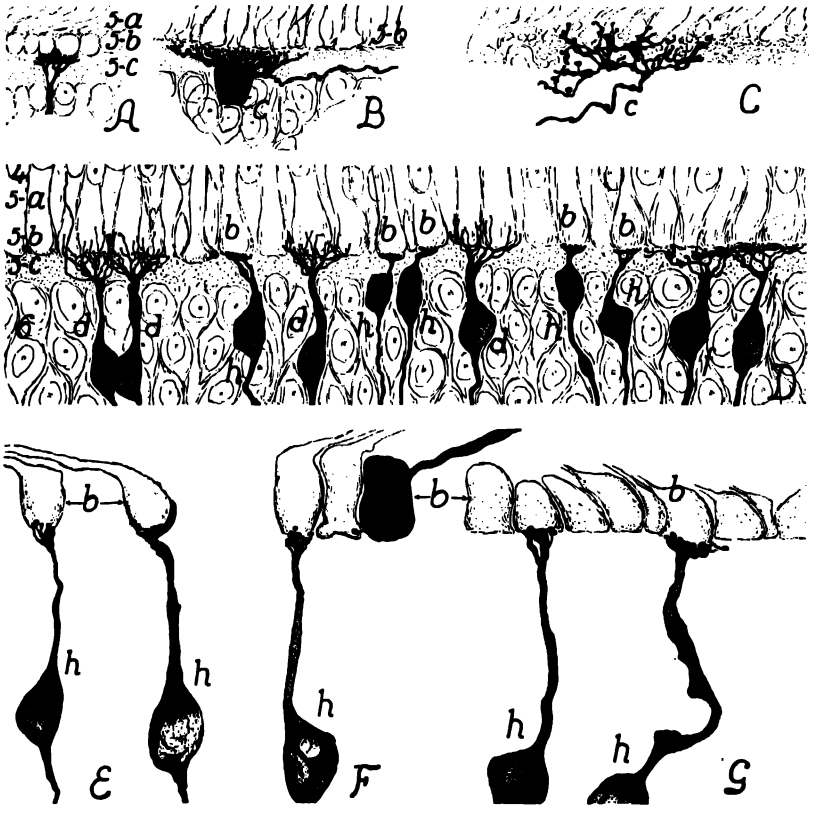

FIG. 133.--Details of bipolar and horizontal cells of the retina of a Rhesus Macaque at various magnifications. Golgi method. *Labeling: c*, horizontal cell (body in sketch *B*, terminal ramification or teledendron in sketch *C*); *d*, mop bipolars, first from the left in middle sketch with Landolt's fiber extending as far as the outer nuclear layer *4*; *f*, flat-top bipolars; *h*, midget or individualized cone bipolars. Note overlapping of dendrites in *d* and *f* bipolars, the first spreading into zone *5-b*, the latter remaining in zone *5-c* of the outer plexiform layer; strict individual synapses of each midget bipolar with a single cone pedicle (*b*), except in sketch *A* (polysynaptic midget bipolar). (*Cf.* Figs. 146, 147, and color Figs. 177–79.)

is attached one "granular clod" from the vitreal side, that is, a dendritic bouquet of one midget bipolar.

In preparations stained with the histoanalytical method of Golgi it has been found that in the central area and particularly in the fovea of Man, Monkey, and Ape, one bouquet of a midget bipolar clings to the underside of each cone pedicle (*b*). The diameter of the bouquet is usually somewhat smaller than the diameter of the pedicle to which it clings (Fig. 133, *E*, *F*, *G;* Fig. 134, *C*, *F*, *G;* Fig. 140, upper two rows). In the retina of the Chimpanzee and less frequently in that of Man and the Rhesus Macaque, midget bipolars are found outside the central area which are the same as those in

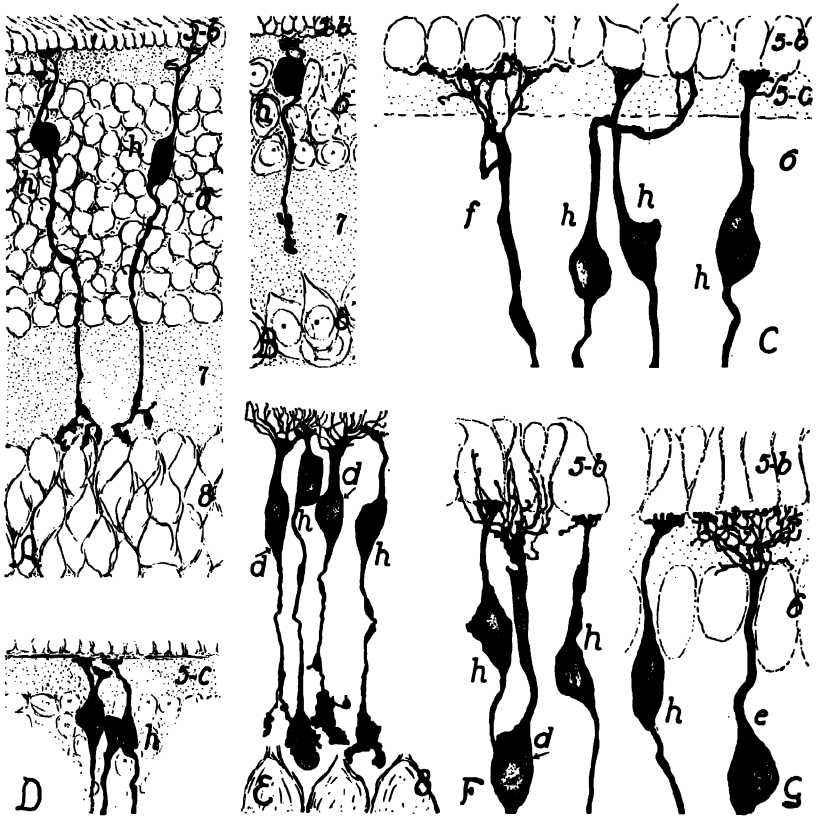

FIG. 134.—Synapses of different varieties of bipolar cells of the retina of a Rhesus Macaque stained with the method of Golgi. *d*, mop bipolars; *e*, brush bipolar; *f*, flat-top bipolar; *h*, midget or individualized cone bipolars. Left-hand sketches drawn at moderate magnification, right-hand sketches at high magnification. In sketches *C*, *F*, and *G* note multiple synapses of *d*, *e*, and *f* bipolars, each related in its own way to the lower ends of photoreceptors, the rods and cones (in zone *5-b*), and strictly individualized synapses of *h* bipolars with the cones alone. Note also structural composition, location, spread, and attachment of upper parts of bipolars, especially of midget "bouquets," to a particular locality of the lower ends of photoreceptors, the mop of *d* bipolar clinging to the sides of both the rods (smaller outlines) and cones (larger contours), *e* and *f* bipolars touching the lower faces of rods and cones, while *h* bouquets touch only the lower faces of individual cone pedicles. Sketch *A* shows two polysynaptic midget bipolars. (*Cf.* Figs. 146, 147, 177, 178, 179.)

the central area in all details, except that each has two or three bouquets related to as many adjoining cones (*h-h*). In Figure 139 all these polysynaptic midget bipolars are labeled with a single *h*. (*See also* such a bipolar in the lower right-hand corner, in Fig. 144, and a much more magnified detail labeled *VI* in Fig. 140.)

The Golgi-stained preparations also show that midget bipolar bouquets have no contact with rod spherules or structures belonging to any other neuron variety. (*Cf.* Fig. 133; *see also* detail at the right-hand end of first row in Fig. 140, and colored schemes in 177, 178, 179.)

12. FUNCTIONAL SIGNIFICANCE OF SYNAPSES OF MIDGET BIPOLAR WITH PHOTORECEPTORS.—The peculiar anatomical relationship of the dendritic bouquets of midget bipolars to the cone pedicles, especially in the central area and fovea, described in the foregoing subsection, indicates the presence of an individual or "private" synapse (*b & h*). In other words, midget bipolars are monosynaptic, individual, or "private bipolars." Furthermore, since they are related only to the cones, they must be considered as the true "cone bipolars."

Because of the arrangement described above, each cone in the central area and fovea is capable of influencing a single midget bipolar, without influencing directly either the immediately adjoining or the more distant midget bipolars.

Those midget bipolars of the extra-areal periphery that have several dendritic bouquets each and are related to as many cones are an exception. They, too, are exclusively cone bipolars, although, being related to several cones, they may be termed "polysynaptic cone bipolars" (*h-h*).

The cone influences in the central area and fovea, in so far as they are concerned with the midget bipolars, are all individualized. Since, however, each cone is synaptically related also to mop (*d*), brush (*e*), and flat-top bipolars (*f*), it is capable of influencing these too, simultaneously or successively, although in a less restricted way spatially or dimensionally. There is still a third channel by means of which a given cone may be able to exert an influence: the horizontal association cells (*c*). (*Cf.* sec. 6, and Figs. 146, 147, this chapter, and colored schemes 177, 178, 179.)

13. INDIVIDUAL SYNAPSES OF MIDGET BIPOLAR WITH GANGLION CELLS.—The synaptical relationships of midget bipolars with ganglion cells are no less remarkable (*see* above-mentioned figures). A thin "vitreal fiber" or "axis cylinder," often provided with a fairly large varicosity, one to each bipolar, descends to the inner plexiform layer, where it terminates with a few lumpy swellings of compact appearance (Fig. 132). These teledendrons are arranged in two tiers, one in the upper, the other in the lower, half of the inner plexiform layer, approximately corresponding with zones *7-b* and *7-d*. They remain, however, at a distance both from the inner nuclear layer and from the layer of ganglion cells. They do not come into contact with the bodies either of the amacrines or of the ganglion cells, their synapses being exclusively with the dendritic processes in the plain substance of the inner plexiform layer.

The mode of their synapsing depends upon the cell variety. With the small or midget ganglions (*s*) their synapses are strictly individual. Each minute, lumpy midget bipolar teledendron is enveloped by the delicate twigs of a dendritic basket of a single midget ganglion cell. In this way a peculiar "axosomatic synapse" of the type called "cog or joggle synapse" by S. Ramón y Cajal, or "hand-clasp synapse" by Herrick is formed. In exceptional cases a midget ganglion is found that has two dendritic baskets related to two midget bipolars (*s-s* in Fig. 143), a counterpart to the bi- or polysynaptic midget bipolars of the extra-areal periphery.

In the great majority of cases, however, the *h* and *s* synapses are strictly individual or "private," especially in the central area and fovea. In this way a chain of three conducting neurons is formed in the retina: cone (*b*) and midget bipolar (*h*) and midget ganglion cell (*s*). Through this chain, in and around the visual axis of the eye, an individual stimulus may be conveyed from each cone along its own private optic nerve fiber to the brain (*cf.* middle sketch in color Fig. 177).

14. MULTIPLE SYNAPSES OF MIDGET BIPOLAR WITH GANGLIONS AND OTHER RETINAL NERVE

CELLS.—In addition to individual synapses with midget ganglion cells (*s*), midget bipolars (*h*) are also related to other ganglion cell varieties designated as "diffuse ganglions" (Figs. 146, 147). These synaptical relationships, however, are different. Each of the ganglion varieties, such as parasol (*m*), shrub (*n*), small diffuse ganglion (*o*), and garland ganglion (*p*), all of which possess more or less widespread dendritic ramifications in the inner plexiform layer, also undergoes a synaptical association with the midget bipolars (*h*). These relationships are not individual or "private" but multiple or polysynaptic, since each of these ganglion cells is related to a larger or smaller number of midget bipolars (as well as to a number of mop, brush, and flat-top bipolars).

By means of this arrangement, in addition to those impulses that arrive via the "diffuse varieties of bipolars" (*d, e-f*), less individualized, diffuse, or global, and apparently summated cone impulses are transmitted from larger areas of the photoreceptor layer through the midget bipolars and conveyed to the brain.

Finally, the centrifugal bipolars (*i*) and the so-called amacrine cells (*k, l*) are also synaptically related to the midget bipolars and may in this way be influenced by the cones.

15. HISTORICAL NOTE ON THE DISCOVERY OF MIDGET BIPOLARS.—The midget variety of bipolar had been seen a number of times, although usually only in part, and had, therefore, been neither accurately described nor correctly interpreted. Certain structures observed by Merkel (1869, 1876, 1877), Gunn (1877), Tafani (1883), Dogiel (1884), Borysiekiewicz (1887, 1894), Kuhnt (1890), S. Ramón y Cajal (1892–93, 1909–11), Schaper (1893), Held (1905), Fortin (1925), Balbuena (1929, 1930), and Kolmer (1930, 1936) evidently were dendritic bouquets or rosettes of midget bipolars. Their true nature and relationships, and hence their functional significance, had heretofore remained unknown. (*See also* Polyak 1934, 1935, 1936, 1941, 1948.)

SEC. 5. GANGLION CELLS OF THE RETINA

1. GENERAL REMARKS ON THE CLASSIFICATION OF RETINAL GANGLION CELLS.—The ganglion cells of the retina represent the third link in the chain of retinal neurons which carries impulses to the brain (Figs. 135–39, 146, 147, and colored Figs. 177, 178, 179).

In the simian and human retina there are at least five distinct varieties of ganglion cells, differing greatly from one another in body size and even more in the locality and manner in which their expansions are spread and in their synaptical connections. These varieties may be subdivided into two groups, depending on whether their expansions overlap and are in contact with numerous bipolars of all varieties, or whether overlapping is absent and they are related to a few bipolars only or even to a single midget bipolar. The first group is represented by diffuse, polysynaptical ganglion cells (*m, n, o, p,* and possibly *r*); the other group contains the single individual, oligosynaptic or monosynaptic ganglion variety (*s*).

There are certain features common to all ganglion varieties. Most have a body in the ganglion cell layer (*8*, in Figs. 127–29). In a few the body is displaced into the inner zone of the inner nuclear layer (*6-d*), these are the so-called "Dogiel's cells" (one such cell is found in each of Figs. 136 and 139). In any case, the dendritic expansions of the ganglion cells spread in the inner plexiform layer. Those with a body in the eighth layer, the majority, spread in the direction of the sclera; the few with bodies in the inner nuclear layer spread their dendrites in

that layer in an inverted fashion, in the direction of the vitreous, hence superficially they resemble the "amacrine cells" (*k*, *l* in Figs. 142, 143).

There is one axis cylinder or axon in each ganglion cell. It is thick in the large cells, and delicate in the small. All axons, or optic nerve fibers, pass into the layer of optic nerve fibers (*9*), whence they reach the optic papilla (Fig. 138).

After they leave the eyeball, these axons are assembled into a trunk, the optic nerve, and continue to the brain as the optic tract (chap. VI, 3). Apparently, there are no side branches

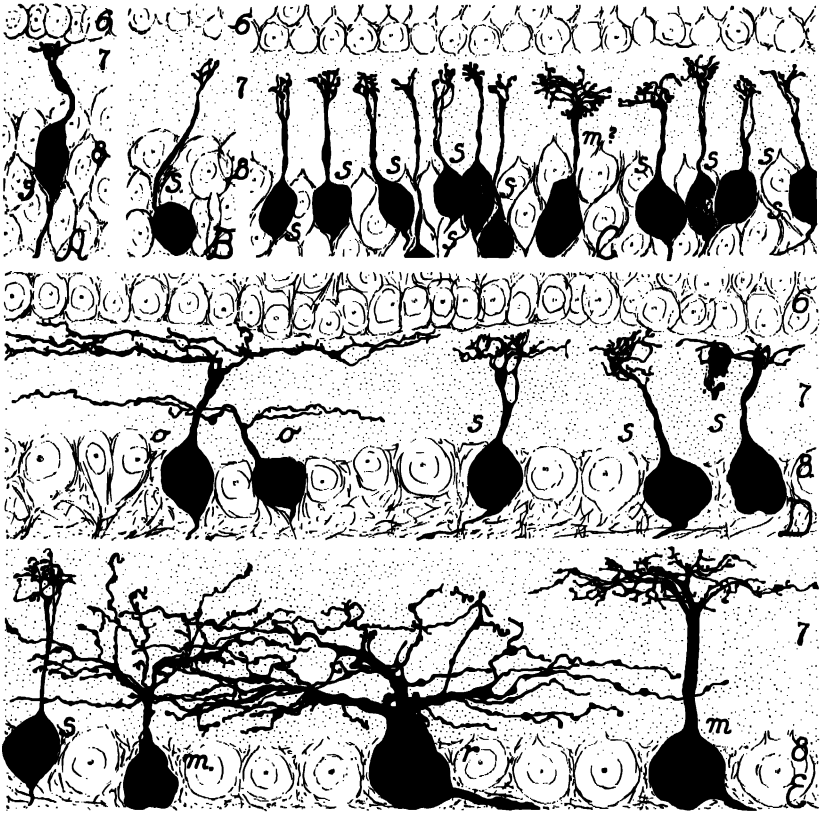

FIG. 135.—Types of ganglion cells of the retina of a Rhesus Macaque stained with the Golgi method: *m*, parasol variety; *o*, small variety with horizontally placed dendrites; *r*, giant ganglion; *s*, midget ganglions. Sketches *A*, *B*, and *C* from central fovea or just outside it; *D* and *E* from region outside the central area. Dimensions of ganglions in and close to visual axis are much smaller than away from it, a reverse from the number which is the greatest around the axis. However, all varieties of ganglions appear to be present everywhere. Note the restricted size of dendritic treetops in midget ganglions of the fovea (*upper sketches*) compared with more robust appearance of the same in the extra-areal regions (*middle and lower sketches*). Owing to its small size and few synaptical contacts, each ganglion cell in the fovea and close to it makes connections with only a few bipolars as compared with the extrafoveal periphery; also, its photoreceptor area is much smaller here, the visual resolution therefore much greater in the axis of the field of view. This is further enhanced by the individual synapses that each foveal and areal midget ganglion undergoes with a midget bipolar, which, in turn, is related to only one cone cell. (*Cf.* Figs. 146, 147, 177, 178, 179.)

or collaterals in the axis cylinders during their course in the retina. Nor do the optic nerve fibers in Man, Ape, Monkey, and other higher Mammals normally possess myelin sheaths within the eyeball; but as soon as they penetrate the cribriform lamina of the sclera and form the optic nerve, they become sheathed. (*See* chap. VI, 2, on the origin and course of optic nerve fibers in the human and simian retina.)

2. UMBRELLA OR PARASOL GANGLION (*m*).—These medium- to large-sized cells (Figs. 135-39) have an approximately spherical body from which one or several stout, trunklike main dendrites stretch into the inner plexiform layer. Here, by dividing repeatedly, an arborization resembling an umbrella or parasol is formed. This arborization is conspicuous because of its density and flatness, being limited to one or two zones, usually *7-b* or *7-d*. The horizontal extent or spread of the dendritic treetop is small in the central area (Fig. 138) and gradually increases to giant proportions in the extra-areal periphery (Figs. 136 and 139).

The synapses of the terminal dendritic twigs occur with the numerous brush (*e*), flat-top (*f*), and midget bipolars (*h*); those of the body with a few mop bipolars (*d*). The synaptical relationships indicate a summating function little restricted in space.

3. SHRUB GANGLION (*n*). This ganglion (Figs. 137, 138) has a body of relatively small size and a loose dendritic ramification, made up of a few thin, twisted branches terminating with contorted, hook-shaped twigs carrying tiny swellings at the ends. In a given segment, the dendritic ramification spreads over the entire thickness of the inner plexiform layer. The terminal dendritic branchlets form a number of ill-defined baskets, into which clumpy axonal teledendrons of a group of midget bipolars (*h*) are fitted. The teledendrons of the brush (*e*) and flat-top bipolars (*f*) are also enmeshed in the dendritic twigs of the shrub ganglion, while those of the mop bipolars (*d*) are in contact with its body. The synaptical relationships indicate a summating role of a special kind and are somewhat more restricted in space than in the parasol variety.

4. SMALL DIFFUSE GANGLION (*o*).—This variety (Figs. 135, 136, 138) is conspicuous because of the diminutive size of the cell body, probably the smallest of all retinal ganglion varieties. The few long, but delicate, filamentous dendritic branches spread horizontally or somewhat obliquely in the sixth layer. The synapses are with a small number of bipolars of all varieties.

5. GARLAND GANGLION (*p*).—This ganglion variety (Figs. 136, 137, 139) has a body of medium size, from which a few main dendrites arise. These divide into a small number of rather thin, but very long, secondary and further branches, the longest of all ganglion varieties, spreading in wavy lines for great distances in the seventh layer. The terminal dendritic twigs, which hang from the longer branches like moss and have minute swellings at the ends, make the entire arborization resemble festoons and garlands.

The bipolar cells whose axonal teledendrons lie enmeshed between the dendritic twigs of the garland ganglion belong to the brush (*e*), flat-top (*f*), and midget varieties (*h*), while the mop bipolars (*d*) are in contact with the body of the garland ganglion.

Considering the great number of bipolar cells related to each single garland ganglion cell, especially in the extra-areal periphery, it is plausible to assume that the function of this variety is a summation of the rod and cone excitations from relatively large areas of the photoreceptor layer.

6. GIANT GANGLION (*r*).—These unusually large ganglion cells (Fig. 135) are found in a more distant part of the extra-areal periphery (*cf.* Fig. 129, sketches *V*, *VI*). They resemble either parasol or garland cells, except that they are larger. They may be merely large varieties of one or another of the afore-mentioned varieties.

7. MIDGET GANGLION (*s*).—The midget ganglion cells of the human and simian retina are conspicuous because of their small, uniform size, extremely reduced dendritic ramifications, mode of synapsing, and numerousness (Figs. 135–39). In fact, the majority of cells in the central area and fovea are midget ganglions.

Their spherical, oval, or pyriform bodies may be found anywhere in the thick eighth layer. A single, thin main "dendritic shaft," either short or long, depending on the position of the body, usually arises from it. If long, the shaft has one or more spindle-shaped swellings that make it resemble a short axis cylinder (thus in Fig. 138).

All dendritic shafts are oriented vertically, more or less, and stretch into the inner plexiform layer. Here each divides into a few secondary and tertiary branchlets, altogether forming a minute dendritic basket whose diameter is usually less than the diameter of its own cell body. These baskets are turned in the direction of the sclera, except in the few midget ganglions with bodies displaced into the inner nuclear

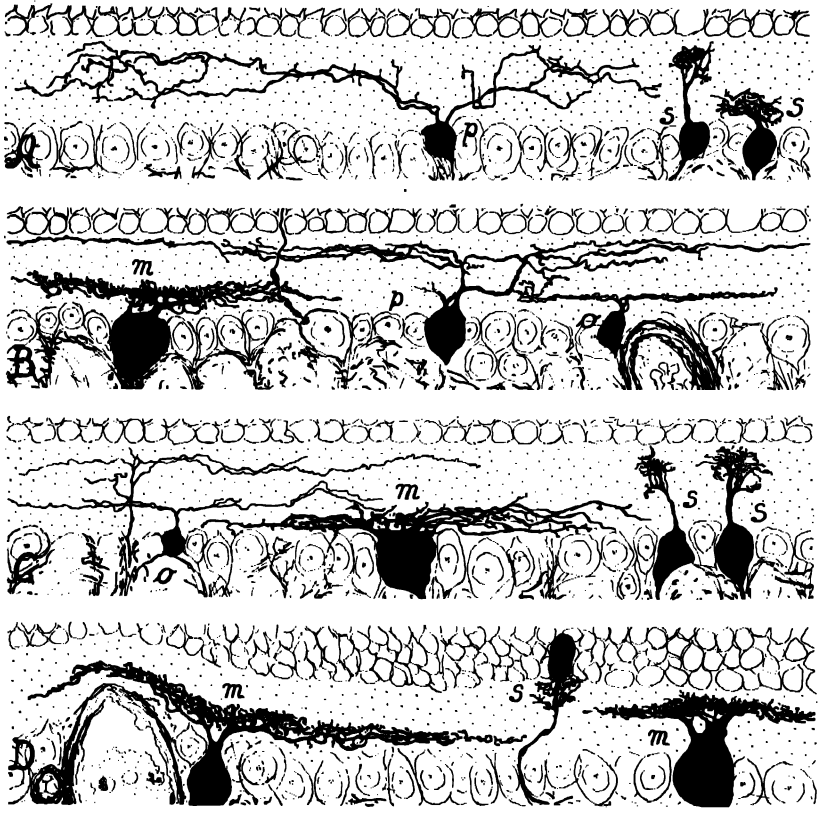

FIG. 136.—Types of ganglion cells of the retina of a Chimpanzee stained with the Golgi method. Extrafoveal and extra-areal periphery. *Labeling: m*, parasol variety; *o*, small ganglions with horizontal dendrites; *p*, garland ganglions; *s*, midget ganglions. Note long meandering dendrites of *p* variety, compared with diminutive dendritic treetops of *s* variety, whereas the size of their bodies remains the same; large bodies and compact dendritic treetops, restricted to a narrow zone of the inner plexiform layer, characterize the *m* variety. In lowermost sketch the body of a midget ganglion is displaced in the inner nuclear layer, its dendrites spreading in the usual manner in the inner plexiform layer, where they undergo synaptical contacts with the bipolars. Since larger varieties have a wide dendritic spread, permitting synaptical contacts with numerous bipolars, in turn gathering impulses from an extensive area of photoreceptor layer, such varieties may be considered as "collectors" or "summators" of impulses. By the same token, midget ganglions are "specialized conductors" of territorially restricted impulses. (*Cf.* Figs. 146, 147, 177, 178, 179.)

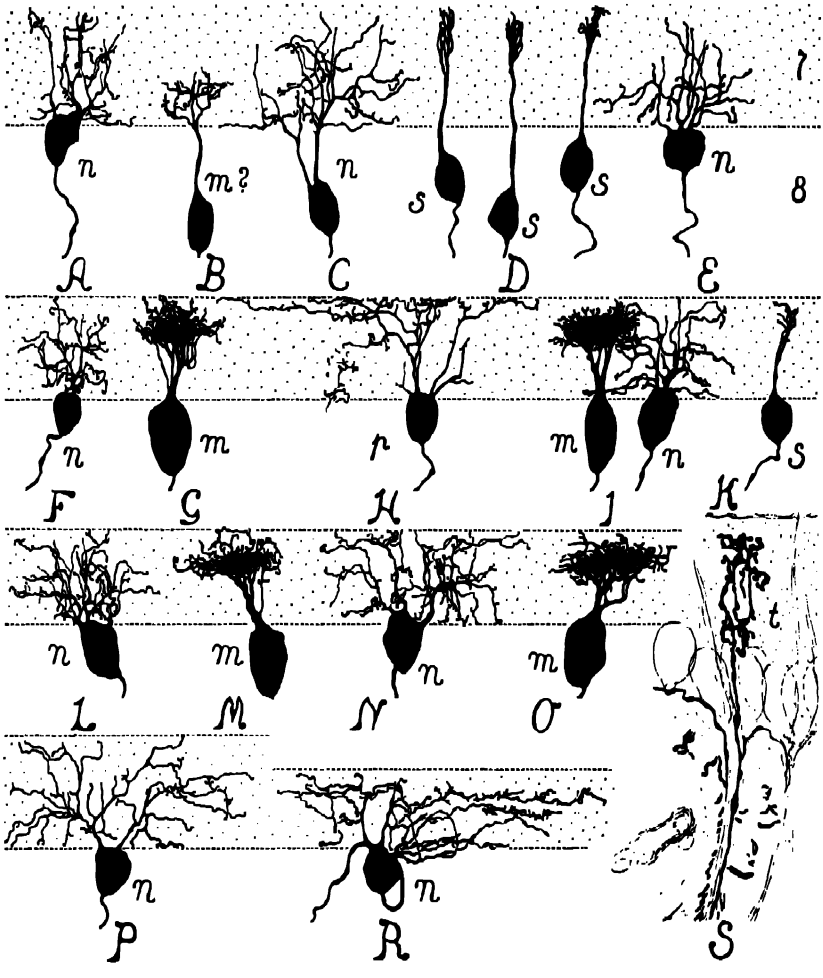

FIG. 137.—Types of retinal ganglion cells of Chimpanzee mostly from central area, stained with the Golgi method. *Labeling: m*, parasol variety; *n*, shrub ganglion; *p*, garland ganglion; *s*, midget ganglions; *t*, termination of a nerve fiber in inner plexiform layer, probably of extraretinal origin. Note the wide spread and loose appearance of the dendritic branching in the *n* variety extending over the whole thickness of the seventh layer, contrasting with the minute treetops in the *s* variety, which, in addition, are restricted to a narrow zone of the same layer, even though the size of the body differs but little in both varieties. In the *m* variety, again, the dendritic treetops are also relatively restricted but are much richer and more compact, whereas the bodies are much larger than in either *n*, *p*, or *s* ganglions. These morphological differences, interpreted functionally, may indicate the collecting of fewer bipolar impulses from a wider photoreceptor territory by the *n* variety than by the *m* variety, which collects a denser stream of impulses from a smaller territory. In the *s* ganglions, again, both the density and the territorial extent of impulses are further reduced. Other qualities of impulses to which each ganglion variety responds undoubtedly also vary, contributing to the complex structural mechanism of the retina. (*Cf.* Figs. 140, 147, 177, 178, 179.)

layer whose dendrite is inverted, and oriented upside down (one such *s* ganglion is to be found in the lowermost sketch in Fig. 136).

Midget ganglion cells are also conspicuous because of the placement of the dendritic baskets in two tiers, approximately corresponding with zones *7-b* and *7-d* of the inner plexiform layer. These tiers are identical with those where the tiny, lumpy teledendrons of the midget bipolar cells (*h*) are placed.

8. INDIVIDUAL SYNAPSES OF MIDGET GANGLION WITH BIPOLARS.—Direct evidence shows that the tiny axonal teledendrons of the midget bipolars (*h*) are individually enmeshed in the dendritic baskets of the midget ganglion cells (Figs. 146, 147, and colored schemes in 177, 178, 179). In this way two series of exquisitely individual or "private" axosomatic synapses are formed (*h & s*), one in the upper, the other in the lower, story of the inner plexiform layer (*7-b* and *7-d*).

On rare occasions one meets with a small ganglion cell which resembles a typical midget ganglion in all details, except that its main dendrite divides into two branches, each forming a basket, one of which is sometimes incomplete (*s-s* in Fig. 143). Such a bisynaptic midget ganglion cell is related to two midget bipolars (Fig. 177, right-hand sketch). Most of the midget ganglions in the central area and fovea, however, are strictly monosynaptic; that is, they are related to single midget bipolars (Figs. 146, 147, and colored Figs. 177, 178, 179).

In the extra-areal periphery small ganglion cells are present which resemble typical midget ganglions of the central area but are cruder and larger in every detail. They are also relatively and absolutely fewer in number, in comparison with ganglions of larger varieties found outside the central area.

9. MULTIPLE SYNAPTICAL RELATIONSHIPS OF MIDGET GANGLION CELL WITH BIPOLARS.—In addition to their relationship to midget bipolars (*h*), each midget ganglion is simultaneously related to bipolars of other varieties (*see* same figures). The synapses with mop bipolars (*d*) are axosomatic, those with brush (*e*) and flat-top bipolars (*f*) are axodendritic. Frequently, an unusually long teledendric twig of a brush or flat-top bipolar is found touching the main dendritic shaft of a midget ganglion, with its terminal varicosity just below the point where the ganglion divides into a terminal basket. However, the relationships with diffuse bipolar varieties are not monosynaptic, that is, they are not single or "private," since several midget ganglions are related to a single mop, brush, or flat-top bipolar; conversely, several diffuse bipolar cells may be related to a single midget ganglion cell.

10. FUNCTIONAL SIGNIFICANCE OF THE SYNAPTICAL RELATIONSHIPS OF MIDGET GANGLION CELL.—The complex synaptical relationships of the midget ganglion cells may, in general, indicate a variety of functions.

First, the individual synapse with midget bipolars is obviously an arrangement by means of which individualized cone impulses are transmitted to midget ganglions, along whose axons they reach the brain: monosynaptic receptor-conductor channel (*b & h & s*).

Second, the synapses with diffuse bipolars appear to be a mechanism by which that part of the cone impulse passing along the bipolars and all impulses originating in the rods in some way influence the midget ganglion cells: polysynaptic receptor-conductor channel (*a & def & s*).

How these synaptical relationships are fitted into the total and more complex mechanism of the retina is discussed in section 8 of this chapter and in chapter IX.

11. HISTORY OF INVESTIGATIONS OF THE GANGLION CELLS.—The retinal ganglion cells, that is, their bodies, were probably seen by Leeuwenhoek (1674, 1684) and by the subsequent early microscopists Fontana (1782), Arnold (1832), R. Wagner (1833), Ehrenberg (1833, 1836), Langenbeck (1836), and especially by Treviranus (1835–38), who called them *papillae* (*see* chap. I, 7 [2]). The fact that they are true nerve cells, however, was recognized only by Valentin (1837), Hannover (1840, 1843), Pacini (1845), Bowman (1846, 1849), and a few others. They have since been studied in detail by many investigators; e.g., Corti (1850, 1854), H. Müller (1851, 1856–57, 1862), Remak (1853), Bergmann (1854), Koelliker (1854), M. Schultze (1872), and Schwalbe (1874).

The retinal ganglion cells were first studied with the analytical methods of Golgi and Ehrlich by Tartuferi (1887) and by Dogiel (1891, 1892, 1893, 1895). The most complete information and classification derives from S. Ramón y Cajal (1889, 1892-93, 1894, 1896, 1899–1904, 1904, 1909 11).

In spite of these efforts, knowledge of the ganglion cell varieties, their synaptical relationships, and probable function, is still extremely limited.

The failure of students of the retina to identify the midget ganglion variety (*s*), to which most of the ganglion cells in the central area and fovea of Man and of the Simians belong and which is obviously of paramount impor-

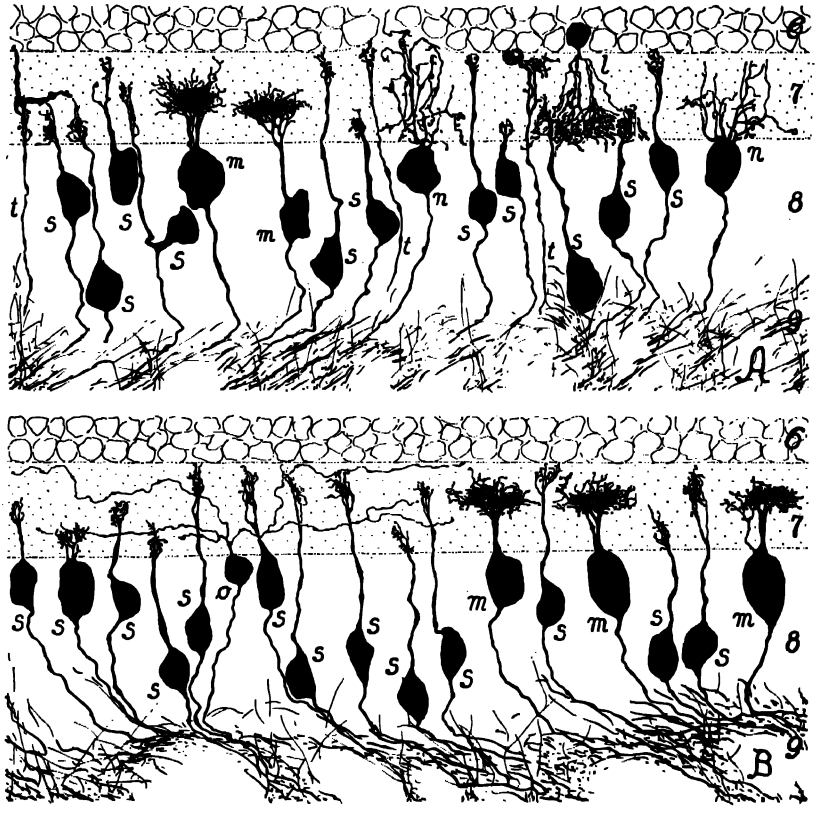

FIG. 138.—Types of nerve cells, mostly ganglions, from central area of the retina of a Chimpanzee, stained with the Golgi method. *Labeling: l*, so-called amacrine cell that in this instance does not possess an axon fiber; *m*, parasol ganglions; *n*, shrub ganglions; *o*, small ganglion with long, loose dendritic branches; *s*, midget ganglions; *t*, terminations of nerve fibers in inner plexiform layer, probably of extraretinal origin (so-called exogenous or centrifugal fibers). Note generally reduced dimensions of all varieties in comparison with the same varieties found in extra-areal periphery of retina shown in Fig. 136; characteristic compact appearance of the treetops in *m*, and the loose appearance of same in *n* and *o* varieties; the minute dimensions and delicate structure of the treetops in the *s* variety located either close to the inner nuclear layer (*6*) or close to the ganglion layer (*8*); descent of all axis cylinders, the actual "optic nerve fibers," down to the fiber layer of retina (9), where they pass over to optic disk, eventually to form the optic nerve. Functional interpretation same as in preceding figure. (*Cf.* Figs. 146, 147, 177, 178, 179.)

tance both for visual acuity and for color vision, was conspicuous.

SEC. 6. ASSOCIATION CELLS OF THE RETINA

1. General remarks. The function of the retinal neurons so far discussed the photoreceptors, bipolars, and ganglion cells described in the preceding pages—is obviously to react to physical "light" and to convey those reactions to the visual centers of the brain. There are other varieties of nerve cells in the retina whose function, speaking broadly, is to distribute photogenic impulses in the retinal tissue itself and thus in some way, either by facilitation or by inhibition or some similar influence, to modify the streams of impulses transmitted to the cerebrum. As far as is known, there are three categories of such neurons: the horizontal cells (*c*), the centrifugal bipolars (*i*), and the amacrine cells (*k*, *l*).

2. Horizontal cells (*c*).—These neurons were so named by S. Ramón y Cajal because of the horizontal spreading of their axon fibers (Figs. 141, 143, 146, 147, and colored Fig. 179). Their oval or irregularly spherical bodies, generally somewhat larger than the bipolars, are found in the one or two uppermost rows of the inner nuclear layer (*6-a* in Fig. 128). The scleral end of the cell is somewhat elongated into a short neck, from which a few short, thick, primary dendrites arise. Spreading in the inner zone of the outer plexiform layer (*5-c*), each of these dendrites divides into half-a-dozen or more minute preterminal and terminal branches which carry at the ends minute spherical varicosities (*c* in Fig. 141). These branchlets and varicosities are assembled into diminutive cups or baskets, not unlike the dendritic bouquets or rosettes of midget bipolars. In shape and size these baskets fit the vitreal faces of the cone pedicles (*b* in Fig. 141; *see also* Figs. 146, 147, and colored Fig. 179). Seen in flat view, a horizontal cell has the appearance of an octopus, with its basket-carrying dendrites spreading in all directions (*c* in Fig. 141).

The size of the cell body, the number of baskets to each cell, and the length of its dendrites vary considerably, depending upon the region. The smallest cells, which have only a few short dendrites and not more than half-a-dozen baskets, are found in the central fovea. The cells increase gradually in size, in the length of dendrites, and in the number of baskets, until in the extra-areal periphery they attain giant size and have several dozens of baskets (thus in the left upper corner, in Fig. 141).

A single axis cylinder originates from the neck of the cell body or from one of its main dendrites. It spreads in a somewhat horizontal direction through the inner zone of the outer plexiform layer (*5-c*), occasionally dipping for a short distance into the inner nuclear layer. At a distance of several hundreds of microns the axon fiber splits repeatedly into a great number of secondary, tertiary, and further branches. The terminal twigs carry minute, approximately spherical swellings at their ends (lowermost sketch in Fig. 140). These together form a fan-shaped terminal arborization or teledendron, which spreads over a territory considerably larger in size than the dendritic spread of the same cell (several such complete arborizations are presented in Fig. 141). There is apparently neither definite nor prevalent direction or orientation; the axis cylinders crisscross in all directions. Both the dendrites and teledendrons in the adjoining cells partially overlap.

The synaptical relationships of the horizontal cells are relatively simple. The dendrites of each cell are in contact with the pedicles of a group of cones. No dendrites are related to the rods. The teledendrons of the axis cylinders, on the contrary, are synaptically related both to the cones and to the rods. Interpreted functionally, this relationship indicates that only the cones are able to activate the horizontal cells, which, in turn, stimulate, at some distance, a group of both rods and cones.

3. Centrifugal bipolar (*i*).—The body of this neuron variety is in the inner nuclear layer (Fig. 142). Its scleral, or outer, and its vitreal, or inner, expansions are oriented vertically; in

this respect it closely resembles the expansions of the centripetal bipolars described in section 4 of this chapter. The expansions, however, differ in appearance. While in the centripetal varieties the morphological features indicate a functional polarity that signifies a flow of excitations from the photoreceptors to the ganglion cells, in the centrifugal bipolar the reverse seems to be the case.

The body and nucleus of the centrifugal bipolar is placed in the lower zones of the inner nuclear layer (*6-c* and *6-d*). The nucleus is

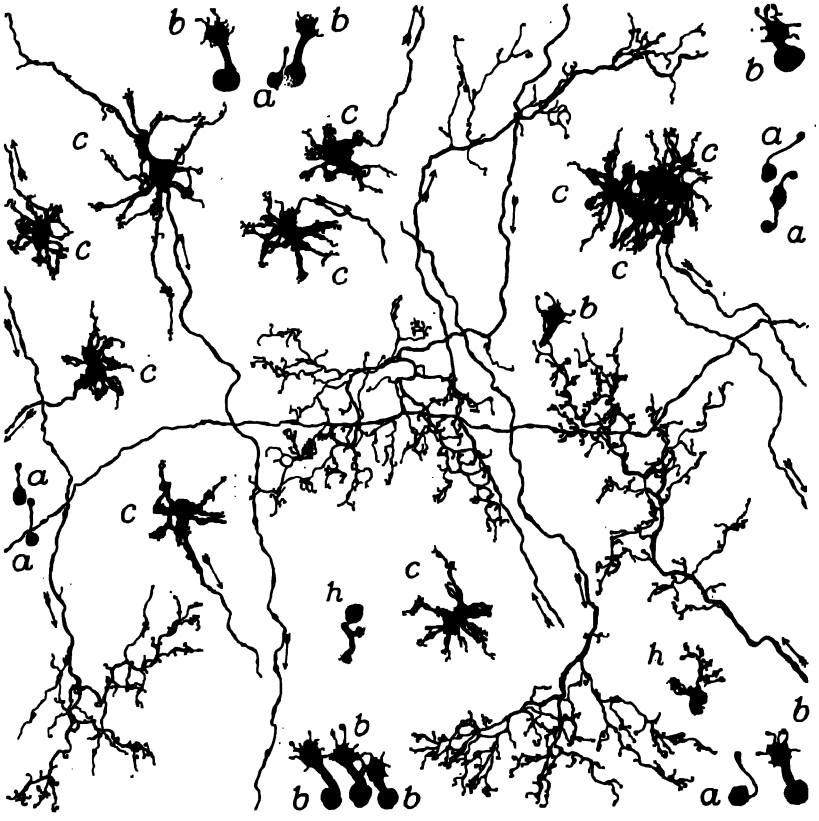

FIG. 141.—Details of structures making up the outer plexiform layer as seen in flat preparations cut parallel to retinal surface. Adult Rhesus Macaque, Golgi method. *Labeling: a*, rods, larger ends representing bodies or inner segments, smaller oval swellings terminal spherules; *b*, cones, their pedicles extending into barbel-like basal filaments, each of which carries a minute terminal varicosity; *c*, horizontal cells, each with several dendritic branches terminating in a cluster of minute twigs forming a basket to fit the lower end of a cone pedicle, and each cell giving rise to a single axon fiber; *h*, midget bipolars of the polysynaptic type with two bouquets, found in extra-areal periphery. Each axon fiber of horizontal cells, provided with spindle-shaped varicosities, terminates with an elaborate ramification or teledendron made up of numerous branches and terminal twigs, each carrying at its end a minute varicose swelling (*see* preceding figure). The arrows along the axons indicate the direction of the spread of the nervous impulses, from the cell body to the teledendron. In the left lower corner and close to lower margin of diagram, two complete teledendrons. In upper left corner a large horizontal cell from extra-areal periphery, other smaller cells from central area. In right upper corner a cluster of several horizontals, showing an overlapping of their ramifications.

usually somewhat larger than that of the centripetal bipolars.

The scleral process, which is a single, relatively thin fiber, with or without spindle-shaped varicosities, meanders between the nuclei of the sixth layer until it reaches the fifth layer. In the inner zone of this layer (*5-c*) it divides into a few short secondary branches. By further division into tiny twigs, each terminating with a small, occasionally a sizable, varicosity at the end, the fiber produces a terminal arborization. The fiber and its arborization appear as an axon with a teledendron. The terminal varicosities of this arborization touch the vitreal faces of the photoreceptors.

The vitreal expansion may be single, or there may be several main branches arising directly from the vitreal end of the cell body. The subdivision into numerous secondary and further branches produces a cluster resembling a dendritic ramification, the terminal twigs of which carry rather large varicosities, and all spread in the inner plexiform layer. The lowermost twigs of the vitreal arborization are in direct contact

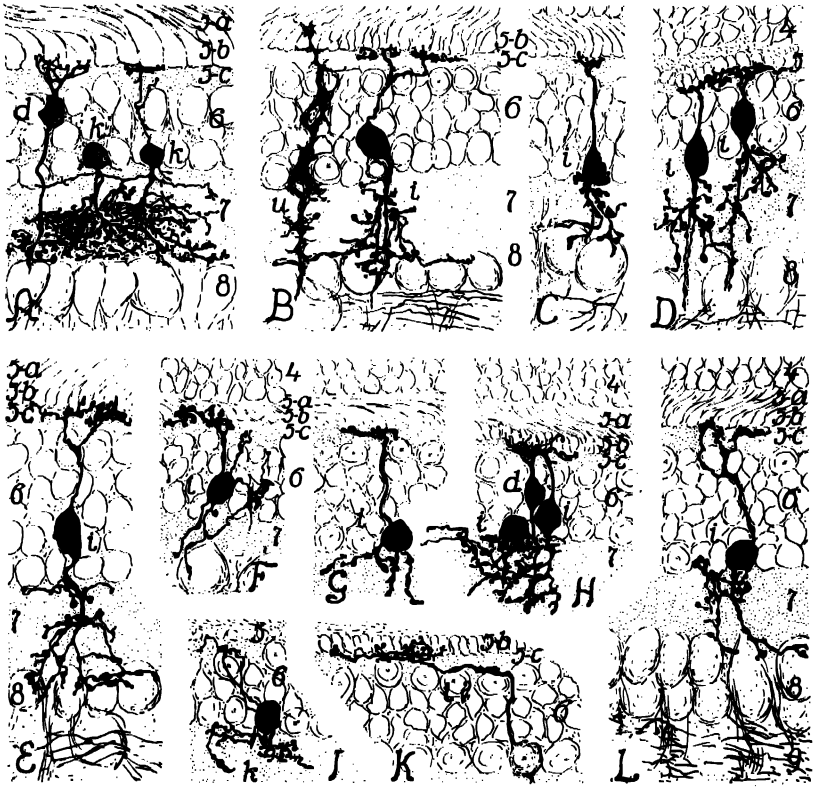

FIG. 142.—Various types of so-called "centrifugal bipolars," formerly identified with "amacrine cells," or elements without an axonal expansion. In centrifugal bipolars the axon-like process ends with a terminal ramification touching the lower extremities of rods and cones in zone *5-b* of the outer plexiform layer. The descending expansions have the appearance of dendritic arborizations spreading in the inner plexiform layer (*7*), where they are in contact with bodies of ganglion cells (*8*). These cells have been interpreted by the author as dynamically polarized or oriented in the direction opposite to that of the "centripetal bipolars" *d*, *e*, *f*, and *h*, hence transmitting impulses from the ganglion cells back to the photoreceptors.

with the bodies of the upper most row of the ganglion cells of the eighth layer. The others, spreading in the plain substance of the inner plexiform layer, apparently undergo synapses with the dendritic expansions of the ganglion cells and of the centripetal bipolars.

The dynamic orientation of this neuron variety remains uncertain. The appearance of its expansions indicates a function opposite to that of the centripetal bipolars: transmission of influences from the ganglion cells, and possibly from the centripetal bipolars, back to the photoreceptors. Such influences may possibly be inhibitory. (*Cf. i* in Figs. 146, 147, and in colored Fig. 179.)

4. Amacrine cells (*k*, *l*).—These neurons were so named by S. Ramón y Cajal because of

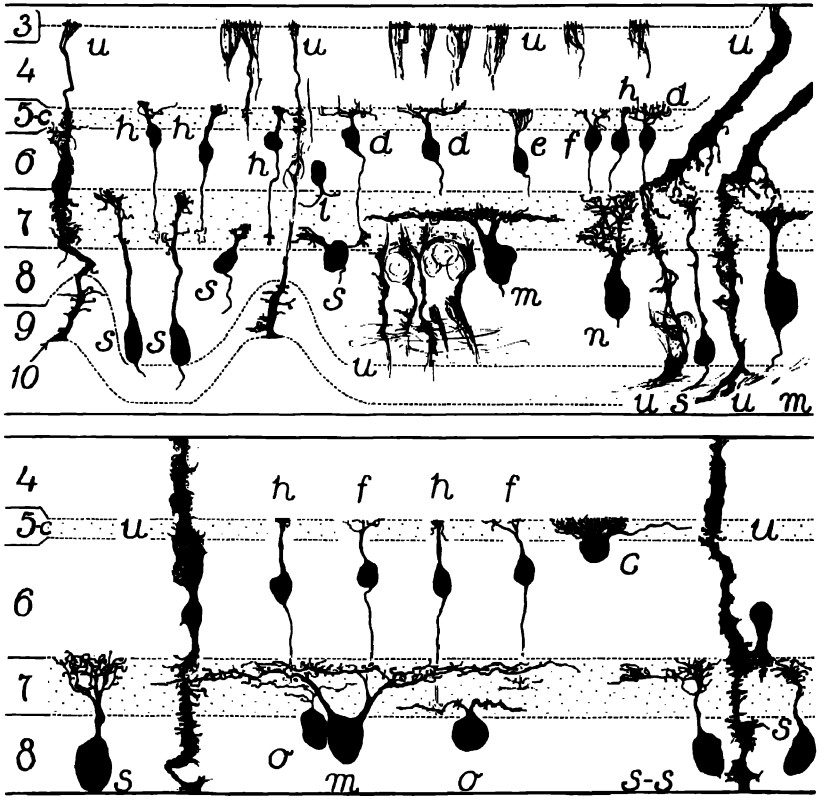

Fig. 143. –Elements of human retina stained with the Golgi method. Upper sketch from a six-month-old fetus; lower sketch from one eight months old. *Labeling: c*, horizontal cell; *d*, mop bipolars; *e*, brush bipolar; *f*, flat-top bipolar; *h*, midget bipolars; *l*, amacrine cell; *m*, parasol ganglion; *n*, shrub ganglion; *o*, small ganglion with horizontally running dendrites; *s*, midget ganglions; *s–s*, bisynaptic midget ganglion; *u*, radial fibers of Müller or their top ends, with so-called "fibrillar baskets." At the right, in upper sketch, radial fibers have already assumed a slanting course, as found in the fully developed fovea and close to it. Note characteristic features by which each neuron variety may be recognized, even though the neurons have still far to go to assume their final form. The notable feature at the earlier age is the "diffuse character" of neurons. Here many collateral branches, thus in *h* and *s*, are still present, which later become discarded. In the advanced age the neurons almost attain their final, streamlined form. These gradual changes are to be interpreted as a functional specialization of various types of neurons in the process of maturing, which appears to be the essence of growth. (*Cf.* following figure.)

the alleged absence of an axis cylinder (Fig. 142, left-hand cell labeled with *k;* Fig. 138, *l*). The cells are conspicuous because of their appearance, great numbers, and enigmatic connections and function.

The amacrine cell body (somewhat larger than that of other cells of the inner nuclear layer but considerably smaller than that of displaced ganglion cells) is in the lowermost zone of the inner nuclear layer (*6-d*). From it one or several main processes descend, which by repeated subdivision produce an "arborization" spreading in the inner plexiform layer.

The arborization is loose, composed of a few long, thin, smooth branches dividing but little, with only a few spindle-shaped varicosities and with terminal spherical and globular swellings. In the other amacrine cells, on the contrary, the arborization is dense, compact, made up of many branches and twigs carrying numerous swellings, buttons, spines, and varicosities of various shapes. The arborization, especially if large, spreads over the entire thickness of the inner plexiform layer, its lowermost twigs touching the bodies of the ganglion cells. In smaller amacrines the arborization, usually at the end of a single descending process, is small and spreads in only one or two of the several zones of the inner plexiform layer.

According to the appearance, size, and area in which the arborizations spread, several varieties of amacrine cells may be distinguished. Future investigation will show whether there is a morphological and functional basis for such subdivisions. In typical amacrines there is no scleral process. In many, however, the vitreal expansion resembles that of one type of centrifugal bipolars (*i*); and perhaps these amacrines are simply incompletely stained centrifugal bipolars.

We must also consider the possibility that some amacrines, especially the larger ones, may possess a horizontal axis cylinder spreading in the inner plexiform layer; fibers often found there which have the character of an axon suggest this (Figs. 146, 179, cell labeled *l*). If this supposition is substantiated, such neurons could be called the "internal horizontal or association cells" —the counterpart of the "external horizontal cells" (*e*) of the outer plexiform layer described in paragraph 2, of this section.

The amacrine cells are present in great numbers in all regions of the retina. They differ only in size the smaller are found in the slope of the fovea and central area, and the larger ones in the extra-areal periphery.

SEC. 7. EFFERENT OR EXOGENOUS FIBERS OF THE RETINA

The structures of the retina described in the preceding sections of this chapter are all instrumental in some way in the transmission of impulses from the photoreceptors to the brain. The visual pathway, accordingly, would be a one-way avenue. Under these circumstances, while the brain could be influenced by impulses arriving from the retina, there would be no means by which the action of the retina could in any way be modified by the central organ, the brain (except antidromically).

Certain fibers resembling terminal arborization of axons, apparently originating outside the retina, possibly in the midbrain, may be the structures through which the retina is influenced by the brain. The so-called exogenous or centrifugal fibers described by several investigators, notably by S. Ramón y Cajal (1909–11) and by Bouin (1895), are of this type. They seem to terminate on or around the bodies of the amacrine cells placed in the lowermost zone of the inner nuclear layer (*6-d*).

This is most probable in the case of avian retinae. It is less certain in other Vertebrates, particularly Mammals. However, similar teledendron-like terminal arborizations have been found by this author in the retina of the Chimpanzee (*t*, in Figs. 137, 138, and colored Fig. 179). The retina may be directly influenced along such efferent fibers by the subcortical visual centers, e.g., the lateral geniculate nucleus (R. A. Pfeifer), the superficial gray layer of the superior colliculus (Edinger, Brouwer), the *ganglion isthmi* (Wallenberg 1898), or the hypothalamus (Weber 1945). A detailed study of this category of neurons in various Verte-

brates, especially in Birds, where it is most promising, is sorely needed.

When, in Man, an eye has been missing for a long period of time, the optic nerve of that side shows complete degeneration and absence of all myelinated fibers when stained for myelin (*see* chap. VI, 2 [1], 4 [2]). Since it is probable that in the human optic nerve all fibers are myelinated (*see* chap. VI, 3 [2]), this could be interpreted to mean that there is no centrifugal fiber system. The evidence, however, is not conclusive, since there is possibly a retrograde degeneration of the centrifugal fibers whose terminals have been cut off.

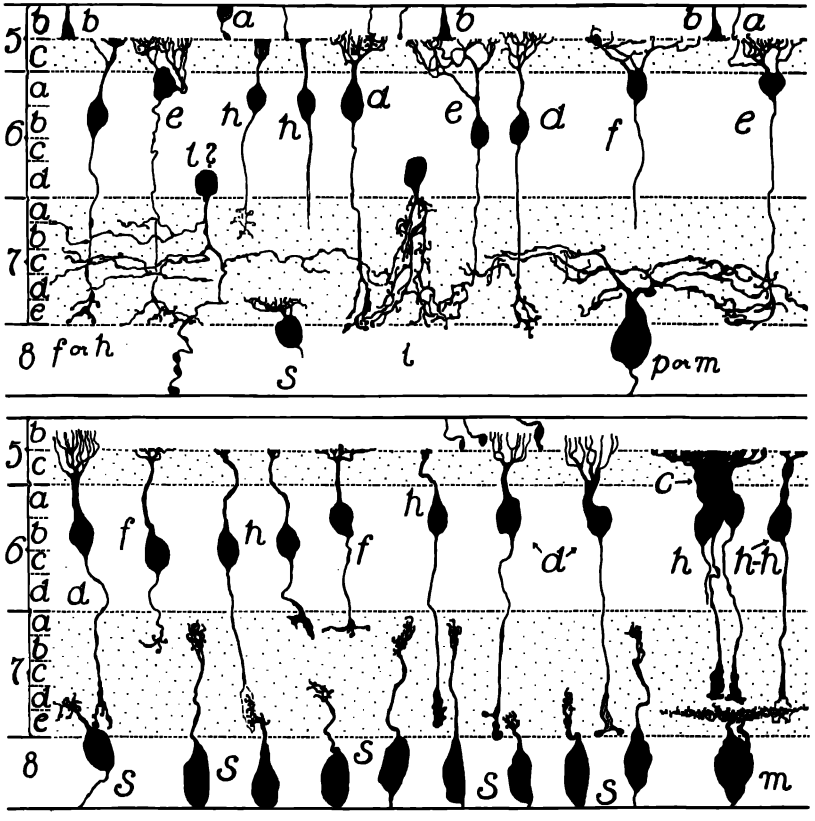

FIG. 144.—Elements of human retina stained with the Golgi method. Upper sketch from a newly born infant; lower sketch from an adult. *Labeling: a*, lower ends of rods; *b*, lower ends of cones with cone pedicles; *c*, horizontal cell accidentally stained with a group of bipolars, simulating Cajal's "giant bipolar"; *d*, mop bipolars, one with an oversized Landolt fiber; *e*, brush bipolars; *f*, flat-top bipolars; *h*, individual midget bipolars; *h–h*, bisynaptic midget bipolar with two complete "bouquets"; *i*, typical so-called amacrine cell without an axon fiber; *i?*, a somewhat similar cell which apparently is a displaced ganglion or "Dogiel's cell," its axon fiber descending to the layer of optic nerve fibers; *m*, parasol ganglion; *p* or *m*, garland or parasol ganglion; *s*, midget ganglion cells. Note immature appearance of neurons in upper sketch, even though they have advanced further toward the adult form they attain in the lower sketch. When comparing mature human and simian retinae, their similarity becomes striking, the cell varieties, in fact, being identical, indicating a practically identical function of the retina in all advanced Primates. (*Cf.* preceding figure.)

SEC. 8. THE FUNCTIONAL GROUPING OF RETINAL NEURONS

1. GENERAL REMARKS CONCERNING FACTORS WHICH DETERMINE THE FUNCTIONAL RESPONSE OF THE RETINA.—The photoreceptors and other nerve cells of the retina, representing more than a dozen distinct neuron varieties, are woven into an intricate and stable tissue pattern (Figs. 146, 147, and colored Figs. 177, 178, 179). This pattern, it must be assumed, in its gross features and in all its numerous details, is a structural expression of functions, of which the constituent neurons of the retina are carriers. It should then be possible, by piecing together the facts which have already been discussed, to single out from the total pattern the systems of neurons that are likely to form various channels along which dynamical changes are propagated. This may show which of the neuron relationships are of primary importance and which are purely accidental, in no way instrumental in generating, propagating, and transmitting specific nervous impulses. (*See* chap. IX on the organization of nervous tissue.)

The criterion by which we may determine functional relationships is synaptical contacts, through which alone these relationships are established. Since, however, all retinal neurons are directly or indirectly connected with one another through their synapses, it is further necessary to assume that their varying modes of reaction are also regulated by the specific responsiveness intrinsic to each neuron variety, in addition to the variation in quality and intensity of the external stimulus, physical light.

With this in view, several neuron systems may be singled out from the permanent retinal structural pattern, depending on whether one or the other, or both, of the two distinct photoreceptor varieties—the rods and the cones—are put into action by light stimulus.

2. ROD SYSTEM (*a* & *def* & *mnoprs*).—The rod system of the retinal neurons (Fig. 145, sketch *A*) is represented by the rods (*a*), by all mop bipolars (*d*), by some brush and flat-top bipolars (*e*, *f*), and apparently by all ganglion cells (*m*, *n*, *o*, *p*, *r*, *s*, in our diagram symbolized by *m* and *s*). Excluded from it are the cones (*b*), midget bipolars (*h*), horizontal cells (*c*), and centrifugal bipolars (*i*); (*cf.* Figs. 146, 147, and colored Figs. 177, 178, 179). Its functional units are composed of a group of rods, a group of diffuse bipolars synaptically related to them, and a group of ganglion cells related to the diffuse bipolars. The localizing value of impulses mediated by this system, even though its conductors are arranged parallel to one another, is somewhat restricted because of partial overlapping. The rod system may be thought of as embodied under conditions when the high-threshold cones cease to be responsive because of decreased intensity of stimulus.

3. CONE SYSTEM (*b* & *defh* & *mnoprs*).—The cone system of the retinal neurons (Fig. 145, sketch *D*) is represented by the cones (*b*), by various bipolars, including the midget variety (*d*, *e*, *f*, *h*), and by all ganglion cell varieties (*m*, *n*, *o*, *p*, *r*, *s*, symbolized by *m* and *s*). Only in the rodless central portion of the fovea do the mop bipolars (*d*) appear to be missing (colored Fig. 177, middle sketch). The constituent functional units of the cone system are made up of the same neurons as in the rod system, with the addition of midget bipolars, except that the photoreceptors are the cones instead of the rods. The localizing value of the impulses mediated by the cone system is limited as in the rod system, and for the same reason: the multiple and partly overlapping synaptical relationships of its polysynaptical constituent neuron varieties (all except *h* and *s*).

In the rodless central territory of the fovea the modified cone system (without *d*) seems to be present as a permanent structural arrangement. Outside the rodless foveal center the cone system is present as a functional potentiality, realized only in case the rod function is elimi-

nated or suppressed (color Fig. 177, lateral sketches).

4. COMBINED ROD AND CONE SYSTEM (*ab & defh & mnoprs*, LATTER SYMBOLIZED BY *m* AND *s*) AND "PURE" OR "PRIVATE" CONE SYSTEM (*b & h & s*).—The first of these two systems of retinal neurons is realized under conditions when both rods and cones are simultaneously activated (Fig. 145, sketch *H*). In this case all neuron varieties related to the two types of photoreceptors participate functionally, forming a "combined rod and cone system." On the other hand, the individual synapses between the cones and midget bipolars and between the latter and the midget ganglion cells suggest that under certain dynamical conditions the cone impulses may be restricted to these neu-

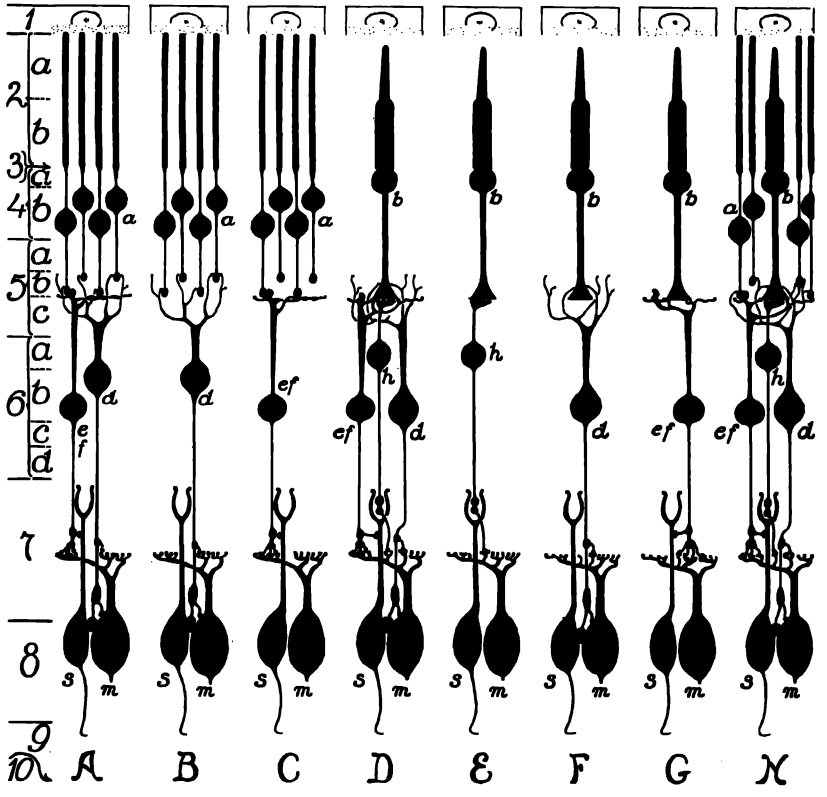

FIG. 145.—Grouping of neurons of the primate retina into functional systems. *Labeling: A*, rod system; *B*, reduced rod system with only the mop bipolar as an intermediary link; *C*, same with only the brush or flat-top bipolar linking rods to the ganglion cells; *D*, cone system, complete, with rods omitted and with all bipolar varieties linking cones with the ganglion cells; *E*, reduced or pure cone system, with rod and cone bipolars omitted, the cones linked to the ganglion cells by the midget bipolars alone; *F* and *G*, constituent elements of the cone system, with either the mop, brush, or flat-top bipolars as intermediary links; *H*, mixed or complete rod and cone system as actually found in the normal duplex primate retina. In this diagram the parasol ganglion (*m*) symbolizes all so-called "diffuse" ganglion varieties (*m*, *n*, *o*, *p*, *r*), while *s* is the midget ganglion closely related to the cones. (For details *see* sec. 8, this chapter.)

rons, or that a portion of the cone excitation may be transmitted as a distinct dynamic entity through these monosynaptical links (*b* & *h* & *s* chain of neurons), while the remaining cone excitation, if any, may pass over to the polysynaptic bipolars and ganglion cells (*b* & *def* & *mnops*) and, in addition, to the horizontal cells (*c*), centrifugal bipolars, and amacrines (*i*, *k*, *l*).

The set of monosynaptic neurons (*b* & *h* & *s*) may, therefore, be considered a "private," or "pure cone," system of the retinal conductor neurons (Fig. 145, *E*, minus diffuse ganglions

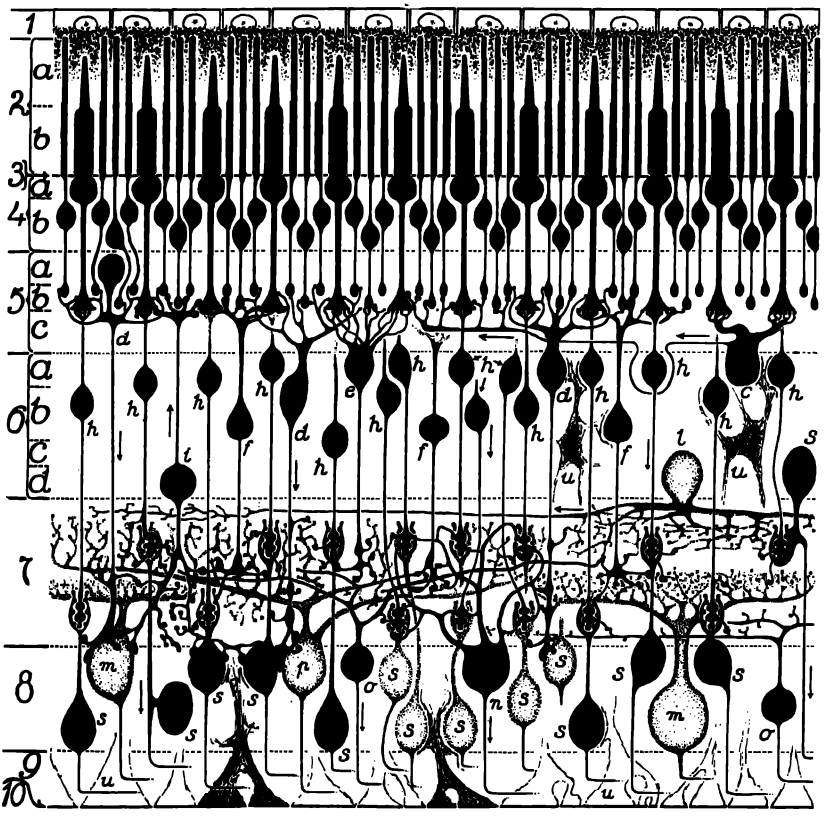

FIG. 146.—Schematic presentation of neuron varieties of primate retina and their synaptic relationships, with the essential features preserved, based on the Golgi method of staining. Layers and zones, indicated along the left margin, same as in Fig. 128. In the upper part of the diagram are photoreceptors, both rods (*a*) and cones (*b*), the bacillary parts sticking into the pigment layer, the inner fibers of the rods terminating with round spherules, and those of the cones, with conical pedicles, which form zone *5-b* of the outer plexiform layer. Here the synaptical contacts are made with upper or dendritic expansions of horizontal cells (*c*), along which the impulses spread in adjoining parts of the retina, and with the bipolars of centripetal varieties (*d*, *e*, *f*, *h*), along which they pass to the inner plexiform layer, where synaptical contacts are established with the ganglion cells (*m*, *n*, *o*, *p*, *s*). From the ganglions arise nerve fibers which, as the optic nerve, enter the brain. Other types of neurons, called "centrifugal bipolars" (*i*), may condition photoreceptors under the influence of the ganglion cells, hence in a direction opposite to that of the centripetal bipolars (*d*, *e*, *f*, *h*). There may be still other neuron varieties whose connections are lateral, spreading in the inner plexiform layer (*l*). This indicates that the primate retina is a complex organ whose function is not only to react to physical light as an external stimulus but also to sort the generated impulses in many ways before they are further transmitted to the brain. (*Cf.* Fig. 147, and colored Figs. 177, 178, 179.)

symbolized by *m*). It is a system organized strictly on a spatial principle, most perfectly expressed in the central fovea, and progressively less so in the para- and perifoveal parts of the central area, with further roughening in the extra-areal periphery. In the axial region of the retina and in its portion of the visual pathway, the private cone system of the conductor neurons makes possible the transmission to the brain of an impulse originating in a single cone as a single dynamic entity, evoking a very restricted subjective photic experience.

5. INTRARETINAL ASSOCIATION OR INTEGRATION SYSTEM. - This system of neurons, as far as it could be identified, is represented by the horizontal cells (*c*) and by the various amacrine cells, including the centrifugal bipolars (*i*, *k*, *l*). The synaptical relationships of the horizontal cells indicate a lateral diffusion of cone influences upon more or less distant groups of photoreceptors, both rods and cones (Figs. 146, 147). A similar diffusion of rod influences appears to be not feasible anatomically. A lateral spreading of influences through the association "amacrine cells" (*k*, *l*), provided that their axons spread laterally in the inner plexiform layer, also seems to be possible. The function of the centrifugal bipolar (*i*) would be the diffusion of influences from the ganglion cells (*m*, *n*, *o*, *p*, *s*) and centripetal bipolars (*d*, *e*, *f*, *h*) upon the photoreceptors (*a*, *b*). Finally, if the presence of exogenous fibers of extraretinal origin (*l*) were substantiated, the means by which brain influences could reach the retina would be identified.

6. DEPENDENCE OF RETINAL RESPONSE UPON AN INTERPLAY OF ANATOMICAL, PHYSIOLOGICAL, AND PHYSICAL FACTORS. - On purely anatomical grounds it is apparent that bipolars of diffuse varieties (*d*, *e*, *f*) serve as links in both the rod and the cone systems (Figs. 146, 147). For the same reason, the five or more ganglion cell varieties (*m*, *n*, *o*, *p*, *r*, *s*) must be considered the constituents of either system. Whether these bipolars and ganglions function in the capacity of mediators of rod or of cone influences or as a "common pathway" or in a selection or combination of influences may depend, in the first place, on whether one or the other photoreceptor variety, or both, are activated by an external physical stimulus.

In the case of a simultaneous stimulation of both kinds of photoreceptors, a complex situation ensues wherein the neurons in question serve as a common pathway. In this case relative rod and cone emphasis in the total response of the conductor neurons may be determined by less conspicuous secondary factors, such as the relative intensity of the initial rod and cone process, the "quality" of a given physical stimulus, such as the wave length, the varying physiological state of the nervous substance following stimulation, or the degree of "fatigue," and many other external and internal factors yet to be determined.

The problem of interpreting the sets of retinal neurons so far known in terms of the basic functional components of the phenomenon of vision - the perception of light, color, and space - is the theme treated in chapter IX of this book.

SEC. 9. SUPPORTING STRUCTURES OF THE RETINA

1. GENERAL REMARKS. - The tissue of the retina, like that of the brain from which it phylogenetically and ontogenetically derives, consists essentially of two components. One is represented by the parenchyma proper—the nerve cells and their expansions; these are the carriers of its specific function. The other constituent is nonspecific in the strict sense, forming, as it does, an appropriate stroma or framework within which the nerve cells and their expansions are lodged. This supporting retinal tissue, as in the brain and in the spinal cord, is the neuroglia, which is also mainly of ectodermal origin. The retinal neuroglia is chiefly represented by the sustentacular cells called "radial fibers," also known as "Müller's fibers," after

H. Müller who discovered them (1851), and to a lesser extent by the accessory neuroglia. (For details and additional figures *see* Polyak, *The Retina.*)

2. RADIAL FIBERS (*u*).—These structures, peculiar to the retina, are considered to be modified astrocytes of neuroglia found elsewhere in the central nervous system. They form the bulk of the retinal supporting framework (Figs. 142, 143, 146, 147).

Each radial or Müller's fiber is a cell with a body, inclosing a nucleus, and its expansions. The nuclei of most radial fibers, conspicuous

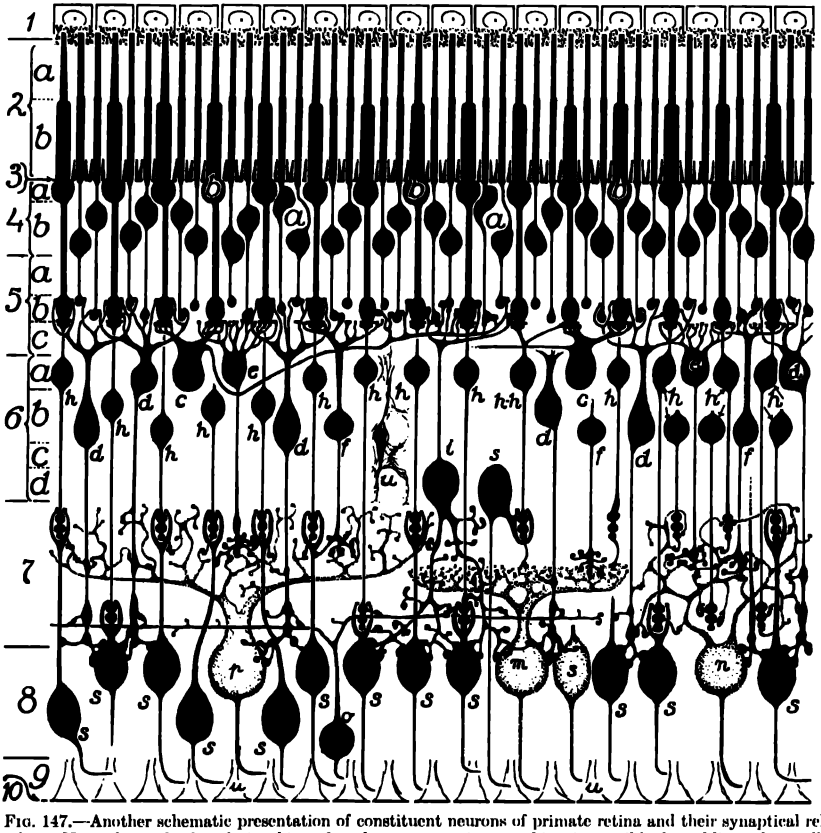

FIG. 147.—Another schematic presentation of constituent neurons of primate retina and their synaptical relationships. Note the multiple relationships of each neuron variety, making it possible for additional so-called functional and dynamic factors to modulate in many ways the reaction elicited in the retinal structures. As an example, an impulse generated in the first cone in the left upper corner, if stimulated by a restricted ray of light, would be transmitted directly to the first midget bipolar from the left (*h*), and through it to the first midget ganglion (*s*). Another impulse generated in the same cone would pass over to the first mop bipolar from the left (*d*), and further to the first two midget ganglions (*s*). The impulse passing through the first midget ganglion (*s*) would necessarily be a cone impulse and would possess a localizing value much better defined than that passing through the first mop bipolar (*d*), since the latter is also a "common path" for the second cone from the left, as well as for a group of rods, being, in addition, related to a diffuse group of ganglion cells (first and second *s* and *p*), hence having a much more diluted "local signature"; and so forth. In summary, the retina is an ingeniously contrived mechanism capable of reacting in many locally and qualitatively different ways to the variety of photic stimuli playing upon its photoreceptor surface. (*Cf.* Fig. 146 and colored Figs. 177, 178, 179.)

even in routinely stained preparations because of their darker hue and angular shape, are located in Man in the third zone of the inner nuclear layer (*6-c; see* Figs. 128, 129). The zone varies, however, with the vertebrate or primate species. A few nuclei are found displaced in the seventh, eighth, or ninth layers.

Enveloped in scanty cytoplasm, the cell body extends from the nucleus in the shape of a narrow pillar, traversing the thickness of the retina bounded by the two limiting membranes (*3* and *10*). The substance of the body incloses one or more thick fibers, whose broadened scleral and vitreal ends, in the aggregate, form the limiting membranes. The cytoplasm, enveloping the main pillar-like fibers and the finer fibers imbedded in it, expands into a multitude of sheets, lamellae, and excrescences, which, by joining with the similar lamellar expansions of the adjoining radial cells, form a complicated meshwork and system of cavities. The details of this latticework vary from layer to layer and even from zone to zone, depending upon the character of the nervous parenchyma they have to support.

The outer limiting membrane (*3*), as mentioned previously (*see* sec. 2 [4], this chapter), is perforated by countless openings, smaller for the rods and larger for the cones. Scleralad to this membrane, minute needle- or spinelike processes stretch along the base of each inner rod and cone segment (visible along line *3*, in Fig. 143). These reinforcements lie imbedded in delicate sheaths, individually enveloping each photoreceptor the "fibrillar baskets."

In the outer nuclear layer (*4*) the delicate neuroglial lamellae form a dainty honeycomb of as many sockets as there are cell bodies to envelop. The spaces of the larger shells and sockets hold the cone bodies, the smaller ones those of the rods. In this way each body of a photoreceptor is incased in its own individual compartment, separating and insulating it from the adjoining rod and cone bodies.

The inner and outer fibers of the rods and cones are also enveloped in neuroglial sheaths which insure perfect insulation. This is especially apparent in the central area, where the outer zone of the fifth layer, Henle's "outer fiber layer" (*5-a*), is quite thick. Here the neuroglial sheaths and fibers, in fact, produce as many tubes as there are nerve fibers (one such tubelike sheath is schematically presented in Fig. 128). The position of these tubes, conforming to the position of the inner rod and cone fibers which they insulate, is oblique in the central area and vertical or nearly so outside it.

In the middle zone of the outer plexiform layer (*5-b*) the supporting and insulating husks or sockets are very small, as are the rod spherules and cone pedicles that make up this zone. The terminal swellings of the photoreceptors, however, are not completely incased, since their vitreal and parts of their lateral sides, where the expansions of bipolars and horizontal cells are in contact with them, are left free.

In the inner zone of the fifth layer (*5-c*) the feltwork of fine neuroglial fibrils resembles a delicate plexus, except for the thick main radial pillars passing through it. Similar plexus-like felting is present in the seventh and ninth layers.

In the sixth and eighth layers (*6* and *8*) the arrangement is similar to that in the fourth layer, except that the sockets are larger. In the layer of optic nerve fibers (*9*) the conically expanded inner ends produce numerous horizontally placed sheets and tubes incasing the fibrous elements. The inner limiting membrane (*10*), finally, appears as a solid, continuous sheet, even though, in reality, it is composed of juxtaposed broadened inner ends of Müller's radial fibers.

The radial fibers and the supporting and insulating framework they produce are present in essentially the same form everywhere in the retinal membrane. In the central fovea and area they are more delicate, made up of finer sheets, narrower tubes, and smaller sockets, altogether forming a finer framework, within which the smaller but more numerous nerve cells and fibers are incased.

3. ACCESSORY NEUROGLIA (*v, x, y*).—The accessory neuroglia of the retina is represented by several elements.

The *neuroglial amacrine cells* or *interstitial spongioblasts* (*v*) of W. Müller (1874) resemble the *k*-variety of the amacrines in the location of their bodies in the innermost zone of the inner nuclear layer (*6-d*) and in the form and size of their expansions, which spread in the inner

plexiform layer (in Fig. 143, one such cell may be seen in the right lower corner, still connected to its radial fiber).

The *astrocytes* (*x*) are mostly found in the inner layers near and in the optic papilla. They resemble the astrocytes elsewhere in all respects, except that they are smaller. Also, two varieties among them may be distinguished: *fibrous astrocytes*, with relatively long and smooth processes, and *protoplasmic astrocytes*, whose expansions are covered with numerous minute, raglike, cytoplasmic sheets and appendages. Their true nature is revealed by the presence of "sucker feet," with which they are attached either to the typical radial fibers or to the capillaries or to larger blood vessels.

The third element, the *microglia* (*y*) of Río-Hortega, with all the features characterizing it elsewhere– a minute body containing an oblong nucleus and a few contorted and twisted expansions covered with a small number of short needle-like spines– is present in the seventh layer. The oligodendroglial cells, in Primates, seem to be absent as a normal structure.

4. Functional significance of supporting retinal structures.—The supporting neuroglial framework formed by Müller's radial fibers and by the accessory neuroglia produces in the retina, in the aggregate, an extremely complicated "honeycomb," with countless minute spaces, slits, interstices, tubes, shells, and husks, into each of which a cell body, an axis cylinder, a dendrite, a branch, or a twig of a nerve cell is wrapped.

The only localities where the insulating neuroglial sheaths are absent are parts of the outer plexiform layer (*5-b*) and parts of the inner plexiform layers (*7*), the two "synaptical fields" of the retina, where a direct contact between the neurons is established. This arrangement apparently insures complete insulation of each neuron and guarantees it against interference by other neurons. The impulses, in this way, are forced to spread along the channels formed by the substance of the neurons and the synaptical contacts.

The neuroglial framework of the retina serves, accordingly, as a mechanical support and a dynamic insulator, holding in place and keeping separated the nervous structures. In this way the neuroglia preserves the countless anatomical and functional relationships as they have developed during the period of embryonic growth and postembryonic maturing process. Without such a supporting and insulating system, the propagation and proper distribution of infinitesimally delicate dynamic changes, varied in quality and intensity, which are called "impulses," through the complex retinal structures during a process of photoreception would be impossible.

But, beyond these two functions—mechanical support and dynamic insulation it is possible and even probable that the neuroglial structures perform other essential functions concerned with normal metabolism, as they also do in various pathological processes.

A problem closely related to the foregoing concerns the relationship of the neuroglial cells to one another. The indications, in this respect, do not favor the concept of a continuous syncytium advocated by Hardesty (1904), Held (1904, 1927, 1929), Holzer (1923), Metz & Spatz (1924), Franz (1927), Akkeringa (1934), and partly also by Alzheimer (1910). Observations tend rather to support the idea that the neuroglial cells, like the nerve cells proper, also preserve a measure of independence as structural elements, a view propounded by S. Ramón y Cajal (1897, 1909–11, 1913, 1932), Achúcarro (1915), Río-Hortega (1916, 1928, 1932), Joseph (1928), *et al.* Even so, in a fully mature retinal tissue, under normal conditions, the honeycomb produced by the supporting structures appears to be mechanically sealed. The insulation of the nervous parenchyma within the retinal honeycomb, however, is only relative, since a means of free exchange of fluids and of the many constituent chemicals dissolved in these fluids must be fully preserved.

5. History of investigations of retinal supporting structures.—The elements of the supporting tissue of the retina were previously observed by Fontana (1782), but were definitely described by H. Müller (1851, 1853, 1856–57), Koelliker (1852, 1854), and Remak (1854).

M. Schultze (1866, 1867, 1869, 1872, 1873) was first to give a comprehensive analysis of the

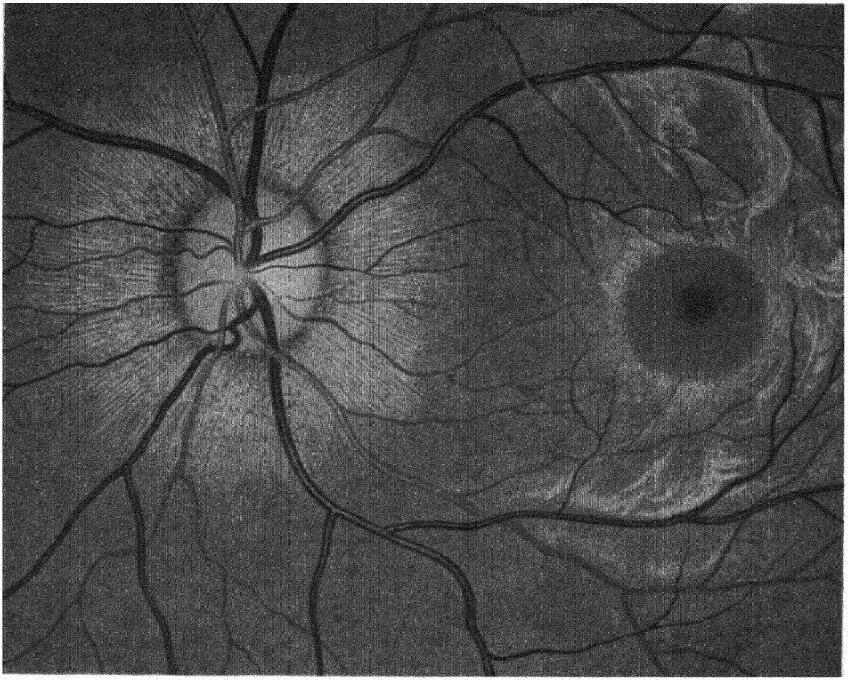

FIG. 148—Fundus or interior of the left eye of a dark-haired English girl 20 years old. Mottled chorioid stroma indistinctly seen in the background. Translucent optic nerve fibers may be traced for a short distance beyond the disk. A circular foveal excavation, encircled by a reflex ring, encloses a cherry-red center, the foveola. A reflex along the arteries (bright red) and veins (dark red) visible. (From G. L. Johnson, *Philos Trans. Roy. Soc. London*, ser. *B*, vol. 194, pl. 1, year 1901.)

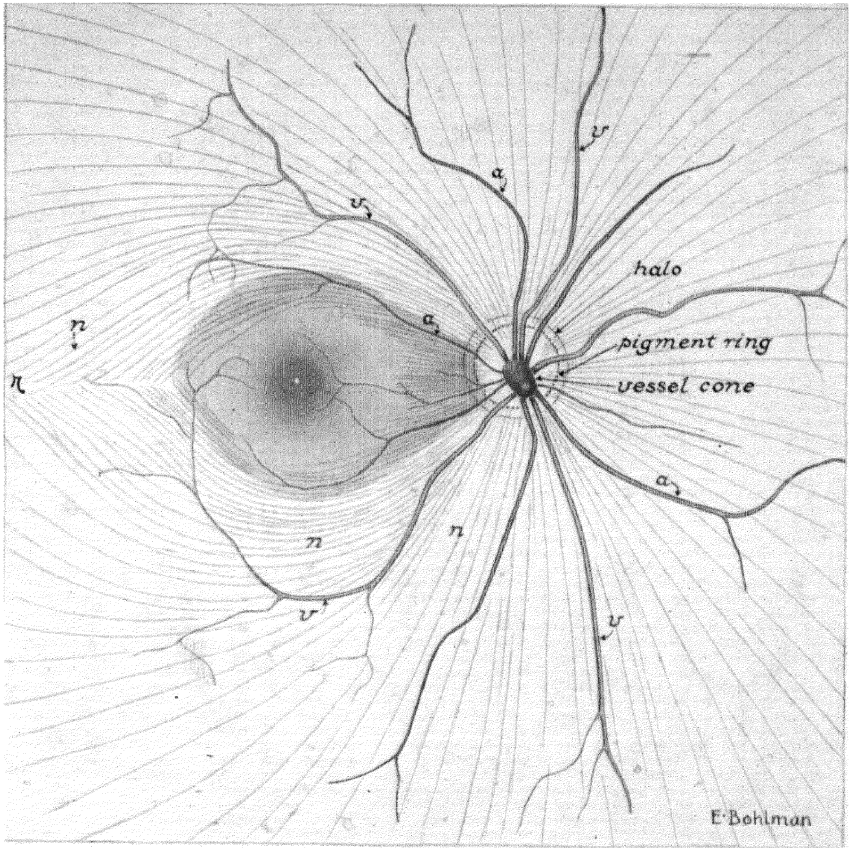

FIG. 149—Fundus or interior of the right eye of a Philippine Tarsier (*Tarsius carbonarius* or *T. philippinensis*) seen ophthalmoscopically in red-free light. Optic papilla encircled by a halo and a pigmented ring, with arteries (*a*, red) and veins (*v*, blue) radiating in all directions. Translucent vessel cone protruding from the papillar center. Bundles of optic fibers (*n*) show a radial arrangement on nasal side (right), and arching above and below the central fovea on the temporal side (left), with a meeting line or *raphé* (*r*) along the horizontal meridian. Macula or yellow spot is represented by a large pear-shaped area with its handle at the papilla, and its expanded portion embracing the foveal excavation, with finer pigmentation and deeper orange tint in the fovea. The fovea is relatively small, its diameter about one-half of that of the papilla. A faint dot-like light reflex indicates the very center of the foveal depression. Note the size of the yellow pigmented area many times larger than the fovea. The central area and fovea are well supplied with blood vessels that approach the fovea, which remains free from visible vessels. (Water-color painting from a sketch made during life by Dr. Frank Stuart Ryerson of Detroit.)

retinal supporting framework; but only the analytical investigations of S. Ramón y Cajal (1889, 1891, 1892–93, 1909–11) clarified its essential features. The neuroglia of the human retina, especially of the central area, found a competent student in Dogiel (1893).

The retinal neuroglia was examined by modern methods by López Enríquez (1926, 1948), Marchesani (1926, 1927), Kolmer (1930, 1936), Díaz (*see* Balbuena 1930), Bulač (1931), and Akkeringa (1934).

Some of their views, e.g., those concerning the structure and the relationships of the outer limiting membrane (Fortin 1926, 1930), on the nonsupporting character of Müller's radial fibers and their peculiar role in photoreception (Police 1928, 1932) and the presence of Held's "universal network" or continuous glial-neurofibrillar *syncytium* (Akkeringa 1934) are at variance with the available evidence.

SEC. 10. OPTIC PAPILLA OR DISK, CENTRAL AREA AND FOVEA, YELLOW SPOT OR MACULA, AND SERRATED MARGIN OR ORA SERRATA OF THE RETINA

1. GENERAL REMARKS ON THE LOCAL VARIATION OF THE RETINAL STRUCTURE.—The structure of the retina proper is not exactly the same in all its expanse but shows considerable regional variation, depending upon the special functional requirements of a particular locality (Fig. 125). Generally, the refinement of structures is greatest in the region where the visual axis touches the membrane (Fig. 129, *I*, *II*). Conversely, the internal makeup is less refined in the extensive territory outside the axial region, with the crudest structures present along its anterior boundary, the *ora serrata* (*V*, *VI*). The gradual structural perfection toward the axis or functional center of the retina is expressed, on the one hand, in a numerical increase in the nerve cells of all varieties, including the photoreceptors, and, on the other hand, in decreased dimensions of the individual cellular and fibrous elements. In this way, spatially much more restricted and more delicately diversified reactions of the structures to minute photic stimuli are possible in the center than in the extra-axial periphery, where the reactions necessarily are of a cruder nature.

Five especially differentiated localities are customarily distinguished in the retina of Man and other Primates: optic papilla or disk (*op*); central area and *macula lutea* or yellow spot; central fovea or central depression, dimple, or pit (*cf*); extra-areal periphery, representing most of the retinal expanse; and the narrow *ora serrata, margo undulato-dentatus*, the serrated, undulating, or dentate margin (*os*) in Subhuman Primates, called the *ora terminalis* (*ot* in Fig. 126).

2. OPTIC PAPILLA, DISK, HEAD, COLLICULUS, OR "HILLOCK" OF OPTIC NERVE.—The spot where the optic nerve is implanted in the eyeball, seen from the retinal side, appears as a more or less circular area nasal to the axial center of the retina (Figs. 148, 149, 165–70). It is composed of optic nerve fibers streaming in from the entire territory of the retina and gathered at the point where they leave the eyeball (*see* chap. VI, 2 [2–5] on the course of optic nerve fibers). After passing through the cribriform or sievelike membrane, a portion of the sclera provided with numerous perforations, the bundles of nerve fibers are assembled into a trunk, the optic nerve (Fig. 125, *on*).

Only the nerve fibers, blood vessels, and neuroglia of the retinal structures are present in the papilla; the nerve cells, photoreceptors, and pigment epithelium are absent. Since the choroid membrane with its pigment-carrying melanophores and blood vessels is also absent, the color of the living papilla is a light shade of pink caused by the blood contained in its moderately developed vascular network.

Several large blood vessels, branches of the central retinal artery and vein, emerge from the tissue of the papilla, usually from a slight dimple, the physiological excavation, and spread in various directions (*see* chap. X, 2 [3], and Figs. 148, 149, 165 70). Since the photosensitive rods and cones are absent in the papilla and since the nerve fibers are insensitive to light, the optic papilla is blind. It corresponds in the field of view to the "blind spot" of Mariotte, situated on the temporal side of the visual axis and not far from it.

3. CENTRAL AREA AND MACULA OR YELLOW SPOT. The central area of the retina is a specially differentiated locality around the visual axis, where the ganglion cells of the eighth layer (*8*) are accumulated in several tiers (Fig. 129, *II, III;* also Figs. 127, 128). In the human retina the nasal boundary of the central area is at the temporal margin of the papilla. On the temporal side, along the horizontal meridian, the central area extends almost an equal distance beyond the foveal center, its total diameter measuring approximately 6 mm. Ophthalmoscopically, the central area roughly corresponds to a central circular territory encircled by the larger blood vessels.

The central area is further characterized by the presence of a peculiar yellow pigment permeating all layers below the outer nuclear layer (*6, 7, 8, 9*), the "yellow spot" or *macula lutea* or *macula flava,* or simply *macula* (Fig. 149). It is probable that the outer plexiform layer or parts thereof, like the thick outer fiber layer of Henle or zone *5-a,* also contain this pigment in the living, as Segal (1951) indicated, but this should be verified in quite fresh material. A careful ophthalmoscopic study in red-free illumination may also help solve this problem.

The pigment of the yellow spot is not granular or crystalline, but diffuse, of the character of a "lake" (*lac, lakh*). In the living, ophthalmoscopically, it is not noticeable except in red-free light (A. Vogt, Koeppe). (*See* sec. 11 [1], this chapter, for discovery of the yellow spot.)

In a freshly opened human or simian eye the pigmented area is visible as a yellow patch temporal to the optic papilla. It may best be seen after a freshly dissected retina has lost its natural transparency and has assumed a whitish coloring because of the coagulation of the protoplasm of its cells and fibers. The color is a clear canary or lemon yellow with a slight tinge of green (the orange-yellow color of the fovea seen ophthalmoscopically during life is caused by the choroid pigment seen through the thinned-out fovea; *see* following section). A small ring-shaped area corresponding to the ridge surrounding the central fovea is most intensively pigmented. The center of the foveal depression, called the *foveola,* itself is almost colorless. Toward the periphery of the central area the coloring fades rapidly. After death and under the action of histological fixatives, especially alcohol, the pigmentation soon disappears.

Chemically, the pigment of the yellow spot has been identified as a hydroxy-carotenoid protein or xanthophyll, probably lutein or leaf xanthophyll (Wald 1945, 1945 16, 1949). In the opinion of Segal (1951) the macular pigment consists of carotenoids identical with the photolytic products of visual purple, apparently mostly of the type of transient orange of Lythgoe and of the transient or indicator yellow. (*Cf.* also E. Hanström 1940.)

The probable function of the macular pigment is to filter out much of the blue segment of the visible spectrum, thus protecting the low-threshold rods of the central area, especially of the fovea, from the dazzling effect of strong daylight. The yellow pigment, together with the ventral layers, is practically absent in the very center, the foveola, coextensive with the external fovea, where only high-threshold cones are present and no such protection is required. The advantage of this arrangement is to preserve the scotopic rod system around the visual axis during the photopic condition for ready use in a rapid transition to scotopic vision. (*See also* Berger & Segal 1949; Segal 1951.)

In this connection it would be of interest to examine ophthalmoscopically and histologi-

cally, for the presence of a pigmented spot, those species which have only an incipient fovea or none at all but have a distinct central area definitely used for fixation and binocular stereoscopic vision. An easily procurable animal with such a retina is the Domestic Cat, and probably the Dog, and possibly many other species with primarily nocturnal habits.

A well-formed, though small, fovea, together with a large pigmented yellow spot, was found ophthalmoscopically, in red-free light, in the which the foveal center, containing only cones, alone remains free from yellow pigmentation. (*See* chap. XIV, 12.)

The human retina attains its maximum thickness of about 400–500 microns close to the center of the central area, just outside the foveal depression. This is chiefly caused by great accumulation of nerve cells and to a smaller extent because of the lengthening of photoreceptors and fibrous elements, especially in zone *5-a*, of this locality (Henle's layer). According to an

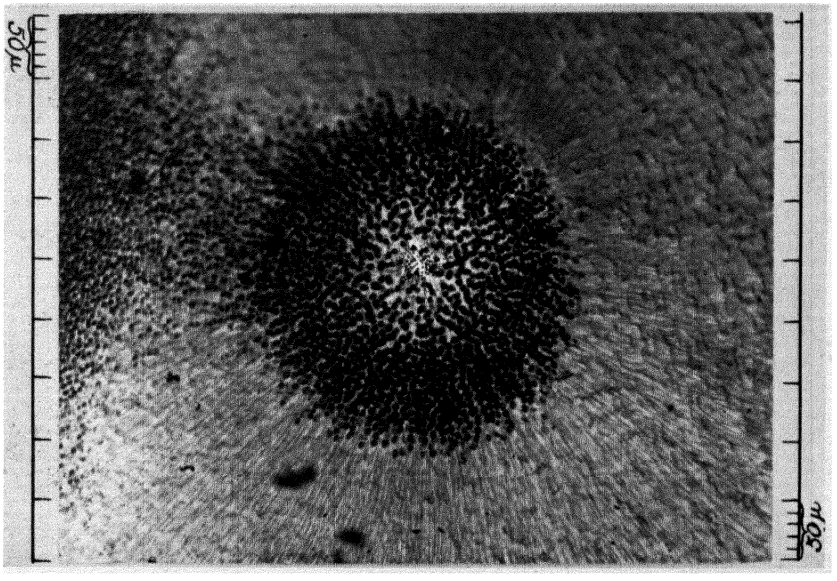

FIG. 150.—Microphotograph of a flat section through the central fovea of the retina of a Rhesus Macaque. In the center a circular accumulation of nuclei of the outer nuclear layer, with a few centralmost cones in the very center, indicating the deepest portion of the outer fovea (*cf.* Fig. 161, *middle sketch*). Bundles of the outer fiber layer of Henle, or zone *5-a*, of the central area radiating in all directions, to hook up with respective parts of the inner nuclear layer displaced laterally, owing to the formation of a foveal depression at the expense of the inner retinal layers. In the upper left corner the central nuclei are continuous with the more distant nuclei of the outer nuclear layer caused by an uneven spread of the specimen. Hematoxylin and phloxin stain, actual magnification in microns indicated along lateral margins.

Philippine Tarsier. The pigmented area apparently also includes the foveal center (*see* colored Fig. 149). The screening-off of the very center of the fovea by yellow pigment, in order to reduce the dazzling effect of strong daylight in the Tarsier, a strictly nocturnal species with no identifiable cones, is to be expected, in contrast with the diurnal Rhesus Macaque and Man, in approximate estimate, half of all ganglion cells of the retina reside in this restricted territory. The proportion may also be much the same in the case of the cones. For this reason, in spite of the much reduced size of the cells, the thickness of all layers is considerably increased in this locality. This is especially noticeable in the eighth layer, where the number of cell rows, in the

vicinity of the foveal pit, increases to as many as six, seven, or eight (Figs. 129, 161).

4. CENTRAL DEPRESSION, PIT, OR FOVEA; FOVEOLA AND DARK SPOT. Approximately in the center of the central area or of the pigmented territory known as the "yellow spot," is found a small circular excavation or depression, the "central" or "inner fovea." In sections vertical to its surface the outlines of the foveal depression resemble, in Man and Anthropomorphous Apes, a bowl with sloping sides (upper sketch in Fig. 161). Its gently rounded fundus or floor is called "foveola" or "little fovea." In most monkey species the outlines of the foveal depression or dimple resemble an inverted pan with a flat floor (Fig. 129, *A*). There is considerable variation in detail in various simian species (Figs. 166–69). The smallest, though well-defined, fovea is present in the South American Night Monkey, *Nyctipithecus* or *Aotes trivirgatus*, and in the Asiatic Tarsier (*Tarsius carbonarius* or *T. philippinensis*) (Figs. 149, 512). The concavity of the fovea faces the

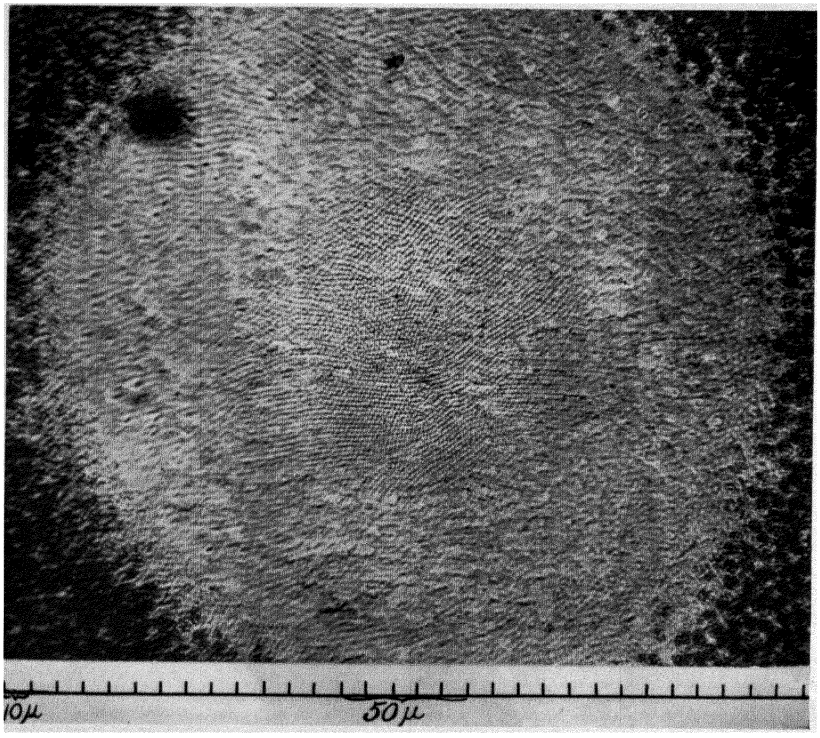

FIG. 151.—Flat section through central fovea of a Rhesus Macaque, stained with hematoxylin and phloxin, photographed with Bausch & Lomb fluorite 4.3-mm. 1.00 oil-immersion objective at 443× magnification, with actual dimensions indicated in microns on the accompanying scale. In the very center a circular territory entirely populated by the cones, the smallest being in its geographic center. The cones are arranged in a continuous, compact formation, without any gaps. The rows of cones intersect in various directions, preponderantly radiating from the geographic center, altogether forming an even-grained mosaic, hence precluding lines of predilection. The area where the cones are visible corresponds to the outer fovea and is surrounded, first, by a belt of less regular structures corresponding to the inner cone segments mixed with rods, and, on the outside, with the dark outer nuclei. (*Cf.* following figures.)

transparent center of the eye filled with the vitreous and is directed toward the pupil (*cf.* in Figs. 125, 126). (*See* sec. 10, this chapter, for history and comparative anatomy.)

In the living, the foveal pit is difficult to examine ophthalmoscopically because of the transparency of the retinal tissue. Its location, shape, and dimensions may, nevertheless, be excavation (370 microns or more) and, because of the absence of blood vessels, there is no sheet of blood to screen off the dark retinal and choroidal pigment (Figs. 148, 149). This dark patch is, in clinical parlance, falsely called "central fovea," and also "macula," but in fact corresponds only to the very center, the foveola.

In fixed anatomical specimens where the

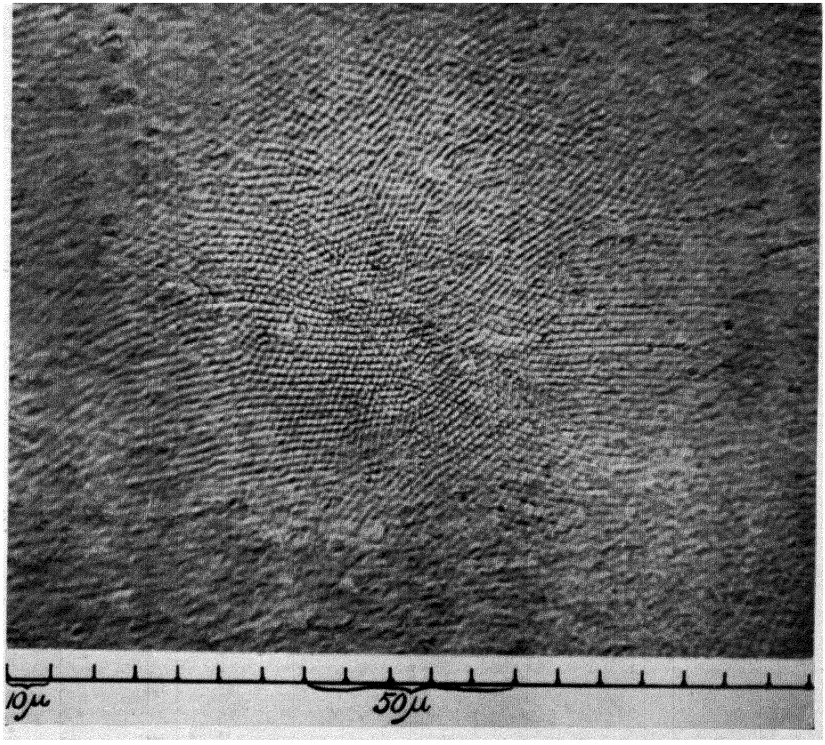

FIG. 152.—Flat section through central fovea of a Rhesus Macaque, presented in the preceding figure, here photographed magnified almost twice (732×), with actual size indicated in microns on the accompanying scale. The even-grained arrangement of the central cone mosaic, resembling a cobblestone pavement, is clearly seen, with intersecting rows radiating in a somewhat irregular way from the geographic center. The smallest cones are present in the very center, gradually and rather rapidly increasing toward the periphery. (*Cf. also* following figures.)

determined with the help of certain landmarks. Its center—the foveola—has a deeper, more saturated appearance than the remainder of the retina, because the thickness of the retina is here reduced to 130 microns or almost one-third of what it is immediately outside the foveal retinal membrane has a whitish color and the red sheet of blood is absent, this dark center is particularly conspicuous and is called "dark macula," or "black spot," *macula nigra*, *punctum niger*, of S. Th. Soemmerring. Ophthalmoscopically, this deepest central portion, the

foveola, is usually marked by a minute reflex of light, the "reflex of the foveola."

Another somewhat circular light reflex surrounding the first at some distance indicates the thick margin or ridge that marks the boundary of the foveal pit, the "foveal (falsely called macular) reflex" (Fig. 363). The retinal blood vessels converge toward it from all sides (*see also* Figs. 148, 149).

The diameter of the entire foveal depression from margin to margin measures, in Man, no less than 1.5 mm., corresponding to 5° in the field of view; the diameter of the foveola alone being approximately 0.4 mm., or 1°20′ of arc in the field of view. In the Rhesus Macaque the corresponding measures of the fovea and foveola are 1 mm., and from 0.25 to 0.35 mm., respectively. The distance of the fovea from the temporal margin of the optic papilla measures approximately 3 mm. in Man and 2 mm. in the Macaque.

The excavation of the central fovea sur-

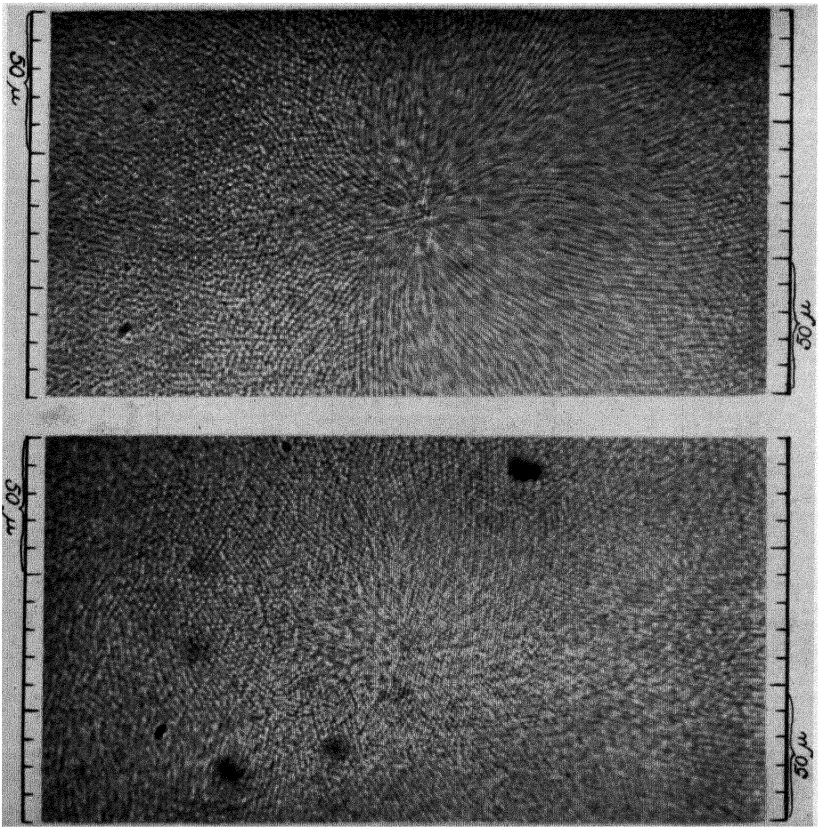

FIG. 153.—Microphotographs of two unstained whole-mount preparations of the retinae of adult Rhesus Macaques showing individual variation of the pattern of the cone mosaic in the very center of the fovea. In the upper photo many, in the lower photo only a few, of the cones have been laid flat in the center, the majority being arranged in a cobblestone pattern. Taken with a Leitz *Ultropak* oil-immersion objective 60×, and ocular 6XB, with transmitted light, at a linear magnification of 635×. Actual magnification indicated in microns on the accompanying scales.

rounded by its wall usually appears ophthalmoscopically somewhat elliptical in shape, although in reality it is circular, as is seen in well-preserved specimens. In some specimens it has a hue slightly brighter, in others a more saturated color, than the orange-red or vermilion of the region surrounding it.

Another conspicuous feature is the arrangement of the larger blood vessels, which circle above and below and at some distance from the fovea (*cf.* same figures, especially Figs. 148, 162). Only smaller branches are seen streaming from all sides toward the foveal margin; their terminals, the precapillary arteries and veins,

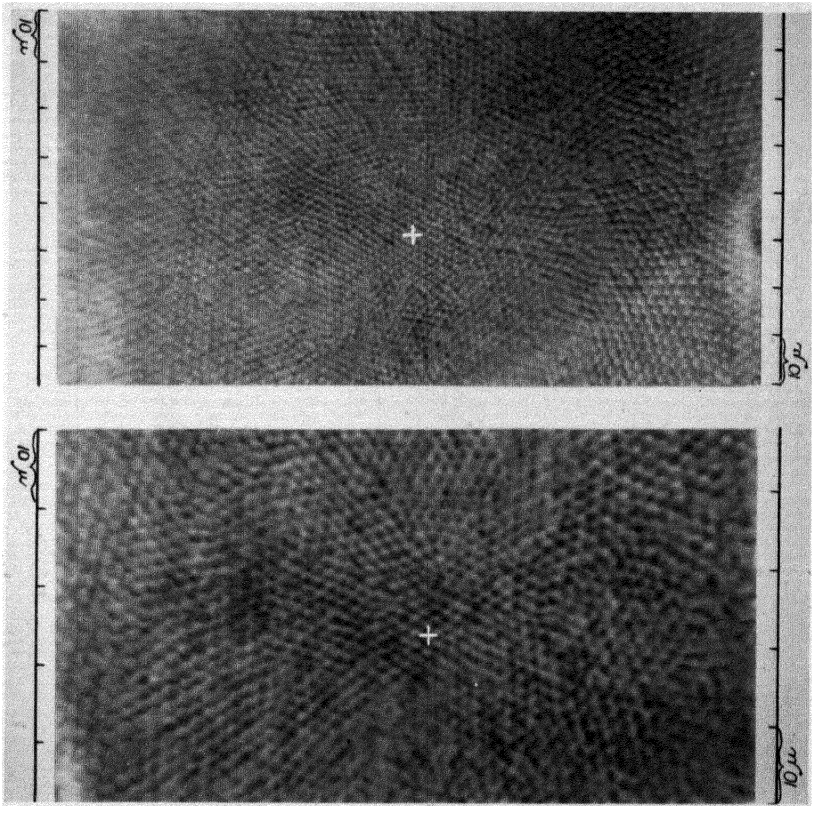

FIG. 154. — Cone mosaic from the very center of the fovea of an adult Rhesus Macaque as seen in an unstained whole-mount preparation of the retina. Microphotographs taken with Leitz *Ultropak* oil-immersion objective 100×, the upper photo with ocular 6XB, the lower photo with ocular 10XB, at the respective magnifications of 1,130× and 1,866×. The actual linear magnifications are indicated in microns on the accompanying scales. Note the characteristic honeycomb appearance of the cone mosaic, resembling a cobblestone pavement; hexagonal shape of individual cones, where clearly visible in sharp focus; the arrangement of cones in irregularly intersecting rows; the smallest cones in the geographic center, indicated by a white cross, from which the cones gradually increase in size toward the periphery; the absence of any gaps whatsoever in the solid cone formation, except for the thin neuroglial partitions visible as grayish lines; the absence of any rods in the central territory, indicating the "rodless area"; the even "grain" of the cone mosaic in a minute territory in the very center, measuring barely 20 microns in diameter, or about one dozen of cone diameters, where the cones are most reduced in size, corresponding with the "focusing" or "fixation point," or rather area, of the field of vision. (*Cf.* preceding and following figures.)

just slip over the margin into the foveal pit. In a small area, corresponding to the deeper portion of the foveal pit, even the precapillary vessels are absent (Fig. 364). This area, in the horizontal meridian, in Man usually measures not less than 550 microns across, or approximately 0.5 mm., which corresponds to 1°50′ of arc in the field of view. The foveola, where, because of the absence of all inner layers, all blood vessels, including the capillaries, are also absent, measures only 400 microns across. In the field of view this avascular or vessel-free area corresponds to 1°20′ of arc, more or less. The extent of this area varies individually. (*Cf.* chap. X, 2 [3].)

It is here that a few words may be added to clarify the confusion still existing concerning the use of the terms "fovea" and "macula." The first, a Latin term meaning a "pit," should be used to connote the excavation, whereas *macula lutea* or "yellow spot" should be reserved for the much larger area containing the yellow pigment visible only in red-free light (Fig. 149). The center of the fovea, appearing ophthalmoscopically as a minute, dark-red patch, is the *foveola* or "little dimple" or "little pit," marked by a foveolar reflex, and is much smaller than the actual excavation of the entire fovea, which is bounded by a circular foveal reflex ring (*cf.* Fig. 363). In this center alone all blood vessels are absent, and the yellow pigmentation, if present at all, is reduced to a minimum.

5. Foveal or central photoreceptors. The photoreceptor layer (*2*) is considerably thicker in the fovea than outside, because of the lengthening of the bacillary portions of the cones (Figs. 129, 161). This layer is thickest in the very center. Here the length of the photoreceptors is almost twice what it is in the foveal periphery. In order to accommodate the greatly lengthened central photoreceptors, the outer limiting membrane is pushed inward, toward the vitreous, forming a shallow dip named the "outer fovea" by Kuhnt and Dimmer (the very center, the deepest point, of this dip is filled with a few centralmost cones; *see* Fig. 150).

The diameter of this locality, where the photoreceptors attain their greatest length in Man, measures approximately 400 microns across, corresponding to 1°20′ of arc in the field of view. This area, accordingly, is practically coextensive with the deepest portion of the inner fovea, or foveola. Likewise, it is the same area that is free from all blood vessels, including capillaries (*see* chap. X, 2 [3]).

In this minute central territory or in a slightly larger area, measuring roughly from 500 to 600 microns across, the photoreceptor layer consists exclusively of cones (Fig. 161, upper sketch, rodless area in layer *2* between broken lines; *see also* Fig. 129). This fact is even more clearly demonstrated in microphotographs in Figures 151–56. In the field of view this rodless center approximately corresponds to from 1°40′ to 2° of arc.

The rodless and avascular center is encircled on the outside by a belt corresponding to the foveal slope, where the rods begin to appear, first singly, or in small groups or short chains, gradually becoming more numerous toward the periphery of the foveal excavation (Figs. 157–60).

In the Rhesus Macaque the central rodless territory is smaller, measuring approximately 200 microns across. Both in Man and in the Monkey the rodless central area, accordingly, is considerably smaller than the foveal excavation, amounting to about half the total foveal diameter, but less than half its area.

The greater length of the foveal cones is caused principally by the lengthening of their outer segments, whereas the inner segments appear, in fact, to be shorter. In a minute area, in the very center, measuring in Man from 50 to 75 microns across, the long, slender cones are all of almost uniform length. They attain their greatest length in the entire retina here; and here alone, or more than elsewhere, their scleral tips are imbedded in the pigmented epithelium (Fig. 161). The thickness of the cones, on the contrary, decreases toward the foveal center, the most centrally located foveal cones being the most delicate in the entire retina.

The length and thickness of the cones in the foveal center vary, depending upon the species. In Man, in the very center, they are approximately 70 microns long and from 1 to 1.5 microns thick in their inner, and 1 micron thick in their outer, segments, corresponding to 14″–21″ of arc in the field of view.

The separating dead intervals between the adjoining cones in the very center, filled by the enveloping neuroglial sheaths, measure hardly more than 0.3 micron, which corresponds to 4″ of arc in the field of view.

Toward the periphery of the outer fovea the thickness of the cones increases rather rapidly, and the length decreases, while the separating intervals also become greater. Just outside the foveal depression the inner segments of the cones are from 3.5 to 4 microns thick, and the outer segments 1.3 microns thick.

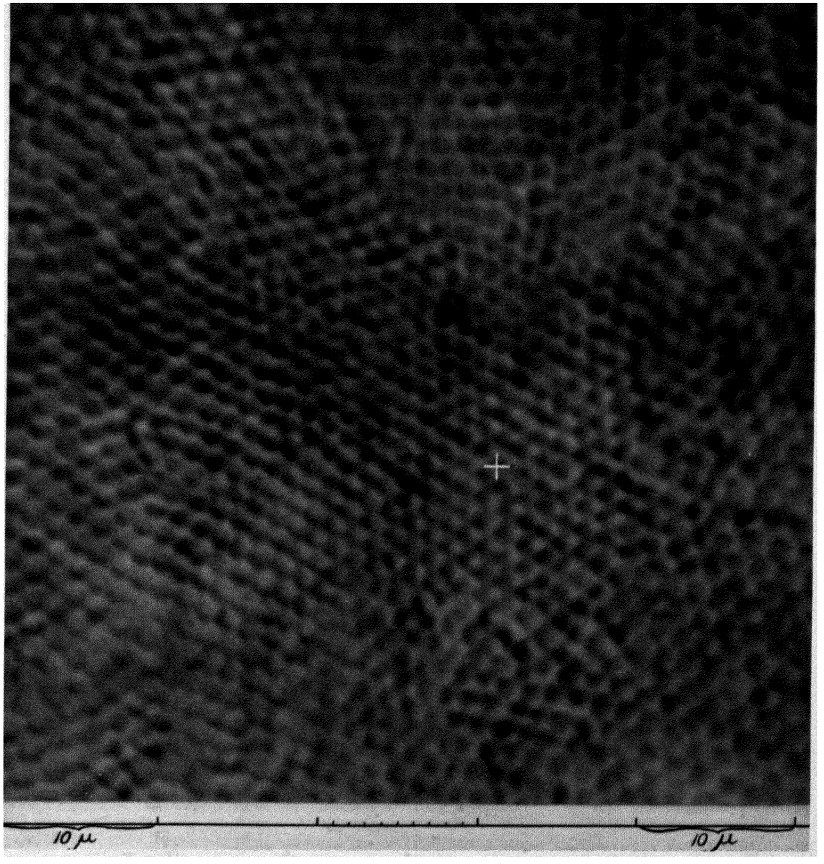

FIG. 155.—Cone mosaic from the center of central fovea from the same preparation presented in the preceding microphotographs (Fig. 154), much more magnified. Actual linear magnification 3,718×, indicated in microns on the accompanying scale. Leitz *Ultropak* oil-immersion 100× objective used with transmitted light. This photo, even better than the preceding one, shows the arrangement of the central cone mosaic, with the following noteworthy details: blunt hexagonal shape of individual cones in optical cross-section; smallest cones in the geographic center, approximately indicated by a white cross, their size gradually increasing away from the center; characteristic and somewhat irregular pattern of cone rows intercrossing in three ways at approximate angles of 60°; marked individual difference in cone diameter in each particular small territory; solid, continuous cone formation, without any gaps and without any rods. This is the part of the photoreceptor screen structurally most fit functionally to resolve the physical retinal image, caught by it, into the most minute details and transmit the stream of nerve impulses to the brain for further mental processing.

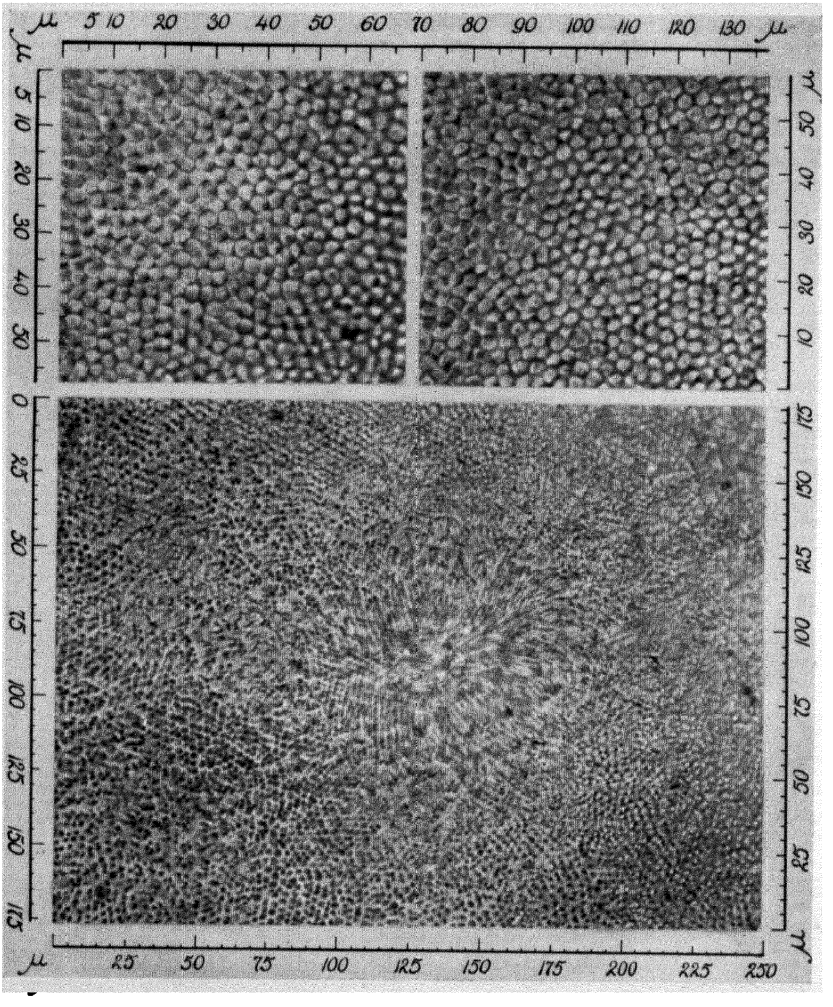

FIG. 156.—Microphotographs of the adult human foveal cone mosaic from a central rodless area. Specimen fixed in 10 per cent formalin, whole-mount unstained preparation, dehydrated in graded alcohols, cleared in terpineol and toluene, mounted in clarite, and covered with a coverslip on a paper frame. Larger photo, taken at 665×, shows a portion of the rodless central area of the fovea, with the foveal center, partly out of focus, approximately in the center of the photo and with cones slightly disarrayed. Smaller photos, magnified 1,227×, also from the same rodless area, but at some distance from the very geographic center, left photo slightly more distant from the center than the right one. Actual magnifications indicated on the accompanying scales. Leitz *Ultropak* oil-immersion objectives 60× and 100×, used with transillumination. Note in the larger photo an arrangement in intercrossing rows similar to that of the Monkey shown in preceding figures, with smallest cones located in the geographic center. The smaller photos show distinctly the character of the central photoreceptor cone mosaic, with irregularly hexagonal individual cones, much varying in shape, size, and arrangement but, on the whole, forming a fairly uniform, evenly grained mosaic. No gaps in normal, well-made preparations are found in the cone mosaic. (*Cf.* preceding figures.)

The number of cones in the territory of the central fovea is absolutely and relatively greater per unit area than anywhere in the extrafoveal regions (Figs. 151–56). In the outer fovea, which is practically coextensive with the foveola, in a circular area measuring about 400 microns across in Man, 20,000 cones may be counted in a whole-mount human specimen. In the field of view this corresponds to 1°20′ of arc.

In the very center of the outer fovea, a minute, irregularly circular island, measuring not more than 100 microns across, is filled with 2,000 of the thinnest cones of practically uniform diameter, the "bouquet of central cones" of Rochon-Duvigneaud. This minute central territory may correspond to 20′ of arc in the field of view.

In the central rodless territory, where the bacillary layer consists of cones alone, measuring about 500 microns asross, which corresponds to 1°50′ of arc in the field of view, the approximate number of cones is 35,000.

In the territory of the entire depression of the central fovea, computed to be 1.75 sq. mm., the number of cones is from 100,000 to 115,000.

In the simian retina the corresponding figures are smaller. The "central bouquet" of a Rhesus Macaque may contain not more than 400 500 cones. In the entire outer fovea, in the same species, measuring approximately 300 microns across, corresponding to the flat foveal floor, the number of cones is approximately 17,000.

In good preparations cut vertically to the retinal surface, the bacillary portions of the central cones appear perfectly straight, with their axes parallel and perpendicular, instead of oblique, as alleged by Koeppe.

In flat preparations of the retina, the "whole-mounts," both fresh unstained and fixed and stained, the cones in the region of the central fovea are closely packed into a solid formation, without any gaps; the entire formation here resembles an evenly distributed mosaic, like the cobblestones in an old-fashioned pavement (Figs. 154, 155, 156). An irregular distribution described by Fritsch and by Kolmer is to be considered an artifact, owing to improper technique.

The smallest cones of the mosaic are around the very center, indicated in our photographs by a white cross. From that center the cones gradually, though somewhat unevenly, increase in size toward the periphery along all radii. There are no gaps in this mosaic, except for the extremely narrow spaces between the adjoining cones. These spaces are filled with delicate sheaths of neuroglia, the "fiber baskets" of Müller's radial fibers, and the vitreal expansions of the retinal pigment epithelium, both already mentioned (sec. 2 [2], and 8 [2], this chapter).

The elements of the foveal photoreceptor mosaic, the individual cones, as they appear in a whole-mount preparation, are mostly hexagonal, less frequently pentagonal in shape, much like the "cells" of a honeycomb (Fig. 156). As in a honeycomb, they are arranged in fairly distinct rows, somewhat arching and cutting across one another in three definite ways at approximately 60°. The pattern is not mathematically regular, as depicted by M. Schultze, but shows numerous irregularities and deviations from a theoretically postulated arrangement.

The arrangement of the "grain" of the central foveal cones as described indicates small preference, if any, for certain directions, lines, or shapes. Each minute hexagonal or pentagonal field of the mosaic of the central photoreceptors corresponds to an individual cone in an optical cross-section.

The smallest cones in the very center in Man measure from 1 to 1.5 microns, in the Macaque from 1 1.3 to 1.5 microns, which corresponds to from 12″ to 18″ of arc in the field of view. The separating glial partitions and blind intervals amount to from one-fifth to one-third of these figures.

The distance from center to center of the adjoining cones in the very center of the fovea, both in Man and in the Rhesus Macaque, is from 1.6 to 2 microns. Considering the minimum (one-tenth) and the maximum (one-fourth) of possible shrinkage caused by the action of the chemicals to which the specimen was subjected during fixation and imbedding, the diameter of the centralmost cones may be estimated, both in Man and in the Rhesus Macaque, at from 1.1 to 2 microns, their intercenter distance at from 2 to 2.6 microns. (My latest measurements show the linear shrinkage not to exceed one-tenth of the original size.)

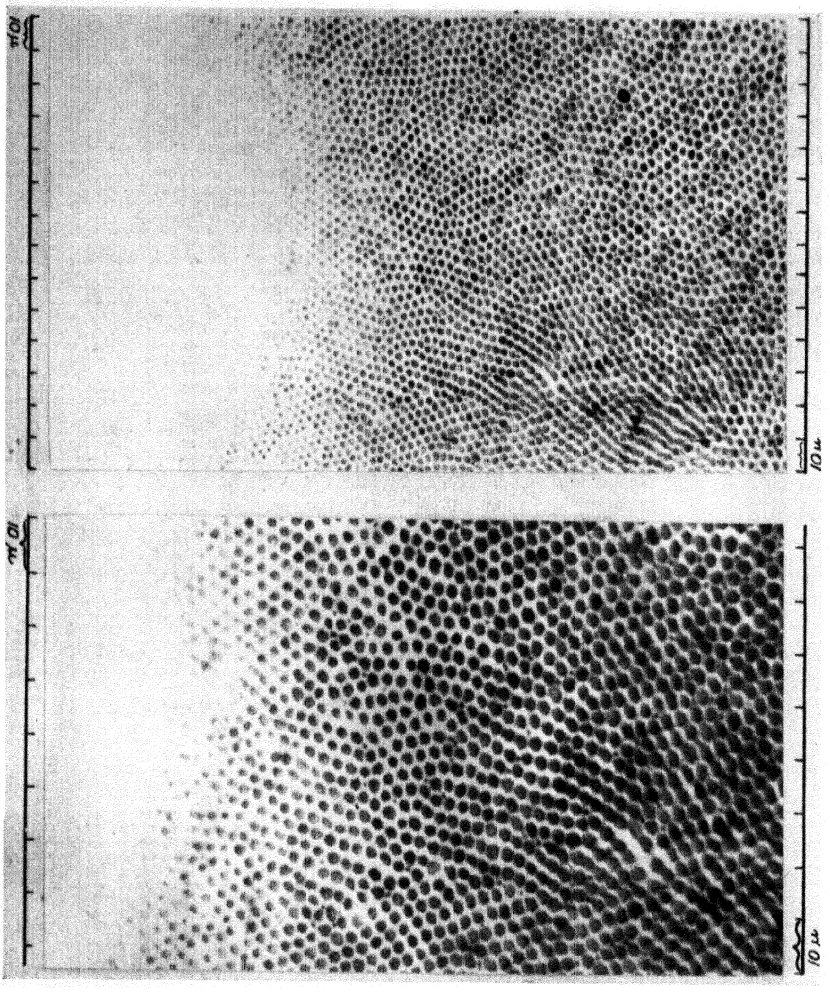

FIG. 157.—Microphotographs of a flat section of the retina of an adult Rhesus Macaque stained with hematoxylin and phloxin, showing photoreceptor mosaic of the central fovea next to the central rodless area, with most centrally located rods (*dotlike structures*) appearing between the cones (*larger structures*). Unstained left ends of photos represent a portion of central rodless area, with the very center farther to the left, outside the photos. Taken with Leitz *Ultropak* oil-immersion objective 60×, and transillumination, upper photo with ocular 6XB, lower photo with ocular 10XB, at the respective magnifications of 635× and 1,053×, with actual magnifications indicated on the accompanying scales. Note complicated and irregular, although even, cone pattern of triply intercrossing rows, with a gradual increase of cone diameter from the center (*left ends*) to the foveal periphery (*right ends* of photos), the gradual increase to right being caused partly by a lower level of the plane of cutting, closer to the base of the cones; few larger and darker cones are those with ectopic nuclei displaced into bacillary layer *2-b*. The much smaller rods appear at first singly between the large cones, gradually appearing in pairs and further increasing in number toward the periphery of central fovea at the right end of the photos (continued in subsequent three figures).

These dimensions of the smallest physiological units harmonize well with the *minimum visibile* of 16".5 to 21" in the Monkey, as found experimentally (Klüver 1933, pp. 230, 231).

The diameter of the inner segments of the central cones, on which the "grain" of the cones and hence the visual resolution depend, was variously estimated by preceding investigators, the given values exceeding more or less considerably the figures given above. These figures, in microns, are: M. Schultze 2–2.5 (Man), 2.8 (*Macaca cynomolga*); H. Müller 3 or less (Man); Koelliker 3 (Man); Merkel 3 (Man); Krause 3 (Man); Kuhnt 2–2.5 (Man); Wadsworth 2.5 (Man); Koster 4.4–4.6 (Man); Schaper 2 (Man); Welcker 3.1–3.6 (Man); Greeff 2.5 (Man); Dimmer 2.3–2.5 (Man); Bird & Schäfer 2.1 (Man); Fritsch 1.5–1.8–4.5–6 (Man); Heine 4 (Man); Rochon-Duvigneaud 1.5–2–2.5 (Man); Henle 2 (Man); Wolfrum 1.2 (Rhesus Macaque); Kolmer 1.5 (*Macaca nemestrina*); Neumann 1.7 (Rhesus Macaque), 1.5 (*Cercoce-*

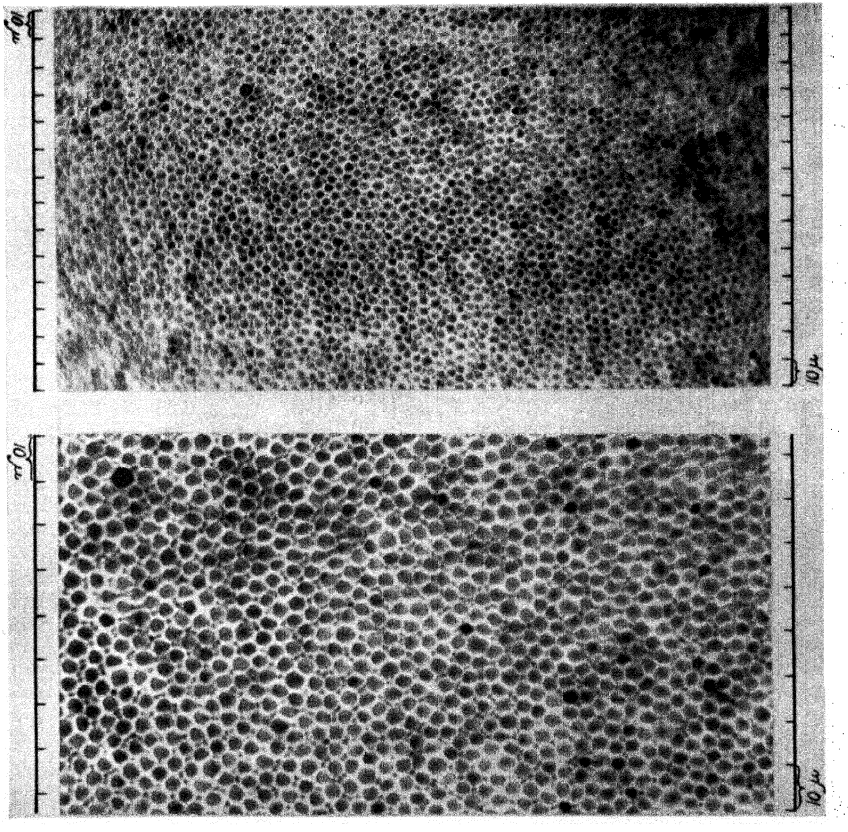

FIG. 158.—Microphotographs of a flat section of an adult retina of a Rhesus Macaque stained with hematoxylin and phloxin, showing a belt of photoreceptors from the foveal periphery outward to that shown in the preceding figure. Same technique and magnification used. The number of dotlike rods has increased considerably, now appearing frequently in pairs, or in short chains or groups of threes or more, although the total distribution pattern is remarkably uniform in spite of the irregularity of the detail. Most cones (*larger structures*) still adjoin their neighbors directly, with a few darker ectopic nuclei found here and there. (*Cf.* preceding and following figures.)

bus torquatus atys); Polyak 2.3–3 (Rhesus Macaque), 1.2–1.5–1.8 (Man), 0.3–0.4 (Golden Eagle, central fovea), 1 (Golden Eagle, temporal fovea); Hartridge 2 (Man, cone diameter), 3–4.1 (Man, intercenter distance).

6. INNER LAYERS OF CENTRAL FOVEA.—The structure of the retinal tissue in and around the central fovea is dominated by the formation of the foveal excavation, a process which takes place during the phylogenetic and ontogenetic development. The mechanism by which this is accomplished is a lateral displacement, from the center toward the periphery, of the various histological elements, such as the bipolars, horizontal cells, amacrines, and ganglion cells. The result of this is a reduction in thickness of the inner layers below the photoreceptor layer, small in the periphery of the fovea and maximal in its center (Fig. 129, *I, A;* and Fig. 161).

In the human fovea the lateral displacement begins in the outer nuclear layer (*4*), here made up entirely of cone nuclei, and progresses in the successive inner layers (Fig. 161, lower sketch). In the very center only two or three somewhat scattered tiers of cone nuclei remain, whereas away from the center the cone nuclei increase to a dozen or so rows, the greatest accumulation in the entire retina being found here.

In the center of the simian fovea (Fig. 129, upper sketch) this thinning of the outer nuclear layer is only slightly indicated, or, speaking phylogenetically, the center of the simian fovea shows merely an incipient process of rarefication of the outer nuclear layer. In the Tarsier the greatest accumulation of the outer nuclei is precisely in the very center of the fovea (Fig. 512).

The outer fiber layer of Henle (*5-a*) composed of inner cone fibers, both in Man and in Monkey, is likewise quite thin in the very center. Its fibers are swept aside as if pulled by centrifugal force. The middle zone (*5-b*) and the inner zone (*5-c*) of the outer plexiform layer, representing synapses of the foveal neurons, are entirely pulled away from the center, more completely in Man than in the Monkey, thus forming the floor of the fovea, or foveola. Here only a few scattered nuclei belonging to the inner nuclear layer (*6*) and an occasional ganglion cell remain as a residue of the inner layers. As a result, almost all structures between the inner limit of the outer nuclear layer (*4*) and the transparent vitreous which fills most of the eyeball are removed, almost completely in the very center and decreasingly so toward the periphery of the foveal excavation.

The importance of this arrangement is discussed under paragraph 7, following. Here it suffices to point out that, in forming the foveal excavation, the synaptical relations between the three categories of conducting neurons (the photoreceptors, bipolars, and ganglions) are as fully preserved as if the arrangement had remained vertical, as it originally was and remains in most of the extrafoveal regions of the retina. The preservation of the original synaptical relations is made possible by the slanting course taken by fibrous elements, in the primate fovea chiefly those of the rods and cones (in *4* and *5-a*), and to a lesser extent also the bipolars and ganglions, in the fovea of Birds and Lizards of all three elements.

The outer nuclear layer is remarkable precisely in the foveal center. Whereas in the extrafoveal regions, including the extrafoveal portion of the central area, the cone nuclei form a single discontinuous row immediately beneath the outer limiting membrane, *3* (thus in *II VI*, in Fig. 129; *see also* zone *4-a* in Figs. 127, 128), this zone is greatly augmented in the center of the foveal excavation, in conformity with the greatly increased number of cones precisely in this territory. In the flat foveal floor of a Rhesus Macaque there are from seven to eight tiers of cone nuclei. In the periphery of the human outer fovea, from eight to ten tiers may be counted. In the very center, exactly beneath the "bouquet of central cones," their number in Man is again reduced to about two or three rather loose rows.

In the territory roughly corresponding to the central locality, all outer nuclei belong to the cones. Here the photoreceptor layer (*2*) is greatly thickened and made up exclusively of cones, the "outer fovea." This central territory coincides with the rodless area. In the human fovea the rodless portion of the outer nuclear layer measures at least 500 microns across, being somewhat more extensive than the floor of the foveal excavation (Fig. 161). In the Rhesus Macaque the most centrally located rod

nuclei also invade the periphery of the augmented central portion of the outer nuclear layer, considerably restricting the extent of the central rodless area (Fig. 129). In the Philippine Tarsier, a nocturnal Primate, all nuclei in the central fovea belong to the rods (*see* chap. XIV, 12, and Fig. 512).

The factors causing the displacement of cells and fibers from the center, which results in the formation of the foveal excavation, remain unknown. It is more than a guess that they are not purely mechanical but are rather combined biochemical, biophysical, and "dynamic" processes which it is not possible further to define at present. The formation of the foveal depression is apparently a result of the natural forces that make living things grow and, for the present, is as much of a mystery as the factors that make a

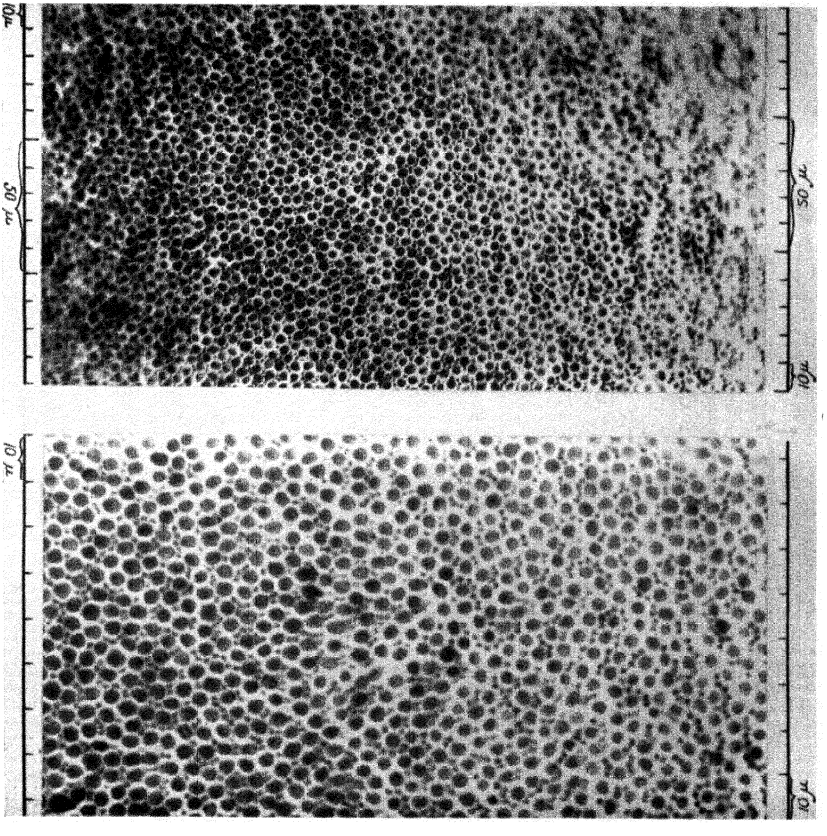

FIG. 159.—Microphotographs of a flat section of the retina of a Rhesus Macaque prepared with the same technique as the preceding photos, showing the photoreceptor mosaic from a circular belt encircling the one presented in the preceding figure, corresponding to the periphery of the central fovea. The cones have further increased in diameter, and the more numerous rods have taken up much of the intervening space, in places encircling individual cones almost completely, with numerous cones, however, still adjoining their neighbors directly. The plane of the cutting at the right end of the lower photo is somewhat higher in the bacillary layer, passing through the cones where they begin to taper, leaving more intervening space between the individual cones. The few cones stained dark are those containing ectopic nuclei. Magnification same as in preceding figure, actual magnification in microns indicated on the accompanying scales. (*Cf.* preceding and following figures.)

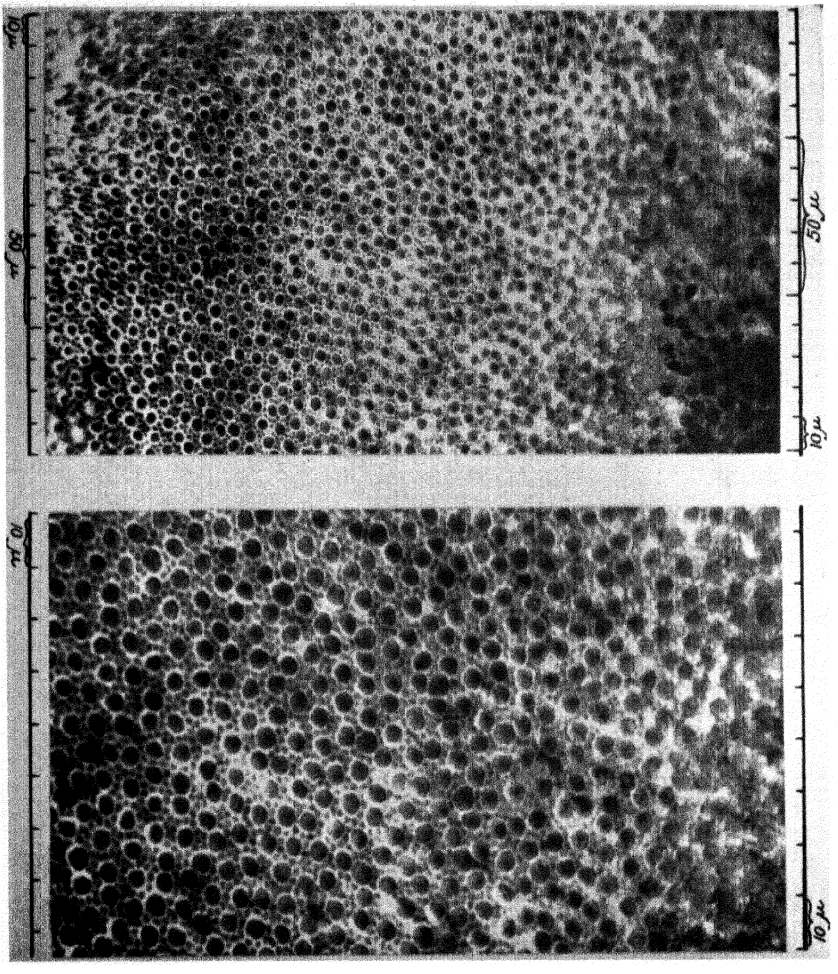

FIG. 160.—Microphotographs of the same series as the preceding photos of flat sections of the retina of a Rhesus Macaque from a locality 750 microns distant from the foveal center, hence just outside the foveal depression (*cf.* Fig. 129). Same technique and same magnification as in the preceding photos. The plane of the cutting at the right ends of photos passes through the outer limiting membrane, in the center of photos through the inner segments, and at the left end of the photos through the outer segments of the photoreceptors. Actual magnifications indicated on the accompanying scales. In this locality of the central area the cones are much stouter, possess smooth, round, or oval contours because here they are not pressing against one another as they do in the central rodless area and are not arranged in very distinct rows. Most of the cones are now encircled by a row of rods, which in places increases to two rows. In other instances the cones still adjoin their neighbors directly along one or the other side, which makes their intercenter distance shorter. Occasionally three or more cones touch one another directly with one of their sides, producing short chains. The rods also increase their diameter in comparison to the thin, most centrally located rods next to the central rodless area in the fovea. But in spite of these slight local variations in size and distribution, the double photoreceptor screen appears remarkably uniformly organized, with no predilection for certain shapes or directions. (*Cf.* preceding figures.)

fertilized ovum or a seed develop into a complex living animal or a plant made up of a multitude of variously differentiated tissues, forming a harmonious whole.

7. FUNCTIONAL SIGNIFICANCE OF FOVEAL DEPRESSION.—From the preceding it is fairly evident that whatever the unknown factors of phylogenetic and ontogenetic mechanics and dynamics involved in the formation of the foveal depression are, the removal of most of the nervous and supporting structures and of most blood vessels from in front of the photoreceptive bacillary layer serves the dioptrical purpose of the eye admirably (Figs. 125, 126, 129, *I*, *A*, 161).

Even though all these structures of the inner layers are normally highly transparent during life, they represent an appreciable dioptrical impediment. The countless irregularly curved surfaces formed by the walls of cell bodies and of their innumerable processes, all of different sizes and undoubtedly of different coefficients of refraction, each acting as a minute lens of different power, taken together form an optical labyrinth in which passing rays of light are multifariously deflected, diffracted, and deviated from their theoretical rectilinear course. That such interference, even though it be relatively slight, would perceptibly reduce the sharpness of definition of the visual image in the layer of photoreceptors of the central fovea, where the need for precision is greatest, is evident. Teleologically, it was in order to avoid this, and not for the purpose suggested by Walls (1937, 1940, 1942), that the foveal excavation was formed by the lateral displacement of optically undesirable inner layers which would otherwise screen off the photoreceptors.

The vertical arrangement of cones in the central area and fovea, as well as in the remainder of the retina, substantiates the foregoing interpretation. If the refractive function of the slanting slopes of the foveal excavation was to increase the size of the foveal image, as suggested by Walls, it would, first, be entirely annulled by the vertical position of the photoreceptors in the bacillary layer, and, second, the increased image area would counteract the resolving power of the foveal photoreceptors, the very purpose for which the diameter of these photoreceptors was reduced to the minimum. Besides, the large size of the flat foveal floor directly contradicts Walls's hypothesis.

The effect of the displacement of the inner layers in the foveal excavation is obvious: a greatly thickened, but spatially delicately organized, bacillary layer of the axial photosensitive cones, as it were, becomes exposed to the undiminished action of light. Above all, this arrangement permits the maximum advantage to be taken of the biologically superior property of "light," viz., its propagation in straight lines. (*See* chap. VI, 2 [2, 3, 4] on the arciform course of fibers in the primate central area, teleologically serving the same purpose by removing the thick fiber bundles from the axial portion of the retina.)

8. STRUCTURAL FEATURES OF EXTRAFOVEAL REGIONS.—The extrafoveal, especially the extra-areal, regions of the primate retina, in contrast with the central fovea and area, are structurally uniform. From the fovea on, the basic architecture of the membrane becomes imperceptibly cruder until in the region of the *ora serrata* it is confused and partly lost (Fig. 129, *VI*).

The most prominent feature of that extensive territory is the presence of both kinds of photoreceptors, rods and cones. Their relative number, however, changes but little. In the vicinity of the fovea, both in Man and in Monkey, there is usually only one rod interposed between two adjoining cones (*II*, in same figure).

In the periphery of the central area two rods separate the cones (*III*). Outside the central area the number of intercalated rods increases to three, or not more than four; this ratio remains constant as far as the *ora serrata* (*IV*, *V*, *VI*).

The thickness of the inner cone segments gradually increases from 4 to 5 microns in the vicinity of the fovea to 5 or 6 microns just outside the central area, and to 7, 8, and, finally, 9 microns close to the *ora serrata*.

The distance between the two adjoining cones also widens from 1–3 microns near the fovea to from 3 to 5 microns in the areal periphery, slowly increasing from 6 microns just outside the area to 8 microns close to the *ora serrata*.

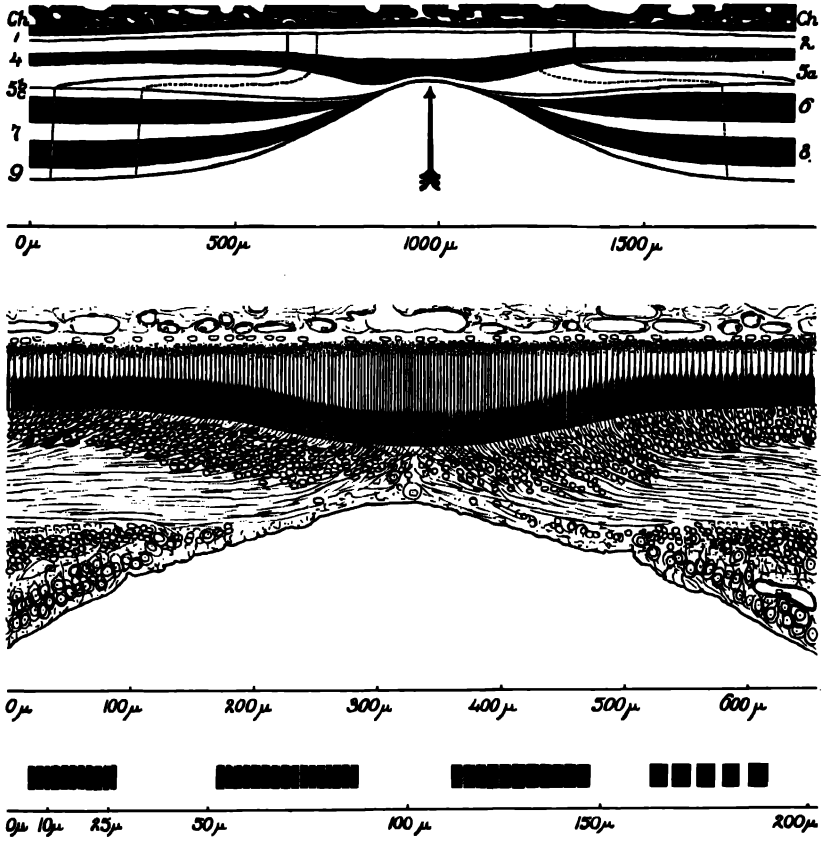

FIG. 161.—Central fovea of human retina. Upper sketch shows semidiagrammatically, in a vertical section, the shape of the central fovea, the arrangement and relative thickness of layers, and the anatomical and synaptical relationships of photoreceptor layer *2* and the outer nuclear layer *4* to the subjacent layers *5–9*. Broken lines in layer *2* indicate the most centrally located rods, their nuclei in layer *4* marked with white dots, the region thus bounded indicating the central territory free from rods—the rodless area. Solid lines in *2* mark the territory of lengthened photoreceptors, called "outer fovea," mostly filled with greatly lengthened and thinned-out central cones. Note synaptical relationship of this outer fovea to the much larger inner fovea, a pit caused by a lateral displacement of all layers below *5-a*. The middle sketch shows the actual structural composition of the deepest portion of the foveal pit. Note the length and thinness of the central cones, their points reaching into the pigment layer. Layer *4* is made up entirely of cone nuclei (*circles*), the few rod nuclei (*shaded*) appearing only outside the outer fovea. In the very center, all layers below *4* are either absent or greatly reduced in thickness, this layer itself being much thinned out, thus facilitating the unimpeded passage of light rays to the photosensitive cones (the course of light from the pupil indicated by an arrow in the upper sketch). Lower sketch shows the relative size and number of cones, from the center of the fovea (*left*), the slope and edge of the outer fovea, and the periphery of the central area (*right*). The accompanying scales indicate actual dimensions in microns. *Ch*, chorioid membrane. (*Cf.* Fig. 512 showing central fovea of a Tarsier containing exclusively rodlike photoreceptors.)

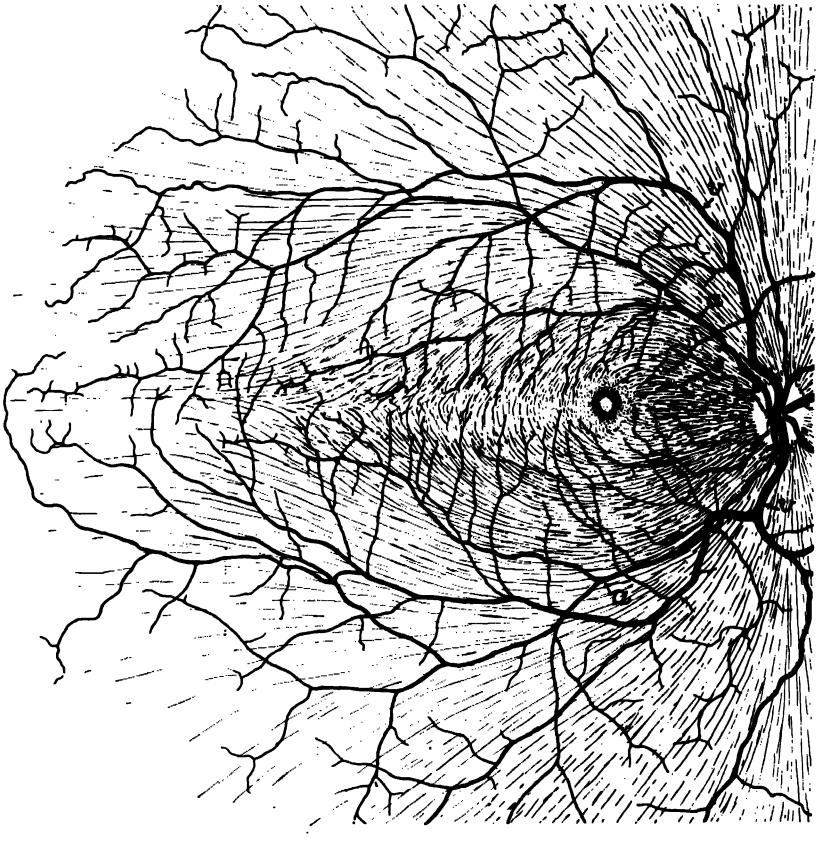

FIG. 162.—Fundus or inside appearance of the right eye of a Rhesus Macaque drawn from a whole-mount preparation of the retina stained during life, or intravitally, with methylene blue. Close to the right margin is the oval optic disk or papilla. From it emerge central retinal blood vessels, the thinner arteries (*a*), and the thicker veins (*v*). These spread in all directions over the retina, repeatedly dividing into smaller branches which ultimately form a continuous capillary network (not seen here, *cf.* colored Fig. 364). This network supplies the layers of the retina inward to the inner plexiform layer, whereas the outer layers are supplied by osmosis via the chorioidal system (colored Fig. 365). The arrangement of blood vessels varies in different parts. In the nasal half of the fundus, not included in this figure (at the right end), vessels radiate from the disk, like the spokes of a wheel. In the larger temporal half of the fundus shown here, the vessels arch above and below the central area of the retina in order to leave it relatively free. Especially is this the case with the central fovea, whose floor, inclosed by a stippled circle, is entirely free from blood vessels, including capillaries. In this way most structures which would impede the free access of light rays to the central foveal photoreceptors are removed (*cf.* Figs. 129, 161). The optic nerve fibers, arising from retinal ganglion cells, indicated by thin, smooth lines in the figure, gather from all points of the fundus toward the optic disk, where they leave the eyeball and form the optic nerve. Their arrangement is similar to that of the blood vessels. They, too, and for the same reason stated above, part above and below the central fovea and area. The line along the horizontal meridian, from the fovea to the temporal margin (*left* in the figure), called *raphé* or "seam," indicates the partition. This line is important for the understanding of the genesis of quadrantic scotomas and hemianopias and for the so-called macular sparing in visual field pathology. (*Cf.* chap. XI, 8, 9.)

The thickness of the rods likewise increases from approximately 1–1.5 microns in and close to the central fovea to 2 microns just outside the central area, and to 2.5 microns and, finally, to 3 microns in the extreme periphery.

The numerical maximum of rods in Man is attained in a belt just outside the central area, approximately 4 mm. distant from the fovea. In the Rhesus Macaque the maximum has already been attained in the periphery of the central area, and it so remains for a short distance outside it.

Other layers also show a proportionate roughening toward the *ora serrata* or *ora terminalis*, where, both in Man and in the Simians, large vacuolar spaces are found. All this, in physiological terms, means a roughening of the function, especially of visual space perception or acuity, outside the central fovea, which, together with the added factor of polysynaptical relationships, further decreases the number of physiological units toward the periphery of the field of view.

SEC. 11. REGIONAL AND COMPARATIVE CHARACTERISTICS OF THE VERTEBRATE RETINA

1. Discovery of yellow spot and central fovea. – The fact that the retinal membrane was not of identical construction in all its parts and that various species of Vertebrates possess peculiarities of their own was recognized relatively late. True, the local peculiarities, either

actually observed or merely assumed, were discussed quite early. Kepler (1604 and later), on theoretical grounds, postulated a more perfect structural organization of the retina in the fundus of the eye than in the parts closer to the *ora serrata*. Valsalva, Morgagni, Briggs, Zinn, and Fontana all described the characteristic fanlike arrangement of optic nerve fibers in the Rabbit and the Hare, while Maître-Jan noticed that the retina was thicker close to the optic papilla than it was farther away. Other regional peculiarities had been observed by Mochring, Lobé, Hevermann, and others.

The systematic investigation of the regional characteristics of the retinal membrane began with the discovery of the "yellow spot," the *macula lutea* or *macula flava*, and of the "central depression" or "central pit," the *fovea centralis*, by Buzzi (1782, 1784) and by S. Th. Soemmerring (1795, portrait Fig. 37). At first, however, both the structure and the function of this most important area of the retina were misunderstood. Soemmerring, for example, thought that the fovea, which, because of its frail structure, can be easily ruptured during dissection precisely in the center, where it is thinnest, was a hole, perforation, or orifice and named it *foramen* or *foraminulum centrale*. He thought that it was responsible for Mariotte's "blind spot" in the field of vision.

For more than four decades this "central orifice," together with the *plica transversa* or

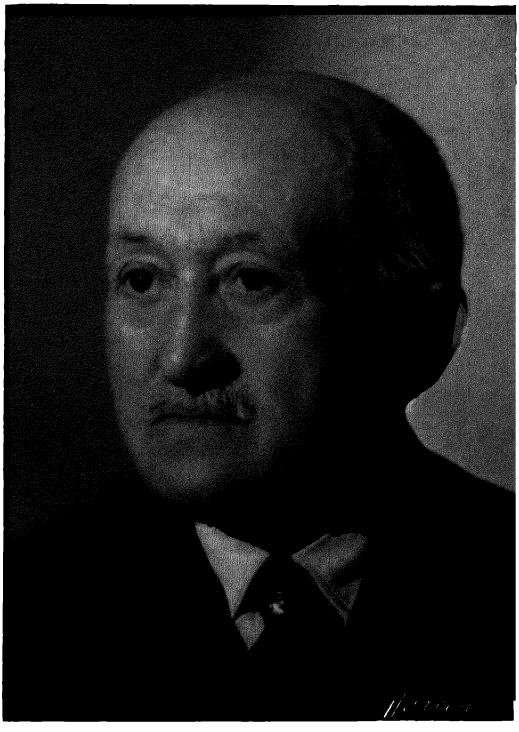

FIG. 163.—André Rochon-Duvigneaud (1863), eminent ophthalmologist of Paris, France, and a lifelong student of the vertebrate eye. Author of numerous papers and monographs on the structure of the eye, and of the book *Les Yeux et la vision des vertébrés*, Paris, 1943. Courtesy of Professor A. Rochon-Duvigneaud.

centralis retinae, a "transverse or central fold," were looked upon as normal retinal structures and were thus described and depicted by F. Arnold (1839), until both were finally recognized as artifacts and post mortem changes. But not until G. A. Michaelis (1838) and especially Bergmann (1854) and H. Müller (1856–57) correctly described and interpreted the peculiar structural features of the central fovea, was the true functional significance of this area as mediator of "central" or direct vision understood and recognized; and not until then were the various erroneous interpretations by Johannes Müller, Home, Blumenbach, Berres, Desmoulins, and others done away with. (*Cf.* sec. 9 [3, 4, 5, 6, 7], this chapter.)

2. Discovery of the arching course of nerve fibers in the human retina.—The peculiar arrangement of the optic nerve fibers in the human retina, circling from above and from below around the fovea, discussed in detail in chapter VI, 2 (2, 3, 4), was first described by W. C. Wallace (1836) and was later confirmed by a number of investigators (Dogiel 1892; Greeff 1900; Koelliker 1854; Koelliker & Müller 1853; Koeppe 1920, 1937; Kolmer & Lauber 1936; C. Krause 1842; W. Krause 1895; G. A. Michaelis 1838–42; Michel 1874; S. Pappenheim 1842; Schwalbe 1874, 1887; A. Vogt 1921, 1937; and others).

Fig. 164.—Gordon Lynn Walls (1905), professor of physiological optics and optometry, University of California at Berkeley, California. One of the most proficient and assiduous modern investigators of the vertebrate eye. Courtesy of Professor G. L. Walls, 1947.

The ophthalmoscopic appearance of the human fundus was much studied by clinical oph-

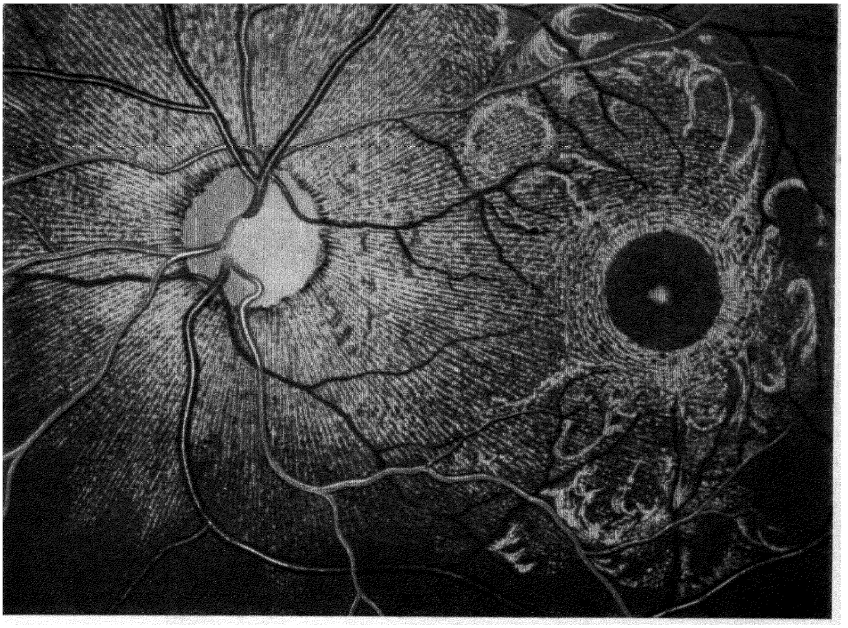

FIG. 165—Fundus or interior of the left eye of a Nubian youth aged 17. Color chocolate-brown, reflexes pronounced, extending over whole central area. Translucent bundles of optic nerve fibers can be traced for a great distance beyond the disk, with the arching above and below fovea well presented (*compare* Figs. 148, 166, 167, 168, 169, 363). Central fovea surrounded by a brilliant circular reflex ring contains a minute reflex in its center. Chorioid vessels not visible. (From G. L. Johnson, *Philos. Trans. Roy. Soc. London*, ser. *B*, vol. 194, pl. 1, year 1901.)

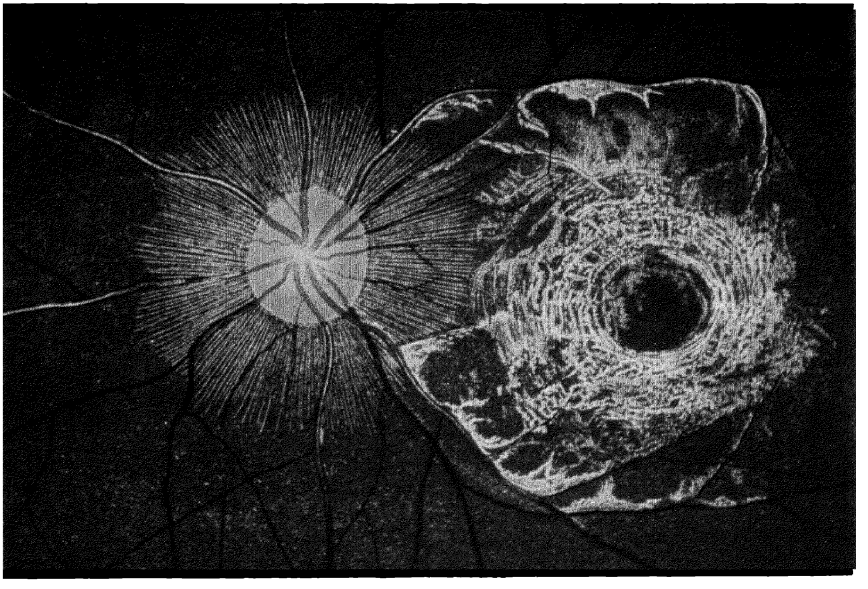

FIG. 166—Fundus or interior of the left eye of a Chimpanzee (*Troglodytes niger*), strikingly resembling that of the Nubian youth in the preceding figure. (From G. L. Johnson, *Philos. Trans. Roy. Soc. London*, ser. *B*, vol. 194, pl. 2, year 1901.)

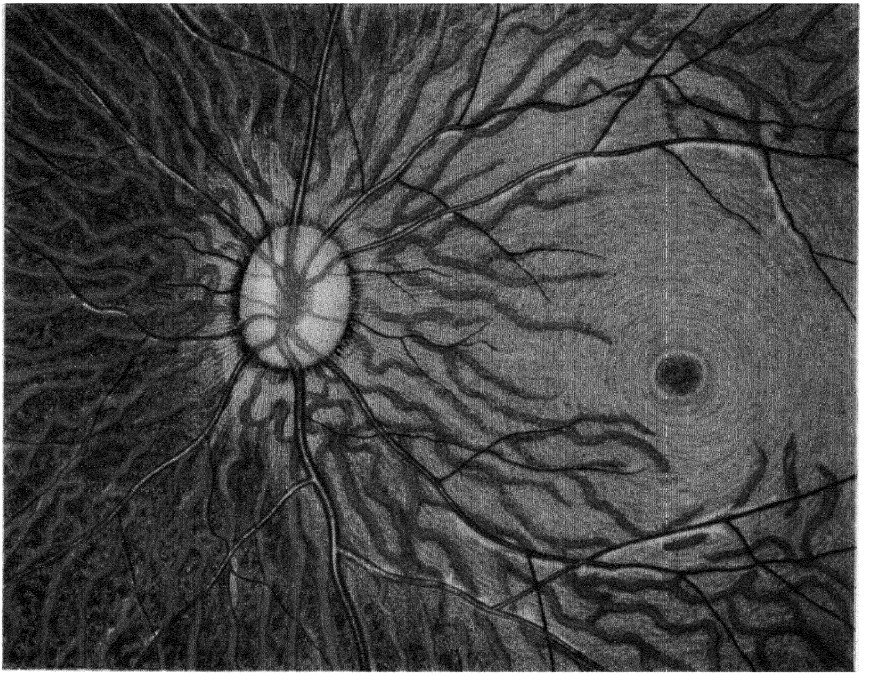

FIG. 167—Fundus or interior of the left eye of a White-Handed Gibbon (*Hylobates albimanus*). Bundles of optic nerve fibers and reflexes prominent. Foveal excavation small. Brown chorioidal stroma covered with black dots can be seen outside the central area where it is obscured by reflexes. On all sides bifurcating chorioidal vessels radiate from the disk ; these can be traced to the periphery. (From G. L. Johnson, *Philos. Trans. Roy. Soc. London*, ser. *B*, vol. 194, pl. 2, year 1901.)

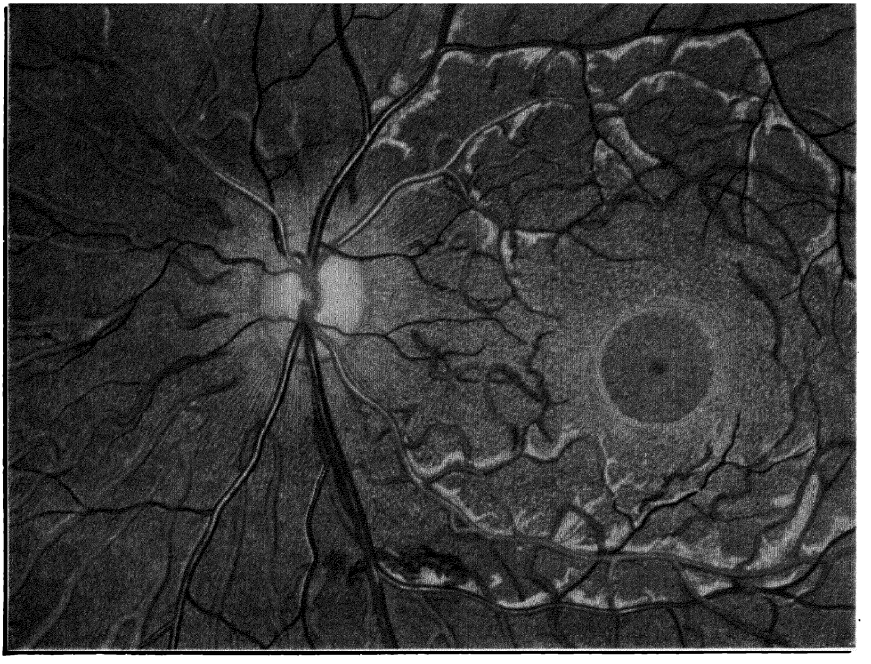

FIG. 168—Fundus or interior of the left eye of a Java Macaque (*Macacus cynomolgus*). The background is without dots, and the chorioidal vessels are arranged as in the Gibbon, being much fewer in number, however. The central fovea resembles human fovea. (From G. L. Johnson, *Philos. Trans. Roy. Soc. London*, ser. *B*, vol. 194, pl. 3, year 1901.)

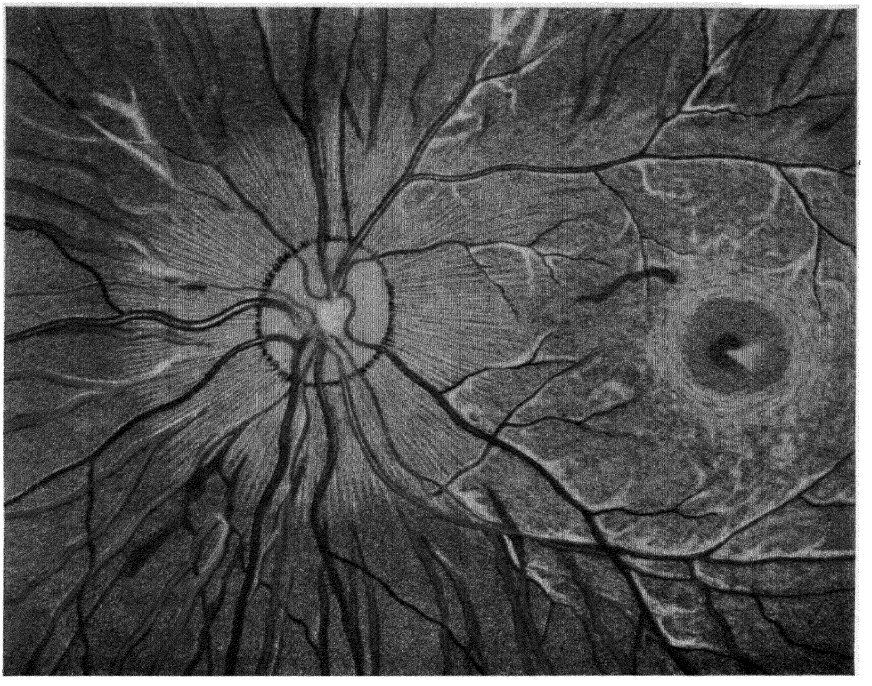

FIG. 169—Fundus or interior of the left eye of a Black-Headed Spider Monkey (*Ateles geoffroyi*), closely resembling that of the Java Macaque. (From G. L. Johnson, *Philos. Trans. Roy. Soc. London*, ser. *B*, vol. 194, pl. 4, year 1901.)

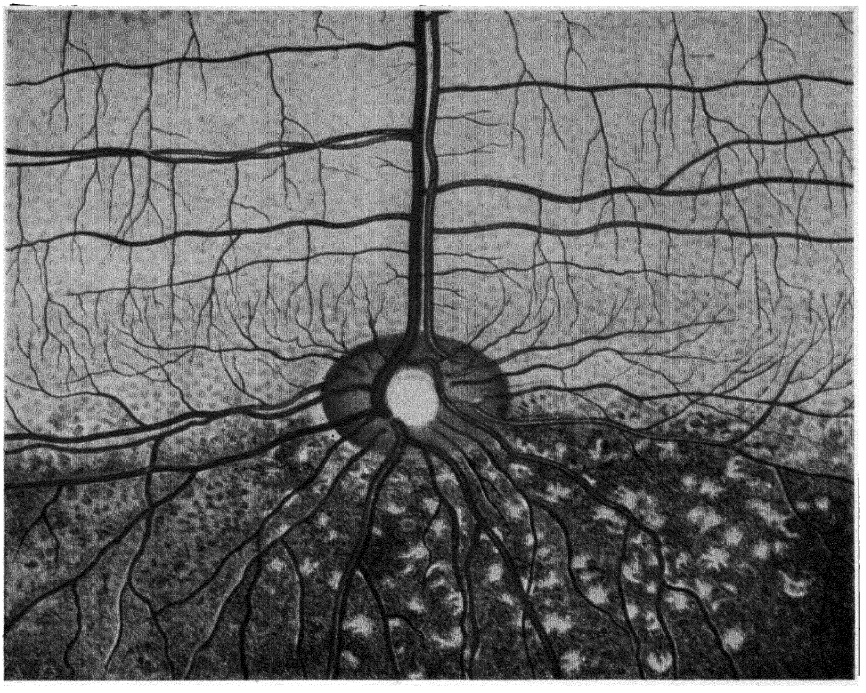

FIG. 170—Fundus or interior of the eye of an Indian Ox (*Bos indicus*), representative of nearly all Ruminants. Papilla is large and horizontally oval, with a central circular depression. From the papilla arise numerous arteries (bright red) and veins (dark red). Principal artery and vein run straight up, giving off strong secondary branches running horizontally. From these numerous smaller twigs descend to a broad, rose-colored, horizontally placed central area, instrumental in acute vision. This area they supply conjointly with other numerous vessels coming from below partly directly from the papilla, and partly arising from larger vessels spreading over lower region of the retina. Lighter colored upper segment of the fundus sharply terminating just below the band-like central area contains so-called *tapetum lucidum* (*t. fibrosum*), a specially constructed tissue layer of the chorioid membrane which reflects light and makes "shining eyes" in nocturnal animals. (From G. L. Johnson, *Philos. Trans. Roy. Soc. London*, ser. *B*, vol. 194, pl. 12, year 1901.)

thalmologists and was later well presented by A. Vogt (1918, 1921), Wilmer (1934), Atkinson (1937), Di Marzio (1937), and Clerici (1943) (for history *see* Rucker & Keys 1950). The eye fundus of the Primates and of numerous other Mammals and Submammalian Vertebrates was well described and beautifully illustrated by G. L. Johnson (1894, 1896–97, 1901, 1927), and in Birds by C. A. Wood (1917). (*Cf.* Figs. 148, 165–69, 172–76.)

3. Comparative studies of central fovea and yellow spot in Man, Apes, and Monkeys.—After the great functional importance of the central fovea and its vicinity was recognized, much attention was paid to it by investigators. Its exact location, size, shape, and other details were studied, and the various light reflexes seen with the ophthalmoscope were noticed; also the extent and other peculiarities of the pigmented yellow spot were described (Dimmer 1907; Holm; Johnson 1892, 1894, 1896–97, 1901; Kreiker 1930; Kühne 1878; Landolt; Leber 1880; Merkel 1869; P. Michaelis; H. Müller 1856 57; Reil 1797; Rollet & Jacqueau; Schirmer 1864; Schmidt-Rimpler; M. Schultze 1866; Wadsworth; Welcker).

The presence of pigmentation in the yellow spot during life was a much debated topic. While accepted by most (Chevallereau & Polack; Ewald; Hoeve 1912; Holm; E. Home 1798; Kolmer & Lauber 1936; Kühne 1878; Riccò; Walls & Judd), it was considered by others to be a post mortem phenomenon (Gullstrand; Nordenson & Nordmark), until it was demonstrated ophthalmoscopically in the living, with the help of red-free light (Koeppe 1918, 1921, 1937; A. Vogt 1918, esp. Pl. 1; also 1921, 1937). A large yellow spot was found in the Tarsier (Fig. 149).

In modern times the central area and fovea were intensively studied. Both, without exception, are present in all Monkeys and Apes, diurnal as well as nocturnal (Figs. 149, 166–69). The size and shape of the fovea, however, vary considerably in different species. The same is true of the structures, especially the cones. The most delicate cones so far have been found in the foveal center in the African Mangabeys (Kolmer 1930). The few nocturnal Primates, such as the South American Three-banded Night Monkey or Douroucouli (*Nyctipithecus* or *Aotes trivirgatus*) and the Asiatic Tarsier (*Tarsius spectrum*), have been considered by most investigators, including modern ones, as having no fovea (M. Schultze, Woollard, Detwiler). However, L. Johnson (1901), a reliable observer, found ophthalmoscopically a well-formed macula in the Night Monkey. A rudimentary fovea was described by Kolmer (1930) in the Three-banded Douroucouli (*Nyctipithecus* or *Aotes trivirgatus*) which was missed by M. Schultze (1872) in the kindred Feline Douroucouli (*Nyctipithecus* or *Aotes felinus*).

In the Philippine Tarsier (*Tarsius carbonarius* or *philippinensis*) Dr. F. S. Ryerson, then assisting the author, found in ophthalmoscopic examination in red-free light a large, yellow-pigmented "macula," with a small fovea and the typical arching arrangement of optic nerve fibers and blood vessels characteristic of all Primates, except the Tree Shrews (*see* Fig. 149; *cf.* also chap. XIV, 12 [9]).

A microscopic examination of sections of the retina of the Tarsier revealed in the corresponding locality a small, shallow, but typical and otherwise well-developed, central fovea in the central area. It was surprising to find in the Tarsier's fovea, including the very center, typical rods, present here as in the rest of the retina, to the complete exclusion of the cone type of photoreceptors: a pure rod retina (Fig. 512).

A well-formed fovea and central area, with an arching arrangement of blood vessels, was also found in a specimen of a Three-banded Night Monkey. (*Cf.* Detwiler 1940, 1941, 1943; Home 1798; Johnson 1901; Kolmer & Lauber 1930, 1936; Menner 1931; Neumann; Max Schultze 1872; Woollard 1927; *see also* chaps. X, 2 [3]; XIV, 12.)

4. Central area and its relation to fovea.—In numerous Vertebrates below the Primates H. Müller (1861) found in the axial region of the retina, instead of a foveal depression, merely an accumulation and a general refinement of photoreceptors and nerve cells, which he called "central area." This especially differentiated area is apparently a forerunner in the process of structural and functional perfection of the axial region which eventually culminates in Primates, many Birds, Lizards, and

Fishes in the formation of a true foveal depression.

In species where a foveal excavation is present, it is practically always found in the central area, as is regularly the case in the Primates.

A fovea without an areal development, according to Kolmer, seems to be present rarely, if ever (Swallows, Kingfishers). A contrary arrangement, a central area without a fovea, has been found in the representatives of all five classes of Vertebrates: Fishes, Amphibians, Reptiles, Birds, and Mammals.

Not all species of a class or an order, but only those with well-developed sight, also have a foveal excavation. Still others which depend little upon sight have neither an area nor a fovea.

In Mammals, which, except for the Primates, have been investigated little, the structural perfection of the axial region of the retina is usually only slight, being expressed merely in a more or less pronounced refinement of the photoreceptors, a moderate accumulation of nerve cells, and the arching course of the blood vessels.

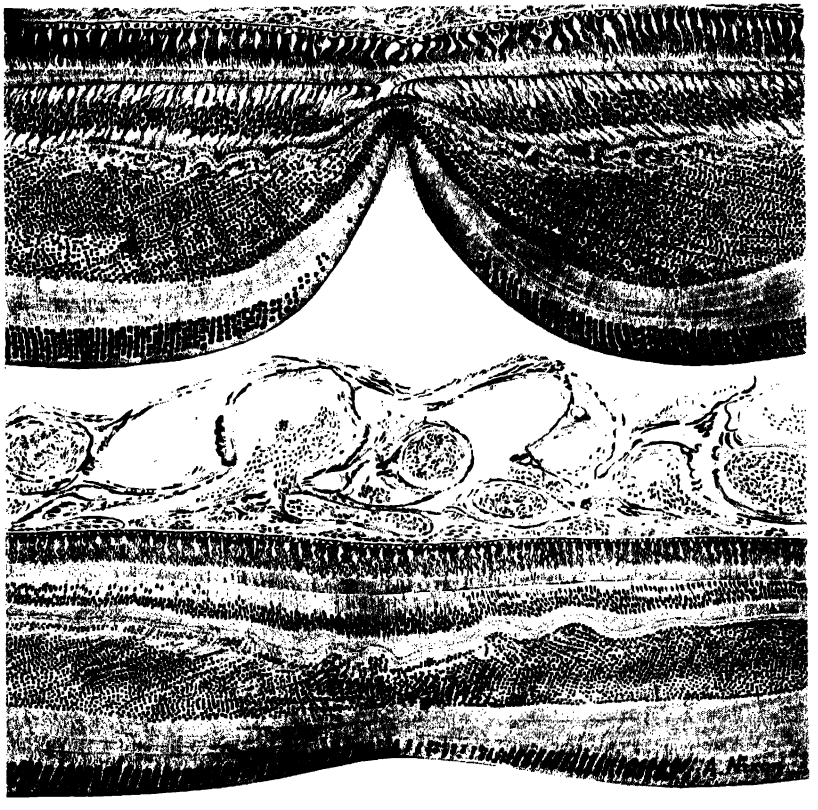

FIG. 171.—Upper figure shows a vertical section through the deep, funnel-shaped central fovea of an American Golden Eagle (*Aquila chrisaëtos*), the lower figure showing a shallow but wider lateral or posterior fovea of the same species. The first is believed to be used independently while in flight by this eminently keensighted bird of prey when scanning the country for prey, the second being used together with the lateral foveæ of the opposite eye in binocular estimating of the distances, or essentially in stereoscopic vision. Approximate magnification 150×. (*Cf.* two foveæ in each eye of the Barn Swallow, in Fig. 469; *see also* Fig. 172.)

This arrangement is present in the Philippine Tree Shrew (*Urogale everetti*), considered now to be the lowest in the order of Primates (*see* chap. XIV, 10). In a few species investigated, such as Cat and Dog, there is also a shallow, rudimentary, or perhaps orimental fovea, associated with a typical arching course of optic nerve fibers.

In many diurnal Rodents, such as Squirrel, Chipmunk, Prairie Dog, and Woodchuck, the cone mosaic is very fine grained in an extensive territory, which may function as a fovea (Walls 1934; *see also* chap. XIV). In Ruminants there usually is a stripelike central area stretching across the retina (Fig. 170).

5. Regional structures of birds' retina. —The Vertebrates whose retina shows the greatest variety in locally differentiated structures are the Birds (Figs. 171 76). Frequently two foveae are found in each eye: a central, nasal or anterior, and a lateral, temporal or posterior, area and fovea.

In the Golden Eagle (*Aquila chrisaëtos*) the central fovea is a deep, narrow, funnel-shaped pit, the lateral fovea a shallow, wide depression (Fig. 171). In the former the photoreceptors are thinner and more numerous; in the latter, a wider area is used for sharp vision. Two foveae are typical of the diurnal birds of prey, such as the Eagles, Hawks, and their diminutive in-

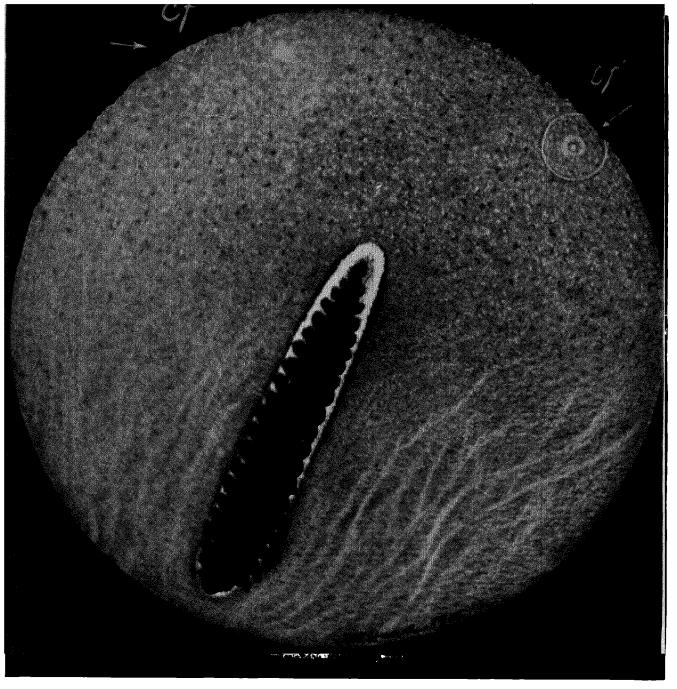

Fig. 172. Fundus of the left eye of a Bald Eagle (*Haliaëtus leucocephalus*) showing two specially differentiated localities of the retina, one a central fovea and area (*cf*) of a somewhat blurred appearance, situated left above the pecten or "comb" (black corrugated structure), and a temporal or posterior fovea and area (*tf*) to right, behind the pecten. Seen ophthalmoscopically during life, the latter structure appears as a brilliant, round, white dot surrounded by a small light-green reflex ring inclosed in a brilliant, narrow, green circle indicating the temporal area. Photo of a colored plate taken from C. A. Wood, *The Fundus Oculi of Birds*, Chicago, 1917. (*Cf.* preceding figure.)

sectivorous counterparts, the Swallows (*see* chap. XIV, 8). Here the two lateral foveae of both eyes apparently serve as an instrument in binocular stereoscopic vision, while the central foveae function independently.

The avian visual apparatus represents a three-pronged mechanism with three visual axes—a common binocular axis directed forward and two monocular axes on the sides, the "visual trident" of Rochon-Duvigneaud (*see also* Alaerts; Best 1930; Delage; Franz 1934; Portier; C. A. Wood 1917). In other species of Birds the number, shape, size, location, coloring, and other peculiarities of the locally differentiated retinal structures vary a great deal, depending on the modes of life, and have been described in detail by a number of investigators (Chard & Gundlach; Chievitz 1891; Detwiler 1940, 1943; V. Franz; Fritsch; Hirschberg 1882; Kahmann; Kajikawa; Kolmer & Lauber 1930, 1936; W. Krause 1894; H. Müller 1863; Polyak 1941 48; Pütter; Rochon-Duvigneaud; Slonaker; Walls 1937, 1940, 1942; C. A. Wood 1917).

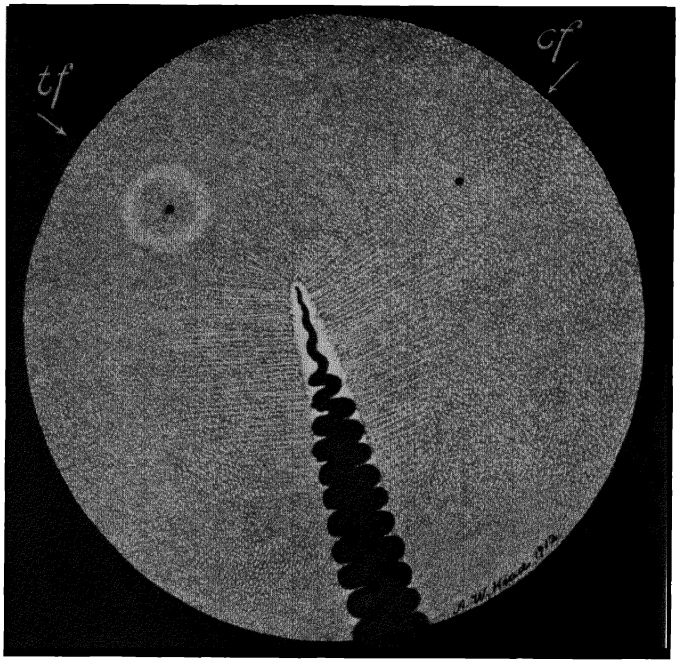

FIG. 173.—Fundus of the right eye of a European Chimney Swallow (*Hirundo* or *Helidon rustica*), identical with American Barn Swallow (*Helidon erythrogaster*), with two specially differentiated localities of the retina, both at about the same level above the upper extremity of the pecten. As in the Eagles, one is the central or anterior (*cf*) fovea, the other the temporal or posterior fovea (*tf*). In the living both foveae appear as small brown dots. The temporal fovea is surrounded by a circular light reflex made up of minute gray dots. Thin bundles of grayish, opaque optic nerve fibers radiate from the disk, to which is attached the pecten or "comb." Photo of a color plate from C. A. Wood, *The Fundus Oculi of Birds*, Chicago, 1917. (*Cf.* Figs. 172, 469.)

6. CENTRAL FOVEA OF REPTILES, FISHES, AND CEPHALOPODS.—In the Reptiles (Lizards, Snakes, etc.), in conformity with their diurnal habits, a well-developed central area and fovea are often present—for example, in the Collard Lizard, Fence Swift, Skink, Agama, Iguana, Varanus, Tuatara (*Hatteria punctata* or *Sphenodon punctatum*) and *Dryophis*.

A relatively large, pitlike foveal depression, with a smooth, gently sloping surface, is present in the American Chameleon (*Anolis virginiensis; see* chap. XIV, 7), and a slightly smaller one in the Horned Lizard (*Phrynosoma cornutum*). The sharp-sighted Chameleon probably has the most differentiated fovea of all Vertebrates, a veritable "living microscope" (Del Duca 1930; Detwiler 1938, 1940; Detwiler & Laurens; V. Franz; G. L. Johnson 1927; Kahmann; Kallgneaud; Rochon-Duvigneaud & Roule; Schiefferdecker; Verrier; Wunder). Even a Cephalopod, *Bathyteutis*, has been found in possession of a foveal formation (Chun).

7. Investigation of minute foveal structures.—The minute structure of the central area and fovea was much studied, in particular in Monkeys, Apes, and Man. Since this work was mostly done with routine, nonanalyti-

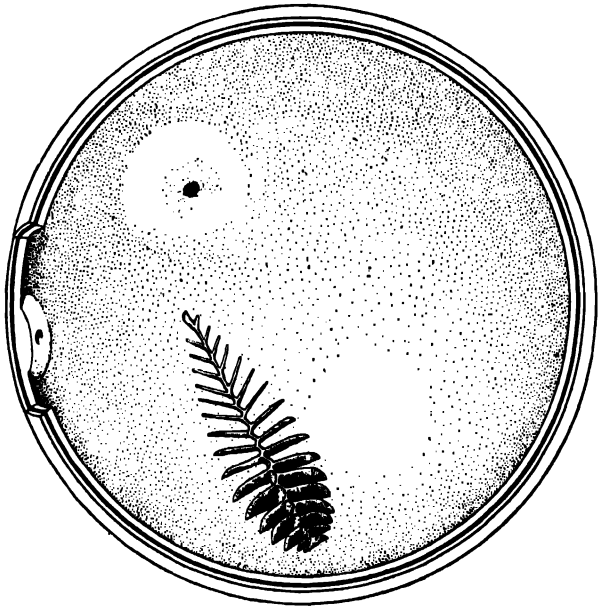

Fig. 174.—Fundus of the right eye of a British Kingfisher (*Alcedo ispida*). Example of a type of avian eye with two foveae-areae, a larger central one above the pecten and a smaller lateral or posterior fovea back of the pecten (*at left, in a cutaway*). From C. A. Wood, *The Fundus Oculi of Birds*, Chicago, 1917.

lius 1892; Knox 1823; Kolmer 1936; W. Krause; Laurens & Detwiler; H. Müller 1862; Osawa; S. Ramón y Cajal 1892–93, 1911; Rochon-Duvigneaud 1917, 1933, 1943; Rochon-Duvigneaud & Roule; Verrier 1930, 1933, 1935; Walls 1934, 1942).

Of the Fishes, practically all maritime Teleosteans have a more or less developed fovea, most pronounced in the species capable of extensive eye movements (Brauer; V. Franz; Gulliver; Kahmann; Kolmer; McEwan; Rochon-Duvical technique, important results have been obtained only with regard to the photoreceptor layer.

A systematic investigation of the synaptical relationships of neurons in the fovea and its vicinity with the Golgi method has so far been carried out only by S. Ramón y Cajal (1892–93, 1911) in the Chameleon and in some Birds, and with Golgi and Ehrlich methods in the Primates by the author of this book (Polyak 1941–48).

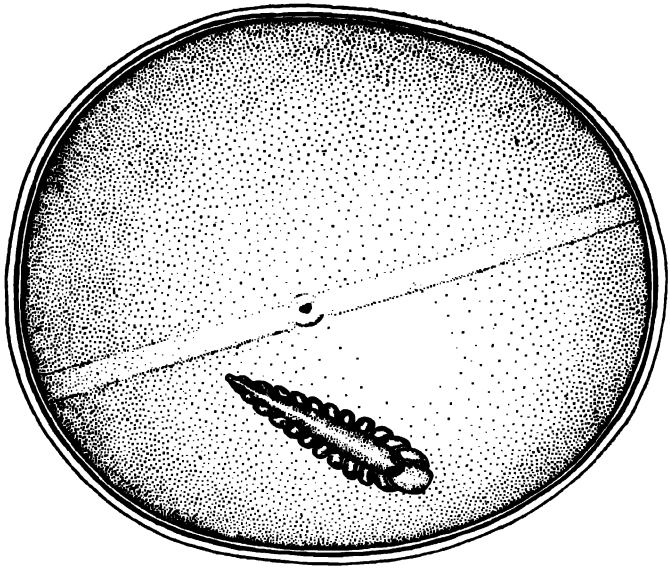

FIG. 175.—Fundus of the right eye of a Black-bellied Plover (*Squatarola squatarola*), with central fovea located within a long, narrow, stripe-shaped area or "retinal band" extending across the entire fundus. From C. A. Wood, *The Fundus Oculi of Birds*, Chicago, 1917.

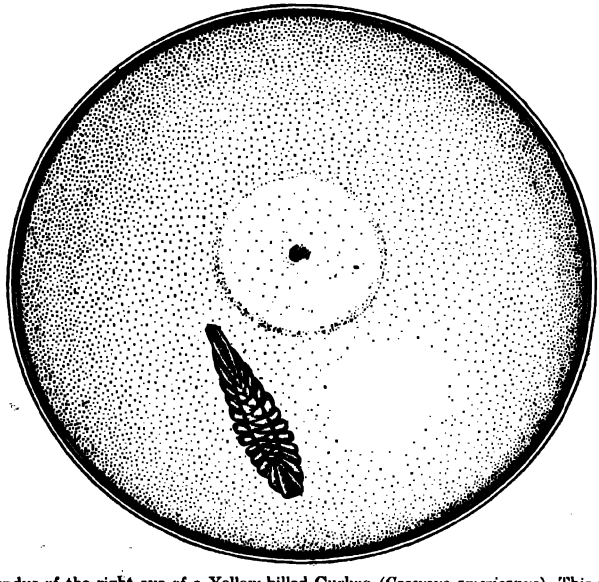

FIG. 176.—Fundus of the right eye of a Yellow-billed Cuckoo (*Coccyzus americanus*). This fundus has but a single circular and unusually large central area in front and above the upper extremity of the pecten, with a fairly spacious, funnel-shaped excavation in its center. From C. A. Wood, *The Fundus Oculi of Birds*, Chicago, 1917.

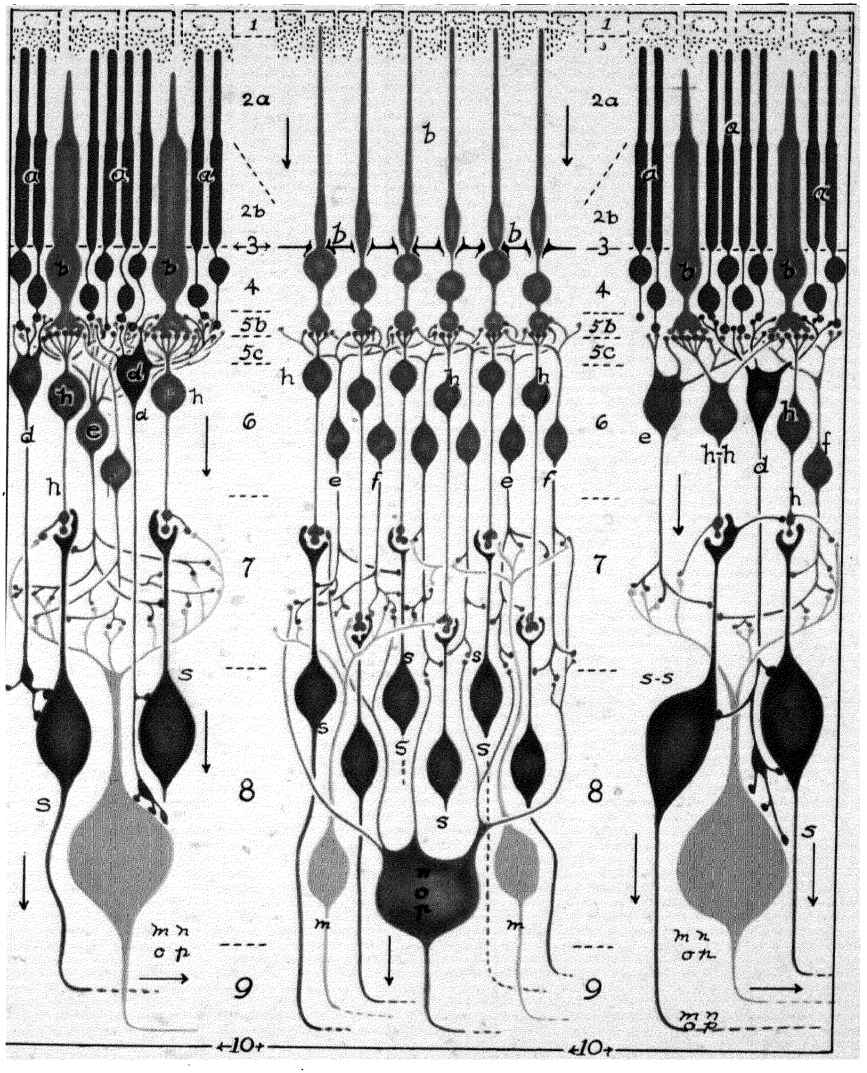

FIG. 177—General scheme of the synaptical connections of the primate retina: right and left sketches from the rod-bearing extra-foveal periphery, middle sketch from the rodless center of central fovea. Layers and zones are indicated in vertical columns separating the three sketches, with pigment epithelium (1), next to the chorioid membrane, the uppermost, and with the inner limiting membrane (10), next to the vitreous, the lowermost. *Abbreviations: a* rods; *b* cones; *d* mop bipolar; *e* flat-top bipolar; *f* brush-top bipolar; *h, h-h* midget or cone bipolars; *m, n, o, p* diffuse ganglion cells; *s, s-s* midget ganglion cells. (*Compare* Figs. 146, 147, 178, 179.)

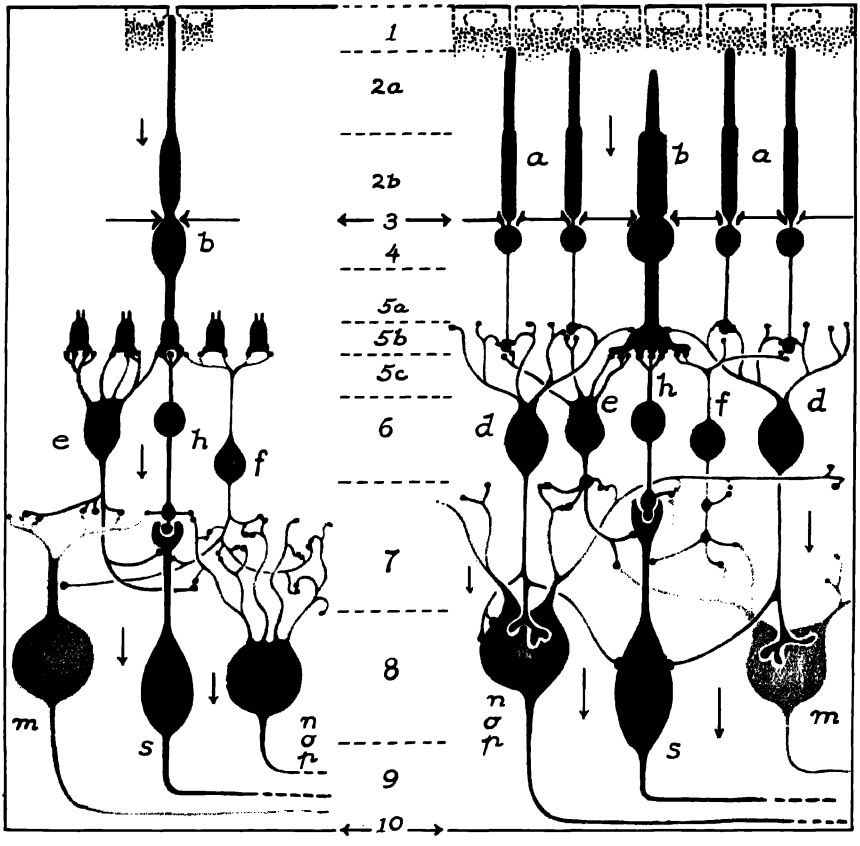

FIG. 178—Diagrams illustrating neuron constituents of the centripetal retinal pathways along which impulses are passed on to the brain, the left-hand sketch from the rodless foveal center, the right-hand sketch from the rod-bearing extra-foveal periphery. In the left-hand sketch all impulses are generated in the cones (*b*), whence they are transmitted to the bipolars and ganglion cells. Of the bipolars there are three varieties (*e*, *f*, *h*), the fourth variety (*d*) not being found here (so far). In the right-hand sketch both rods (*a*) and cones (*b*) are a source of impulses which are transmitted to all four bipolar varieties (*d*, *e*, *f*, *h*), and further to the ganglion cells (*m*, *nop*, *s*). Some rod and cone impulses, accordingly, use, on the bipolar level, the same structures (*d*, *e*, *f*), while the midget bipolars (*h*) are used for cone impulses alone. On the ganglion level all cell varieties serve both for the rod and cone impulses. The factors which determine the locality, quality, and intensity of the impulse ultimately entering the brain are many, and are as yet little understood: structural, pertaining to the kind and organization of synaptical organelles, and the very character of the constituent substance; and the physical and dynamical factors which multifariously vary from case to case, as well as according to situation. (*Compare* Figs. 146, 147, 177, 179.)

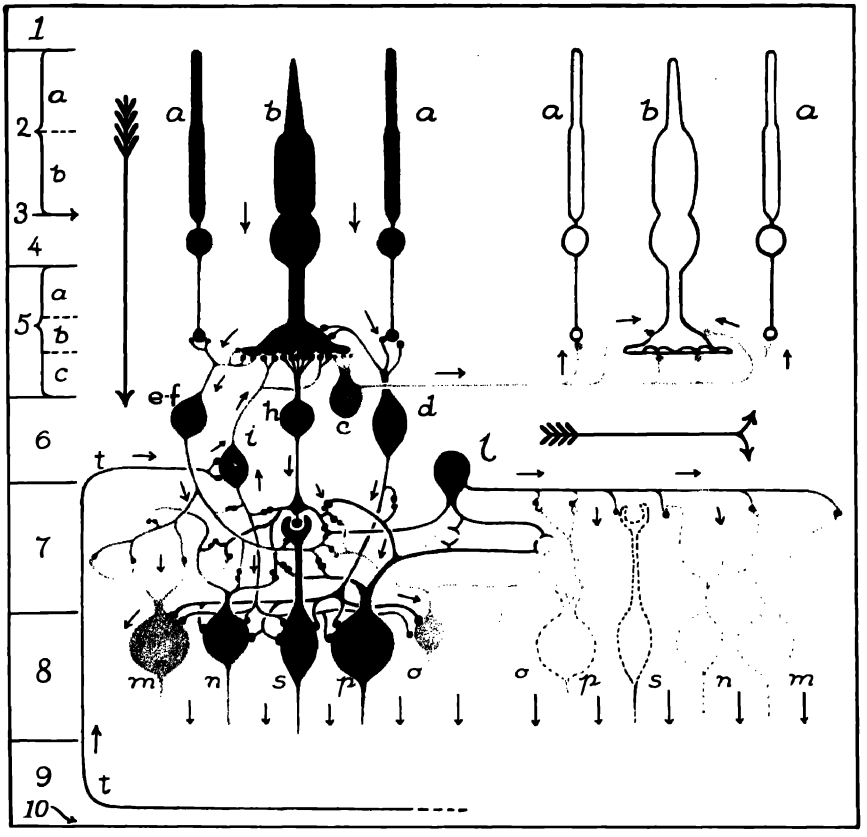

FIG. 179—Diagram of the essential constituent neurons and their synaptical relationships in the primate retina. The left solidly drawn half of the diagram symbolizes the structures used as a direct pathway of impulses from a given stimulated group of photoreceptors to the brain. The right half of the diagram given in outlines indicates structures surrounding the first group which are not directly stimulated by physical light, and are influenced only indirectly by way of associational neurons: the horizontal cells (*c*) and associational "amacrine" cells (*l*). In case the cones (*b*) are stimulated alone, all bipolars are activated, which in turn stimulate all varieties of ganglion cells; the rods (*a*) in this setup remain inactive. When the rods (*a*) alone are stimulated, all bipolars except the midgets (*b*) are activated, again stimulating all ganglion varieties even though in a different way. When the cones are stimulated, in addition to the activation of bipolars, the horizontal cells (*c*) are also activated which would remain inactive if the rods alone were stimulated. The stimuli from the horizontal cells in turn are transferred upon a group of both varieties of photoreceptors at some distance from the point stimulated by the physical light. This influence may be interpreted as an active inhibition. A similar role may be ascribed to the centrifugal bipolars (*i*) by which the same group of stimulated cones is again influenced from the ganglion cell level, or from the brain via the centrifugal exogenous fibers (*t*). What role other associational neurons (*l*) play is as yet beyond calculation except that in some way they "condition" the structures surrounding the stimulated locality. (*Compare* Figs. 146, 147, 177, 178.)

Chapter VI

Optic Nerves, Chiasma, Tracts, and Subcortical Visual Centers

SEC. 1. COMPONENT PARTS OF THE VISUAL SYSTEM

1. GENERAL PLAN OF THE VERTEBRATE VISUAL SYSTEM.—The chain of physiological processes subjectively experienced as "sight" or "vision" is initiated in the retinal photoreceptors, the rods and cones, through the action of the luminous form of radiant energy called "light." From the photoreceptors of the eyes, the impulses pass along the optic nerves to the central nervous organ, the brain. In this organ reactions take place by means of which the individual adjusts himself in a suitable way to the environment whence the photic stimuli emanate or are reflected.

The visual adjustment may be either simple, immediate, and automatic or of varying degrees of complexity and remoteness in time. To use a few simple biological examples, when a cloud which has obscured an area moves away, the intensive light stimulus causes the pupils of the eyes to contract, and the stimulus is cut down. A very different situation arises when a shadow of specific shape, size, and motion—cast, for example, by a flying Eagle or Hawk—moves across the photoreceptor surface of the retina of a potential object of prey, such as a Rabbit. Even though this elicits but an infinitesimal dynamic change in the nervous structures of the retina, the "symbolical value" or the "specific biological significance" which such a stimulus represents for a Rabbit releases a complex chain of reactions whose purpose is the avoidance of danger of extinction. Its obverse takes place in the visual system of an Eagle or a Hawk, cruising for hours over the prairies and forests, deliberately scanning and mentally evaluating countless objects before its visual apparatus fulfils the biological role assigned to it: the acquisition of food or the meeting of a mate, both fundamental tasks in the maintenance and preservation of the individual and the species.

Some physiological demands upon the visual system, accordingly, are simple. To satisfy these smoothly and speedily, a relatively simply organized central mechanism suffices, which for the most part works automatically. Other situations, on the contrary, require complex machinery whose prompt response is largely determined by traces of past individual and phylogenetic experience stored in the cerebral substance.

2. AFFERENT VISUAL PATHWAY OR SYSTEM.—Whatever the visual stimuli, the impulses elicited in the retinal structures must be conveyed to the central nervous system and distributed therein, in order to serve any useful purpose. For in Vertebrates, as far as is known, there are no other avenues by means of which motor or other responses could be elicited by light. (Humoral agents, too, must act via the brain or spinal cord; local skin reflexes which do not lead directly to a change in animal behavior are excluded from present considerations.) The anatomical set of structures serving that purpose may be called the *afferent visual pathway or system*. It is made up of agglomerations of nerve cells and of bundles and tracts of nerve fibers organized into a complex mechanism, all held together by supporting and other structures which assure its physical existence and keep it in proper functioning order.

The visual system of Man and his primate relatives, the Monkeys and Apes, may be roughly subdivided into three parts according to anatomical features, location, and connections

(Fig. 180): (1) infranuclear or peripheral division (*r, on, ch, otr*); (2) subcortical visual nuclei, which represent the intermediate division (*cols, lgn, pgn, pulv*); and (3) supranuclear or central division (*vis rad, stra*). Each component structure of this system has its own peculiar features, in addition to those common to several or all. Each is connected with the others in some way, and all these components together form an intricately built and interdependently functioning mechanism.

3. INFRANUCLEAR DIVISION OF THE VISUAL SYSTEM.—This division of the visual system is composed of the retinae of the eyes (*r*), the two optic nerves or bundles (*on, nervi* or *fasciculi optici*), the bridgelike union or apparent intercrossing of the optic nerves, called the chiasma (*ch, χιασμα*, or *chiasma nervorum opticorum*), and of the two optic tracts (*otr, tracti optici*), by which the optic nerves apparently continue beyond the chiasma to the brain.

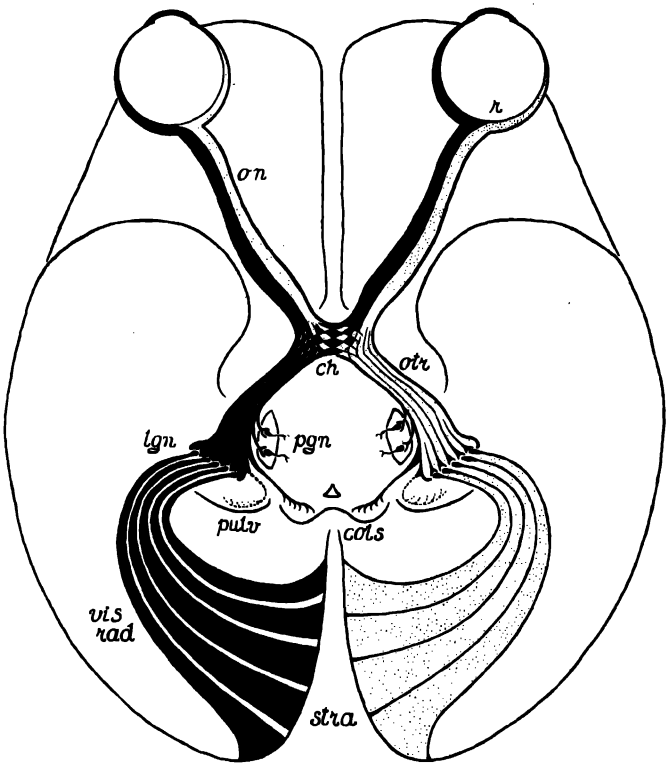

FIG. 180.—Diagram of the human visual system drawn into an outline of the brain. The infranuclear division is made up of the eyes, including the retinae (*r*), optic nerves (*on*), chiasma (*ch*), and optic tracts (*otr*), the latter terminating in subcortical visual centers, the principal one of which is the lateral geniculate nucleus (*lgn*), with subsidiary pregeniculate nucleus (*pgn*), superior colliculus (*cols*), and possibly also the pulvinar of the thalamus (*pulv*). The supranuclear division consists of the visual radiations (*vis rad*) originating in the lateral geniculate nuclei and terminating in the striate areae (*stra*) of the occipital lobes. Fibers originating in the inner or nasal halves of the retinae intercross in the chiasma. In consequence, while each optic nerve represents the retina of its own eye, the portions of the visual system above the chiasma represent ipsilateral homonymous halves of both retinae or contralateral halves of the fields of view.

4. INTERMEDIATE DIVISION OF THE VISUAL SYSTEM OR SUBCORTICAL VISUAL CENTERS.— The subcortical visual nuclei, centers, or stations are those parts of the brain in which the optic nerve fibers, originating in the retinae, terminate, or where the efferent fibers that terminate in the retinae originate. In each half of the brain there are, in Man and other Primates, at least three and possibly more such centers.

The principal and most elaborately organized center is the laminated lateral geniculate nucleus or body, or *l.g.n.* in the restricted sense (*lgn, nucleus geniculatus lateralis dorsalis* or *corpus geniculatum laterale dorsale*). It is a homologue of the dorsal portion (*pars dorsalis*) of the geniculate nucleus of Infraprimate Mammals.

The other subcortical visual center is a smaller, cap-shaped nucleus of gray substance adjoining the first on the dorsal, dorsomedial, and medial sides, the pregeniculate gray substance or nucleus (*pgn, substantia grisea praegeniculata, nucleus praegeniculatus, corpus geniculatum laterale ventrale*). This nucleus, in turn, is a homologue of the ventral portion (*pars ventralis*) of the geniculate nucleus of the Lower Mammals.

Both these nuclei, first described in this way by Nissl (*see* Koelliker 1896, pp. 540–43), and the medial geniculate nucleus (a constituent of the auditory system), represent the "metathalamus." With the hind part of the thalamus, called *pulvinar* or "cushion" (*pulv*), which also may be in a slight degree directly related to the visual system, they form a part of the inter- or betweenbrain, or *diencephalon*, one of the principal subdivisions of the brain.

The fourth subcortical visual center is the superior or anterior hillock (*cols, colliculus superior*, or *c. anterior*). It is a part of the midbrain or *mesencephalon* (another major subdivision of the brain), in particular, that called *tectum* or "roof." Each of the three or four nuclei is differently organized structurally, has its own particular connections with other parts of the brain and its own specific function.

5. SUPRANUCLEAR DIVISION OF THE VISUAL SYSTEM.—The supranuclear or central division of the afferent visual pathway is represented by two bulky systems of nerve fibers originating from the nerve cells of the two laminated lateral geniculate nuclei, the visual or optic radiations, one in each cerebral hemisphere (*vis rad, radiatio optica*). In addition, those portions of the cerebral cortex directly related to the visual system, the striate areae, one area in each occipital lobe (*stra, area striata*), where the fibers of the visual radiations terminate, are also considered constituents of the supranuclear division.

The afore-mentioned nervous structures, peripheral, nuclear or subcortical, and cortical, are all in one way or another concerned in the transmission or reception of impulses generated in the photoreceptors of the retinae—the rods and cones. In some of these centers the retinal impulses initiate more or less subconscious reflex acts, automatic in character, which regularly accompany the visual act, for example, the constriction of the pupils of the eyes. Again, in other centers, especially in the laminated lateral geniculate nuclei and in the striate areae, the messages arriving from the retinae are further elaborated into physiological processes that underlie a conscious subjective experience of vision.

6. THE VISUAL SYSTEM IN A WIDER SENSE.— The structures discussed in the preceding paragraphs represent the afferent visual pathway and centers of the visual system in the restricted sense. There are numerous other structures, nervous and nonnervous, anatomically and functionally closely related to the afferent visual system which make its harmonious working possible. These are, on the one hand, the extrinsic and intrinsic eye muscles and the coordinating centers of the brain stem and cortex. Their task and that of other related structures, such as the various tracts, nuclei, and nerves, both sensory and motor, is to furnish a machine which can direct the gaze toward the object of visual attention and form sharp retinal images. On the other hand, to a visual system in the wider sense also belong portions of the occipital, parietal, and temporal regions of the cerebral cortex outside the striate areae, which are considered a substratum of the psychic visual functions.

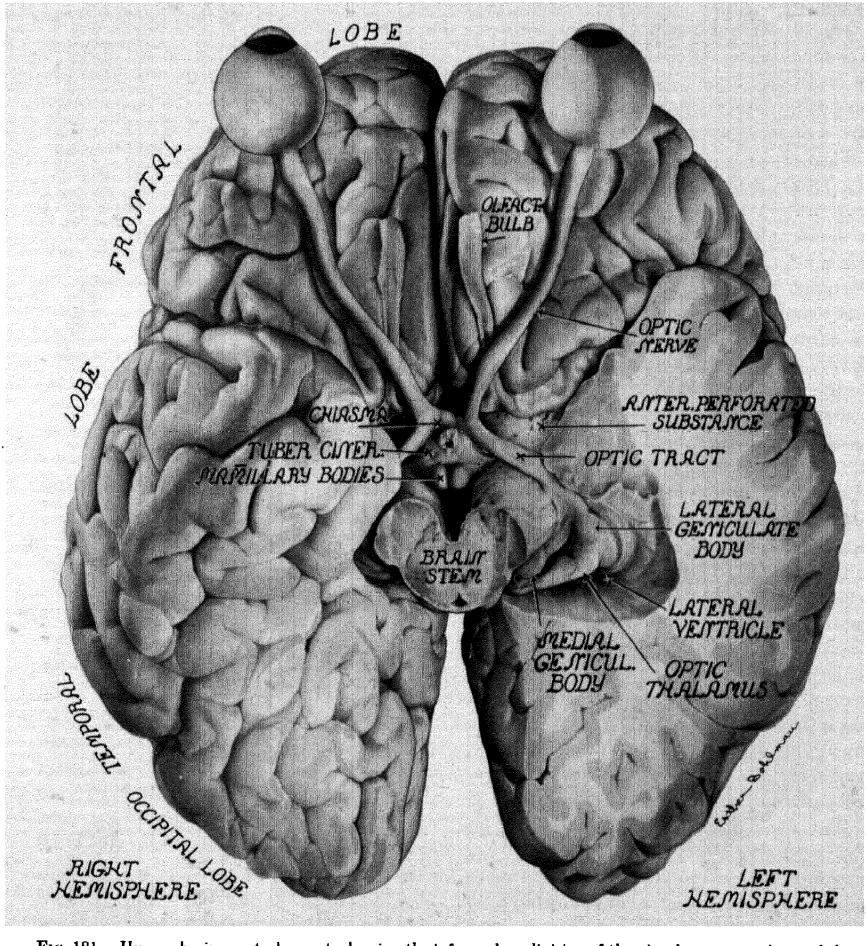

FIG. 181.– Human brain, ventral aspect, showing the infranuclear division of the visual system made up of the two eyeballs, optic nerves, the chiasma, and two optic tracts; the subcortical visual stations, the lateral geniculate body or nucleus and the pulvinar of the thalamus, are made visible on the left side (*right* in the figure) by removing portions of the temporal and occipital lobes of the brain. The right hemisphere of the brain intact, the brain stem with superior colliculi and the hypophysis removed.

SEC. 2. ORIGIN AND COURSE OF THE OPTIC NERVE

1. Origin and functional significance of optic nerve fibers.—The optic nerve fibers of the infranuclear division of the afferent visual pathway preponderantly, if not entirely, originate as axis cylinders or axons of the retinal ganglion cells (layer *8* in Fig. 128; *cf. also* chap. V, 2 [9, 10], 5). It is probable that the axons of all or almost all nerve cells in the eighth layer of the retina and those in the sixth layer designated as "displaced ganglion cells" or "Dogiel's cells" help make up the optic nerves.

When, in a monkey, an optic nerve, a tract, or a lateral geniculate nucleus is cut or destroyed, if care is taken to avoid any damage to the blood supply of the eyeball, the ganglion cells of the eighth layer suffer a retrograde degeneration within a few days and disappear almost completely in a few weeks. (This occurs in the entire expanse of the retina if the optic nerve of that eye is cut and in the corresponding homonymous halves only, when one optic tract is interrupted or one lateral geniculate nucleus destroyed.) The few remaining ganglion cells also show more or less pronounced pathological conditions: reduction in size, uneven outlines, displaced nuclei, and poor staining. The loss is especially pronounced in the central area close to the edge of the foveal depression. Here the ganglion layer, normally containing from six to eight tiers of well-formed, deeply stained, and closely packed cells, is reduced to a single or double discontinuous row of pathologically changed cells intermingled with a few nuclei which belong to the blood vessels and to the supporting tissue. A few nerve cells, however, remain in fairly good condition for as long as one year after the experiment.

Why some ganglion cells of the retina survive, even after a prolonged lapse of time, is a question to which no positive answer can be given at present. By way of conjecture, it is possible to assume that the surviving ganglion cells are a part of the intraretinal association system, whose axis cylinders do not leave the membrane but terminate in it not far from their origin, in analogy with the horizontal cells, *c* (*see* chap. V, 6 [2]). Another possibility is that these are aberrant or freak cells, incompletely differentiated and in some ways not conforming to type; such cells are found in small numbers among other categories of the retinal elements, notably among the bipolars.

Whether all axis cylinders of the optic nerve, in Man and other Primates, belong to the category of afferent neurons—that is, those conveying impulses generated in the retina to the brain—or whether there are also efferent axons, or those originating in the brain and terminating in the retina, by means of which central influences may reach the photoreceptors, is a problem still to be solved. From the investigations of S. Ramón y Cajal (1888, 1889, 1892 93, 1895, 1911), Bouin (1895), Dogiel (1895), Weber (1945), and others, the presence of such fibers is fairly certain in Birds and in Axolotl, but they have not yet been definitely shown to exist in Mammals. (*Cf.* chap. V, 7.)

2. Course of optic nerve fibers within the retina.—In the ninth layer of the retina, the optic nerve fibers are assembled into numerous bundles, fewer and containing coarse fibers in the retinal periphery and more numerous and made up of a great number of delicate fibers in the axial or central region.

Examined in suitably made whole-mount preparations, for example, stained intravitally with methylene blue (Fig. 162) or observed ophthalmoscopically with proper technique (Fig. 148), all fiber bundles on the nasal side are seen to converge in straight lines, like the spokes of a wheel, toward the hub represented by the optic papilla or disk. On the temporal side, however, only a few of the many short, delicate fiber bundles, those originating from the nasal edge of the fovea and passing directly to the temporal margin of the papilla, take a straight horizontal course. All other bundles above the horizontal meridian originating in the upper, lower, and temporal segments of the foveal pit circle in more or less distinct arches or sweeping curves above and below the fovea to the papilla. This is as true of the bundles arising from the upper, lower, and temporal segments of the central area surrounding the fovea, which, in the aggregate, form the "papillomacular bundle," as it is of those bundles arising from the corresponding portions of the extra-areal temporal

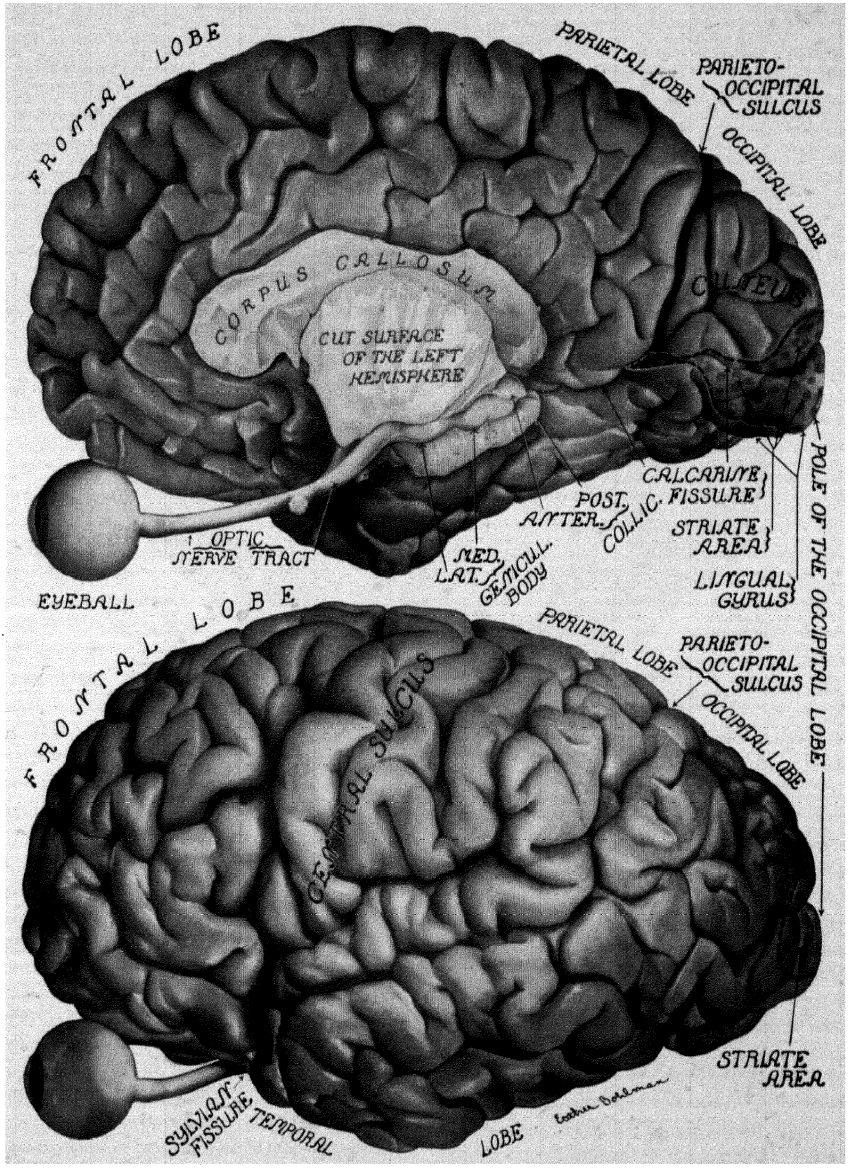

FIG. 182.—Human brain, upper figure showing the inner aspect of the right hemisphere, lower figure showing the outer aspect of the left hemisphere. Visible parts of the visual system are the eyeballs, optic nerves, chiasma, optic tracts, lateral geniculate nucleus or body, anterior or superior colliculus, and striate areae of the occipital lobes (*coarsely stippled*).

periphery and the adjacent zone of the nasal retinal half.

The arciform bundles of the optic nerve fibers follow rather closely the larger arteries (*a*) and veins (*v*), which, from above and below, encircle the central area, into which they send numerous smaller blood vessels. An obvious result of this arrangement is the elimination of the obstructing optic nerve fibers from the central area and fovea. An arching course of the perifoveal fibers, similar to that found in Man, Monkeys, Apes, and the nocturnal *Nyctipithecus* and Tarsier (Fig. 149), is also found in some other Mammals, such as the Cat, which possess a distinct central area, even though they do not have a pronounced foveal depression. (*Cf.* chap. V, 10 [7], 11 [2].)

vision line, called the *raphé* or "seam," stretching on the temporal side from the fovea along the horizontal meridian to the *ora serrata* (Figs. 149, 162). It is a line which separates bundles of nerve fibers originating in the upper temporal quadrant from those originating in the lower temporal quadrant. This anatomical cleavage, found in the human and simian retina and in that of the Tarsier, is an important architectural arrangement whose effect continues in the visual pathway as far as the visual centers of the cerebral cortex. It is the anatomical basis of the homonymous quadrantic hemianopias of central origin. (*Cf.* secs. 6, 11, this chapter; chap. VII, 3 [3], 4, 6; chap. X, 8, 9; and chap. XII, 6, 7, 8.)

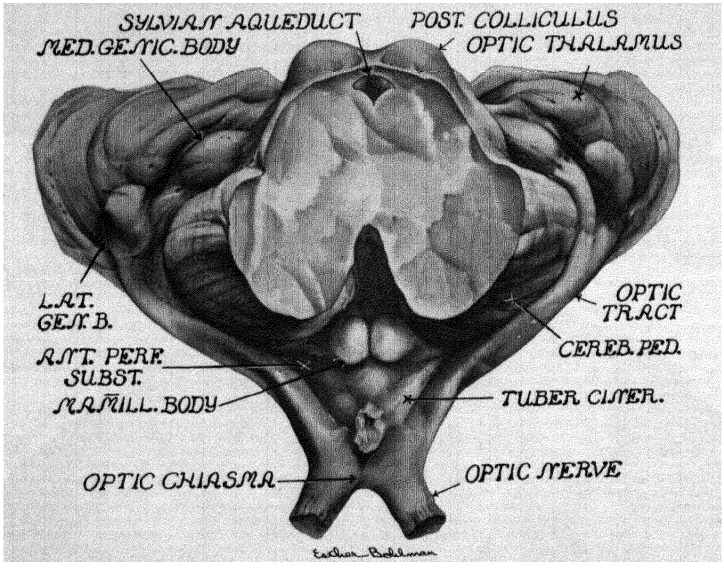

FIG. 183.—Posterior aspect of the human midbrain and betweenbrain, showing optic nerves joined in the chiasma and continuing, as optic tracts which terminate in subcortical visual centers, in the lateral geniculate nuclei or bodies, and seemingly also in the thalami.

3. TEMPORAL RAPHÉ OR SEAM OF THE RETINAL NERVE FIBERS.—Another noteworthy feature of the primate retina, directly related developmentally and functionally to the formation of the foveal depression, is a horizontal di-

The separation of the optic nerve fibers along the horizontal meridian temporal to the central fovea is somewhat less distinctly duplicated by a "vascular raphé." In this zone only small blood vessels and capillaries cross the horizontal line; the larger arterial and venous stems are absent here,

In living persons of the white race, the arciform course of the retinal optic nerve fibers, ordinarily not visible ophthalmoscopically, may be seen only when red-free light is used (A. Vogt 1918, 1921, 1937; *see also* colored plates in Heine 1918; Wilmer 1934; Kolmer 1936; Atkinson 1937; Di Marzio 1937; for early references *see* chap. V, 11 [2]). In colored races the peculiarly arranged fibers around the optic disk and central area are noticeable as translucent streaks (Johnson 1901).

4. FUNCTIONAL AND PATHOPHYSIOLOGICAL SIGNIFICANCE OF THE ARCHING PERIFOVEAL OPTIC NERVE FIBERS.—The obvious functional effect of the peculiar arrangement of optic nerve fibers in the vicinity of the central fovea is precisely the same as that of the foveal depression. Since, because of developmental and teleological-creative factors (*see* chap. XIII, 1, 2), light must first pass through the entire thickness of the retinal substance, in order to reach the photoreceptor layer situated outside (*2*, in Fig. 161), an inordinate thickening of the inner layers (from *10* to *4*) and, in particular, of the optic nerve fibers (*9*) would be an unwelcome impediment precisely in the axial region where their numerical increase, necessitated by the refinement of spatial discrimination, is greatest. It is therefore logical to find the inner layers of the retina in this locality displaced laterally, a process most completely carried out in the foveal center, the foveola (*see* chap. V, 10 [7]). Conversely, this displacement unavoidably results in the ridgelike accumulation of nerve cells around the foveal pit and, at a somewhat greater distance from it, of the more mobile optic nerve fibers. What evolutionary and developmental factors brought about such highly purposeful and useful arrangements remains at present entirely unknown.

The anatomical, physiological, and pathological consequences of the lateral or centrifugal displacement of nerve cells and fiber bundles in the central area are easier to understand. Anatomically, the result is a separation of the upper from the lower extrafoveal fibers by those that originate in the foveal depression and its immediate vicinity. That this should be so along the stretch between the fovea and the optic papilla—since the fibers of the retina are arranged in a flat plane -is self-evident. The effect of the interposition of the "papillomacular bundle" and foveal pit between the upper and the lower extrafoveal fibers, however, is felt far beyond the central area. For only by circuitous routes can the fiber bundles arising from the more distant extra-areal zones of the two temporal retinal quadrants reach the papilla, while avoiding an overlapping of the foveal pit and its fibers. This, in turn, necessitates separation of the upper quadrantic fibers from the lower all along the temporal stretch of the horizontal meridian as far as the ora serrata. Literally, the extra-areal optic nerve fibers of the upper and lower temporal quadrants become separated by the interposition of the foveal-areal or "macular" fibers. The significance of this fact for the understanding of the intrinsic organization of the entire visual system, especially of the mechanism responsible for quadrantic hemianopia, has been studied by Rønne (1909, 1917, 1919, 1944) and is dealt with in detail in chapters VII, 4, 6; IX, 8; and XII, 6, 7, 8, in this book.

The peculiar arciform arrangement of the circumfoveal fiber bundles is apparently responsible for a curious entoptical phenomenon seen under certain conditions and known as "blue arcs of the retina" (Purkinje 1825; H. Müller 1859; Ladd-Franklin 1926, 1928; Judd 1929; B. Friedman 1931; Newhall 1937). At any rate, the arrangement of these fibers is practically identical with the "blue arcs" found by Dolecek & Launay (1945). The interesting question concerning the mechanism and factors involved in the production of "blue arcs" still remains to be answered. The impedance of the rays of light normally passing through the thick fiber bundles or their change in quality and intensity in comparison with the surrounding regions, where the rays have a freer course, is the probable cause of different responsiveness in the archlike zones of the photoreceptors, which are normally relatively screened off by corresponding bundles, which, during the entoptical stimulation, may produce this peculiar subjective phenomenon.

5. FASCICULAR COMPOSITION OF THE OPTIC PAPILLA.—The individual bundles of optic nerve fibers which originate in limited segments of the retinal surface, in spite of the arciform

course in and around the central area, preserve, on the whole, their relative position as they stream toward the papilla (*optpap* in Fig. 225; *see also* Figs. 148, 149). In the nasal region of the retina, where the arrangement of bundles is almost perfectly radial, this is obvious. Here all fibers from a given narrow wedge-shaped segment at the papillar margin also appear to be of a more or less semicircular shape. Here the extra-areal fibers streaming from the peripheral regions, because of their dislocation in order to avoid the central area and fovea, are assembled principally at two points on the papillar margin: in the left eye, as seen with the ophthalmo-

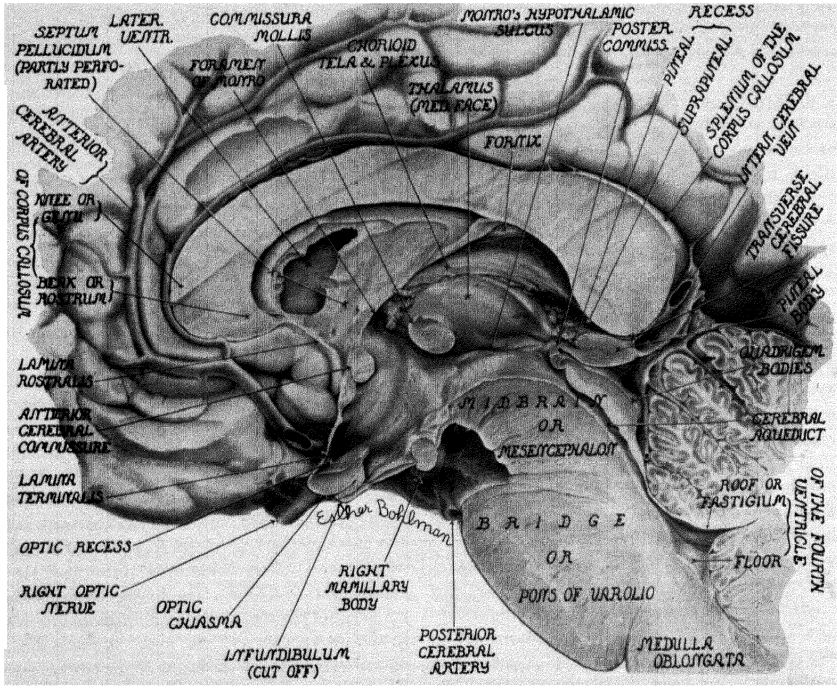

FIG. 184.—Median aspect of the human betweenbrain and brain stem cut along sagittal plane (*right half*). The parts of the visual system visible are a stump of the right optic nerve, the cut surface through the optic chiasma, and the quadrigeminal bodies or colliculi of the midbrain. Note structures and spaces immediately adjacent to optic chiasma, which are: the lamina terminalis; the optic recess of the third cerebral ventricle; the infundibulum or "funnel" of the diencephalon (with hypophysis torn off); the anterior cerebral artery in front of the chiasma; and the posterior cerebral artery behind the infundibulum and mammillary body in the interpeduncular fossa. Note also the position of the quadrigeminal bodies relative to the pineal gland and to the cerebral aqueduct, through which the third ventricle, and through it the two lateral ventricles, communicate with the fourth cerebral ventricle, all structures important in normal exchange of cerebrospinal fluid and in the cerebral pathology of this region. (For further topography *see* accompanying figures, and X-ray figure of the head in chap. VIII, and also colored plates in chap. X.)

segment converge toward the same point in the papilla.

In the temporal region, because of the arciform course of bundles around the central area and fovea, the areas that belong to a given fiber scope in an upright picture, those from the upper quadrants between approximately 1 and 2 o'clock, and those from the lower temporal quadrants between 4 and 5 o'clock, at the papilla; and in the right eye between 10 and 11 and

between 7 and 8 o'clock at the papilla, respectively. Between these two sections there is a rather wide intermediate temporal sector, in the left eye corresponding to between 2 and 4 o'clock, and in the right eye to between 8 and 10 o'clock, where the numerous thin bundles from the central area and fovea reach the papilla: the "papillomacular bundle."

In the papilla, accordingly, fibers from the axial region of the retina occupy an approximately wedge-shaped temporal segment, surrounded from above and below by bundles originating in the extensive extra-areal portions of the upper and lower temporal quadrants.

Since in the optic nerve there is a further shifting of the bundles by which the axial or areal-foveal fibers are gradually brought into a central position, it is possible that such displacement is being prepared during the intraretinal course. For example, the extreme peripheral fibers, originally superficial, may gradually sink deeper and be the first to slip into the papilla, in this way leaving the fibers from regions closer to the central fovea and area on the papillar surface and thus bring them closer to the center of the papilla.

SEC. 3. HISTOLOGY OF THE OPTIC NERVES, CHIASMA, AND TRACTS

1. General remarks on the optic nerve.—The optic nerves—also termed *optic fascicles*, since, for embryological reasons, they may be compared with the fiber tracts of the brain—are thick, tough, and more or less cylindrical structures, one to each eye, by means of which the eyeballs are connected with the brain. At present, however, only the portions between the eyeballs and the chiasma are customarily called "optic nerves" (*on* in Fig. 180; *see also* Figs. 181, 182, 183, 184). The portions between the chiasma and the subcortical visual nuclei of the brain are called "optic tracts" (*otr* in Fig. 180, also above-mentioned figures; *see* chap. II, 12 [7]).

Each optic nerve is made up of a considerable number of bundles of myelinated optic nerve fibers—preponderantly, if not entirely, axis cylinders of the retinal ganglion cells—firmly held together by supporting tissue (Fig. 185). The appearance of the optic nerve on a cross-section varies. In the longer intraorbital portion it is fairly round or cylindrical in shape; in the posterior segment inclosed in the bony optic foramen or channel, just before it joins the nerve from the opposite eye in the bridgelike chiasma, it becomes somewhat flattened in the dorsoventral sense. The diameter, without the arachnoid and dural sheaths, varies, accordingly, from 3 to 5 mm., more or less. The length of the optic nerves, in adult human individuals, attains approximately 5.5 cm., or slightly more than 2 inches. In a fully grown male Gorilla, the famous "Bushman" of Lincoln Park Zoo in Chicago, a dorsoventral diameter of the optic nerve was 3 mm., a transverse diameter 5–6 mm., and the total length of the nerve the same as in Man.

It remains an open question whether, in addition to the fibers that are the axis cylinders of the retinal ganglion cells, there are other fibers in the optic nerve whose origin is in the brain and which may terminate in the retina. The fact that a severed optic nerve degenerates completely does not necessarily militate against the presence of such efferent fibers, as pointed out previously (chap. V, 7).

2. Structure of the optic nerve.—In its anterior portion close to the eyeball, the optic nerve, in Man and other Primates, appears, on cross-section, to be an assemblage of approxi-

mately five hundred bundles of varying sizes and shapes (Fig. 185). Each bundle is made up of a number of myelinated optic nerve fibers differing considerably in thickness (fibers devoid of myelin sheaths, found in many Lower Vertebrates, according to Bruesch & Arey, are absent in Man and Monkey). The bundles are separated from one another by rather coarse septa (sing. *septum*, in Latin) or partition-like sheets of interstitial connective tissue represented by the connective cells and fibers (collagenous and elastic).

In a cross-section through the nerve, the interstitial septa appear as a network in whose meshes bundles of nerve fibers lie imbedded. Small blood vessels, both arteries and veins, the majority of which are apparently of pial origin, are present in fair numbers in the interfascicular partitions. Contrasting with this is a delicate network of interstitial tissue within the bundles themselves. This tissue appears to be exclusively neuroglial, chiefly represented by the astrocytes and their fibrous expansions. Blood vessels of any kind, including capillaries, seem to be absent in the fiber bundles.

The pattern of the bundles and partitions is not the same along the whole length of the optic nerve but changes considerably in different localities and possibly also in different individuals. In the distal portion of the nerve close to the eyeball the largest accumulation of connective tissue is in its center. Here it forms the central connective tissue strand (*cs*), in which the central blood vessels, an artery (*ca*), a vein (*cv*), and a few smaller branches are imbedded. In the longer proximal portion of the orbital division of the optic nerve closer to the optic foramen, this structure and the central vessels are absent. (*See* chap. X, 2, on central vessels.)

The immediate investment of the entire

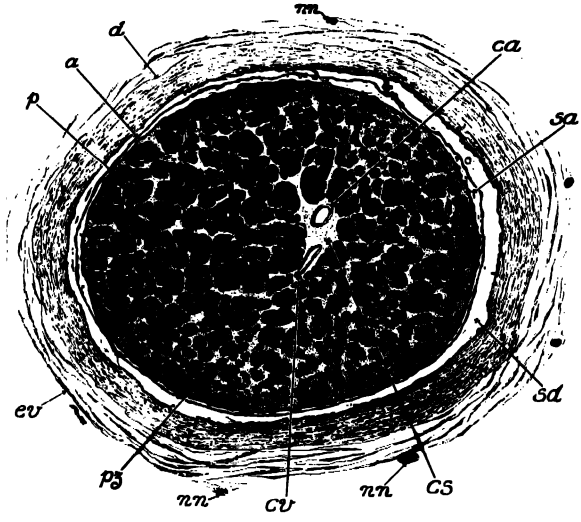

FIG. 185.—Cross-section of the human optic nerve close to the eyeball. The nerve proper is made up of numerous larger and smaller bundles of myelinated nerve fibers (*solid black*) separated from one another by *septa* (sing. *septum*), or partitions of connective tissue containing blood vessels. The connective tissue is most abundant in the center, where it forms a "central supporting tissue strand" (*cs*) containing the central artery (*ca*) and central vein (*cv*). Just underneath the pial membrane (*p*) a peripheral zone of connective tissue (*pz*) may be distinguished. On the outside the optic nerve is surrounded by three sheaths or vaginae: the pia mater (*p*) and arachnoid (*a*), which are thin and interconnected by strands and inclose the subarachnoid space (*sa*), and the thick and tough dural sheath (*d*), whose epivaginal connective tissue (*ev*) is the outermost. The space inclosed by the dura and arachnoid is the subdural space (*sd*). Attached to the dura from outside are several thin dural nerves (*nn*). Weigert method of staining, magnified 20×.

trunk of the optic nerve proper and, in fact, a part of its substance is a thin layer, the most superficial, of the connective tissue framework: the pia mater or pial sheath (*p*). It contains numerous small blood vessels, both arteries and veins, whose branches penetrate with the connective septa into the thickness of the nerve which they supply with blood. Outside the pial sheath and not far from it is the second envelope of the optic nerve, which, owing to its thinness, is called the arachnoid membrane or spider-web sheath (*a*). This delicate membrane is devoid of blood vessels. It is attached to the underlying pial sheath by numerous thin threads, filaments, and strands. The narrow space inclosed by it and the pial sheath is the subarachnoid space (*sa*). The pial and arachnoid sheaths, because of their thinness, are called leptomeninges or "thin envelopes" (sing. *leptomeninx*).

The third and outermost investment of the optic nerve is a thick, tough fibrous sheath, the dura mater or dural sheath (*d*). Because of its thickness and toughness, it is called *pachymeninx*. It is composed principally of a thick, dense, inner circular layer and a more loosely arranged outer layer of connective tissue cells and fibers. The latter, principally made up of longitudinal fibers, is the epivaginal connective tissue or zone (*ev*). The dural sheath contains but few small blood vessels, mostly in the epivaginal zone, and a fair number of thin nerves (*nn*) in the same zone, each nerve made up of a few thick, well-myelinated nerve fibers. The space between the dura and the arachnoid is the subdural space (*sd*). It is crossed by a small number of somewhat thicker trabecules or threads.

At the proximal or central end of the optic nerve the three investments—the two thin inner leptomeninges, and the single outer thick pachymeninx—are continuous with the corresponding envelopes of the brain—the pia, arachnoid, and dura mater. At the optic channel the dural sheath merges with the periosteal lining of that locality and of the fundus of the orbital cavity, the periorbita. At the distal, peripheral, or bulbar end the dural sheath of the optic nerve alone is continuous with the scleral tunic of the eyeball, whereas the two leptomeninges terminate blindly here.

The arrangement and other peculiarities of the constituent nerve fibers seen in cross-section show noteworthy variations in different sections of the optic nerve. In most of the bundles the fibers vary more or less in thickness or caliber. That is, in addition to the thin fibers, there are always some thick ones. The average thickness of fibers, however, varies considerably from place to place. In the portion of the nerve at some distance from the eyeball, the coarsest fibers are found in a peripheral zone along the circumference, the width of that zone not exceeding one-tenth to one-eighth of the nerve diameter. Conversely, the thinnest fibers are assembled in the centrally located bundles surrounding the central connective tissue strand containing central blood vessels. Here the bundles are thickly packed with a great number of very thin fibers, the thinnest in the nerve and the most nearly uniform in caliber and distribution. In the immediate vicinity of the eyeball, bundles composed largely of thin fibers are found along the temporal margin.

3. STRUCTURE OF THE OPTIC CHIASMA AND TRACTS. The X-shaped junction of the optic nerves, named the *chiasma* by the ancient anatomists because of its similarity to the Greek letter chi (χ), is a short, stout bridge, through which, in Mammals, a partial exchange of fibers between the two nerves is made. Those fibers which, in Man and other Primates, originate in the somewhat larger nasal half of the retina, pass from one nerve, through the chiasma, and join the opposite optic tract, whereas the fibers arising from the temporal side of the retina proceed in the lateral portions of the chiasma, without decussation, from the optic nerve to the corresponding optic tract.

In anatomical appearance, histological structure, physiological significance, and phylogenetic origin and perfection, the optic chiasma is unique among all cranial nerves and probably among all nerves of the peripheral nervous system, approaching in its peculiar arrangement that of the "commissures" of the brain and spinal cord.

The gross anatomical appearance of the chiasma is subject to considerable individual variation, in the length, width, and thickness of the bridgelike portion and in the four angles formed by the four nervous bars which it joins.

There are short and stout forms of the chiasma with acute anterior and posterior angles and obtuse lateral ones. The other extremes are those where the bridge is broadened and flattened, with resulting wide anteroposterior angles. Various anomalies are transitions to pathology, with a separation of one or another part as a distinct bundle, or atrophy, an abnormality which, in the extreme, culminates in the absence of the chiasma. (*Cf.* chap. II, 8 [4].)

In histological makeup the chiasma and the optic tracts vary somewhat from the optic nerves, in that the former largely lack connective tissue partitions. In a cross-section through the optic tract the nerve fibers appear, therefore, more evenly distributed. In the chiasma, however, owing to the partial crossing, numerous minute fiber bundles intertwine in various ways, producing a peculiar pattern which resembles in places the "herringbone" weave in cloth.

Both the chiasma and the optic tracts are invested by the meningeal sheaths: a rather thick pia mater containing numerous blood vessels and bounded on the outside by a thin, avascular arachnoid membrane. The exception is the side where the chiasma and the tracts are attached to the brain. Here the leptomeningeal investments are absent, and the chiasma and tracts merge directly with the cerebral substance. A special dural or pachymeningeal sheath, on the other hand, is absent both in the chiasma and in the optic tracts and is represented by a common dural envelope incasing the entire cerebrum. (*See* sec. 5, this chapter, on the comparative anatomy; *see* sec. 6, on the fascicular composition of the chiasma.)

4. Fiber number in the optic nerves of various vertebrate species.—The number, kind, and arrangement of fibers in the optic nerve vary a great deal, depending upon the biological importance and use of the visual system in a particular vertebrate species. In general, in those animals in which vision is the most important sense, the optic nerve is relatively thick and rich in fibers. In contrast is the thin optic nerve of species relying chiefly upon other senses, such as smell, taste, and hearing.

The optic nerves of Primates and Birds, in which sight has become the dominant sense, contain by far the greatest number of fibers. In the human optic nerve, for example, the number of the fibers which may be counted on a cross-section reaches and even exceeds the formidable figure of 1,000,000 (W. Krause; Polyak 1941, 1948; Bruesch & Arey 1942). This is in remarkable contrast with the fibers in the human auditory nerve, which, on the average, number only 30,000, although hearing is second in importance to sight (Rasmussen 1940).

In the Macaque, the number of optic nerve fibers, according to Bruesch & Arey (1942), is as high as 1,200,000. Other figures, according to the same authors, are: Hagfish 1,579; Brook Lamprey 5,217; Dogfish Shark pup 113,000; Guitar Fish 74,600; Sting Ray 39,700; Shovelnosed Sturgeon 13,500; Bowfin 114,000; Goldfish 53,000; Bullhead 26,000; *Necturus maculosus* 362; *Ambystoma tigrinum* 2,004 (6,000–10,000, according to Herrick 1941); Toad 15,500; Frog 29,000; Turtle 105,000; baby Alligator 105,000; Horned Toad 129,000; Duck 408,000; Chicken 414,000; Pigeon 988,000; Canary Bird 428,000; Duck-Bill or *Platypus* 32,000; Opossum 82,100; Small Brown Bat 6,940; Cat 119,000; Dog 154,000; Rabbit 265,000; Pig 681,000; Sheep 649,000.

The small number of fibers in Fish and in Amphibians living in a poorly lighted habitat (Bullhead, Goldfish, *Necturus*, *Ambystoma*) or in those that are largely parasitic (Hagfish, Lamprey) is remarkable. The macrosmatic or nocturnal Fishes, such as the Shark and Sturgeon, are little, if any, better supplied.

The largely nocturnal Mammals, such as the Opossum, Dog, and Cat, rank considerably below the lowly Rabbit in the number of optic nerve fibers; but most poorly provided of all are the macroacoustic Bats.

The Birds, with their exquisitely developed sight, equal in this respect, on the whole, the Primates, whose visual system is the best developed among Mammals. The great number of optic nerve fibers in the Pigeon, Pig, and Sheep is noteworthy.

Another interesting fact obtained by Bruesch & Arey is the absence of fibers devoid of myelin in most Mammals, including the Monkey and Man, and in all Birds which they investigated. This appears to indicate an improvement of performance or quality of func-

tion, in comparison with the lower ranks of Vertebrates, in which a considerable number of fibers are without myelin.

The observation of these authors that in man "some 38% of all fibers entering or leaving the central nervous system do so by way of the optic nerves" appears of particular significance. This fact, compared with the relatively small number of fibers in the auditory nerve found by Rasmussen, does as much as a lengthy analysis to prove the overwhelming importance of human vision. A true appraisal of the importance of vision in living beings, however, may be expected only after a systematic investigation of all principal factors concerned: anatomical, physiological, and biological. (*Cf.* chap. XIV.)

SEC. 4. COURSE AND TERMINATION OF THE FIBERS OF THE INFRANUCLEAR DIVISION OF THE VISUAL SYSTEM IN GENERAL

1. Anatomical procedures for the study of the course and termination of the optic nerves.—There are many methods by means of which it is possible to determine where a certain nerve or bundle of nerve fibers originates and terminates in the brain. The first step, ordinarily, is to examine gross specimens and sections without the aid of elaborate magnifying apparatus, such as a microscope, or with the help of slight magnification only. This may be followed by a careful dissection of well-fixed specimens. In this way, by duplicating the procedure of the anatomists of the past, much may be learned about the optic nerves and tracts and about the various related nuclei and centers of the brain (Figs. 181–84). As pointed out previously, however (*see* chaps. II, III, IV), this method permits us to determine with some certainty only relatively crude connections, while the minute relationships cannot be definitely determined in this way. More information may be gained through the study of a series of sections of specimens stained by one of the modern methods (e.g., Nissl's, Weigert's; *see* Polyak, *The Retina*, chaps. II–VI).

Far more reliable results may be obtained by combining one of the histological methods with the experiment. The procedure of Marchi is such an experimental histopathological method, much utilized in the investigation of the fiber systems of the brain and spinal cord. It is based upon the property of selective staining in black against the lighter background of those myelinated nerve fibers or bundles of fibers that have been damaged and in consequence have degenerated. These may then be easily followed in serial sections as far as the stations of the brain where they terminate. The results of experiments upon the infranuclear division of the visual system of several representative species where this technique was applied are described in the following paragraphs.

2. Course of the fibers in the optic nerves, chiasma, and tracts and subcortical visual nuclei, as determined by experiment.—When an eye is removed in an experimental animal, for example, Monkey, Pigeon, Rat, Guinea Pig, or Cat, the optic nerve fibers originating in that eye degenerate and may conveniently be studied along their course as far as their termination in the various subcortical visual stations or nuclei of the brain (*see* Figs. 186, 190, 191, 192). Such a series of sections shows that the optic nerve on the side of the removed eye degenerates completely in all animals. Whereas, however, in Birds the opposite or contralateral tract alone shows degeneration, in nearly all investigated Mammals both optic tracts degenerate, even though only partly, the

degree of involvement of the ipsilateral tract depending upon the species. The optic nerve of the opposite side, corresponding with the intact eye, remains normal or practically so in all cases.

The fact that the optic nerve of the remaining eye does not contain degenerated fibers indicates that there are probably no commissural fibers directly linking the two eyes, as was assumed by a number of investigators of former times (F. Arnold 1839; Pagano 1897; Myers 1901; Parsons 1902; Dubreuil & Dupuis-Dutemps 1904).

In the chiasma of the optic nerves, both in

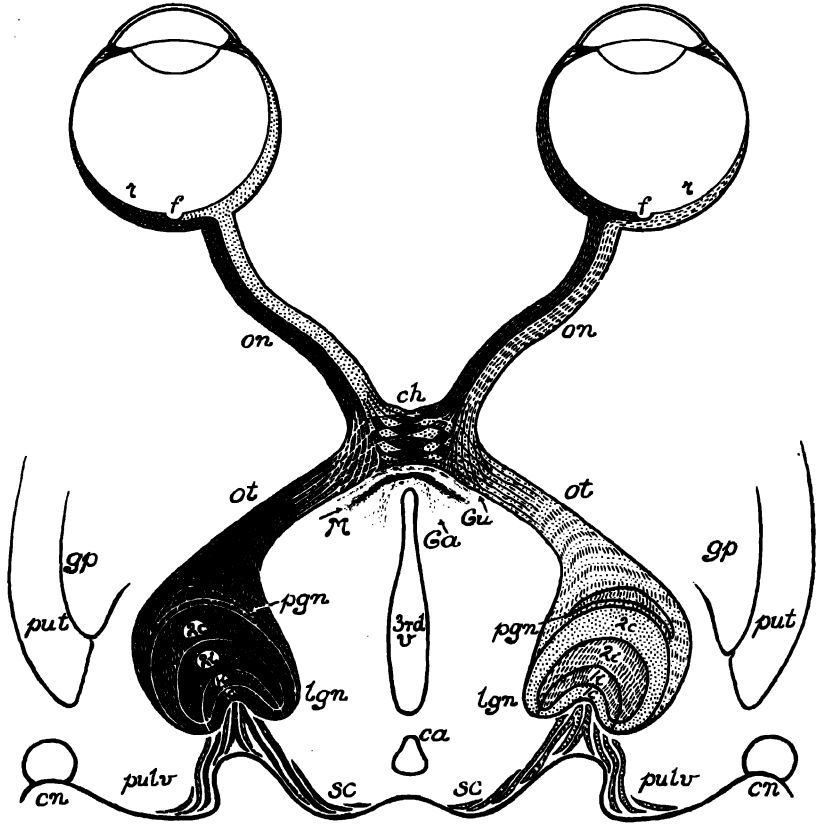

FIG. 186.—Infranuclear and intermediate or nuclear divisions of the visual system of a Monkey (Rhesus Macaque). Optic nerve fibers originating from the retinae (*r*) of both eyes are assembled in the two optic nerves (*on*). After a partial crossing of nasal fibers in the chiasma (*ch*), they continue as optic tracts (*ot*) and terminate in the subcortical visual nuclei: laminated lateral geniculate nuclei (*lgn*), pregeniculate gray nuclei (*pgn*), superior colliculi of the midbrain (*sc*), and possibly also in the pulvinars of the thalami (*pulv*). No other nuclei of the brain, such as the globus palljdus (*gp*), the putamen (*put*), and the caudate nucleus (*cn*) of the striate bodies, or the commissures of Gudden (*Gu*), Meynert (*M*), and Ganser (*Ga*) are directly related to the visual system. Other abbreviations: *ca*, cerebral aqueduct; *f*, central fovea; *3rd v*, third cerebral ventricle. Note the termination of nondecussating ipsilateral and decussating contralateral fibers in separate layers of the laminated nucleus (to be identified by corresponding stippling) and a conjoint termination of both fiber categories in the pregeniculate nucleus and the superior colliculus. Based on an experiment where one eye was removed and the specimen was stained with the Marchi method for secondary degeneration of nerve fibers. (*Cf.* Figs. 190, 191, 192.)

the Cat (Fig. 192) and in the Monkey (Fig. 186), it is found that almost half the fibers cross from the severed optic nerve to the contralateral tract, while a little more than half pass over to the tract of the same side. Not all decussating bundles, however, take the shortest course. Some deviate from it, describing more or less complicated circuitous routes. The detouring is more pronounced on the inferior than on the superior levels of the chiasma. In general, the bundles closer to the anterior limit of the chiasma make a loop-shaped detour in the terminal portion of the opposite optic nerve, and the bundles in the posterior edge of the chiasma make a detour in the initial portion of the ipsilateral tract, before they cross over to the contralateral optic tract.

In Man and in the Monkey the phenomenon of the detouring chiasmal fibers is even more pronounced (*see* sec. 6, this chapter, and Figs. 193, 196, 198). While crossing, the decussating bundles spread over the entire anteroposterior expanse of the chiasma. As soon as they enter the contralateral optic tract, the decussating fibers, streaming in numerous bundles, spread over the entire thickness of that tract. The nondecussating fibers arising from approximately the temporal halves of the two retinae are confined to the lateral zones of the chiasma, leaving the larger intermediate section entirely to the two decussating systems. The nondecussating fibers also spread over the entire thickness of their own tract as soon as they enter it.

The supraoptic commissures and other similar decussating fiber systems of the adjacent region of the hypothalamus, of varying development and appearance in different species, apparently have no direct connection with the visual system except topographically (*cf.* Probst 1905; Herzog 1906; Ariëns Kappers *et al.* 1936). At least three such systems may be distinguished in Man and in the Monkey. On the lower levels and immediately adjoining the chiasma along its posterior margin is the inferior posterior, or ventral, supraoptic commissure of Gudden, made up of a great number of delicate myelinated fibers (*Gu*, in Fig. 197). Next to it at a somewhat higher level and separated by it from the chiasma proper is the superior posterior commissure of Meynert (*M*), consisting of a few bundles of slightly thicker and much more deeply stained fibers, which can be traced back along the tracts for some distance. The third, closest to the anterior limit of the third cerebral ventricle, is the dorsal supraoptic, or anterior hypothalamic, decussation or commissure of Ganser and Forel (*Ga*). In Man it is composed of two or more loose strands of extremely delicate myelinated fibers skirting the third ventricle, along whose sides they can be followed back into the hypothalamus, leaving the columns of the fornix laterally (*F*, in Fig. 197). Still other similar fiber systems have been announced by Hannover & Obersteiner ("ansate commissure"), Marie & Lerie, and Moeli ("residual bundle"); (*see* Obersteiner 1912, p. 501).

In the optic tracts the fibers, both crossed and uncrossed, spread over the entire thickness, as soon as the region of the chiasma is passed. The fibers are uniformly distributed, indicating an intimate and uniform mingling of the two systems, the decussating and the nondecussating. The exception is the inner-lower, or ventromedial, corners of the tracts, where the crossed fibers from the extreme anterior segments of the nasal halves of the retinae alone are present, the "monocular fibers." The relative number of fibers, however, increases from the wedge-shaped, ventromedial end to the bulkier, club-shaped, dorsolateral extremity; conversely, the thickest fibers are found in the first, the thinnest near the surface in the latter, part of the tracts.

The fibers remain confined to these structures along the entire length of the tracts in Man, Monkey, and Cat. The only exception is, perhaps, a few fibers which, in the Cat, enter a locality in the hypothalamus along the inner contour of the tract for a short distance. In Monkey and in Man, however, no myelinated optic nerve fibers pass into the various nuclei of the hypothalamus and subthalamus, such as the supraoptic nucleus or basal optic ganglion, ectomammillary ganglion, isthmic ganglion, etc. Nor could any side tracts described in the Lower Mammals and Inframammalian Vertebrates, such as the transverse peduncular tract of Gudden (*tractus peduncularis transversus*) or the anterior and posterior accessory optic tracts or bundles of Bochenek (*fasciculus* or *tractus opticus accessorius anterior* and *posterior* or

"basal optic root"), be identified in Man, Monkey, and Cat. If there are such connections within the brain stem in the visual system of these species, they must be represented by nonmyelinated fibers (on these *see* S. Ramón y Cajal 1911, Fig. 255; *see also* Bruesch & Arey 1942). Hence it is probable that, especially in Primates, unlike some Lower Mammals and Inframammalian Vertebrates, there are no optic connections below the level of the lateral geniculate nucleus or that, if present, they are, at most, only slight. (*Cf.* sec. 5, this chapter.)

All optic nerve fibers from the retinae, as far as evidence from experiments with the Monkey, Pigeon, Rat, Guinea Pig, and Cat indicate, terminate in the subcortical visual nuclei of the brain stem (Figs. 186, 190, 191, 192; *see also* sec. 5, this chapter). There is no certain indication that any of these fibers continue farther up or that any reach the cerebral cortex (as formerly believed, e.g., by Gudden). In the Cat and in the Monkey and presumably also in Man, the greater majority of all optic fibers and practically all thick ones terminate in the laminated or dorsal portion of the lateral geniculate nucleus (*lgn*). Those that continue beyond are thin fibers, with only a few thicker ones interspersed (Fig. 187). These delicate fibers enter the pregeniculate and pretectal nuclei and the superior colliculus of the midbrain. The number of these direct optopregeniculate and optotectal fibers is approximately equal on both sides, both in the Cat and in the Monkey, indicating that each eye contributes about an equal share of decussating and nondecussating fibers to both the right and the left sets of these subcortical visual nuclei. The way these fibers are distributed in each nucleus is further dealt with in detail in the following paragraphs and sections of this chapter.

3. THE TERMINATION OF OPTIC NERVE FIBERS IN THE LAMINATED LATERAL GENICULATE NUCLEUS.—When degenerated optic nerve fibers are followed from the chiasma to their terminal stations in a continuous series of sections, treated by Marchi's technique, through the optic tracts and adjoining parts of the brain of a monkey, where one eye had been removed 2 or 3 weeks before the animal was sacrificed, it is found that both tracts are about equally affected and that both lateral geniculate nuclei receive about an equal number of degenerated fibers.

By far the greatest majority of degenerated optic nerve fibers enter the laminated lateral geniculate nucleus. They invade it in dense streams through its frontal extremity and also from the inferior aspect around the hilum. Other aspects of the nucleus, especially the lateral and the upper, are used less or not at all.

The thickest optic nerve fibers enter the lateral nucleus at its ventral or inferior aspect. They come from the inner-lower pointed "wedge" of the optic tract. Their termination is in two segments, a ventromedial and a ventrolateral, flanking the "notch" or hilum of the nucleus. These fibers, exclusively decussated, arise from the anteriormost segment of the contralateral nasal retina and correspond to the opposite monocular temporal crescent in the field of view, as discussed in section 11, in this chapter. The medium-thick and the fine fibers from the remaining larger portion of the tract, including its bulky upper end, are the mixed decussating and nondecussating fibers from the binocular portions of the homonymous halves of both retinae, coincident with the side of the examined geniculate nucleus (nasal half of the left retina and temporal half of the right retina in the case of the right-side geniculate nucleus; and vice versa). Spreading in numerous bundles, which approximately continue the slanting anteroposterior course of the tract fibers, they are distributed according to their topographical relationships to various segments (on coronal cross-sections) and levels of the nucleus (in the longitudinal sense) in which they terminate (*see* sec. 7, this chapter). Their principal mode of distribution is through the arciform and somewhat longitudinally arranged bundles, apparently largely coinciding with the intercellular fibrous laminae.

Except in the inferior and medial aspects of the lateral geniculate nucleus, only relatively few afferent optic nerve fibers are included in the thick perinuclear fibrous capsule enveloping the entire laminated nucleus. Most fibers of the perinuclear capsule, especially at the dorsolateral and posterior aspects of the nucleus, as well as the "triangular field" of Wernicke, are accordingly made up of geniculocortical and

possibly corticogeniculate fiber systems (*see* chap. VII, 3 [2]).

Each preterminal arciform bundle consists of thinner fibers intermingled with a few thicker ones. The average thickness of the fibers decreases from the region of the hilum, where the coarsest fibers are found, toward the upper rounded extremity of the nucleus, where the fibers are most delicate. The pattern of distribution in the laminated lateral geniculate nucleus in that respect closely resembles the distribution of the thick and thin fibers in a cross-section through the optic tract (*see* preceding subsection, in this section).

Since numerous fibers terminate at a greater or lesser distance from the point of entry at the anterior extremity of the nucleus where it is joined to the tract, they have to pass through a longer or shorter stretch of the nucleus. This is especially true of the delicate fibers arising in the homonymous halves of the two foveae and central areae. In order to reach their destination at the posterior extremity of the nucleus, these are obliged to traverse almost its entire anteroposterior extent (*cf.* sec. 7 [3–5], this chapter).

4. The termination of the optic nerve fibers in pregeniculate and parageniculate gray nuclei. The relatively large laminated geniculate nucleus of the Primates is the principal subcortical visual station where most optic nerve fibers and almost all the thicker ones terminate. The other terminal station is a small, crescent-shaped area resembling a skullcap, pressed at a slant to the dorsal convex extremity of the laminated nucleus: the pregeniculate gray nucleus, *substantia grisea praegeniculata*, or *griseum praegeniculatum* (*pgn* in Figs. 186, 187). This nucleus is found along approximately the anterior third or half of the longitudinal extent of the bulkier laminated portion, or the lateral geniculate nucleus in the restricted sense (*see* nucleus marked with * in Figs. 200, 214, 215). (*See* sec. 10, this chapter, and *pgn* in Figs. 210, 212, 222, for structural details of the nucleus.)

In Man and in the Monkey the pregeniculate nucleus is made up of one or more somewhat disconnected rows of minute fiber bundles (*pgn* in Fig. 187, *A*) and a considerable number of mostly small fusiform nerve cells, with a few of rather fair size (Figs. 211, 212, 213, 222). The bundles consist of delicate myelinated nerve fibers. In transverse coronal sections these bundles appear cut at a somewhat oblique angle. In the experiment where one eye is removed, these fibers degenerate in great numbers, approximately equal on both sides, manifesting their origin from the optic tracts and hence from the retinae, both crossed and uncrossed. Their passage from the tract to the pregeniculate nucleus is gradual, the fibers becoming detached on successive posterior levels.

The fibers which enter the pregeniculate nucleus are of the same fine caliber as are the delicate fibers which fill the central-areal and foveal segments of the subjacent laminated nucleus along its upper convex margin, whence some of them emerge. The experimental evidence shows that they all arise from the central area in and around the fovea of both retinae (*cf.* sec. 7, this chapter, and Figs. 202, 203, 204). Whether these fibers represent axis cylinders of a special variety of retinal ganglion cells or whether they are merely collateral branches of the same optic nerve fibers whose principal teledendrons or terminal arborizations are in the laminated nucleus can be determined definitely only with the help of good Golgi preparations. Considering their great number, a guess may be ventured that they are side branches of fine axis cylinders, whose ganglion cells of origin reside in the central area and fovea of both retinae and whose principal termination is in the intermedioposterior areal-foveal segment of the laminated nucleus.

In approximately the middle third of the longitudinal extent of the laminated nucleus, after the cap-shaped portion of the pregeniculate nucleus disappears, a narrow strand of small and medium-sized fusiform nerve cells is found closely attached to the medial or inner margin of the laminated nucleus: the parageniculate nucleus or *griseum parageniculatum*. This strand may be followed farther in the subthalamus, with whose cells it merges (thus *pgn* in Fig. 209; *see also* Figs. 211, 212, 215). It contains nerve cells of the same appearance as those found in the more dorsally situated pregeniculate nucleus, with which it is continuous. The cell strand marks the avenue along which the pre- and parageniculate nuclei have mi-

grated during their ontogenetical and phylogenetical development from the subthalamus. Some of the fine bundles of afferent fibers described earlier enter that region also, as at *x*, in Figure 187, *B*. (*See* secs. 7, 8, and 9, this chapter, for additional anatomical details; *see* sec. 10, this chapter, for probable function.)

5. THE TERMINATION OF OPTIC NERVE FIBERS IN THE PULVINAR OF THE THALAMUS AND IN THE SUPERIOR COLLICULUS OF THE MIDBRAIN.— The thick perigeniculate fibrous capsule which envelops the laminated lateral geniculate nucleus does not cease at the caudal end of that nucleus but continues for some distance posteriorly (Fig. 187, *C*, *D*, *E*). Especially those fibers that form the ventral segment of this capsule gradually shift medially and join those that form the medial segment of the same capsule. In this way a narrow, compact "intergeniculate fiber lamina" (*il*) is formed, separating the lateral geniculate nucleus (*lgn*) and pulvinar of the thalamus (*pulv*) on the lateral side from the medial geniculate nucleus on the medial side (*mgn*). Farther back, this "intergeniculate lamina" splits into two thin superficial fiber layers. One of these becomes the zonal stratum of the pulvinar, specifically of its inferior or posterior nucleus, whose inferior surface it lines (*z*). The other layer (*y*) covers, in a similar way, the exposed inferolateral surface of the medial geniculate nucleus.

Most of the fibers of both these superficial strata gradually turn medially and proceed to the superior colliculus (*sc*) of the same side by way of the brachium (*bsc*), where this brachium forms a superficial medullary layer (*y*). A few of these medullated fibers enter the thin zonal layer of the colliculus and the gray superficial cell layer. A similar course is pursued by the decussating optic nerve fibers in the opposite half of the brain in order to reach the "cap" of the contralateral colliculus (Fig. 187, *F*). In this way both superior colliculi receive direct optic nerve fibers from each eye; that is, each colliculus is supplied by both the decussating and the nondecussating fibers originating in the homonymous halves of the two retinae. In the Monkey, the number of fibers of both categories is approximately equal.

In the zonal stratum of the medial geniculate nucleus, the majority of fibers which eventually pass over to the superior colliculus are quite fine, with a few thicker ones interspersed. In the zonal stratum of the pulvinar, the optic fibers are all thin. Whether or not these fibers also terminate in this structure, there is, unfortunately, no way of telling. Undoubtedly, part of them, probably the majority, use this locality merely as a passage, along which they rejoin the rest (*y*), eventually passing over to the brachium (*bsc*) and thus reaching the colliculus (*sc*). All along their course in the two zonal strata (*z*, *y*) and in the brachium (*bsc*) these fibers remain close to the surface, immediately underneath the pial cover.

The terminal distribution in the colliculus of these direct optic nerve fibers is peculiar (*sc*). Here they enter a narrow zone at the base of the "cap," which, if viewed from above, would appear circular. The center or summit of the colliculus receives no myelinated optic nerve fibers (Fig. 187, *E*, *F*). A considerable number of direct fibers may reach the pretectal nucleus as well as the colliculus proper, an observation less certain in the Monkey than in the Cat.

The direct optotectal nerve fibers do not decussate in the midbrain, either in the posterior commissure or in the fiber systems which connect the superior colliculi of the right and left sides. Each superior colliculus, accordingly, is a terminal station of fibers coming from the optic tract and lateral geniculate nucleus of its own side: the right-hand colliculus receiving nondecussating fibers arising from the temporal half of the retina of the right eye and fibers arising from the nasal half of the retina of the left eye decussating in the chiasma; and vice versa. The relation of the two retinae to the optic tectum in the Monkey, accordingly, duplicates that of the lateral geniculate nuclei, according to the principle of homonymity.

Since no direct optic fibers cross in the midbrain, there is no way for the fibers decussating in the chiasma to recross to the side of the midbrain ipsilateral with the side of their retinal origin —an arrangement which would annul the effect of the chiasmal decussation. Nor do the fibers not decussating in the chiasma pass over to the contralateral side in the midbrain, as was assumed by Landolt, Charcot, and Ferrier in their attempts to explain "macular sparing" (*see* chap. III, 7 [4], 9 [6], and chap. XII, 8).

The system of direct optic nerve fibers terminates principally in the superficial medullary stratum, to a lesser extent in the zonal stratum, of the superior colliculi and probably in the pretectal nuclei and perhaps also in restricted territories of the tegmental region of the midbrain of both sides just above the medial geniculate nuclei, adjacent to the brachia of the superior colliculi. It is noteworthy that no other parts of the midbrain, e.g., deep layers of the superior colliculi, the whole of the inferior colliculi, the tegmentum, the periaqueductal gray substance, and the oculomotor nuclei, receive such fibers. It is also very probable that the direct optic nerve fibers passing through the zonal layer of the medial geniculate nucleus do so without entering into synaptical and functional relationships with that nucleus, being in but loose contact with it.

In summary, the optic nerve fibers of retinal

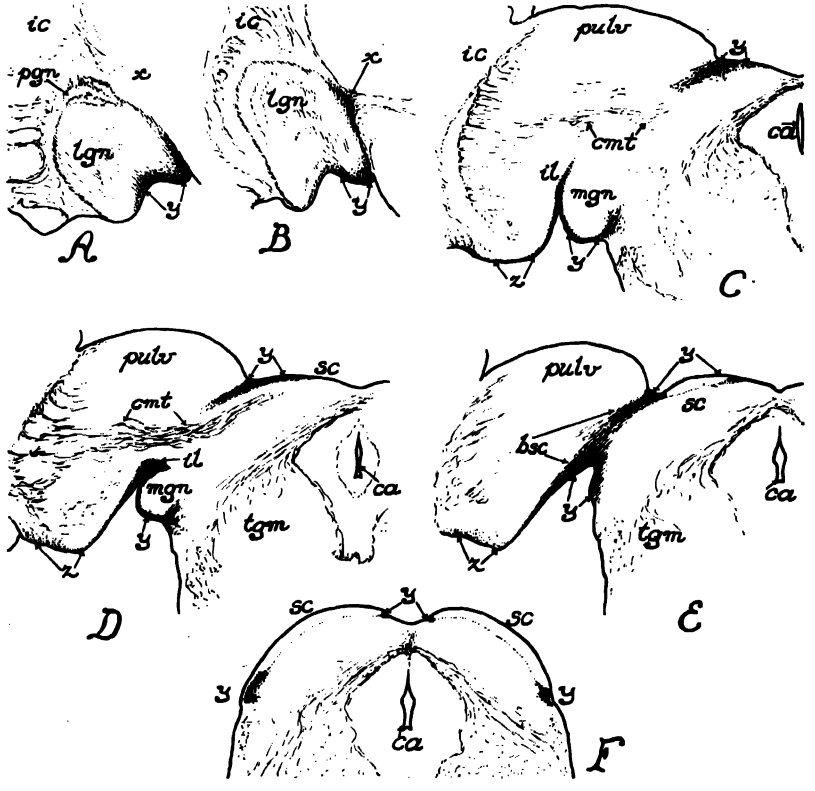

FIG. 187.—Termination of optic nerve fibers other than those in the laminated lateral geniculate and in the pregeniculate nuclei, as found in a Rhesus Macaque where one eye was removed experimentally and where the degenerated fibers were stained according to the Marchi procedure (degenerated fibers indicated by stippling). The following systems of fibers of retinal origin were found: *x*, direct fibers to parageniculate nucleus and subthalamus; *y*, similar direct system to superior colliculi of midbrain; *z*, system of direct optic nerve fibers to the pulvinar of the thalamus (poorly developed and doubtful). *Labeling: ca*, cerebral aqueduct; *cmt*, cortico-mesencephalic tract from occipital lobe (remaining normal in this experiment); *bsc*, brachium of superior colliculus (in part degenerated); *ic*, internal capsule; *il*, intergeniculate lamina (in part degenerated); *lgn*, laminated lateral geniculate nucleus; *mgn*, medial geniculate nucleus; *pgn*, pregeniculate nucleus; *pulv*, pulvinar of thalamus; *sc*, superior colliculi of midbrain; *tgm*, midbrain tegmentum. (*Cf.* preceding figure and Fig. 221.)

origin terminate, in both the simian and the feline brain, principally in the laminated lateral geniculate nuclei, whence the visual radiations to the striate areae of the occipital lobes originate (*see* chap. VII, 3). Few, if any, of them may enter the adjacent zone of the subthalamus; in the Cat some perhaps may enter the hypothalamus. A considerable number of mostly delicate optic nerve fibers, probably collaterals of the thicker ones terminating in the laminated geniculate nucleus, enter the pregeniculate gray nucleus (whence a special fiber tract, the indirect optomesencephalic system, described in section 10 in this chapter, proceeds to the subthalamus and the tegmentum of the midbrain). Still other numerous thin, and a few thicker, direct optic nerve fibers, probably also collaterals, pass by way of the intergeniculate lamina, the zonal stratum of the pulvinar of the thalamus, and the medial geniculate nucleus, over to the "cap" of the superior colliculus of the same side by way of its brachium. No optic nerve fibers of retinal origin reach directly any part of the thalamus proper, with the possible exception of the inferior-posterior nucleus of the pulvinar; nor do any extend as far as the periaqueductal gray substance of the midbrain and the oculomotor nuclei.

Not all fibers in the superficial medullary layer of the superior colliculus are of retinal origin, some apparently being branches of the somesthetic, vestibular, auditory, and descending occipital corticotectal oculomotor pathways (*see* S. Ramón y Cajal 1909 11, and others). The great number of direct fibers of the visual pathway reaching the superior colliculi, however, testifies to the importance of that system, whatever its function may be. It is noteworthy that this system, obviously a phylogenetic residue of a much bulkier one in Inframammalian Vertebrates, should be as well developed, if not better, in the Monkey as in the Cat, even though the "encephalization" or migration of the visual function from the brain stem toward the forebrain is assumed to be further advanced in the Monkey than in the Cat. Indications are that in Man, too, a direct optomesencephalic system not only is present but is an important and essential component part of the central visual mechanism (Juba 1939).

What the proper function of the system of direct optic nerve fibers terminating in the superior colliculi may be remains to be determined by future investigation. In the Lower Vertebrates, particularly in Fishes, where there is no forebrain cortex, all optic nerve fibers necessarily terminate in the brain stem, principally in the optic lobes– which may be considered homologues of the superior colliculi of the more advanced Vertebrates. At this phylogenetic level the optic tectum is the uppermost station of the visual system, also performing the higher or psychic functions of a commemorative or mnestic, integrative, and reproductive nature.

On successively higher phylogenetic levels, most of these functions are gradually transferred to the cerebral cortex, until in the Primates, especially in Man, practically all of them are dependent upon the cortex. As Klüver demonstrated in his experiments with monkeys, however, a notable residue of the original functions still remains, even after a complete removal of both striate areae of the occipital lobes of the brain. Such are certain primitive or elemental photognostic reactions which may be defined as "the ability to respond differentially to various quantities of light or differences in luminous flux densities at the eyes"; even though an animal thus mutilated and gnostically blind is not able to recognize either the size, color, or distance of visual objects, it still can choose those whose total amount of emanated or reflected photic energy is greater, regardless of whether the cause is the greater intensity, the greater size, or the lesser distance, than that of other objects simultaneously offered. Whether the superior colliculi alone, with, perhaps, parts of the midbrain, or together with the thalamus (posterior or inferior nucleus of the pulvinar, pregeniculate nucleus) are responsible for this elemental visual function remains an open problem.

This much by now appears certain: the visual pathway necessary to elicit a constriction of the pupils on stimulation of the retinae by light does not pass through the superior colliculi but is subtectal. The experiments involving the removal of the superior colliculi where no substantial impairment of the pupillary light reflex was observed do not leave much doubt about this (Knoll; Bechterew 1883; Ferrier & Turner

1898; Levinsohn 1904, 1909; Bernheimer 1909; Keller & Stewart; Magoun 1935). In agreement with this are other experiments where neither a constriction nor a dilatation of the pupils was seen on stimulation of the superior colliculi (Ranson & Magoun 1933). The evidence seems to point toward a subtectal location of the pupillary reflex pathway: an indirect or pregeniculo-tectal pathway, originating in the pregeniculate gray nucleus and terminating in the periaqueductal gray substance around the oculomotor nuclei. (*See* sec. 10 [3], this chapter, and Fig. 223 for more complete information on the pupillary reflex pathway.)

SEC. 5. STRUCTURAL PECULIARITIES OF THE INFRANUCLEAR AND NUCLEAR DIVISIONS OF THE VISUAL SYSTEM IN THE LOWER VERTEBRATES AND INFRAPRIMATE MAMMALS

1. Variations of the visual system in Vertebrates. The general plan according to which the vertebrate visual system is organized is basically identical, in the entire Chordate Phylum, beginning with the class of the Cyclostomes at the bottom of the phylum, through the various Fishes, Amphibians, Reptiles, Birds, to and including the Mammals at its top. Everywhere the photoreceptors are represented by two symmetrically placed retinae incased in the eyeballs, each connected crosswise by an optic nerve or its equivalent to the contralateral visual centers of the brain. The deviation introduced into this uniform organization by the emergence of an additional peripheral photoreceptor, the parietal or "pineal eye," in Lampreys and some Reptiles, and of the parapineal eye of the Lampreys, is only an apparent one, since its frequent presence as an orimental organ or as a rudimentary vestige shows it to be an original structure of the vertebrate organization. The phylogenetical and ontogenetical factors responsible for the uniform organization of the vertebrate visual system are discussed in chapter XIII, 2, 3.

The basically uniform organization of the

vertebrate visual system, however, is merely a background for an infinity of detailed execution. This concerns not only such elemental facts as the thickness of the optic nerves, the number of optic nerve fibers, the way the optic nerves reach the primary visual centers, and the mode of their termination therein, but also the distribution of fibers to the various subcortical stations, the shifting of emphasis from the mesencephalic centers to those of the diencephalon, with the resulting transference of most of the visual functions to the forebrain cortex. Finally, the introduction of a partial decussation in Mammals culminates, in the Carnivora and in the Primates, in the creation of a frankly binocular, stereoscopic, visual apparatus, bringing about the rearrangement or reorganization by which the basic character of this system is modified.

In the following paragraphs the visual system of a few representative Vertebrates is briefly described, and the pertinent functional factors discussed. (*See also* chap. XIV.)

2. STRUCTURE OF THE OPTIC CHIASMA IN INFRAMAMMALIAN VERTEBRATES. The structure of the chiasma varies a great deal in different classes, orders, and even smaller subdivisions and individual species of Vertebrates (Figs. 188, 189). It is commonly believed that in all Vertebrates below the Mammals there is complete decussation, e.g., in Fishes, Amphibians, Reptiles, and Birds. This belief is to some extent based on theory, as well as on factual observations. Only in Mammals, it is believed, does a portion of the optic nerve fibers, small in the lower orders (e.g., Cetacea, Insectivora, Rodentia) and increasing toward the Order of Primates, remain on the same side and terminate in the ipsilateral hemisphere of the brain. Even, however, in orders where decussation is complete, or seems to be so, there is much variation in detail. While in some species there may be a simple crossing, whereby the two optic nerves decussate in bulk, without undergoing any more relationship than that of a contact, in others the two optic nerves may be separated into a smaller or larger number of bundles or sheets, intertwined and interlaced in many different ways. Even in the same species the pattern may vary from level to level. In the Golden Eagle (Fig. 189), for example, the crossing appears in some planes to be massive, in bulk, while in other planes it is a complicated plaiting of several small interlaced bundles, forming an intricate pattern.

Where the crossing is in bulk, one optic nerve simply passes above or below the other. There seems to be no rule determining which nerve is above and which below. In the Northern Pike (*Esox estor* or *E. lucius*), for example, in one individual the right, in another individual the left, nerve is above. Only a systematic study of the various species, on a statistical basis, could determine whether or not there is some preference in this respect. (*See* chap. III, 9 [5]; and chap. XIV for additional information.)

The distribution of the afferent optic nerve fibers that enter the optic tectum varies according to the phylogenetic standing of the vertebrate species. In the Rabbit, according to Pavlow, Berl. Minkowski, Brouwer & Zeeman, and Overbosch, only the contralateral superior colliculus receives such fibers in great numbers, indicating a complete or nearly complete decussation of the phylogenetically older portion of the infranuclear visual system. In the more advanced Mammals, such as the Cat and the Monkey, according to Overbosch and Minkowski, both superior colliculi are the terminals, with the contralateral receiving the majority, the optic nerve fibers terminating in the superficial gray layer. The lateral geniculate nuclei, according to Ariëns Kappers (1929), receive fibers from both eyes, whereas each superior colliculus, as a phylogenetic reminiscence, receives fibers only from the contralateral eye. (*Cf.* following subsections, this section.)

The side tracks of the visual pathway also seem variously developed in different species. The "transverse peduncular tract" (*tractus peduncularis transversus*) of Gudden, and the "accessory optic tract" (*fasciculus accessorius optici*) of Bochenek, according to Overbosch, both degenerate when one eye is removed, but only in the Rabbit and Guinea Pig and not in the Cat and the Monkey.

The functional interpretation of complete decussation given by Johannes Müller (1826) was the absence of stereopsis in the Inframammalian Vertebrates. Subsequent investigations, however, incontestably demonstrate the er-

roneousness of this generalization. Beginning with the Fishes and increasing in various degrees in the higher classes of Vertebrates, stereoscopic binocular vision is present. This caused a number of investigators in modern times to question or completely reject Müller's opinion, according to which partial decussation of the optic nerves is regarded as the basis of stereoscopic vision in the Higher Mammals, including Man (Ovio 1927; Walls 1942). Further considerations, however, indicate that this is another extreme even less justified than the first. More in accord with observed anatomical and physiological facts is the assumption that the problem of providing Vertebrates with binocular stereopsis has been variously solved by the various vertebrate classes. What may be the particular mechanism of stereopsis in Birds, which gives them the ability to judge depth and distance visually with exquisite precision, in spite of

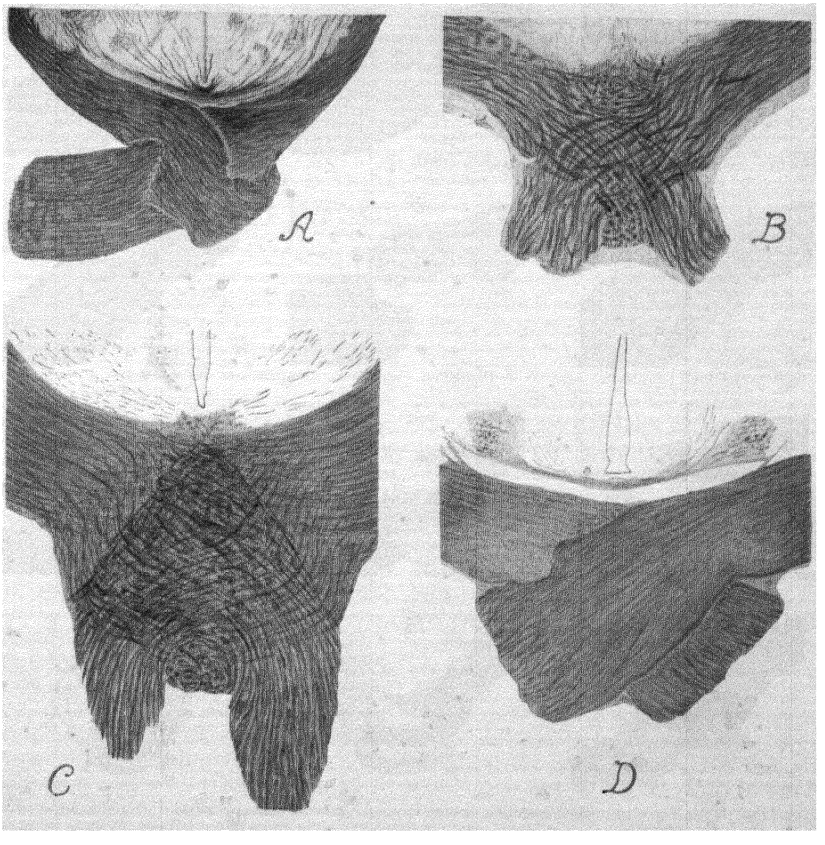

FIG. 188.—Structure of the chiasma of optic nerves in various Vertebrates. *A*, Collared Lizard (*Crotaphitus collaris*), showing a massive decussation; *B*, Guinea Pig (*Cavia porcellus*) with chiasma made up of intertwining fiber bundles; *C*, Rabbit (*Lepus cuniculus*), where chiasma is also made up of numerous intertwining bundles; *D*, Golden Eagle (*Aquila chrisaëtos*), showing at this level a massive decussation of thick optic nerves which on other levels show a complicated pattern of interdigitation (*see* following figure). Note also the entrance of fine fiber bundles into ventralmost portion of hypothalamus just below the slitlike third ventricle, in *B* and *C*. (*Cf.* following figures.)

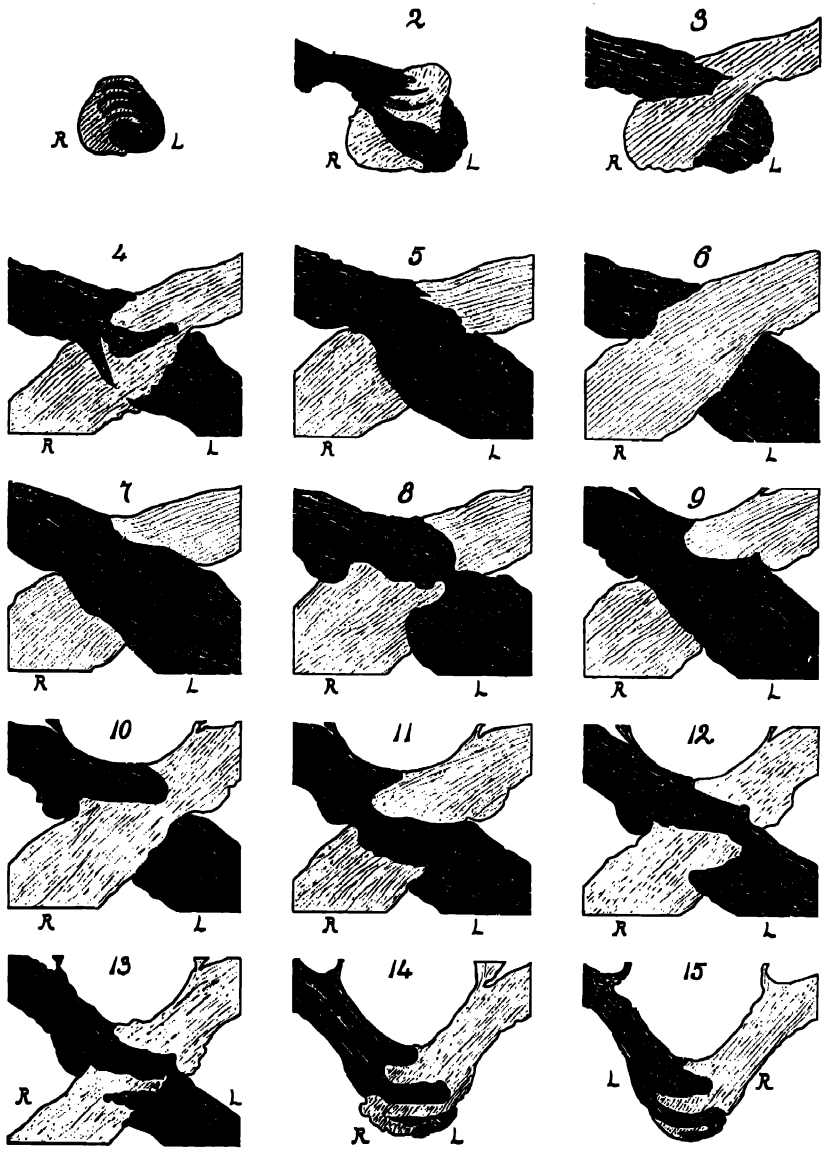

FIG. 189.—Chiasma of the optic nerves of a Golden Eagle (*Aquila chrisaëtos*) presented serially at approximately equal intervals from the rostral (*1*) to the caudal (*15*) levels. *L*, optic nerve of the left eye; *R*, optic nerve of the right eye. Note a massive decussation on the intermediate levels (shown also in *D*, in the preceding figure) and a splitting-up into fibrous laminae on the anterior (*1*, *2*) and on the posterior levels (*14*, *15*) through the chiasma.

complete or almost complete decussation, is a subject to be discussed separately. (*Cf. also* chap. XIII, 2, 3; and chap. XIV.)

3. THE VISUAL SYSTEM OF THE PIGEON.—The visual apparatus of Birds is an object of great scientific interest. This is motivated both by the structural perfection of the Bird's eye and retina and by the role that sight plays in this class. Additional interest stems from the problem of the nature of the neuromechanical organization which achieves such a high degree of tridimensional stereoscopic vision in Birds (a fact easily observed in such common species as the Sparrow or Pigeon) and is possessed in a remarkable degree by such good fliers as Hawks, Eagles, Kites, Swifts, and Swallows.

When one eye is enucleated in a Pigeon, the optic nerve of that eye is found to be apparently completely degenerated, while the other nerve remains normal (Fig. 190). When sections of a specimen stained by the Marchi technique are examined serially, the fibers are seen to continue directly from the affected optic nerve (*on*, black) to the contralateral optic tract (*otr*), which is found to be solidly degenerated. The decussation in the chiasma is complete, and no fibers pass over to the ipsilateral tract, in contrast with the partial decussation found in Mammals (Figs. 186, 191, 192). The structure of the chiasma is typically "plaited," with normal bundles from the intact nerve alternating with degenerated ones from the affected nerve, with no exchange of fibers between the two systems (*cf.* Fig. 189). Above the chiasma the optic fibers, after a shorter or longer course, are distributed over the various parts of the midbrain, where they terminate.

By far the greater majority of optic fibers terminate in the contralateral half of the diencephalon. First, a dense formation of coarse fibers accumulates in a narrow but compact formation next to the initial portion of the optic tract. From here these fibers pass into the reticular-like formation of the large oval core of the midbrain. They completely avoid both the thick periventricular area and the compact bundle of medullated fibers in the ventral region of the rotund core. These coarse fibers scatter between the cells of the latter formation in approximately its inferior fifth, where they terminate. Caudal to the chiasma, this portion, representing perhaps as much as one-fifth of the optic fiber system, becomes superficial, lying on the exposed ventral face of the brain just lateral to the tuber cinereum of the hypothalamus, being flanked on the lateral side by the ventralmost extremity of the optic tectum. Another accumulation of nerve cells, the lateral geniculate nucleus (*lgn*), immediately adjoining the optic tract, is entered by a fair number of optic nerve fibers; other similar but more numerous fibers pass more laterally for some distance into a crescent-shaped formation just lateral to the rotund core.

The majority of optic nerve fibers, mostly thin, spread over the surface of the contralateral optic lobe, or optic tectum (*optec*), whose thick superficial medullary fiber layer, the optic stratum (*strop*), they largely form. From this coating they gradually enter into layers of the cortex-like gray substance of the lobe immediately subjacent to the optic stratum and terminate therein.

Not all optic nerve fibers, however, terminate in the contralateral half of the cerebrum, as one would be led to expect from the completeness of decussation in the chiasma. The exception is two small fiber sheets in the supraoptic area. The first one detaches itself, immediately after decussation of the optic nerves in the chiasma, from the contralateral optic tract, and as a slender stream of thin fibers hugging the ipsilateral optic tract it enters the so-called lateral geniculate nucleus of the ipsilateral side. The other similar fiber system arises from the contralateral tract at a little distance from the first, and, in the closest proximity of the periventricular gray substance, it proceeds into the ventral area of the rotund core of the ipsilateral side.

In summary, the subcortical visual apparatus of the Pigeon is overwhelmingly decussated, with optic nerve fibers originating in the retina of one eye terminating in the centers of the contralateral half of the meso-diencephalon. There are no indications that any fibers of one optic nerve join the ipsilateral tract during decussation in the chiasma, or above it after decussation, in order to reach the ipsilateral optic tectum. Nor do any fibers of retinal origin which have crossed to the contralateral optic

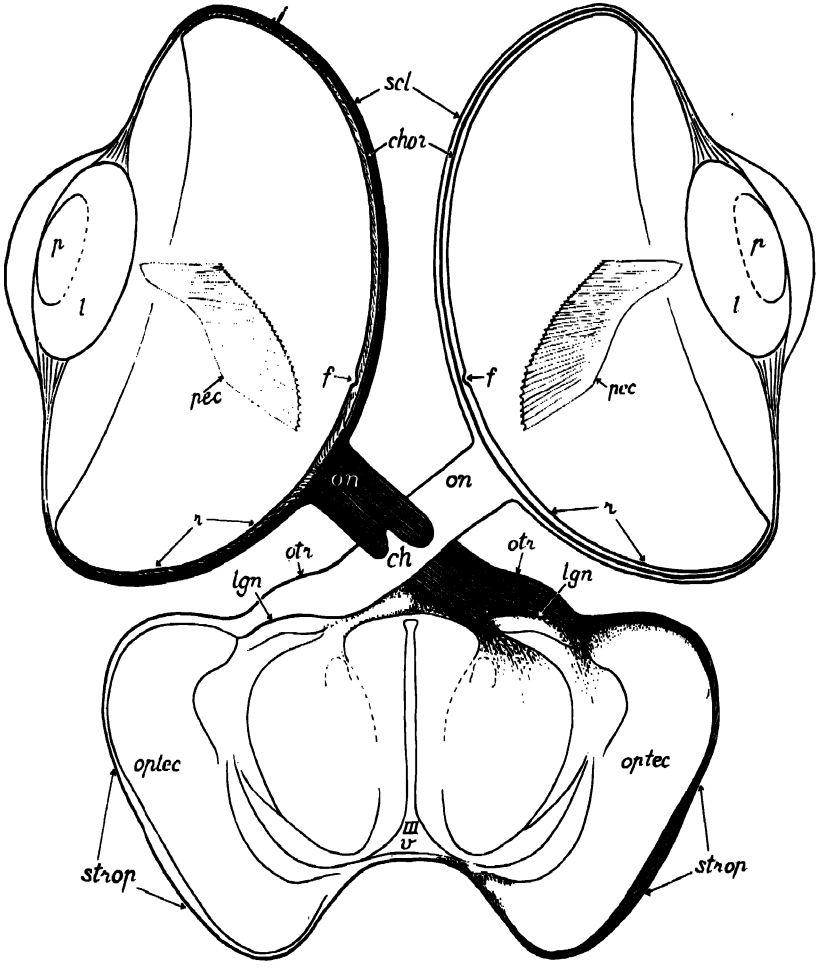

FIG. 190.—Diagram of the visual system of a Pigeon (*Columba livia domestica*). The left eye was experimentally removed (*black in figure*), and degenerated optic nerve fibers (*black*) were followed to their terminal stations in the brain. Marchi stain. The left optic nerve (*on*) degenerated completely, the right nerve remained normal, demonstrating a complete decussation in chiasma (*ch*). Beyond the chiasma the majority of fibers pass over to the optic stratum of contralateral optic lobe (*strop, optec*) of the midbrain, with numerous coarse fibers also entering the core of the brain, some entering the so-called lateral geniculate nucleus (*lgn*). However, two smaller fiber systems deviate from the principal decussating stream and recross to the ipsilateral side, where they enter the lateral geniculate nucleus and the core of the midbrain. These recrossing fibers may account in part for the ipsilateral pupillary reflex and in part for the presence of an overlapping of both monocular fields of view found by J. Levine (1945) and may indicate a phylogenetical beginning of a partial decussation found in almost all Mammals (*cf.* following figures). No retinal fibers recross in the roof of the midbrain (at *III v*), in the Pigeon. *Labeling: ch*, chiasma; *chor*, chorioid; *f*, foveæ; *l*, lens; *lgn*, lateral geniculate nucleus; *on*, optic nerve; *optec*, optic tectum; *otr*, optic tract; *p*, pupil; *pec*, pecten; *r*, retina; *scl*, sclera; *strop*, optic stratum of midbrain (optic lobes); *III v*, third cerebral ventricle.

lobe recross to the optic lobe of the same side, for example, by way of the intertectal or posterior commissures. The only exception is two minute fiber systems, which, after decussation in the chiasma, recross in the suprachiasmal region to terminate in the ipsilateral core of the mesencephalon and the lateral geniculate nucleus on the side where they originate. None of these recrossing fibers reaches the ipsilateral optic tectum, however. What further connections, if any, there may be between the diencephalic nuclei, mentioned above, and the ipsilateral optic tectum and possibly the forebrain unfortunately remains unknown.

A remarkable feature of the avian visual system is its complexity, comprising a variety of subcortical visual centers directly related to the retinal fibers. This, in addition to the relatively enormous size of the optic lobes and the elaborate structure of the optic tectum, which far exceed their mammalian homologues, the superior colliculi of the midbrain, and equal the structure of the mammalian striate cortex, indicates a functional emphasis upon the midbrain in the organization of the avian visual apparatus.

Whether or not the preceding presentation of the avian visual system is valid for all representatives of this class can be determined only by additional investigation. It is possible that an almost complete decussation is found only in species in which vision is completely or largely panoramic. This assumption is borne out by the visual behavior of the Pigeon, with very restricted simultaneous use of both eyes (*cf.* Levine 1945). Other avian species in which the simultaneous use of both eyes in a binocular visual act has definitely been ascertained, for example, the Golden Eagle and the Barn Swallow, may conceivably possess a visual system in which a fair portion of the optic nerve fibers recrosses in the suprachiasmal region to the ipsilateral side, effectively creating a condition similar to the partial crossing of advanced Mammals, such as the Primates, which have binocular stereoscopic vision. (*Cf.* chap. XIII, 2, 3, and chap. XIV.)

4. The visual system of the Rat.—When one eye is removed in a rat, the optic nerve of that side degenerates solidly, while the nerve of the preserved eye remains normal (Fig. 191). In the chiasma, most degenerated fibers are seen decussating to the contralateral optic tract, a very small number proceeding to the tract of the same side. The proportion of decussating to nondecussating fibers is approximately ten or twenty to one.

The decussation in the chiasma is fairly massive, in thick bundles, with much intertwining of the right and left bundles. The majority of decussating fibers are rather coarse; they represent the bulk of the chiasma and subsequently the larger lateral portion of the tract. The finer fibers are in the posterior segment of the chiasma; in the initial portion of the tract these form the inner division next to the hypothalamus.

In the region of the chiasma, most degenerated fibers appear to keep strictly within the boundaries of this structure. The exceptions are a few localities where the optic nerve fibers leave the chiasma and tracts and enter the substance of the hypothalamus.

The first such area is the thin floor of the third ventricle between the chiasma and the ventricle. The fibers entering this locality are fairly coarse and compactly arranged. This formation is the "hypothalamic optic root" of Frey or "the intermediate hypothalamic optic bundle" (Fig. 191, *iaot*). A few of these fibers indicate their termination by a slight scattering in the adjoining ventralmost area of the hypothalamus, representing the floor of the third ventricle.

Another locality where the fibers leave the chiasma and optic tract is a narrow zone next to the chiasma but slightly lateral to the first area between the chiasma and the floor of the third ventricle, where a few fibers are seen to spread out within the adjoining portion of the hypothalamus (*laot*, in same figure). These fibers are found on the contralateral side only. It is not possible to determine from the degenerated myelin alone whether or not these fibers terminate here.

In a third system of deviating optic nerve fibers found on levels throughout the posterior segment of the chiasma and caudal to it, this is more certain. Upon closer examination, posterior levels of the chiasma are found to be made up of thinner fibers, contrasting with the coarser fibers which make up the anterior,

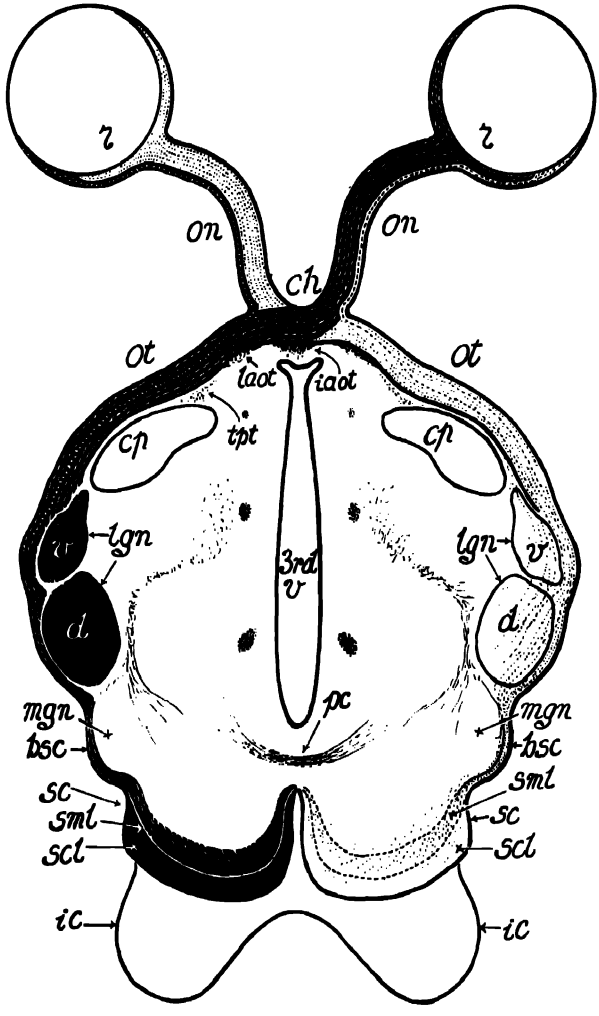

FIG. 191.—Infranuclear and nuclear divisions of the visual system of a Rat (*Mus norvegicus*). Note the overwhelming preponderance of nasal decussating and the minute size of temporal nondecussating portions of optic nerves; the relatively large size of the ventral portion (*v*) of the lateral geniculate nuclei (*lgn*), compared with the dorsal portion (*d*); the large size of the superior colliculi (*sc*); the distribution of optic nerve fibers to both portions of the lateral geniculate nuclei; the termination of almost half of all optic fibers in superior colliculi; no communication between superior colliculi by means of afferent optic nerve fibers; the presence of accessory or collateral optic tracts in hypothalamus (*iaot*, *laot*). *Labeling: bsc*, brachium of superior colliculus of midbrain; *ch*, chiasma of optic nerves; *cp*, cerebral peduncle; *d*, dorsal portion of lateral geniculate nucleus; *iaot*, intermediate accessory optic bundle; *ic*, inferior colliculus of midbrain; *laot*, lateral accessory optic bundle; *lgn*, lateral geniculate nucleus; *mgn*, medial geniculate nucleus; *on*, optic nerve; *ot*, optic tract; *pc*, posterior commissure; *r*, retina; *sc*, superior colliculus; *scl*, superficial cell layer of superior colliculus; *sml*, superficial medullary layer of superior colliculus; *tpt*, transverse peduncular tract; *v*, ventral portion of lateral geniculate nucleus; *3rd v*, third cerebral ventricle.

bulkier, principal portion. These posterior thin chiasmal fibers may be followed into the contralateral tract; they constitute the inner division of this tract, next to the hypothalamus. Whereas the compact, more laterally situated, coarse-fibered division proceeds up in the tract toward the lateral geniculate nucleus and midbrain, the medially situated inner, thinner fibers hug the inferior contour of the hypothalamus, where they make connection with two cell nests, one of them in the most lateral region next to the cerebral peduncle, the other situated about midway. The latter is the "lateral hypothalamic optic bundle" (Fig. 191, *tpl*). Part of this system of deviating optic nerve fibers, also entirely decussated, may be tentatively identified with Frey's "basal optic root of the hypothalamus," the "transverse peduncular tract" of Gudden, and the "posterior accessory optic bundle" of Bochenek and Tsai. The employment of the Golgi or some other analytical method alone may show whether or not these deviating fibers actually terminate where they seem to. The remaining larger territory of the hypothalamus and the subthalamus appear to receive no fibers belonging to the visual system.

The greater majority of optic nerve fibers and practically all coarse fibers remain within the optic tracts to their termination. The tract contralateral to the removed eye appears solidly degenerated. In the ipsilateral tract, only a few degenerated fibers are seen. On the contralateral side, numerous thick and thin bundles and single coarse and medium-thick fibers enter the lateral geniculate nucleus, where both its ventral and its dorsal divisions are invaded (*v*, *d*). In the dorsal nucleus (the phylogenetic oriment, or beginning, of the laminated lateral geniculate nucleus of advanced Mammals, especially Primates), the entering optic nerve fibers are arranged in regular bundles parallel to the outline of the nucleus. On the ipsilateral side the degenerated fibers in the tract and lateral geniculate nucleus, identically arranged, are numerically only a fraction, perhaps one-twentieth, of the decussated optic nerve fibers in the contralateral optic tract and subcortical visual centers.

Beyond the lateral geniculate nucleus the degenerated optic nerve fibers proceed, on the contralateral side, in great numbers to the pulvinar of the thalamus, where they form its thick zonal stratum. Some of these fibers pass into the substance of the pulvinar, where they scatter between its cells, indicating their termination therein. In all three terminal stations of the betweenbrain—the ventral and dorsal portions of the lateral geniculate nucleus and the pulvinar -the incoming optic fibers are most numerous close to the surface, next to the zonal stratum, gradually decreasing in numbers as deeper layers are entered. The entire extent of the zonal stratum of the pulvinar of the thalamus is abundantly degenerated, medially as far as the dent separating the thalamus from the habenular nucleus, which remains free. On the ipsilateral side the degenerated optic fibers behave in a similar way, except that numerically they represent but a fraction of the fibers found in the diencephalic nuclei of the contralateral side. Other parts of the betweenbrain, especially the medial geniculate nucleus, with the exception of its superficial zonal stratum, made up of fibers passing to the midbrain, receive no afferent visual fibers.

Posteriorly to the betweenbrain, the optic nerve fibers continue to, and into, the superior colliculus, which they enter by way of its brachium or arm. On the contralateral side the brachium is solidly degenerated; on the ipsilateral side not at all. Whereas, then, the contralateral geniculate nucleus in both the dorsal and the ventral parts, the pulvinar of the thalamus, and the contralateral superior colliculus of the midbrain are abundantly supplied with afferent optic nerve fibers, on the ipsilateral side the diencephalic stations receive a small number of fibers, while none enter the superior colliculus.

In the contralateral superior colliculus of the midbrain, the optic fibers enter the superficial medullary layer in great numbers. These fibers are fairly coarse, soon dividing into an abundance of fine and very fine granules of myelin, filling the entire layer. Numerous fine granules, droplets, and "dust," in streams, invade the superficial cell layer of the colliculus from below, indicating their termination herein. The zonal stratum and the layers ventral to the superficial medullary layer, with the possible exception of a few degenerated fibers immediately beneath the latter layer, remain entirely free. In the col-

liculus the decussated optic nerve fibers spread exactly to the mid-line, where they abruptly stop, none of them recrossing to the ipsilateral colliculus.

In summary, the visual system of a phylogenetically low-ranking Mammal such as the Rat is preponderantly crossed. This is entirely the case with the phylogenetically older portion of the system terminating in the superior colliculus. This portion of the Rat's visual system duplicates the conditions of a practically completely decussated visual system of the Inframammalian Vertebrates, such as the Birds (see Fig. 190), Reptiles, Amphibians, and Fishes (*cf.* also chap. XIV). The diencephalic connections in the Rat, however, are different. Here, even though at least nine-tenths of the optic fibers decussate, a small, yet not negligible, fraction remains ipsilateral, on the side of origin, and terminates in the lateral geniculate nucleus and the pulvinar of that side. The central visual mechanism, such as that found in a Rat, accordingly, represents an incipient stage in a phylogenetic process of reorganization which culminates in the frankly semidecussated system of visually advanced mammalian orders, such as the Carnivora and the Primates.

Still another fact about the Rat's visual system appears noteworthy. Whereas the number and thickness of optic nerve fibers that terminate in the midbrain are much above the number and caliber of the delicate fibers terminating in the superior colliculi of the Monkey, in the Rat possibly amounting to as much as one-third or more of the total number, the abundant terminations in the lateral geniculate nucleus and pulvinar of the contralateral side in the Rat indicate the increasing importance of the diencephalon even in the lowest mammalian ranks. The relative distribution of the afferent visual fibers in the Rat already shows a definite tendency to shift the emphasis from the midbrain, where it is dominant in the Inframammalian Vertebrates, to the forebrain, an evolutionary transformation completed in the advanced Mammals, the Monkeys, Apes, and Man. (*Cf.* sec. 7, this chapter, and chap. XIV.)

5. The visual system of the Guinea Pig.—The constituents of the infracortical division of the visual system of a Guinea Pig are essentially the same as those found in the Rat. There are, however, some important differences.

The optic nerve of the removed eye degenerates completely, the nerve of the intact eye remains normal. The structure of the chiasma is plaited, thin sheets of fibers of the right and left nerve interdigitate as they cross to their respective tracts. The chiasmal decussation is almost complete, the number of fibers, mostly of coarse caliber, which pass to the ipsilateral tract, is quite negligible, amounting to barely 1 per cent of the total. The "intermediate hypothalamic optic bundle" consists of a fair number of thin myelinated fibers scattered in a small area in the ventralmost zone of the hypothalamus, beneath the third ventricle. The "lateral hypothalamic optic bundle" is thin, consisting of a few dozen delicate myelinated fibers. This system, as in the Rat, is present on the contralateral side only. It does not terminate in the hypothalamus and may be followed beneath the cerebral peduncle for quite a distance in the caudal direction. However, it was not possible to find its terminal locality with certainty (possibly it is the "tegmental optic nucleus" of Tsai). No other system of optic fibers deviating from the principal pathway and terminating in the between- and midbrain was found, which contrasts with the multifarious connections described by some modern investigators (Frey; *see also* Ariëns Kappers *et al.* 1936).

The distribution of the afferent optic nerve fibers to the lateral geniculate nucleus, the pulvinar of the thalamus, the pretectal area, and the superior colliculus closely resembles that in the Rat. Roughly, about half the fibers may terminate in the lateral geniculate nucleus, including both divisions, the dorsal and the ventral, and in the pulvinar, the other half terminating in the pretectum and the superior colliculus. The diencephalic termination is almost entirely contralateral; the mesencephalic, exclusively so. In the two divisions of the lateral geniculate nucleus the incoming optic fibers spread over the whole thickness of the nuclei. In the cap of the contralateral superior colliculus, the fibers terminate in the entire superficial cell layer, gradually decreasing in number and fiber size toward the zonal stratum, which remains free.

In summary, the peripheral division of the visual system of the Guinea Pig is almost com-

pletely decussated, in this respect more closely resembling the conditions of the Inframammalian Vertebrates than does the visual system of the Rat. In both species the connections with the dorsal portion of the lateral geniculate nucleus and the thalamus, both frankly cortical dependencies, are, by comparison with the Carnivores and Primates, restricted; and the connections with purely subcortical stations, such as the ventral portion of the geniculate, the superior colliculus of the midbrain, and others, still prevail. This intimate connection with the noncortical dependencies of the brain stem is even more emphasized in the Guinea Pig by a greater abundance of optic fibers terminating in the midbrain.

In the light of this observation, the Guinea Pig appears even less removed than the Rat from the probable conditions of hypothetical early Mammals and their phylogenetic ancestors, in which the mesencephalic centers of vision predominated.

6. THE VISUAL SYSTEM OF THE CAT.- The feline visual system is especially instructive because of the clear-cut results obtained in experiments involving the enucleation of one eye and the subsequent application of the Marchi method of staining (Fig. 192).

The optic nerve of the side where the eye is removed, as in other Vertebrates, degenerates completely. Many fibers are coarse and therefore easy to follow to their terminal stations. The "intermediate hypothalamic optic bundle" is absent, since no fibers pass from the chiasma into the hypothalamus beneath the floor of the third ventricle. If there is such a connection, it must be by way of the nonmyelinated fibers. The proportion between decussating and nondecussating fibers is almost equal. In the two tracts the fibers keep strictly within these structures, and there is no "basal optic root" or "lateral hypothalamic optic bundle" to be found.

The principal terminal stations of the optic tracts are the lateral geniculate nuclei, especially the laminated or dorsal portions. The geniculate nuclei of both sides receive about an equal number of fibers, or the contralateral receive, at most, slightly more than half. The distribution of incoming fibers is asymmetrical, that is, the ipsilateral and contralateral fibers terminate in different layers of the nuclei (*cf.* sec. 6 [5], this chapter).

The ventral nucleus, which preserves its original position beneath the laminated dorsal nucleus fairly well in the Cat, is also entered by a great number of optic fibers. Being thin and scantily myelinated, however, these fibers can easily be overlooked when the attention is concentrated upon the principal stream of coarse fibers passing over to the laminated portion. An attentive examination shows minute bundles and single degenerated fibers scattering in the gray substance, indicating that in the Cat, too, as in the Rat, Guinea Pig, and Monkey, the ventral portion of the lateral geniculate, or pregeniculate, nucleus is one of the subcortical visual centers. (*Cf.* O'Leary 1940.)

Beyond the lateral geniculate nucleus the optic nerve fibers continue in great numbers to the pretectal region and to the tectum of the midbrain. They are, however, all of fine caliber in comparison with the coarse fibers terminating in the betweenbrain. A few of these fibers may enter the pulvinar of the thalamus, but the greater majority pass to the superior colliculi, where they form the superficial medullary layer. There is no appreciable difference between the right and the left superior colliculus in the number of optic nerve fibers which terminate there.

The visual system of the Cat is noteworthy because of the features in which it resembles that of the Rodents and because of those in which it differs from it and approaches that of the Primates. The degree of reorganization attained by the Cat is most striking. The Guinea Pig, in this respect, represents the lowest level, the reorganization in this species being in an incipient stage, with only a few fibers passing over from the chiasma to the tract of the same side. In the Rat this process advances further, with probably not less and possibly more than 5 per cent of the fibers remaining on the same side. In the Opossum, according to Bodian (1937), about one-fifth of the fibers do not decussate. In the Cat, with almost as many fibers remaining on the same side as those that cross, the reorganization of the visual system has attained a level indistinguishable from that found in the Monkey.

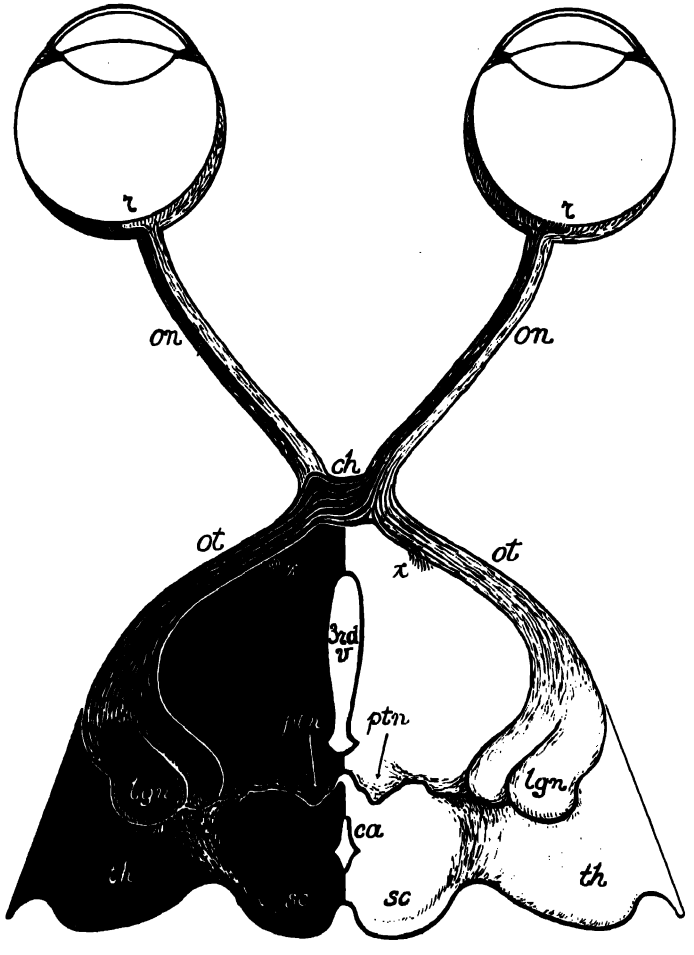

FIG. 192.—Infranuclear and intermediate or nuclear divisions of visual system of a Cat (*Felis domestica*), based upon an experiment where one eye was removed and where degenerated fibers, stained according to the Marchi technique, were followed as far as their terminal stations. The fibers originating in the right homonymous halves of both retinae, right temporal and left nasal, are presented in black lines on white ground; fibers originating from the left retinal halves are presented in white lines on black ground. In the optic chiasma, tracts, and subcortical visual centers, the fibers originating in the right eye alone are drawn, to show their course, arrangement, and termination. Note the clear-cut division of decussating and nondecussating fibers in the chiasma; the spreading of decussating fibers over the entire anteroposterior width of the chiasmal bridge, with the anterior bundles describing detours into the contralateral optic nerve before passing over into the contralateral tract, where they are distributed over its entire thickness; the similar spreading of nondecussating fibers in the ipsilateral tract after passing through the chiasma, of which they form the lateral portion; the different arrangement of crossed and uncrossed fibers in the right and left lateral geniculate nuclei, but the identical arrangement on both sides in all other nuclei; about an equal division into decussating and nondecussating fibers, thus producing a semidecussation or equal division of crossed and noncrossed fibers in the Cat's visual system. *Labeling: ca*, cerebral aqueduct; *ch*, chiasma; *lgn*, lateral geniculate nuclei; *on*, optic nerves; *ot*, optic tracts; *ptn*, pretectal nuclei; *r*, retinae; *sc*, superior colliculi; *th*, thalamus; *x*, uncertain termination of optic fibers in hypothalamus; *3rd v*, third cerebral ventricle. (*Cf.* Figs. 186, 190, 191.)

A profound change has also taken place, in a definite shifting of the emphasis toward diencephalic and hence toward cortico-telencephalic connections, as compared with the Rodents. Whereas in the Guinea Pig and almost as much in the Rat a goodly half of the retinal fibers continue to the superior colliculus, this tectal connection in both rodent species being exclusively contralateral (as in the Inframammalian Vertebrates), in the Cat the superior colliculi of both sides are included, even though proportionately much less than in the Rodents. In both features referred to, the organization of the visual system of the Cat is approached, though not attained, by the Opossum, a nocturnal marsupial Mammal with partly carnivorous habits (*see* Bodian 1937).

A third way in which the Cat differs from the Rodents is the emancipation of its visual system from the hypothalamic and other accessory connections (even though in Rodents these also need to be further investigated, particularly with histoanalytical methods).

The feature which remains common to all mammalian species is the termination of the optic nerve fibers in both the ventral and the dorsal divisions of the lateral geniculate nucleus. Such a connection, easy to demonstrate in Rodents, had until now been questioned in the Cat (Barris, Ingram & Ranson 1935). Its presence in this species, as well as in the Monkey (*see* par. 7, this section), makes it a uniform occurrence in all Mammals so far investigated; aside from its relative obscurity, the ventral geniculate nucleus suffers because of the luxuriant development of the dorsal laminated geniculate nucleus as a station included in the afferent cortical pathway. (*Cf.* sec. 10, this chapter.)

7. SIMILARITIES AND DIFFERENCES BETWEEN THE PRIMATE AND INFRAPRIMATE VISUAL SYSTEMS.—The peculiarities of a primate visual system, for example, that of the Monkey, and those of the Infraprimate Mammals may advantageously be studied after the removal of one eye and the treatment of specimens of the brain according to the Marchi method of staining. In such serial sections all myelinated fibers which degenerate may be followed along their course to the various stations at which they terminate. The detailed arrangement of fibers in the Monkey is presented in section 4 of this chapter, while in this subsection only those features are dealt with which appear characteristic of the Primates in contrast with the visual mechanisms of the Infraprimate Mammals. (*Cf.* Fig. 186.)

In the Monkey, as in the other Vertebrates, the optic nerve on the side of the removed eye apparently degenerates completely. If there are any normal fibers left, they are lost to view in the mass of degenerated ones. In the contralateral normal nerve, however, a few scattered degenerated fibers may be found. The supraoptic commissures of Gudden, Meynert, and Ganser appear normal. An "intermediate hypothalamic optic bundle" in the center, between the chiasma and the deepest point of the third ventricle, cannot be identified with certainty. A small number of slender, tangentially cut bundles, made up of very fine myelinated fibers, spreading in the lowermost zone of the hypothalamus next to the chiasma, may possibly be interpreted in this way. The presence, however, of such a connection could be made certain only with the application of the Golgi method or of Ehrlich's vital methylene blue stain, which alone could demonstrate the actual teledendric terminations.

The similarity between the primate visual system and that of the Lower Mammals, such as the Rodents, manifests itself, in general, in the termination of the optic nerve fibers in both divisions of the lateral geniculate nucleus, the dorsal and the ventral. In the Monkey, the dorsal division is represented by the larger laminated nucleus (*lgn*); the ventral, by the smaller pregeniculate gray nucleus (*pgn*). Because of a rotation during the process of development, the relative positions of the two are reversed in comparison with the original phylogenetical condition, the larger laminated nucleus assuming, in the Monkey, a ventral, the pregeniculate nucleus a dorsal, position. The difference in size of the two nuclei, already noticeable in Rodents, becomes even more accentuated in Primates, with a great increase in bulk and an elaborate lamination of the dorsal division and a relative recession of the ventral.

Both divisions of the lateral geniculate nucleus, as the experimental evidence clearly

shows, are richly supplied with afferent optic nerve fibers. The kind of fibers terminating therein differs, however; those in the laminated nucleus are relatively coarse, while those passing to the pregeniculate nucleus are uniformly thinner. The number of fibers terminating in the pregeniculate nucleus, while probably much smaller than that terminating in the laminated nucleus, is still quite large, even though they are less conspicuous because of their thinness. The pregeniculate fibers spread in numerous delicate bundles to all parts of the nucleus except its upper extremity, from which depart fibers which originate in it. They stop at the nuclear boundary and must therefore be interpreted as actual terminals and not as "fibers of passage."

The luxuriant development of the simian laminated nucleus indicates that it serves as a cortical dependency. In contrast with it is the relative reduction of the pregeniculate nucleus in the Monkey, which has no ascending connections with the forebrain cortex. All this is the consequence of a general tendency of the visual apparatus to become directly incorporated in the cortical mechanism. This tendency, noticeable in the Inframammalian Vertebrates, such as Lizards, and in the Lower Mammals, such as the Rat and Guinea Pig, is here only in its incipient stage, the corticalization of the visual apparatus attaining its maximum in the Order of Primates.

The mesencephalic connections of the primate visual system are in contrast with the diencephalic. Here an opposite trend is noticeable. Whereas in all Mammals so far investigated, from the lowest to the highest, part of the retinal fibers continue directly to the midbrain optic tectum, this direct optotectal connection undergoes a gradual decline in the Carnivora, which is even more marked in the Primates, where it is reduced to a very tenuous relation by delicate myelin fibers.

In the Monkey these direct optotectal fibers are included in the zonal stratum of the pulvinar of the thalamus and of the medial geniculate nucleus and in the intergeniculate lamina, whence, assembled in the brachium of the superior colliculus, they reach the roof of the midbrain. The number of these fibers is but a minute fraction of the number of thick and medium-thick fibers terminating in the laminated nucleus and is also much below the fine fibers which enter the pregeniculate nucleus. The numbers of ipsilateral and contralateral optotectal fibers in the Monkey are almost equal, with perhaps a slight preponderance of the contralateral, a faint phylogenetic reminiscence of a preponderantly or entirely decussated visuotectal system in Lower Vertebrates.

It is not possible to ascertain, on the basis of Marchi preparations alone, whether or not these direct optotectal fibers in the Monkey terminate in the pulvinar of the thalamus and in the medial geniculate nucleus. It is apparent from a complete absence of degenerated myelin in these nuclei that their superficial zonal layers are used merely as a convenient passage to the colliculus.

The termination of the vestigial optotectal fibers in the Monkey is in the superficial medullary and cell layers of the superior colliculus, precisely the same place in which the abundant and much thicker fibers of the Rodents terminate.

Another point worth mentioning is the strict observance of the barrier between the right and the left superior colliculus by the incoming optotectal fibers. Whether these fibers enter only the contralateral colliculus, as in the thick, numerous, and completely decussated optotectal fibers of the Guinea Pig and Rat, or pass over to both colliculi, as in the Cat and Monkey, they never recross in the intercollicular commissure. A "tectal decussation" of afferent optic fibers, assumed by some, does not exist. This and other features of the intrinsic organization of the vertebrate visual system indicate certain deep-seated tendencies, probably based upon definite functional requirements tendencies which remain dominant whether or not a certain part of the central visual apparatus is well developed or remains vestigial and in spite of a profound change introduced by a partial crossing in the chiasma. (*Cf.* chap. XIII, 2.)

Finally, in no Mammal do the optic fibers continue so far as the inferior colliculus, the tegmental region of the midbrain, or the oculomotor and other nuclei related to the visual and other functions, aside from the few exceptions mentioned in the preceding paragraphs. (*See* sec. 10, this chapter, for other details.)

SEC. 6. THE CHIASMA OF THE OPTIC NERVES AND THE REPRESENTATION OF THE HOMONYMOUS HALVES OF THE RETINAE IN THE LATERAL GENICULATE NUCLEI

1. Pathological and experimental evidence of the partial decussation of the optic nerves. When one eye is removed in a human subject or an experimental animal, the fibers in the respective optic nerve degenerate after a few days or weeks. The brain specimen of such a case, when treated with the staining method of Marchi and cut into serial sections, permits the course of selectively stained degenerated nerve fibers to be traced from the point of lesion to their termination in the subcortical visual centers (*see* sec. 4 [1], this chapter). Such series of sections show the severed optic nerve to be completed degenerated, while the nerve of the opposite intact eye remains normal.

In the chiasma the behavior of degenerated fibers varies according to the vertebrate class, as pointed out in the preceding sections. Whereas in the Inframammals, the Fishes, Amphibians, Reptiles, and Birds, the degenerated fibers simply pass over to form the contralateral optic tract (Figs. 188, 189, 190), in Mammals some fibers enter the tract of the same side (Figs. 186, 191, 192). In the Lower Mammals—for example, the Rat, Guinea Pig, and Rabbit—a few fibers only do not decussate; in the advanced Mammals, such as the Cat, Monkey, and Man, almost half the optic nerve fibers do not cross but pass to the tract of the same side.

In Mammals and especially in the Primates,

a partial crossing in the chiasma, accordingly, brings about a fundamental rearrangement, which changes the anatomical, physiological, and pathological character of that entire portion of the visual system which is above the chiasma; whereas below the chiasma each optic nerve is related to its own eye, in the suprachiasmal portion and as far as the cerebral cortex each half of the visual pathway is related to both eyes.

This evolutionary rearrangement of the completely decussating visual system characteristic of the Lower Vertebrates into the partially crossed mammalian visual system is the result of a long phylogenetic process of adaptation to the more perfect utilization of inherent potentialities of visual space perception. There is good reason to view this rearrangement as neither accidental nor irrelevant. For reasons discussed elsewhere in this book, partial decussation of the afferent visual pathway must be declared an essential anatomical factor upon which the three-dimensional binocular vision of Man and other Primates is based (*cf.* chaps. IX, XIV, XV).

In the following an attempt is made to analyze the peculiar structure of the human and simian optic chiasma, tracts, and lateral geniculate nuclei and their functional significance.

2. Fascicular composition of the chiasma.—The intermediate bridgelike portion of the chiasma in the Cat, Monkey, and Man is formed by the crossing fibers originating from the two slightly larger inner or nasal halves of both retinae. The decussating bundles turn toward one another and intermingle in complicated ways as they cross to the opposite tracts. The mingling, however, is by no means haphazard but rather orderly, according to a fixed, stable plan.

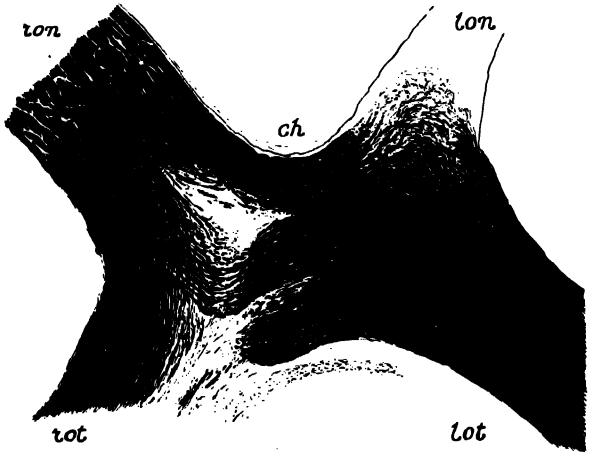

Fig. 193.—Fascicular composition of human optic chiasma in a case whose left eye was lost twenty-four years before death, as revealed in horizontal sections. The left optic nerve (*lon*), right in the figure, is completely degenerated, the right (*ron*) remained normal. The chiasma (*ch*), as well as both optic tracts (*rot, lot*), are partly degenerated. Note the detouring fibers in both nerves. Weigert method of staining; magnification 7×. (*Cf.* following figures.)

In Man the initiation of a partial exchange of fibers takes place in the proximal portions of the optic nerves, 3–4 mm. before the chiasma is reached (Figs. 193–97). This, as far as it is possible to judge from the arrangement of fiber bundles in human cases with one eye missing, consists of a longitudinal rotation of the optic nerve around its own axis, amounting to about 90° (clockwise in the left nerve and counterclockwise in the right one when viewed from behind). In this way, approximately the inner

half of the fibers originating in the nasal half of the retina come to lie on the lower side of the optic nerve, making the monocular-crescentic fibers originating in the most anteronasal portion of the retina lowermost (Fig. 225).

The monocular fibers, the stoutest in the nerve, enter the ventralmost zone of the chiasma, where, pursuing a somewhat oblique course, they cross to the contralateral optic tract. Here they arrange themselves into a narrow crescent-shaped zone in and around the somewhat pointed ventromedial margin of the tract. On the chiasma, from its anterior to its posterior extremity (Fig. 193).

they occupy approximately the upper two-thirds, from below the center to as far as the dorsal surface adjoining the hypothalamus (Figs. 202, 203; *cf.* following section). The remaining fibers, originating from the successive zones of the binocular portion of the extra-areal periphery of the retina, are arranged in an orderly way in the remainder of the available space in the chiasma (Fig. 225).

In crossing, few bundles take the shortest course. Most, in fact, describe larger or smaller loops, some shallow, others sharp, in all parts of

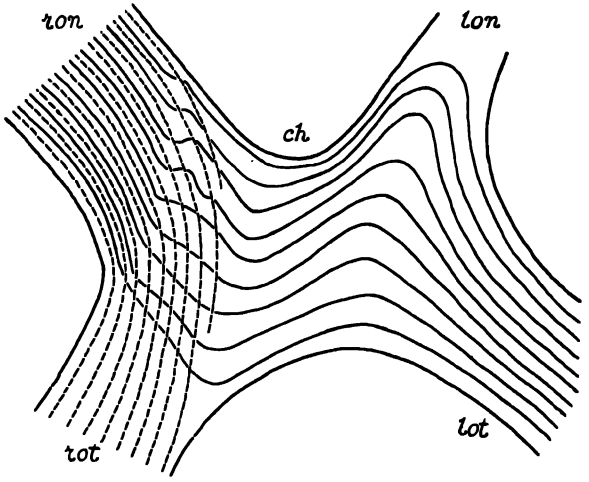

FIG. 194.—Schematic presentation of the preceding figure to show the fascicular composition of the human chiasma. The nondecussating fibers drawn in interrupted lines, the decussating fibers in solid lines. The mingling of the two fiber systems in the right optic nerve (*ron*) is only an apparent one caused by the twisted position of that nerve, the actual course of fibers being presented in the following figure. *Labeling: ch*, middle, connecting link or bridge of chiasma; *lon*, left optic nerve, degenerated owing to the loss of that eye; *lot*, left optic tract; *ron*, right optic nerve; *rot*, right optic tract.

ventral levels through the chiasma, these crescentic fibers, after crossing, seem to form the lateralmost portion, that is, the deepest part of the crotch formed by the junction of the ipsilateral nerve and the tract. Since these fibers, corresponding to the monocular crescent, are totally crossed, they degenerate in one tract only, namely, that opposite the removed eye or injured optic nerve.

The central-areal and foveal fibers, or "macular bundle," are located in the middle third of the longitudinal extent of the chiasma, where

The loops that push, for as much as 2 mm., into the adjoining portion of the optic nerves, named "anterior knee" by Wilbrand, are conspicuous. Attention was called to this peculiarity by Michel (1887), Koelliker (1896), Cramer (1898), Wilbrand (1904, 1926, 1930), and others. These anterior loops can be studied particularly easily in cases where one eye has been missing for some time. Such preparations show the loops more pronounced in the human than

in the simian chiasma (*cf.* Figs. 186, 198, 199, with Figs. 193, 194, 195, 196). The detouring loops are flatter and invade the optic nerves to a lesser extent on levels through the upper portion of the chiasma, closer to the hypothalamus, than on levels closer to the inferior surface of the chiasma.

Only a part of these arches belong to the contralateral decussating fibers (after they have crossed in the chiasma), the others, mixed with the former, are the ipsilateral decussating fibers (just before they enter the chiasma). The nondecussating ipsilateral fibers, on the whole, deviate least from the shortest course. Only in the adjoining portion of the optic nerve are some of these fibers fitted into the anterior loops (Fig. 193). But even these soon join the rest and pass over to the optic tract of the same side in a solid formation, hugging, in the lateral portion of the chiasma, the lateral crotch formed by the nerve and the tract.

On the ventral levels through the chiasma (Fig. 197) the two systems of nondecussating fibers are far apart, being separated by the de-

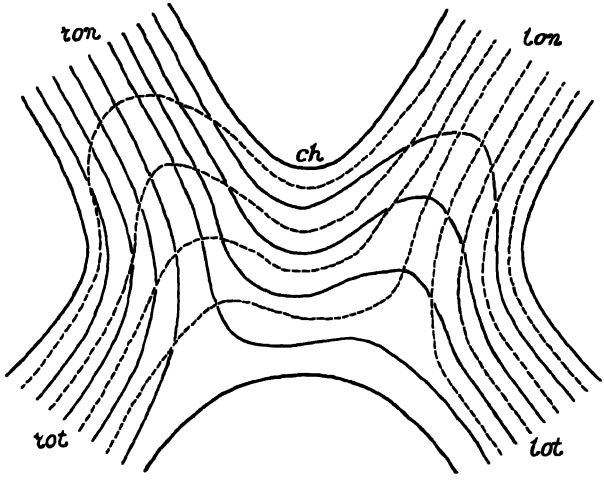

FIG. 195.—Fascicular composition of human chiasma showing decussating and nondecussating fibers of both optic nerves side by side; separation of the nasal fibers in the chiasma, their detouring course and spreading over the entire anteroposterior thickness of the chiasma and their entrance into contralateral tracts, where the crossed and noncrossed homonymous fibers, apposited to their respective syndynamic mates, spread out over the entire thickness of the corresponding tract. Fibers originating from the right optic nerve drawn in solid lines; those from the left nerve in interrupted lines. *Labeling: ch*, chiasma; *lon*, left optic nerve; *lot*, left optic tract; *ron*, right optic nerve; *rot*, right optic tract. (*Cf. also* a similar arrangement in the chiasma of the Monkey and of the Cat, in Figs. 186, 192, 198, 199.)

third element of these loops in the proximal portion of the optic nerve is the ipsilateral nondecussating fibers.

In the final analysis, the deviating fiber loops of the optic nerves just in front of the chiasma belong to the nasal fibers of both sides, the ipsilateral (before crossing) and the contralateral (after having crossed in the chiasma) and, in addition, to some nondecussating ipsilateral temporal fibers. No comparable detouring fiber bundles have been found in the initial portions of the optic tracts.

cussating fiber bundles, in particular the monocular-crescentic. On the dorsal levels the two systems approach each other somewhat, coming closer together, without, however, touching in the chiasmal bridge (Figs. 192, 402). It is noteworthy that even in their own territory the nondecussating fibers do not seem to be entirely separated from the decussating ones with which they intermingle.

The fiber pattern in every normal human chiasma is probably always basically the same except for nonessential details. Exceptions are

aberrations, where, e.g., decussation is absent or where, on the contrary, there are no ipsilateral fibers (on both of these, unfortunately, information is scanty; *see* chap. II, 8). Individual variations in detail, sometimes pronounced, concern such particulars as a broader, longer, and flatter, or a shorter and stouter middle portion; an acute or obtuse angle of juncture of the looping course resembles that of Man and Monkey; the detours, however, are less extensive (Fig. 192).

Another question to be considered concerns the character of the nerve fibers which make up the chiasma. It is to be assumed that, in order to preserve the individuality of the impressions of the two retinae as far as the visual centers,

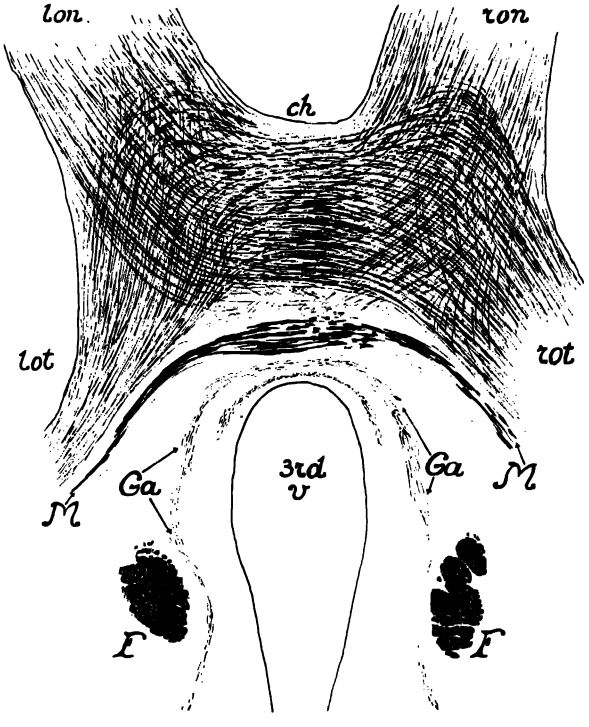

FIG. 196.—Horizontal section through the human optic chiasma and the adjacent region of the betweenbrain (hypothalamus), showing the course and arrangement of decussating and nondecussating optic nerve fibers and their topographical relations to the system of supraoptic commissures, to the third ventricle, and to other nearby structures. Weigert method. Level of the section dorsal relative to that of the following figure. Magnification 7×. *Labeling: ch*, chiasma of optic nerves; *F*, fornix; *Ga*, Ganser's commissure; *lon*, left optic nerve; *lot*, left optic tract; *M*, Meynert's commissure; *ron*, right optic nerve; *rot*, right optic tract; *3rd v*, third cerebral ventricle. Note detouring fibers in the initial portions of both optic nerves, resembling those in the Monkey and in the Cat (*see* Figs. 186, 192).

two optic nerves and tracts; and the like. In the simian chiasma the arrangement of fiber bundles closely resembles the human, except for the flatter course of detouring loops (Figs. 186, 198, 199). In the feline chiasma, too, the fibers should remain undivided. As S. Ramón y Cajal found in the Rabbit and Koelliker in the Cat, however, a small number of fibers bifurcate, that is, each fiber divides into two branches, with one of them entering each optic

tract (rarely do both fibers continue in the same tract).

Whether or not similar bifurcating fibers are present in Higher Mammals, particularly in Primates, including Man, is not known. Perhaps such branching fibers, found only in the Lower Mammals but absent both in the higher ones and in the Inframammalian Vertebrates, indicate a phylogenetic initiation of a partial crossing, or a beginning of the separation of fibers destined to join the ipsilateral tract from those that pass over to the contralateral.

3. Arrangement of decussating and nondecussating fibers in the optic tracts.—The course of decussating and nondecussating fibers in the optic tracts is peculiar and of fundamental importance to the function of the visual system.

In the lateral portions of the chiasma and in the initial portions of the optic tracts, the crossed nasal fibers already mingle with those from the temporal half of the retina that do not cross (Figs. 195, 199). The decussating fibers join, in a strictly orderly way, their respective

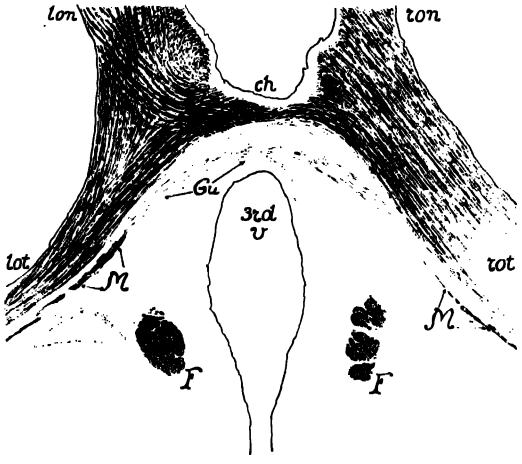

Fig. 197.—Horizontal section through the human optic chiasma and adjoining parts of the hypothalamus on a level ventral to that shown in the preceding figure, to show the topography of the visual system and of the supraoptic commissures. *Labeling: ch*, chiasma; *F*, fornix; *Gu*, Gudden's commissure; *lon*, left optic nerve; *lot*, left optic tract; *M*, Meynert's commissure; *ron*, right optic nerve; *rot*, right optic tract; *3rd v*, third cerebral ventricle. Weigert method of staining; magnification 5×. (*Cf.* preceding and following figures.)

It may be assumed that in the Lower Vertebrates—Fishes, Amphibians, Reptiles, and Birds—where complete decussation is present, there is neither need nor occasion for bifurcation. The Higher Mammals, e.g., the Primates, on the other hand, are already beyond the initial stage, with nondecussating fibers clearly differentiated from those which still pursue the original plan of complete decussation. (*See* chap. II, 8, 12 [3, 4, 8]; chap. III, 9 [3–6]; chap. IV, 6 [6], for the investigation of the chiasma in the past; *see* chap. XI, 2, for clinical interpretation.)

"corresponding" or homodynamic mates or bundles that do not decussate. The mingling of the two sets of fibers appears to be not entirely homogeneous but rather occurs in thin sheets, although the entire arrangement of the segments of the tract is according to retinal topography, as further described in section 7 in this chapter.

Each tract, accordingly, is made up of fibers originating from the homonymous halves of both retinae arranged topographically. The only part of the tract that contains but one set of fibers, the decussating, is the inner, ventro-

medial, wedge-shaped margin, where fibers from the anterior monocular portion of the nasal half of the contralateral retina alone are present.

In other words, the right tract contains direct, or nondecussating, ipsilateral fibers from the temporal half of the right retina and the decussating contralateral fibers from the nasal half of the left retina; in the left tract the situation is reversed. Functionally, because of the "dark-chamber" effect of the eye, the right tract represents the left halves, the left tract the

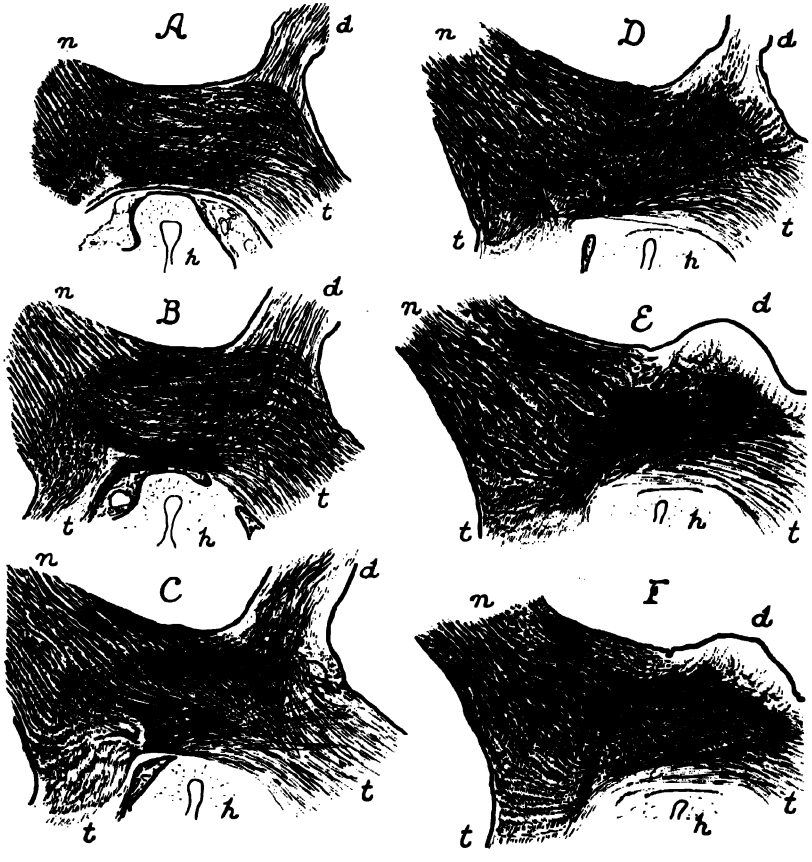

FIG. 198.—Fascicular composition of the optic chiasma of a Rhesus Macaque where the right optic nerve degenerated almost completely (*d*), owing to the scooping-out of the retina of right eye after birth two years earlier. A composite figure showing horizontal sections at approximately equal intervals through the ventral half of the chiasma, section *A* being close to the ventral surface, section *F* corresponding to a level passing through the middle of the chiasma. Note an extremely complex arrangement of countless intertwining bundles, their true arrangement given schematically in the following figure; spreading of decussating fibers over the entire anteroposterior thickness of the middle portion of the chiasma; decussating fibers making detouring loops in the contralateral nerve, much flatter than those found in the human chiasma; separation of nondecussating fibers in the lateral portion of the chiasma, and their entering the ipsilateral optic tract; few fiber bundles in the right optic nerve remaining normal owing to incomplete destruction of the right retina. Weigert stain. *Labeling: d*, degenerated optic nerve; *h*, hypothalamus next to third ventricle; *n*, normal optic nerve; *t*, optic tracts. (*Cf.* following and preceding figures.)

right homonymous halves, of the two monocular fields of vision (*see* chap. I, 5 [5, 6]).

What time and effort it took for these simple anatomical and physiological facts to become understood and generally accepted, since they were first correctly interpreted by Isaac Newton, was discussed on several occasions in the chapters dealing with history. The most weighty evidence in support of partial crossing in the chiasma is, of course, the hemianopia or half-blindness observed in a unilateral lesion of the suprachiasmal portion of the visual pathway (*see* chap. XI). The anatomical study of the chiasma and tracts in Man, Monkey, and Ape, in particular in pathological cases and in experimentally; for example, in a monkey by a complete transection of one optic tract. In such an experiment the cutting of the optic nerve fibers causes retrograde degeneration of the retinal ganglion cells. In Nissl-stained horizontal sections through both eyes, the degeneration appears strictly limited to the ipsilateral retinal halves homonymous with the damaged tract, while the contralateral halves remain normal in every respect. In such an experiment the cleavage line separating the normal from the degenerated retinal halves, corresponding with the principal vertical meridians which are invisible in histological preparations of the normal retina, is clearly shown to pass exactly through the

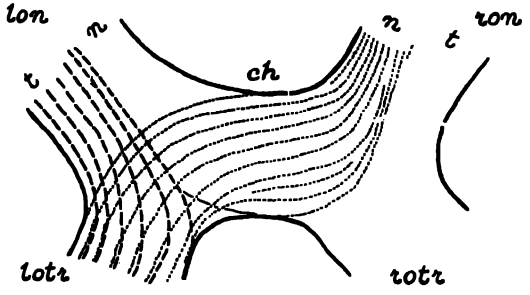

FIG. 199.—Position of the homonymous temporal nondecussating fibers (*broken lines*) in the temporal half of the left optic nerve (*lon*) and of the nasal decussating fibers (*dotted lines*) in the nasal half of the right optic nerve (*ron*) and the manner of their joining in the left optic tract (*lotr*), based on an experiment with a Rhesus Macaque illustrated in the preceding figure. Note while in the optic nerves the corresponding fibers occupy half, they spread over the entire thickness of the chiasma and tract as soon as they enter these structures, and, in the tract, each corresponding bundle joins its homonymous mate; hence each tract is made up of both categories of fibers, that is, representing ipsilateral homonymous halves of both retinae and contralateral halves of both monocular fields of view.

ments, heretofore played a lesser role (*see* chap. III, 9).

Ophthalmoscopically an absence of the optic nerve fibers may be determined in vivo in corresponding retinal halves in patients suffering from homonymous hemianopia caused by lesions of the optic tract or the lateral geniculate nucleus (Lauber 1927).

4. EXPERIMENTAL EVIDENCE OF THE SEPARATION OF IPSILATERAL FROM CONTRALATERAL FIBERS ALONG THE VERTICAL RETINAL MERIDIANS.—Clear evidence of the separation of the nasal from the temporal optic nerve fibers in the retinae of both eyes along the principal or dividing vertical meridians may be obtained experi-

centers of both foveae and foveolae. The separation of the nasal from the temporal halves of the retinae along the principal vertical meridians, accordingly, is complete and is wholly extraretinal, being caused by the crossing of nasal fibers in the chiasma.

The experiments referred to show, in the first place, the anatomical basis of the homonymous organization of the supranuclear division of the primate visual system, owing to which unilateral lesions manifest themselves in homonymous hemianopia. In addition, they show that the foveal or "macular" optic nerve fibers, originating from the right or left foveal halves, do not cross the vertical dividing meridian either in the retina or in the optic nerve, con-

trary to a view held by some investigators to explain the "central" or "macular sparing" in many cases of homonymous hemianopia. (*Cf.* chap. XI, 8, 9.)

5. SEPARATE TERMINATION OF IPSILATERAL FROM CONTRALATERAL OPTIC NERVE FIBERS IN THE LAMINATED LATERAL GENICULATE NUCLEI. —The crossed and uncrossed optic nerve fibers, apparently evenly and fairly intimately intermingled in the optic tracts, become disentangled again in the principal, laminated, lateral geniculate nuclei, where they terminate in separate layers, as first observed by Minkowski (*see* chap. IV, 6 |6|; *see* secs. 1, 4, 8, this chapter; and Figs. 180, 210, 215, etc., for terminal stations and the structure of the lateral geniculate nucleus).

The evidence for this is easy to furnish. When, e.g., in a monkey, one eye is removed experimentally and Nissl-stained sections through both laminated nuclei are examined several months or years later, the nuclei are found partly degenerated (Fig. 200). This may also be observed in human cases where one eye was lost some time prior to death. Since the affected nerve cells are not damaged directly, the process is termed transsynaptic or transneuronal atrophy or degeneration. In each laminated nucleus certain cell laminae or layers are found to be degenerated, while others remain normal. In particular, those layers which degenerate in the nucleus of one side remain normal in the contralateral nucleus; and vice versa. In this respect the two laminated geniculate nuclei appear as a positive and a negative. Still another noteworthy fact becomes apparent: the normal and degenerated layers either alternate or adjoin.

A detailed analysis of a continuous series of sections reveals that in the anteriormost portion of the laminated lateral geniculate nucleus (Fig. 200, *G*) there are four layers; two magnocellular, made up mostly of large cells (*1i*, *1c*), and two parvocellular layers, composed mostly of small cells (*2i*, *2c;* compare also Figs. 210, 211, 213). In an experiment in which the retina of the left eye of a newly born Macaque was scooped out and the animal sacrificed two years later, on the side of the damaged eye the two inner layers which form the core of the nucleus —one magnocellular (*1i*) and one parvocellular (*2i*)—were found to be degenerated (white layers in the figure); in this way these two layers reveal their connection with the ipsilateral nondecussating optic nerve fibers (*L* columns in Fig. 200, sketch *G*). The remaining two layers, also one magnocellular (*1c*) and one parvocellular (*2c*), preserved the normal structure because their relationship to the contralateral decussating fibers had not been disturbed (layers in solid black, in sketch *G* of the *L* columns). In the lateral geniculate nucleus contralateral to the removed eye, the arrangement of the normal and degenerated cell layers was precisely the reverse (sketch *G* in *R* columns). After a lapse of considerable time, the histopathological changes in the affected layers of either side consist in a complete disappearance of most of the nerve cells and a considerable increase in the neuroglia. A few less affected cells are found here and there, however. The process of degeneration in the two magnocellular layers is, on the whole, less severe.

In the much larger posterior portion of the laminated lateral geniculate nuclei, particularly in their intermediate foveal-areal segments (*cf.* secs. 7 and 11, this chapter; and Fig. 225), the arrangement of normal and degenerated layers is more complicated (Fig. 200, sketches *F*–*A*). Here the number of layers increases to six or even more by the splitting of each of the two original parvocellular layers (*2i*, *2c*) into two (*2iα*, *2iβ*; *2cα*, *2cβ*), a process of differentiation fully carried out only in the posterior or caudal tip of the nucleus (sketch *A*, same figure).

Of these six layers, on the side of the removed eye (*L* columns), in addition to the inner magnocellular layer (*1i*) and the parvocellular layer which adjoins it (*2iα*), another layer containing small cells is degenerated (*2iβ*), thus showing its relationship to the ipsilateral optic nerve fibers. The other three layers, a magnocellular (*1c*), and two parvocellular (*2cα* and *2cβ*), which are the terminal stations of the contralateral fibers, remain normal. In the geniculate nucleus contralateral to the removed eye (*R* columns), the arrangement of the normal and degenerated cell layers is exactly the reverse.

In summary, in the less differentiated and apparently phylogenetically older anterior portion of the lateral geniculate nucleus (sketch *G*,

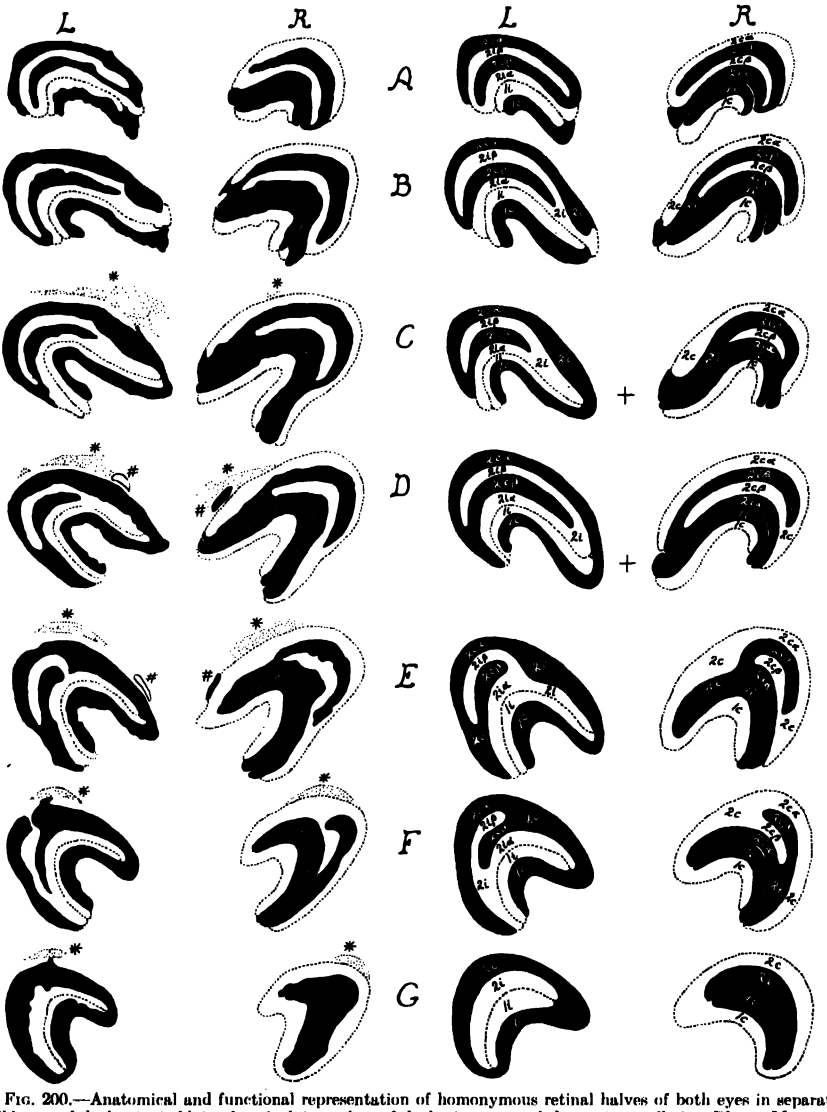

FIG. 200.—Anatomical and functional representation of homonymous retinal halves of both eyes in separate cell layers of the laminated lateral geniculate nucleus of the brain, as revealed experimentally in a Rhesus Macaque whose left retina was removed at birth. The two left columns represent camera lucida drawings of coronal sections through the left (*L*) and right (*R*) nuclei at approximately equal intervals, the two right columns being schematized presentations of the same. The sketches from *A* to *G* show levels from the most posterior to the most anterior extremities of the nuclei. The normal layers are given in solid black; the degenerated layers in white. The pregeniculate nuclei, in the left columns given in stippling, are marked with asterisks (*), the displaced portions of laminated nuclei, solid black or white, are marked by double crosses (#). The sketches in right-hand columns, marked with simple crosses, represent variations in detail of the arrangement of laminae. The numerals and small Latin and Greek letters indicate laminae and sublaminae.

partly also sketches *B–F*) each ipsilateral layer —one magnocellular and the other parvocellular—is juxtaposed with its particular magno- and parvocellular contralateral mate. Where six (or more) layers are present (partly in sketch *F* and increasingly so toward sketch *A*), a similar arrangement makes possible an intimate contact of the additionally differentiated layers, the ipsilateral to its contralateral mate (*2iα* to *2cβ* and *2iβ* to *2cα*).

6. PROBABLE FUNCTIONAL SIGNIFICANCE OF THE SEPARATE TERMINATION OF THE IPSILATERAL AND CONTRALATERAL FIBERS IN THE LAMINATED LATERAL GENICULATE NUCLEI.—The effect of the complicated arrangement in the principal subcortical visual station, the laminated lateral geniculate nucleus, described in the foregoing paragraph is obviously to bring close together those ipsilateral and contralateral optic nerve fibers (nondecussating and decussating) whose origin is in the functionally synergical or homodynamical portions of the homonymous halves of both retinae the "corresponding points" bundle for bundle, point for point; even though, as yet, the two systems or sets of conductors do not merge into a single, common pathway.

Since each set of fibers, ipsilateral and contralateral, is related to two, and in the larger posterior portion, the foveal-areal segment, of the geniculate nucleus, to three, cell laminae, it is probable that there are two or three categories or varieties of optic nerve fibers in each set. Each fiber variety or combination of varieties arises from a particular variety, or combination of varieties, of the retinal ganglion cells. Each fiber variety or category is related to one particular cell lamina, and all varieties or categories of each set are juxtaposed in an orderly way with their functional homodynamical contralateral mates, according to the retinotopical principle, bundle alongside bundle.

This assumption also agrees with, and in turn explains, the observation that in minute injuries to the striate cortex the zones of degeneration pass through all cell laminae of the ipsilateral geniculate nucleus, indicating a common origin in narrow, serially arranged segments of the nucleus, and a common termination of fibers of all sets and of both sides, four or six fiber categories in all, in the same minute territories of the striate area (*see* chap. VII, 5).

In summary, in the intermediate or nuclear and in the supranuclear divisions of the visual system, including the laminated lateral geniculate nuclei and the visual radiations, the homodynamical "corresponding retinal points" are in the closest proximity, without, however, as yet merging into single binocular functional units. (*Cf. also* sec. 9 [10], this chapter; and Figs. 219, 220, 361, 439.)

The probable original condition from which the phylogenetic perfection of the primate laminated lateral geniculate nucleus developed was apparently represented by two cell layers: one related to the ipsilateral, the other to the contralateral, set of optic nerve fibers. The impetus for this early differentiation may have been given by the inception of stereopsis, conjointly with the beginning of partial decussation of the optic nerve connected with it. With further differentiation of the geniculate nerve cells into two neuron varieties the second step in the progressive elaboration of vision each of the original two layers divided into two, one magno- and one parvocellular layer, four layers in each nucleus. This, in order to make possible a close apposition of the ipsilateral and contralateral homodynamical bundles of retinal fibers (presumably also differentiating into two varieties), necessitated an arrangement by means of which the crossed and the noncrossed small-cell layers came to lie alongside each other. When, by a further differentiation of neurons, the small-cell layers again divided into two each—a third step—the same principle was observed by which each category of optic nerve fibers and geniculate cells of one side lay alongside its functional counterpart or mate of the other side, while at the same time preserving the original retinotopical relationships.

The segregation of the nerve cells of the laminated lateral geniculate nucleus into distinct layers appears to be a process which, both phylogenetically and ontogenetically, marks an organizational perfection of the visual system. In the Inframammalian Vertebrates geniculate stratification is not noticeable, or, at best, it is in its incipient stage. Here such an arrangement is apparently obviated by an elaborate

organization of the optic lobes of the midbrain. Information is as yet scanty on conditions in species in which vision is a leading or dominant sense. It is noteworthy, however, that even at the base of the primate tree, in the Tree Shrew (*Tupaia, Urogale*), the cells of the dorsal portion of the lateral geniculate nucleus show a definite tendency toward laminated arrangement. In other primitive representatives of the Order of Primates, e.g., Mouse Lemur, Coquerell's Dwarf Lemur, *Lemur catta*, and quite definitely in the Lower Monkeys, lamination is already completed (Le Gros Clark 1932; *see* chap. VIII, 3, and chaps. XIV, XV, this book, on primate phylogeny).

In the human embryo up to the age of twenty weeks and more, the cell distribution shows no trace of stratification. In the early postnatal period the stratification of the human lateral geniculate nucleus, though completed, is still of a simple pattern, bearing a marked resemblance to that of an adult Chimpanzee (Fig. 214). Also there is sufficient evidence to support the view that in human adults there is considerable individual variation in the pattern and complexity of the arrangement of the cell and fiber layers of the nucleus. (*See* Figs. 209, 215, and secs. 8 and 9, this chapter.)

SEC. 7. TOPOGRAPHICAL OR DIMENSIONAL REPRESENTATION OF THE RETINAE IN THE INFRANUCLEAR DIVISION OF THE PRIMATE VISUAL SYSTEM AND IN THE SUBCORTICAL VISUAL CENTERS

1. General remarks.—The belief that the optic fibers originating from various restricted areas or "points" of the retinal surface are not scattered haphazardly in the optic nerves, tracts, and visual centers but are arranged according to a certain stable order is quite old. Ibn al-Haitham of the Arab Period, Des Cartes, Briggs, John Taylor, Zinn, and Munk, to men-

tion only the most important philosophers and investigators of the past, entertained this idea, believing that such an anatomical arrangement might be a factor responsible for the exquisitely spatial character of the sense of sight (*cf.* chap. II, 10 [2]; 11 [2, 6]). How this concept gradually gained ground with the coming of modern clinical and experimental research, in spite of persistent opposition, is dealt with elsewhere. (*See* chap. III, 9 [7 9]; chap. IV, 4 7.)

In recent times it was especially the clinical and pathoanatomical work of Wilbrand, Henschen, and Rønne (Roenne), followed by the experiments of Brouwer (1923, 1926), Brouwer, Zeeman & Houwer (1923), Brouwer & Zeeman (1925, 1926), Zeeman (1925), Brody (1934), Penman (1934), and Le Gros Clark & Penman (1934), that not only substantiated this belief but also clarified the essential makeup of the infranuclear division of the visual system (*see* chap. IV, 6).

The results of these efforts may be briefly summarized as follows. The areal-foveal or "macular" bundle in the optic papilla and in the section of the optic nerve close to the eyeball is located in the temporal segment. At some distance behind the eyeball the areal-foveal bundle gradually assumes a central position. On the outside it is surrounded by the extra-areal fibers oriented according to the four retinal quadrants, the temporal and nasal quadrants preserving their respective places in the temporal and nasal halves of the optic nerve. In the proximal portion of the nerve, the areal-foveal bundle assumes a dorsal position (Zeeman). In the chiasma and the optic tracts, the same bundle preserves its dorsal position and terminates in the intermediate segment of the lateral geniculate nucleus along the dorsal outline (Widmark, Rønne). Henschen's view, according to which the "macular bundle" had a central position throughout its entire course as far as the lateral geniculate nucleus, was in this way corrected.

The exact arrangement of the retinal quadrants was revealed through the experiments of Brouwer & Zeeman and Le Gros Clark & Penman. These investigators found the upper homonymous quadrants to be represented dorsomedially, the lower quadrant ventrolaterally, and the fovea-macula in the intermediate segment between. In the tracts, geniculate nuclei, and superior colliculi of the midbrain, because of the decussation of the nasal fibers in the chiasma, only the homonymous halves of both retinae are represented. The anterior monocular portion of the nasal retinal half is represented singly in the contralateral tract and geniculate nucleus.

In order to make clear the internal organization of the infranuclear division of the afferent visual system, several selected experiments performed upon Rhesus Macaques are described. In each individual a minute lesion was made in one eye by means of an electrolytic needle, in each case in a different part of the retina. The lesions were made under ophthalmoscopic control and were examined ophthalmoscopically during life. In most experiments *intra vitam* sketches were made of the location, size, and shape of the lesion, and in all cases a careful study was made of both fresh and preserved specimens, and the sketches were corrected or remade.

Two weeks after the operation the animals were sacrificed, and the specimens were investigated histologically, according to the Marchi and Nissl techniques, the eyes for the exact location and extent of the lesions; the optic nerves, chiasma, and brain for the study of secondarily degenerated fibers.

An acknowledgment for technical assistance in these experiments is due here, in the first place, to Dr. P. C. Kronfeld, to Dr. B. L. Gifford, and to Dr. F. S. Ryerson, all at that time connected with the University of Chicago.

2. Experiments with the interruption of papillomacular fibers in the retina (Expts. 1 and 2). In Experiment 1 a single, well-outlined lesion of oval shape was made between the ridge of the foveal pit and the papilla (Fig. 201, *les*). Most of the lesion was below the horizontal meridian. From comparison with the arrangement of optic nerve fibers in this area as found in the same simian species (*see* Fig. 162), it was reasonably certain that all fibers interrupted in this experiment belonged to the decussating variety originating from the nasal half of the foveal depression, the majority belonging to the lower nasal quadrant, and some to the adjoining portion of the upper nasal

quadrant, of the central fovea, in addition to those of the adjoining portion of the extrafoveal central area whose cells of origin were destroyed directly by the lesion.

In the optic nerve of the affected side a single well-outlined area of degeneration was found (Fig. 201). On levels next to the eyeball (*A*) the area corresponded to a radius stretching on the temporal side, in the horizontal meridian, from the central vessels (*cv*) to the periphery of the nerve. The bulk of the foveal fibers were assembled somewhat closer to the temporal periphery, with a tail stretching toward the center. The affected bundles were rather solidly degenerated, being surrounded by a narrow zone of scattered degeneration. On a level corresponding to the entrance of the central vessels, the zone of degeneration became slightly displaced toward the center, with its inner tail now pointing downward along the central vessels and with some fibers extending to the lower surface of the nerve (*B*). Midway between the entrance of the central vessels and the chiasma, the zone had definitely reached the center of the nerve, even though it still preserved its original shape and compactness fairly well, maintaining

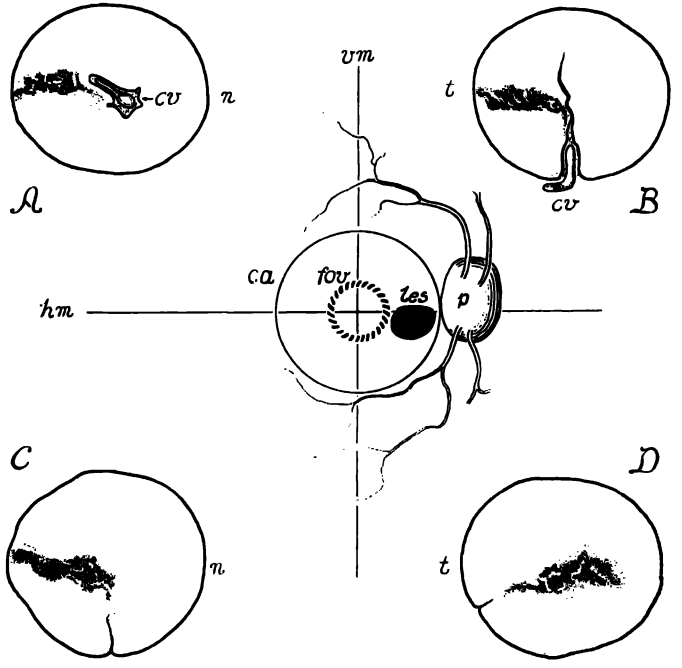

FIG. 201.—Foveal or so-called papillomacular bundle of the right optic nerve of a Rhesus Macaque degenerated in consequence of an experimental lesion made in the retina of the right eye between the central fovea and optic papilla (Expt. No. 1). Marchi method of staining. The center of the figure shows the fundus of the right eye with the oval optic disk (*p*), from which emerge central retinal blood vessels, on the temporal side enveloping a central area (*ca*) and fovea (*fov*) in its center, with vertical and horizontal meridians indicated (*vm*, *hm*). The single, sharply localized lesion (*les*), given in solid black, is mostly below the horizontal meridian. The four sketches show sections through the optic nerve at the following levels: *A*, just behind the eyeball; *B*, at the point of entrance of central blood vessels (*cv*); *C*, midway between the above-mentioned point and the optic chiasma; *D*, close to the chiasma. The nasal and temporal margins of the nerve are indicated by *n* and *t*. Note a temporal marginal position of the foveal bundle in most of the optic nerve and its gradual assumption of a central location only in the portion of the nerve close to the chiasma. (*Cf.* following figure.)

its contact with the temporal periphery of the optic nerve (*C*). As the proximity of the chiasma was approached, the foveal bundle severed its contact with the temporal surface of the nerve (*t*) and, by a further shift in the nasal direction, assumed a central location (*D*).

A noteworthy feature of the areal-foveal bundle of fibers of the optic nerve was its compactness, permanence of shape and position, and preponderantly temporal location. Another peculiarity was the relatively large degenerated area and the great number of fibers composing it. Even if the generous assumption were made that most of the fibers originating from the nasal half of the foveal pit were interrupted, the estimated area on a cross-section of the optic nerve that would have to be attributed to the entire central area and fovea would hardly be less than one-third, and probably more, of the total area of the optic nerve.

In Experiment 2 a lesion of approximately the same size and only slightly differently located from that in the preceding experiment was made (Fig. 202). The lesion (*les*) resembled a cleft, given in solid black, surrounded by a less affected belt, indicated by stippling in the figure. Judging from the arrangement of optic nerve fibers in Figure 162, the axons of the ganglion cells residing in the upper nasal quadrant of the foveal pit alone were interrupted, in addition to those of the adjoining extrafoveal portion of the central area, whose residing cells of origin were affected directly.

In the optic nerve of the eye experimented upon, as in the preceding experiment, a single well-delimited area of degeneration was found. On levels immediately behind the eyeball the degenerated area appeared roughly of the same size and shape (*on1*). This agreed with the almost identical size of the lesion made in a similar locality of the retina. The location of the degenerated area, however, was slightly above the one in the preceding experiment, accounted for by the location of the lesion above the horizontal meridian. At the entrance of the central vessels the degenerated fibers began to gather closer to the central vessel cleft, while the peripheral end of the zone, still extending as far as the temporal margin of the nerve (*t*), touched it at a higher point (*on2*). Midway between the entrance of the central vessels and the chiasma, the areal-foveal bundle had become central, preserving contact with the temporal margin of the nerve by means of a narrow trail of scattered fibers (*on3*). Closer to the chiasma, preparatory to decussation, the bundle changed considerably in shape (*on4*). It preserved its central location, producing a new pointed limb spreading toward the lower face of the nerve. In addition to the principal one, another minute degenerated bundle could be followed on all sections along the upper periphery of the optic nerve; this small bundle was probably made to degenerate by the needle piercing the coats of the eyeball, in its upper periphery, during the experiment.

In the chiasma (*ch*), on the anterior levels (upper sketch), the areal-foveal bundle, while still retaining for a space its former compact structure, gradually moved toward the center, its fibers spreading over more than the upper half of the bridge as far as its upper limit immediately adjoining the hypothalamus. On the middle levels these fibers gradually passed to the other side and, for the most part, arranged themselves close to the upper contralateral corner of the chiasma (lower sketch). Other parts of the chiasma were relatively free of these fibers, and the two lateral extremities and approximately the ventral third were entirely free.

The tracing of degenerated areal-foveal fibers in the suprachiasmal portion of the infranuclear and nuclear divisions of the visual system was quite easy. The first noteworthy fact was the complete crossing of all fibers that were caused to degenerate in this experiment. All fibers above the chiasma were found on the contralateral side (right, in figure), and none on the ipsilateral side (left, in figure). This agreed well with the size and location of the retinal lesion, by which only the fibers originating in the nasal half of the foveal pit and central area were interfered with, while those originating in the temporal half of the fovea and area, circling at some distance above and below the first, remained unimpaired (*cf.* Fig. 162).

In the contralateral optic tract the zone of degeneration resembled a narrow wedge, with its broad upper end at the upper rounded contour and its sharp lower extremity pointing to the narrow lower edge of the tract (*otr*, right side, in Fig. 202). The most delicate and most

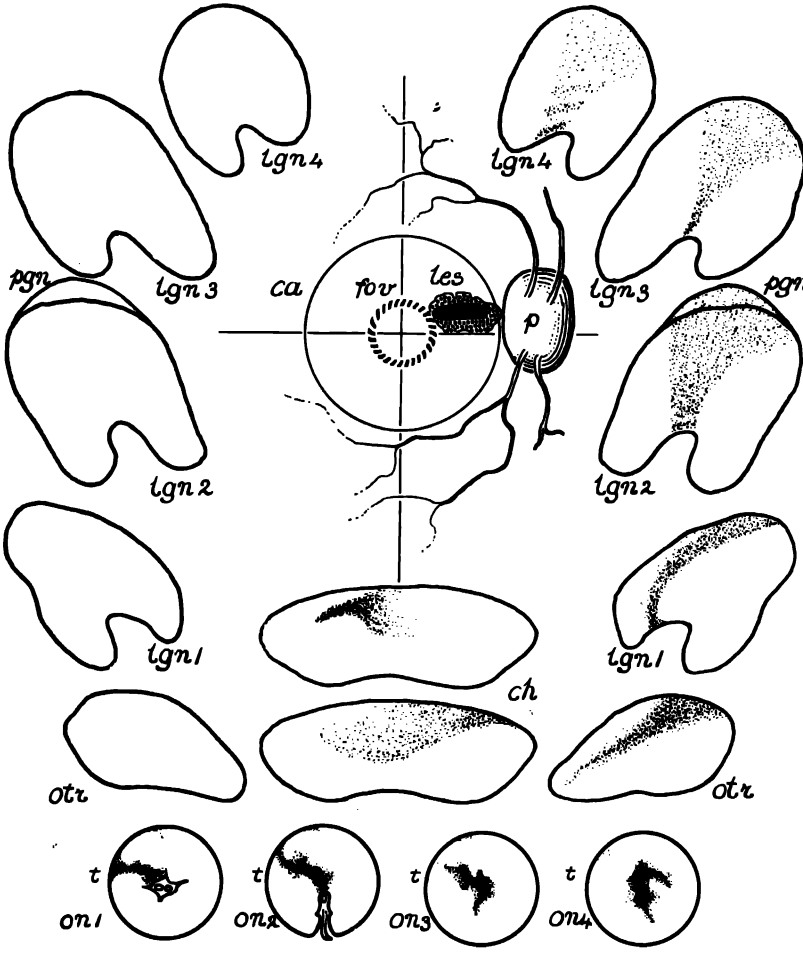

FIG. 202.—Central foveal or "papillomacular" bundle of a Rhesus Macaque demonstrated experimentally along its entire course from the origin in the retina and as far as the termination in the subcortical visual centers of the brain (Expt. No. 2). Degenerated fibers given in stippling of various density, as found in various sections, made visible with Marchi stain. Upper center represents right fundus, with the papilla of the optic nerve (*p*), with radiating central blood vessels encircling the central area (*ca*) and fovea (*fov*), divided by a vertical and horizontal meridian. The lesion, made with an electrolytic needle, is located between the fovea and the papilla, its intensively destroyed center given in solid black, its less affected periphery indicated by coarse stippling. The four lowermost sketches represent the following levels through the right optic nerve: *on1* just behind the eyeball; *on2* at the point of entry of central vessels; *on3* midway between the latter and the chiasma; *on4* close to the chiasma. The foveal bundle at first has a radial position between the temporal margin (*t*) and the central vessels, gradually disengaging itself from the margin and becoming central close to the chiasma. The foveal fibers keep within the dorsal half or so in the chiasma and are entirely decussated, since, in this experiment, the lesion was located in the nasal half of the central area. The fibers enter the left optic tract (right *otr*) and left lateral geniculate nucleus (right-hand sketches), where they may be followed from the anterior (*lgn1*) to the posterior level (*lgn4*). They take a position in the intermediate segment of the tract and nucleus and also enter into the pregeniculate nucleus (*pgn*). No degenerated fibers in this experiment enter the ipsilateral, right, tract and nucleus (left-hand sketches in figure), since the temporal half of the central area and fovea was spared. Note the laminated arrangement of fibers in *lgn 4*.

numerous fibers were assembled at the top, the coarser ones in the lower, pointed extremity of degeneration. The inferior limit of the zone corresponded fairly well to the axis of the tract, indicating the approximate position of the horizontal meridian.

In the lateral geniculate nucleus the zone of degeneration also resembled a wedge, with the broad end at the upper extremity and the narrow end at the hilum. On the anterior levels, the zone was narrow and placed in about the inner or medial half of the nucleus (*lgn1*). On the central levels the zone widened considerably (*lgn2*), again becoming somewhat reduced toward the posterior extremity of the nucleus (*lgn3* and *lgn4*). The most numerous, though most delicate, fibers were found on the posterior levels. The boundaries between the degenerated and the normal segments of the nucleus were found to be surprisingly sharp.

Another noteworthy feature was the termination of the areal-foveal fibers in the pregeniculate gray nucleus of the contralateral side (*pgn*).

3. Experiment with lesion in the central fovea (Expt. 3).—A very small, practically microscopic, lesion (*les*) measuring in diameter barely one-fourth of a millimeter, and sharply outlined, was confined to the upper nasal quadrant of the foveal depression (Fig. 203). It is fair to assume from the minute size of the lesion and its location that all degenerated optic nerve fibers found in the visual pathway in this experiment belonged to the "foveal" or "macular" bundle. The overwhelming majority of fibers was found passing through the upper segment of the chiasma (*ch*) to the contralateral tract and geniculate nucleus (right, in the figure). The degenerated fibers were numerous and all of delicate caliber. The thinnest and most numerous fibers were found along the upper margin of the tract and geniculate nucleus.

In the tract the fibers were assembled into a fairly compact, wedge-shaped sector, whose sharp lower end pointed toward the narrow ventromedial margin and whose blunt end spread along the convex dorsolateral extremity of the tract (right *otr*, in figure). The narrow core of the area, also bladelike or wedge-shaped, was most intensively degenerated.

Since the minute lesion in the fovea was located close to the horizontal meridian, it is fair to regard the inferior lateral side of the narrow, intensively degenerated zone, approximating the axial line of the tract, as representing the horizontal meridian (*hm*).

On the rostral or anterior levels through the lateral geniculate nucleus (right *lgn1*), the degenerated area was still wedge-shaped, gradually becoming wider on the middle levels (right *lgn2* and *lgn3*) until, toward the caudal or posterior extremity of the nucleus (right *lgn4*), it expanded over somewhat more than its dorsomedial half. Also in the latter locality the area extended down to the ventral margin at the hilum of the nucleus. The fibers, obviously nearing their termination, spread over an area larger than that on the anterior levels of the nucleus, where they were assembled into a compact sector made up of "bundles of passage."

4. Features distinguishing representation of the central fovea in the optic nerves, chiasma, tracts, and lateral geniculate nuclei.—The experiment just described (Fig. 203), in addition to the two preceding experiments (Figs. 201, 202), was illuminating in several points.

First, it showed that the "central fovea," or "macula" in clinical parlance, is projected onto the posterior portion of the lateral geniculate nucleus, somewhat wedged between the medial and lateral segments belonging to the extrafoveal parts of the homonymous retinal halves, including the monocular crescent.

Furthermore, the termination of the fibers from the upper foveal quadrant in the medial half or so of the lateral geniculate nucleus, in the posterior extremity (right *lgn4*), indicated an arrangement of the "foveal" or "macular" quadrants in the geniculate nucleus according to the rule found by Brouwer & Zeeman for the retina as a whole: the upper quadrants medial, and the lower quadrants lateral.

Next, the experiment demonstrated a relatively large area of the cerebral representation of the fovea when compared with its small size in the retina. Also, the thinness and great number of the foveal fibers agree with the small size and great number of the ganglion cells in, and close to, the foveal pit (*see* chap. V, 2 [9], 5 [1, 7], 9).

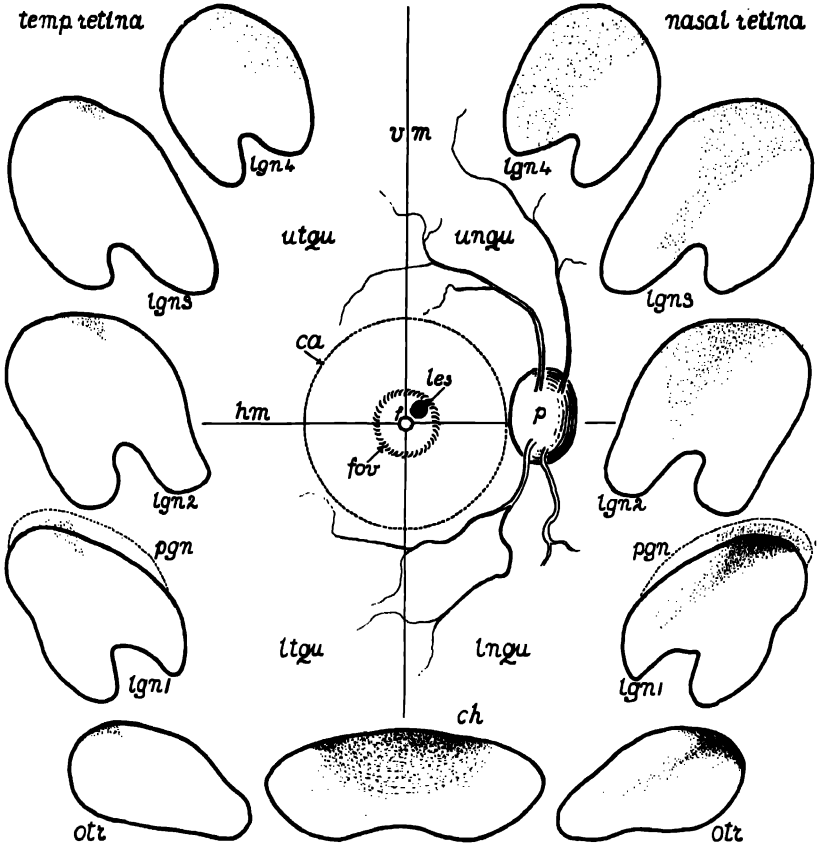

FIG. 203.—Central or "papillomacular" bundle, its origin and termination demonstrated in an experiment (Expt. No. 3). A single, minute, sharply outlined lesion (*les*) was made with an electrolytic needle in the upper nasal quadrant of the fovea (*fov*) of the right eye of a Rhesus Macaque. The lesion extended almost to the flat foveal floor (small circle *f* in the very center), and possibly slightly affected adjacent portions of the upper temporal and lower nasal quadrants beyond the vertical and horizontal meridians (*vm*, *hm*). Degenerated fibers, stained with the Marchi method, were found to decussate almost entirely in the chiasma (*ch*) to the left or contralateral side (right-hand sketches in the figure), with only a few fibers forming a minute bundle which passed over to the right or ipsilateral side (left-hand sketches). In the chiasma (*ch*) foveal fibers were confined to the upper two-thirds. In the tracts and nuclei these fibers spread over a wedgelike segment in the intermediate portion, with a broad end at the upper margin and a sharp point facing down, toward the hilum of the nucleus. The fibers were very numerous and delicate, the thinnest along the top, the thicker in the sharp point. Very fine fibers entered from the laminated nuclei into pregeniculate nuclei of both sides (*pgn*). Only a few fibers were found in the intergeniculate lamina, and none in the superior colliculi of the midbrain or in the pulvinar of the thalamus. Note remarkably sharp outlines of the degenerated segment; its stable shape and location on the cross-sections and the gradual widening of terminal area of the segment as the fibers approached their destination in the posterior extremity of the nuclei. This experiment makes it possible to determine the approximate position of the vertical and horizontal meridians and of the fixation points along the entire course of the infranuclear and nuclear divisions of the visual system. *Labeling: ca*, central area; *ch*, chiasma; *f*, foveola or foveal floor; *fov*, central fovea; *hm*, horizontal meridian; *les*, lesion; *lgn*, laminated lateral geniculate nuclei; *lnqu*, lower or inferior nasal quadrant; *ltqu*, lower temporal quadrant; *otr*, optic tracts; *unqu*, upper nasal quadrant; *utqu*, upper temporal quadrant; *vm*, vertical meridian. (*Cf.* preceding and following figures, especially Figs. 162, 204, 205.)

Finally, in this way was demonstrated the separate course of the "foveal" or "macular" bundle in the dorsal or upper portion of the chiasma (*ch*) and in the intermediate sector of the optic tract (right *otr*), here extending as far as the upper blunt margin of the tract but not reaching the pointed lower margin, as well as the course of the "macular" bundle through the entire longitudinal extent of the laminated lateral geniculate nucleus before reaching the posterior end of the nucleus.

In the same experiment, additional hints concerning the minute organization of the infranuclear division of the visual pathway may be gleaned from the small zone containing degenerated fibers on the side ipsilateral to the operated eye (left, Fig. 203). In position and shape this zone resembled the contralateral degenerated area just described, except that it was much smaller. It was located at the blunt upper margin of the tract (left *otr*) and the nucleus (left *lgn1* to *lgn4*). The zone of degeneration was sharply outlined against the normal parts (white in the figure) and was composed of minute bundles of delicate fibers solidly packed in a triangular field. The bundles remained close together throughout their course in the tract and in most of the laminated lateral geniculate nucleus. In the posterior fourth of the nucleus (left *lgn4*), however, they scattered over approximately the upper inner fourth. This minute degeneration was apparently caused by a slight encroachment of the lesion upon the adjoining upper temporal quadrant of the fovea, beyond the invisible vertical meridian or line by which the area of decussating fibers is separated from that of the nondecussating optic nerve fibers.

The preceding observations were noteworthy in several respects. First, the small size of the degenerated foveal bundle originating in a fraction of the foveal surface showed the representation of the fovea in the brain to be not merely "global," or roughly "quadrantic," as was alleged by some investigators (e.g., Pierre Marie, Brouwer & Zeeman, and others), but rather detailed and restricted to the posteriormost fourth of the nucleus (*cf.* chap. IV, 6 [4]).

Considering the relative crudity of the experimental technique used, the minute dimensions of the degenerated bundle, its compactness and sharp outlines, and the fact that it did not mix with the adjoining bundles which remained normal—all these factors strengthened the belief that, minute though the actually demonstrated representation of the fovea was, it was still far more gross than the minuteness of the actual foveal representation in the lateral geniculate nucleus. Considering, further, that the observed minute zone of degeneration contained at least several hundred fibers, it seems that in the portion of the visual pathway related to the central fovea each elemental conductor unit is made up of more than a single neuron and a single axon or nerve fiber. This last-mentioned conclusion corresponds favorably with the minute structure of the central fovea previously described (*see* chap. V, 9, 10).

5. Fiber connections of the central fovea with the pregeniculate gray nucleus. In Experiments 2 and 3, in addition to the coarser fibers terminating in the large laminated lateral geniculate nucleus, numerous and quite delicate fibers that pass over to the smaller cap-shaped pregeniculate nucleus were of interest (right-side *pgn* in Fig. 202, and *pgn* on both sides in Fig. 203). These fibers, obviously, are identical with the thin myelinated fibers of similar location described elsewhere (sec. 10, this chapter). Like the coarser optic fibers which terminate in the laminated nucleus, the thin fibers terminating in the pregeniculate nucleus are also of retinal origin, as the experiments with the enucleation of one or both eyes show (*cf.* secs. 4 [4], 5, this chapter). The fibers in question are homologous with the portion of optic nerve fibers terminating in the ventral geniculate nucleus of the Infraprimate Mammals described in section 5 (*see* Fig. 191).

These numerous thin afferent optic fibers are worthy of attention, and for several reasons. One is their origin in the central fovea and area of the retina, whence the pupillary light reflex can most readily be elicited (C. Hess 1907, 1908, 1916; Gasteiger 1934). The other reason is the linkage of the pregeniculate nucleus, and hence of the macular segment of the infranuclear division of the visual system, to the oculomotor nuclei of the midbrain by means of a

fiber tract originating in the pregeniculate nucleus, the pregeniculo-mesencephalic tract (*cf.* sec. 10, this chapter).

All this evidence supports the opinion that the delicate optic fibers passing from the laminated geniculate nucleus to the pregeniculate nucleus are part of the pupillary reflex pathway. This opinion, in turn, agrees fairly well with the pathway of pupillary light reflex plotted experimentally by Ranson & Magoun (1933) and Magoun *et al.* (1936). It is also noteworthy that within this geniculo-pregeniculate connection a marked degree of localization is found, as evidenced by the experiments here presented.

6. Experiments with lesions in the central area (Expts. 4 and 5).—In another experiment (Expt. 4) a somewhat larger lesion (*les*) was made (Fig. 204). It spread over almost the entire upper temporal quadrant of the fovea (*fov*) and over a portion of the adjoining quadrant of the central area (*ca*), besides probably also slightly impinging upon the upper nasal quadrant of both.

In the tracts and geniculates the degenerated fibers were found to be, as expected, overwhelmingly confined to the side ipsilateral with the operated eye (left, in the figure), with only a few fibers found on the contralateral side (right, in the same figure). In the chiasma the degenerated area, with the exception of a few decussating fibers, was entirely confined to the ipsilateral corner, which in the preceding experiments had remained unaffected. In the ipsilateral tract (left *otr*) and in the geniculate nucleus (left *lgn1* to *lgn4*), the degeneration appears as a cruder mirrored replica of the area of degeneration on the contralateral side in Experiment 3 (right, in Fig. 203). Since in Experiment 4, as in Experiments 2 and 3, the lesion extended practically to the horizontal meridian, the temporal demarcation line of the degenerated zones in all three cases indicated the position of the horizontal meridian in the tract and in the lateral geniculate nucleus. Again, since only the central area and fovea were damaged, the area of degeneration was confined to the intermediate areal-foveal sector. The innermost portion of the medial segment, both in the tract and in the lateral geniculate nucleus, remained normal, since fibers originating from the extensive undamaged extra-areal regions of the upper temporal quadrant of the retina were not affected. Finally, as in Experiments 2 and 3, delicate degenerated fibers were found passing from the principal degenerated area of approximately the anterior half of the laminated lateral geniculate nucleus (*lgn1* and *lgn2*) to the pregeniculate nucleus (*pgn*).

In Experiment 5 a small circular lesion (*les*) was made in the upper temporal quadrant of the central area not far from the edge of the foveal pit (Fig. 205). Considering the peculiar arching and somewhat radiating course of bundles of the optic nerve fibers emerging from the fovea (*cf.* Fig. 162), it is likely that only part of them were interrupted, the principal damage having been done to a compact nest of ganglion cells forming the wall of the foveal pit.

Owing to the location of the lesions at some distance from the horizontal meridian, it is fair to assume that neither the ganglion cells nor the outgoing fibers of the lower areal and foveal quadrants, separated as they are by the raphé, were affected. Since, as in Experiment 4, by far the greater number of degenerated fibers remained on the ipsilateral side (left, in the figure), the indication is that, in spite of the proximity of the lesion to the principal vertical meridian, very little damage was done to the upper nasal quadrant.

Unlike the preceding experiments, the degenerated area in the chiasma (*ch*) did not expand so far as the upper margin, and practically all degenerated fibers were of a nondecussating variety.

In the ipsilateral tract (left *otr*) the wedge-shaped area also did not extend to the upper margin. This was also true, to some extent, of the ipsilateral geniculate nucleus (left *lgn1* to *lgn4*), where the most extensive degeneration was found close to the hilum along the axial line. The considerable difference in distribution of degenerated fibers in the posterior fourth of the geniculate (left *lgn4*), where, unlike the preceding experiments, the area of degeneration approached, but did not quite reach, the dorsomedial margin, agrees with the extrafoveal location of the lesion.

On the other hand, the lateral boundary of the degenerated area, although the location of the lesion was at a considerable distance from

the lower quadrant, was identical with that found in Experiments 2, 3, and 4, suggesting either an interruption of all fiber bundles down to the horizontal raphé or a vascular interference as far as the raphé which marks the horizontal meridian.

The confinement of degeneration to the inner or medial approximate half of the geniculate nucleus agrees with the preceding observations, the lesions, in all these experiments so far considered, being in portions of the retina above the horizontal meridian. Again, the portions of the medial segment in the anterior three-fourths of the lateral geniculate nucleus which remained

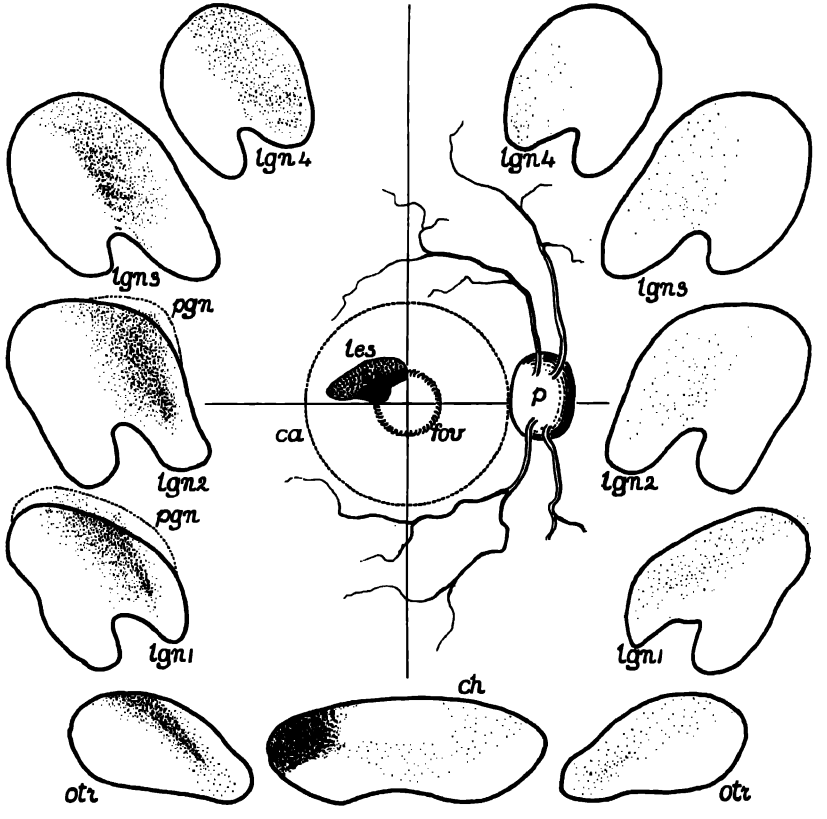

FIG. 204.—Representation of the central area of the retina of a Rhesus Macaque in the chiasma, optic tracts, and geniculate nuclei (Expt. No. 4). A single small lesion (*les*) was made electrolytically in the upper temporal quadrant, most intensively damaging the rim of the foveal depression (*solid black*), with less extensive damage spreading into the adjacent extrafoveal portion of the central area in the same quadrant as far as the vertical and horizontal meridians (*coarse dotting*). In the chiasma almost all degenerated fibers passed over to the tract and geniculate nucleus of the same side (*left* in figure), ipsilateral with the eye operated upon, with only a few fibers decussating to the contralateral side (*right* in figure). This experiment shows fairly accurately the location and extent of the upper foveal and areal quadrant, of the horizontal meridian, and of the fixation point in the optic tract and laminated lateral geniculate nucleus. The few decussating fibers may have been affected by the location of the lesion close to the vertical dividing meridian and could be followed into the opposite tract and nucleus (*right* in figure). Note an indication of a lamellar arrangement of fibers in the ipsilateral laminated nucleus and the entrance of fine fibers into the pregeniculate nucleus from the subjacent degenerated segment. Labeling same as in Fig. 203.

free from degeneration (left *lgn1* to *lgn3*), as in the preceding experiments, indicated the terminal areas of fibers originating from the extensive central-areal and extra-areal territories of the upper temporal quadrant, which in Experiment 5 also remained undamaged.

In contrast with the preceding two experiments, however, the number of delicate degenerated fibers passing over to the pregeniculate nucleus (*pgn*, in left *lgn1*) in the fifth experiment was negligible. Since the foveal excavation was not affected, this suggests that the fovea is the principal source of afferent geniculo-pregeniculate fibers serving as a pupillary reflex pathway.

7. Experiment with a lesion along the boundary of central area (Expt. 6).—In the

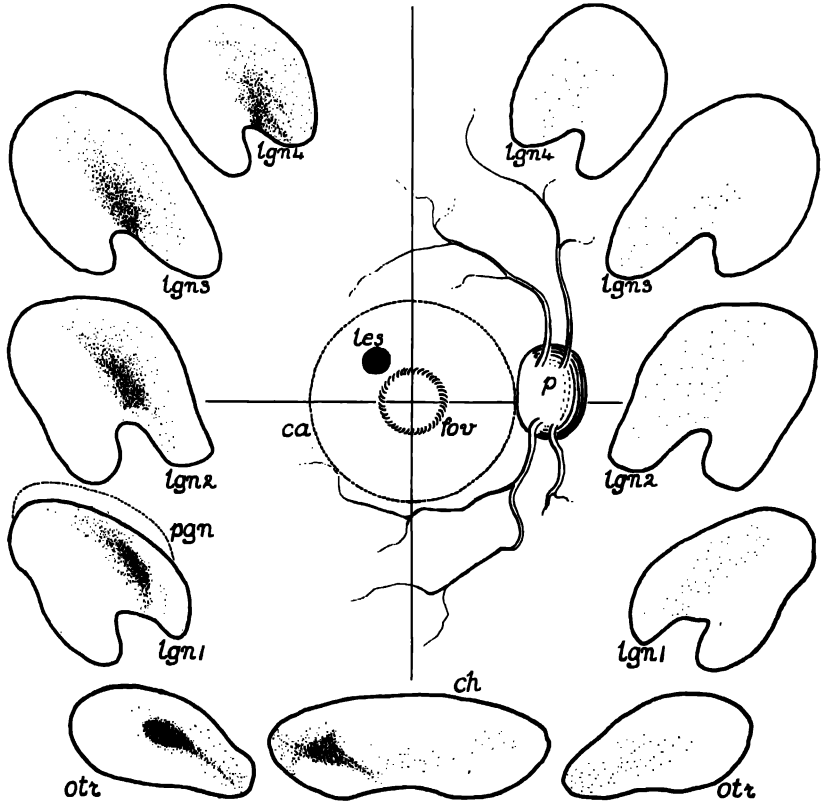

Fig. 205.—Representation of the central area of the retina of a Rhesus Macaque in the chiasma, in the optic tract, and in the lateral geniculate nucleus (Expt. No. 5). A single, small, circular, sharply outlined lesion (*les*) was located in the upper temporal quadrant of the central area (*ca*) outside the central fovea (*fov*), at an almost equal distance from the vertical and horizontal meridians. In the chiasma (*ch*), tract (*otr*), laminated geniculate nucleus (*lgn*), and pregeniculate nucleus (*pgn*), degenerated fibers were found almost entirely on the side ipsilateral with the operated eye (right side, *left* in figure), the few decussating fibers being caused to degenerate by the general conditions unavoidable in the experiment. This experiment shows principally the location and extent of the extrafoveal fibers of the central area in the optic tract and lateral geniculate nucleus and also indicates the position of the horizontal meridian. Very few fibers pass over from the laminated nucleus into the pregeniculate nucleus, indicating the foveal depression as the principal origin of this system (*see* preceding figures). Labeling same as in Fig. 203.

sixth experiment, a small, oblong lesion (*les*) was made along the upper boundary of the central area, astride the principal vertical meridian, apparently extending almost equally in the upper nasal and in the upper temporal quadrants (Fig. 206).

Because of the symmetrical location and to some extent also because of the peculiar course of the optic nerve fibers circling around the central fovea (*see* Fig. 162) and the similar distribution of blood vessels in the central area and fovea, the fiber bundles and cell areas affected by the lesion in both upper retinal quadrants must have been somewhat similar, extending chiefly along the upper circumference of the central area (*ca*). Because of this, a roughly semicircular zone in the upper periphery of the central area and in the region outside it, extending for some distance in the temporal direction along the horizontal raphé, must have been destroyed. In any case, the central fovea (*fov*) and the fibers originating in it, the "papillomacular bundle," were spared. These factors may explain the somewhat similar shape, extent, and location of degenerated areas in both tracts (*otr*) and lateral geniculate nuclei (*lgn*), the degeneration on the contralateral side (right, in the figure) being only slightly more intensive, though spreading a bit less, in the intermediate central-areal segment than on the ipsilateral side (left, in the figure).

The degeneration in approximately the medial half of both geniculate nuclei, as in the preceding experiments, agrees with the location of the lesion in the upper retinal quadrants above the horizontal meridian.

The course of degenerated fibers, both decussating and those remaining on the same side, particularly in the chiasma (*ch*), at first slants downward toward the mid-line, where they touch the inferior margin; in this way they assume the ventral position which they maintain in both tracts (*otr*).

In the lateral geniculate nuclei (*lgn1* to *lgn4*) it is also the ventromedial margins that are most heavily degenerated. The contrast between Experiment 6 and Experiments 2, 3, and 4 is especially apparent in the posterior fourth of the lateral geniculate nuclei. Whereas in the latter experiments (Figs. 202, 203, 204, *lgn1* to *lgn4*) the central foveal fibers terminate as far as the upper convex margin of the nucleus (this is especially evident on the ipsilateral side of Expt. 3, left, in Fig. 203) and while in Experiment 5 the fibers, mostly extrafoveal from the central area, do not quite reach the upper margin of the nucleus (Fig. 205, *lgn4*), in Experiment 6 the situation is precisely reversed (Fig. 206, *lgn4*). Here the larger upper portion, close to the convex extremity of the nuclei, remains free, the degeneration being confined to a zone in the ventromedial tip and around the hilum of both the right and the left nucleus. The larger dorsal portion in the posterior half of the lateral geniculate nucleus, accordingly, is the terminal area of those optic nerve fibers that have their origin in and near the central fovea.

It is remarkable that the fibers from the fovea in Experiment 6 escaped injury—in spite of the proximity of the lesion and unavoidable damage to some branches of the upper temporal artery and vein! The collateral connections with the surrounding vessels that remained intact—that is, with the descending branches of the upper temporal artery and vein and also with the lower temporal vessels, but principally with the macular arterioles, venules, and capillaries—were apparently sufficient for the maintenance of blood supply in the entire foveal pit and in most of the central area (*see* Figs. 148, 162).

Another noteworthy feature in this experiment is the delicate fibers to the pregeniculate gray nucleus, which remained normal. This again, as in Experiment 5, indicated that most, if not all, of these fibers originate in the central fovea, as shown in Experiments 2, 3, and 4.

8. Experiments with lesions in extra-areal periphery (Expts. 7 and 8).—In the seventh experiment a small circular lesion (*les*) was made in the upper temporal quadrant above the large blood vessels (Fig. 207). Owing to the location of the lesion, both fibers from the locally damaged ganglion cells and others sweeping to the optic papilla in wide arches from the more distant periphery of the upper temporal quadrant were interrupted and were caused to degenerate (*cf.* Fig. 162). Since the lesion was not far from the principal vertical meridian, some damage also occurred in an adjoining group of ganglion cells and nerve fibers

in the upper nasal quadrant. Hence the areas of degeneration in the two tracts and geniculates were almost identical, the reaction on the ipsilateral side (left, in the figure) being somewhat more intensive.

The first point of interest in this experiment concerned the restriction of degeneration to the ventromedial tip of the tracts (*otr*) and the geniculate nuclei (*lgn*). As in the preceding experiments, the medial location agreed with the damage to the upper retinal quadrants. The confinement of degeneration to the most ventral zone both in the tracts and in the geniculate nuclei was in contrast with Experiments 2, 3, 4, and 5, and resembled Experiment 6. In this respect, Experiment 7 was the reverse of those experiments in which the central area or fovea was damaged and degeneration in the upper portion

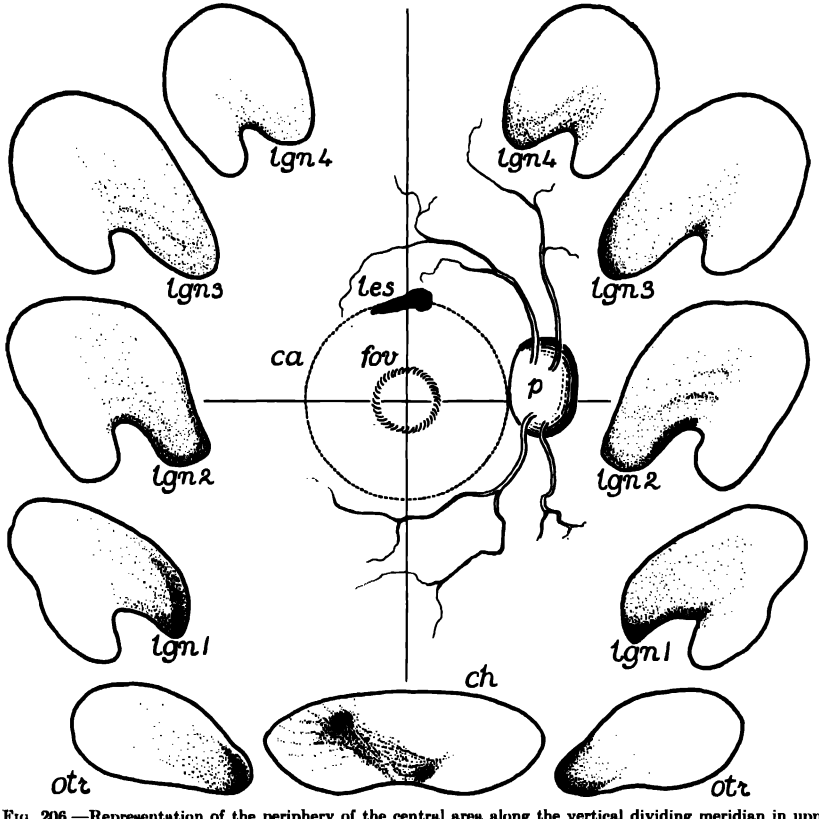

FIG. 206.—Representation of the periphery of the central area along the vertical dividing meridian in upper retinal quadrants in a Rhesus Macaque (Expt. No. 6). A single, small, oblong, and sharply localized electrolytic lesion (*les*) was made in the upper periphery of the central area (*ca*) astride the vertical meridian in the upper retinal half. The degenerated fibers, partly decussating in the chiasma, were found to be in numbers, location, and area of distribution almost the same on the ipsilateral side as on the contralateral. This experiment, owing to the fact that no damage was done to the central fovea, shows no degeneration in the tip of the posterior fourth of the lateral geniculate nuclei (*lgn4*), precisely the parts where foveal fibers were found to terminate (*cf.* Fig. 203). It further demonstrates the separation of nondecussating from decussating fibers by the vertical meridian and indicates the approximate location of the horizontal meridian in the tracts and geniculate nuclei. Labeling same as in Fig. 203.

of the nucleus was found. The portions of the retinae located at some distance from the central fovea and area and closer to the ora serrata, accordingly, are represented in the dorsomedial and ventrolateral edge of the optic tracts and in the ventral margins of the lateral geniculate nuclei which flank the hilum.

Noteworthy, further, was the small number or relative scarcity of degenerated fibers in this experiment. Here their number was only a fraction of the degenerated fibers found in Experiments 2, 4, and 5 and was far below the number of fibers in Experiment 3, with a much smaller lesion. Obviously, the number of optic nerve fibers from the same surface area is many times larger in the central area, especially the fovea, than in the far periphery—a fact that agrees with the direct observation of the number of ganglion cells and fibers found in different regions of the stained whole-mounts and cut sec-

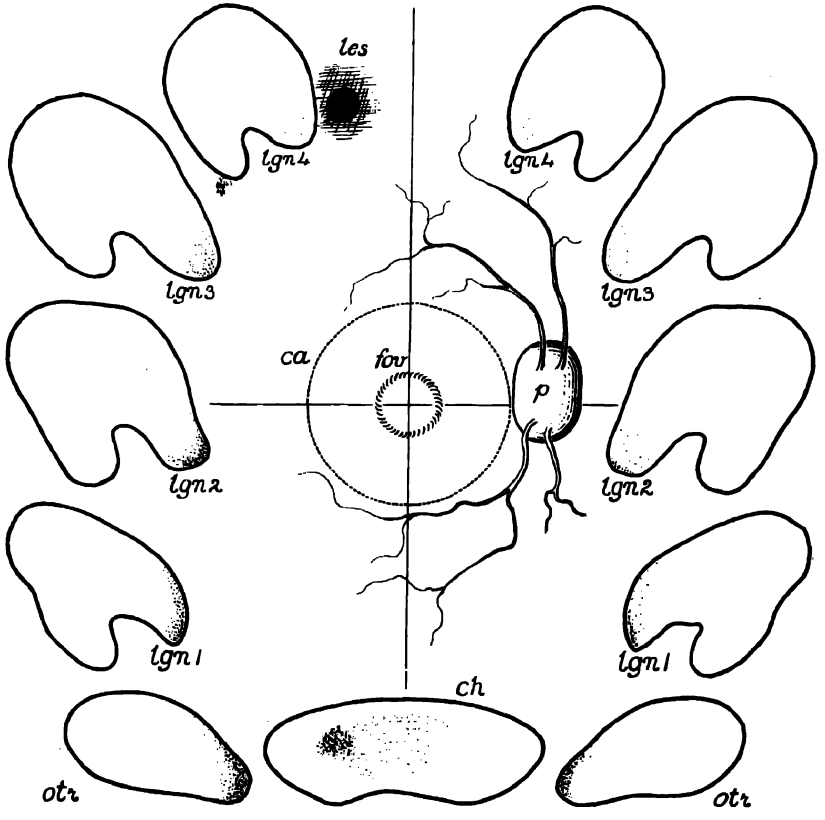

FIG. 207.—Representation of the extra-areal periphery of the retina in a Rhesus Macaque (Expt. No. 7). A small, circular, and somewhat diffusely outlined lesion (*les*) was made electrolytically in the upper temporal quadrant not far from the vertical meridian, but at a considerable distance from the central area (*ca*) and its arching fibers. The areae of degeneration were found to correspond fairly closely on both sides, the number of fibers being somewhat less on the contralateral, left side (*right* in the figure). In the lateral geniculate nuclei the zones of degeneration were confined to the extreme ventral tips of medial segments. This experiment shows the location of fibers originating from the distant retinal periphery in the lateral geniculate nuclei. No fibers were found to enter the pregeniculate nucleus. Labeling same as in Fig. 203.

tions (Fig. 129). Another interesting observation showed that in this experiment, where fovea and central area were spared, the delicate fibers to the pregeniculate nucleus did not degenerate.

In Experiment 8 a small circular lesion (*les*) was made in the upper nasal quadrant not far from the optic papilla (Fig. 208). Because of the peculiar arclike arrangement of the intraretinal optic nerve fibers described before (Fig. 162), a large sector of the retinal bundles was destroyed. This sector included a portion of the extra-areal periphery of the upper temporal quadrant extending as far as the raphé, excepting its farthest periphery (*cf.* Fig. 207, where fibers from the distant periphery alone degenerated).

In addition, a portion of the adjoining upper nasal quadrant was damaged directly. On the other hand, the fiber bundles arising from the central fovea and area, in spite of the proximity of the lesion to the papillomacular bundle, escaped entirely.

Since the portion of the temporal quadrant

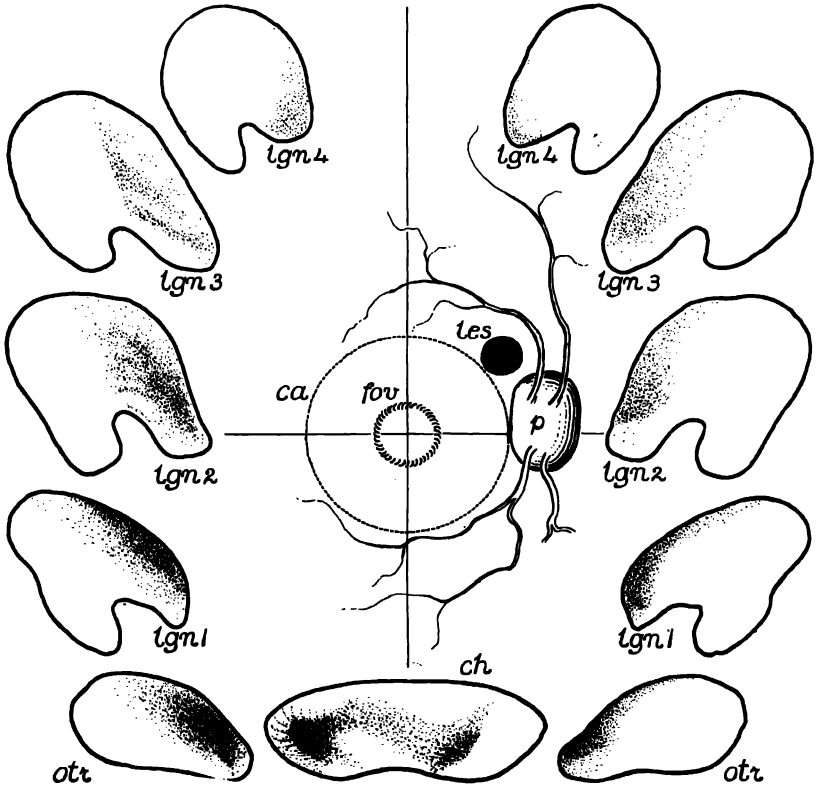

FIG. 208.—Representation of the extra-areal retinal periphery with, perhaps, a part of the adjacent central area, in a Rhesus Macaque (Expt. No. 8). A single, small, circular lesion (*les*) was made electrolytically at the upper extremity of the optic papilla (*p*), just touching the upper nasal quadrant of the central area (*ca*). Owing to the peculiar arching course and the convergence of optic nerve fibers close to the papilla, illustrated in Fig. 162, somewhat different segments in the two upper retinal quadrants were obliterated, indicated by the asymmetric areae of degeneration in both lateral geniculate nuclei (*lgn*). Note an absence of degeneration in the foveal segments of the nuclei (*lgn4*), and a laminar arrangement of degenerated fibers in *lgn2* and *lgn3*. Labeling same as in Fig. 203.

destroyed differed from that eliminated in the nasal quadrant, the degeneration in the two tracts and geniculates also varied considerably in size, shape, and location. In the optic tract of the ipsilateral side (left *otr*, in Fig. 208) and in approximately the anterior half of the ipsilateral geniculate nucleus (*lgn1* and *lgn2*), the degeneration in the medial segment spread as far as the axial line; the lateral segment contained no degeneration, since its fibers originate in the unaffected lower quadrants separated by the horizontal raphé.

Obviously, the fibers from the upper and lower extra-areal quadrants meet, in the anterior half of the lateral geniculate nucleus, along a portion of the mentioned axial line, precisely as they do along the horizontal raphé in the temporal half of the retina. In the posterior half of the nucleus, on the contrary, the two quadrantic sets of the extra-areal fibers, the upper and the lower ones, are separated, leaving between them a wedgelike central-areal and foveal representation, which widens toward the posterior extremity of the nucleus until it spreads over almost the entire nucleus (left *lgn3* and *lgn4*, in Fig. 208).

In the contralateral geniculate nucleus the area of degeneration is even smaller and more limited to the medial sector, leaving free a greater area around the axis of the nucleus. This negative evidence also shows the intermediate posterior segment to be a terminal region of the central-areal and foveal fibers, which agrees with the positive evidence shown in Experiments 2, 3, and 4 (*lgn4*, in Figs. 202, 203, 204).

The extra-areal segments in the lateral geniculate nucleus, accordingly, flank the intermediate central-areal and foveal segment on both sides, repeating the arrangement found in the retina, where the central area and fovea and the "papillomacular bundle" are encircled by fiber bundles originating from the extra-areal parts of the retina from above, below, and on the temporal side (*cf.* Fig. 162). In the contralateral tract and geniculate nucleus (right *otr* and *lgn1–lgn4*, in Fig. 208), the area of degeneration hugging the medial margin does not extend into the ventromedial tip of the nucleus, avoiding a part of the zone where fibers from the distant retinal periphery terminate (shown in Figs. 206, 207).

Also, the area is demarcated toward the center of the nucleus on the contralateral side by a curved, instead of a straight, line, as found in Experiments 3–6, as well as on the ipsilateral side of the same experiment except on the posterior levels, *lgn4* in Figure 208. Since no central-areal and foveal fibers of the nasal quadrant were damaged, the intermediate segment in the tract and the geniculate, particularly in the posterior extremity of the latter, remained intact (right *lgn3* and *lgn4*, in figure).

Finally, as in other experiments where the lesion was outside the foveal pit, no delicate fibers from the principal laminated nuclei to the pregeniculate gray nuclei degenerated in this experiment.

9. SUMMARY OF THE TOPOGRAPHICAL REPRESENTATION OF THE RETINAL SURFACE IN INFRANUCLEAR AND NUCLEAR DIVISIONS OF THE PRIMATE VISUAL SYSTEM.—Taking into consideration the principle of symmetry on both sides of the horizontal meridian, the evidence from the experiments on monkeys described in the preceding paragraphs makes it possible to devise a scheme of detailed topographical representation or "projection" of the retinal surface in the infranuclear division of the visual system, and especially in its principal terminal station, the laminated lateral geniculate nucleus (Fig. 225; *see also* sec. 11, this chapter).

In the optic nerve (as in the papilla), along approximately three-fourths of the postbulbar stretch, the areal-foveal fibers are located in the temporal half of the nerve (Figs. 201, 202). Only gradually, in the proximal fourth of the nerve close to the chiasma, does this bundle definitely assume a central location. The bundle is organized quadrantically, the upper temporal and nasal quadrants being above, the lower temporal and nasal quadrants below, a line which corresponds to the horizontal meridian (*optpap* in Fig. 225). The extra-areal portions of the respective quadrants, close to the eyeball, are then next nasal in line in the nerve, with the temporal crescent fibers most inward, along the nasal margin of the nerve.

Closer to the chiasma, the areal-foveal bundle assumes a more central location and becomes surrounded on all sides by the extra-areal fibers, arranged according to the quadrants (*optn* in same figure). Along this proximal

stretch of the nerve, however, the position of the quadrants changes, owing to a rotation of the optic nerve around its axis, with the upper quadrants becoming more nasal and the lower quadrants more temporal. The monocular crescentic fibers, in consequence, form the ventromedial margin of the nerve, a position they preserve after decussation in the contralateral optic tract.

In the chiasma the areal-foveal or "macular" bundle occupies a dorsal position (Fig. 225). The decussating halves of the fibers of this bundle, mainly on intermediate levels through the chiasma, occupy, closer to the center, about the upper two-thirds of the chiasma immediately underneath the hypothalamus; the two nondecussating halves forming the two dorsolateral corners of the chiasma, an approximate position maintained by them and their contralateral mates, after decussation, in the tracts as far as the geniculate nuclei. (This result from the experiments with monkeys agrees in substance with the position of macular fibers in the human chiasma as described by Rønne 1910.) The remainder of the chiasma, roughly represented by the inferior half, is formed by the extra-areal fibers, with the monocular crescentic bundles being situated ventral- and posteriormost.

In the suprachiasmal portion of the visual system each side represents only half of both retinae. According to the scheme (Fig. 225), each optic tract and lateral geniculate nucleus, on a cross-section vertical to its longitudinal axis, may be thought of as composed of a series of thin lamellae or sheets of fibers arranged roughly parallel to one another. The pattern of distribution of these lamellae fairly well resembles the arrangement of the quadrants and zones of the retinal surface. Owing to a partial decussation in the chiasma and the resulting doubling of the homonymous fibers, each tract and lateral geniculate nucleus represents homonymous halves of both retinae or of the crossed homonymous halves of both monocular fields of view.

The representation of the retinal surface in the geniculates and tracts, even though highly accurate, is not absolutely identical. The first qualification is introduced along their course by a slight shifting of fibers with respect to one another, owing to which the complete pattern becomes somewhat changed, even though the essential features of the retinal arrangement are preserved. In spite of the shifting, the individual conductor units at both ends remain close to their original neighbors, that is, they keep the same relative order in the terminal station, the lateral geniculate nucleus, that is present at the origin of the cable in the retina.

The second qualification is caused by the necessity to tie up in an orderly way, with the original topographical relations fully preserved, the retinal units arranged two-dimensionally, with their respective homodynamical cell groups in the lateral geniculate nucleus arranged according to a tridimensional pattern.

The third qualifying factor is the difference or change in the relative size of the receptor units of the retina and the corresponding terminal units in the lateral geniculate nucleus. This change takes place in the nucleus in an opposite sense from that found in the retina. In the foveal center the receptor units are identical with the single cones; outside it, with the increase in cone diameter and with the addition of the rods, wider spacing, and polysynaptical grouping, the photoreceptor units gradually increase in area toward the retinal periphery. In the lateral geniculate nucleus the opposite tendency is observed. Here the largest units are in the posterior intermediate segment, where the foveal center or foveola is represented, the smallest units being in those sectors where the extreme retinal periphery is represented.

There are, finally, indications that the representation of upper and lower quadrants is not exactly symmetrical with respect to the horizontal meridian as a divide, but is rather somewhat lopsided, a greater area or volume being related to the upper than to the lower quadrants on both sides of the line representing that meridian. This would indicate a somewhat greater importance of the inferior halves of the fields of view, especially so in Man, with his upright posture and terrestrial habit, in comparison with the arboreal species of the Primate Order, most of which use all four extremities for locomotion (*see* chap. XV).

Figure 225 summarizes in detail the retinal "projection" in the lateral geniculate nucleus of the Monkey. In it the right-eye retina (viewed

from the front) is divided into two halves by the principal vertical meridian (*vm*), passing through the foveal center. The larger nasal half, in black, sends its fibers to the contralateral geniculate nucleus (right, in the figure), the smaller temporal half, in white, to the ipsilateral nucleus (left, in the figure). A horizontal meridian (*hm*), likewise passing through the foveal center, further divides each half of the retina into two quadrants, upper and lower, separating the retinal surface into four quadrants, upper and lower nasal (black) and upper and lower temporal quadrant (white).

A further subdivision is established by concentric smaller and larger circles, all centered in the foveal center (corresponding to the "points of fixation" in the fields of view). Each quadrant and zone is differently shaded, the upper quadrants with vertical, the lower quadrants with horizontal, lines, the density of the shading increasing from the periphery to the foveal center.

The smallest circle, closest to the fixation point, incloses the foveal center, corresponding to the deepest portion of the foveal excavation, or foveola, which practically coincides with the rodless central territory free of blood vessels. The next belt, encircling the rodless area, corresponds to the slopes of the fovea as far as the rim of the foveal excavation. The third circle from the fixation point represents the extrafoveal portion of the central area, on the nasal side extending as far as the optic papilla (*op*). The largest circular belt surrounding the central area corresponds to the spacious extra-areal periphery of the retina. On the temporal side (left, in the figure) this belt extends as far as the ora serrata or serrated margin of the retinal membrane. It incloses that larger portion of the retina which, in the normal binocular visual act, co-operates with, or is functionally overlapped by, the same portion of the retina of the opposite eye. On the nasal side (extreme right, in the figure), the retina extends for some distance beyond the binocular portion. This crescent-shaped portion of the retina corresponds to the monocular portion of the field of view, which does not have a counterpart in the field of view of the opposite eye.

While the arrangement of the quadrants and belts in Figure 225 is accurate, their relative sizes, for purposes of more lucid presentation, are given at a different relative magnification. The area of the rodless and vessel-free center of the central fovea, e.g., actually amounting to approximately 2 per cent of the field of view in the horizontal meridian, is increased in the scheme almost tenfold (area inclosed by the first circle from the center). The central area (third circle from the center), on the other hand, was magnified less. (For the actual figures *see* chap. V, 10.)

The optic tracts and lateral geniculate nuclei, being above the chiasma and hence above the point of decussation of the nasal fibers, represent the homonymous halves of both retinae or the hemiretinae because of a suprachiasmal doubling. The ipsilateral tract and geniculate nucleus (left, in the figure) represent the temporal half; the contralateral tract and geniculate (right, in the figure) represent the nasal half of the right retina. The horizontal meridian, represented by fairly straight lines placed approximately in the center of the tracts and geniculates, divides each of these structures into two halves, each half corresponding to one retinal quadrant. The upper quadrants are located on the dorsomedial side of the horizontal meridian, the lower quadrants on the ventrolateral side. This meridian, in turn, terminates at its upper extremity with a small semicircle (*f*), indicating the position of the centralmost foveal fibers, corresponding to a minute nest of very small foveal cones named by Rochon-Duvigneaud the "bouquet of central cones." It is these cones that function as the centralmost point of the visual apparatus or, in the field of view, as the "point of fixation."

The various belts and quadrants, as is easily understandable from the figure, have a definite location, size, and shape in the tracts and geniculates. In Figure 225, these are represented according to their actual relative sizes. The salient feature is the location, shape, and size of the central fovea (densely shaded areas at the upper extremities of the sketches). In the tracts, where the foveal fibers are close together, they form a narrow wedge at the blunt upper end, with the axis following the horizontal meridian, the sharp end of the wedge pointing toward the medioventral, attenuated extremity of the tract. The foveal-areal wedge does not quite

reach the middle of the horizontal axis and shows a flaring along the rounded upper contour of the tract.

In the lateral geniculate nucleus the foveal representation on the anterior levels close to the optic tract is still restricted, since the foveal fibers here are only "fibers of passage." On the middle level of the longitudinal extent of the geniculate nucleus, the foveal representation begins to increase in area, doing so rapidly in the posterior half, until in its posterior fourth the foveal fibers spread over most of the nucleus. Here, as in the tract and in the retina, the fovea preserves its central location. Whereas, however, in the tract and close to the anterior end of the geniculate it is flanked by fibers representing all belts of the retina, the farthest being the monocular crescentic fibers, the flanking belts gradually decrease in size toward the posterior end of the nucleus until the monocular representation ceases to exist. In this way it is possible to preserve a very accurate topographical relationship of the retinal surface in a compact tridimensional structure like a lateral geniculate nucleus.

The remainder of the hemiretinal surface is arranged in an orderly fashion around the hemifovea in approximately the same order as in the hemiretina: first, the extrafoveal portion of the central area outside the fovea; next, the extra-areal binocular periphery outside the central area, and the monocular crescent outside the extra-areal binocular periphery. In the tract, the respective quadrants meet across the horizontal meridian, forming an approximately semicircular belt arranged concentrically with respect to the fixation point (*f*). In the lateral geniculate nucleus the upper and lower quadrants of the monocular crescent are separated by a notch or dent, the hilum, in this structure. The extra-areal binocular quadrants on anterior levels are held together only by a slender bridge squeezed between the notch below and the areal-foveal core above.

This process of separation is completed on the middle levels. Here the areal core breaks through the extra-areal binocular belt and establishes direct contact with the hilum. The separation, on caudal levels, proceeds further, with the extrafoveal quadrants of the central area also eventually separated from each other, permitting the foveal segments direct access to the hilum. It is likely that this separation culminates in a similar pushing aside of the upper and lower segments of the periphery of the fovea, leaving the representation of the rodless foveal center, or foveola, alone, to form the caudal tip of the lateral geniculate nucleus.

The general mechanical causes that have brought about these changes in the internal topography and external configuration of the lateral geniculate nucleus are: an inclusion of the space-requiring nerve cells, together with their dendritic expansions; the presence of teledendric ramifications of the incoming optic and probably other categories of nerve fibers; and the addition of a greatly increased vascular net, indispensable for the greater metabolism required by a nerve center.

The other factor is a disproportionate numerical increase in the nerve cells in the foveal and areal core of the nucleus, only partially compensated downward by the reduced size of the cells in the same foveal core. This appears to be the principal factor causing the upper contour of a cross-section of the lateral geniculate nucleus to assume a round, evaginated shape, instead of the straight line which the principal vertical meridian in the retina, represented by it, actually is. The same necessity that, in the retina, caused an accumulation of histological elements in a thickened central area, especially in the foveal ridge, produced a rounded bulge in the geniculate nucleus, in order to accommodate the greatly increased number of central-areal and foveal cells.

The configuration of the lateral geniculate nucleus, both external and on a cross-section, varies in different species of the Primate Order. In spite of this variation, the principal features are easily recognized, and accurate topographical homologies may be established. (*See* secs. 8, 9, this chapter, and accompanying figures for the minute structure of the lateral geniculate nucleus; *see* chap. VII, 5-7, for the functional organization of the supranuclear division of the visual system.)

10. Dimensional organization of the visual system in infraprimate verte-

BRATES.—The topographical representation, or, as it is also called, the "point-to-point" or "one-to-one projection," of the retinal surface in the infranuclear and nuclear divisions of the visual pathway has been studied most thoroughly in the Primates, because of its great importance for the understanding of the functional organization of the human visual system and its pathology. Also, since the laminated lateral nucleus is the principal terminal station of the optic tract, most attention was paid to its topographical relation to the retina.

The available information, scanty though it be, shows that a similar topographical relation is present in other subcortical visual stations. Such an arrangement was demonstrated experimentally in the superior colliculi of the midbrain in various infraprimate species, e.g., Opossum, Rat, Rabbit, and Cat (Brouwer 1923; Overbosch 1927; Lashley 1934; Bodian 1937).

Concerning the Inframammalian Vertebrates, unfortunately, there is little positive knowledge. Lubsen (1921) showed the presence of retinal projection in a Fish. This was further confirmed, and a similar arrangement found in *Triturus taeniatus*, a European Newt, by Ströer (1939, 1940).

These observations, because of the low phylogenetic standing of the Fishes and Amphibians, are of great interest, since they show the "point-to-point" representation of the retinal surface to be a basic plan of organization of the vertebrate visual system. In the American Newts *Ambystoma* and *Necturus* and in the Catfish *Ameiurus*, however, Herrick (1941, 1942, 1948) was able only partially to confirm Ströer's observations by finding, in addition to a generalized, diffuse, nonspecific system of thick optic nerve fibers, another system of thin and more numerous fibers that are possibly organized retinotopically.

The investigation of the intrinsic organization of the visual system of the Inframammalian Vertebrates and its interpretation in the light of the specific habits of a particular species still remain largely a task of the future. As far as is known, it justifies the assumption that a more or less elaborate "dimensional" organizational plan may be expected in all species except those whose vision has been eliminated. Such expectation is based upon indirect evidence: large eyeballs, an advanced differentiation of retinal structures, a formidable optic nerve made up of a great number of fibers, and well-developed visual centers of the midbrain possessing a structure resembling that of the mammalian cortex. Such features are characteristic of many Fishes, Lizards, and most Birds. In many cases, such as Birds of Prey, Insectivorous Birds, and certain Lizards (Chameleon, *Anolis*, *Agama*), a "point-to-point" organization of the central visual apparatus, in its structural refinement and functional performance, may equal, and occasionally surpass, that found in the best "visual Mammals," the Primates, including Man. Such a postulation is in accord with the notable experiments upon the visual apparatus of Salamanders and Frogs executed by Stone *et al.* and by Sperry. (*Cf. also* chap. XIV.)

SEC. 8. MINUTE STRUCTURE OF THE PRINCIPAL OR LAMINATED LATERAL GENICULATE NUCLEUS

1. GENERAL REMARKS.—The laminated lateral geniculate nucleus, or body, of the simian and human brain is the principal and structurally most elaborate subcortical visual center (Fig. 209, *LGN;* also Fig. 210 and sec. 1 [4], this chapter). It is probable that, together with the pregeniculate gray nucleus (*pgn*), the laminated

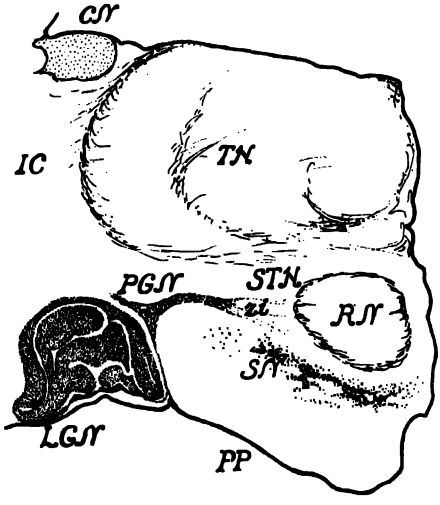

FIG. 209.—Cross-section through half of the human diencephalon, or betweenbrain, showing the topographic relationships of the principal constituent structures: laminated lateral geniculate nucleus (*LGN*), pregeniculate nucleus (*PGN*), subthalamus (*STH*), zona incerta of subthalamus (*zi*), red nucleus (*RN*), substantia nigra or dark substance (*SN*), pes pedunculi of "foot" of the cerebral peduncle (*PP*), thalamus (*TH*), internal capsule (*IC*), and caudate nucleus (*CN*). Note that the pregeniculate nucleus (*PGN*), laterally attached to the laminated nucleus (*LGN*) and medially extending through the zona incerta to the red nucleus (*RN*), indicates a path along which the lateral geniculate complex, represented by the laminated nucleus (dorsal portion of lateral geniculate nucleus) and the pregeniculate nucleus (ventral portion of lateral geniculate nucleus of Lower Mammals) migrated during phylogenesis and ontogenesis. (*Cf.* Figs. 210–15, and also Figs. 183, 186, 191.)

nucleus represents the "lateral geniculate nucleus" of the betweenbrain of the Infraprimate Mammals (*lgn* in Fig. 191).

Phylogenetically, the larger laminated or lateral geniculate nucleus proper of the Primates appears, then, as a homologue of the "dorsal portion" or *pars dorsalis* (*d*, a derivative of the thalamus proper), the smaller pregeniculate gray nucleus as a homologue of the "ventral portion" or *pars ventralis* (*v*, a derivative of the subthalamus) of the primitive Mammals.

The reverse topographical arrangement found in the primate brain, with the principal laminated nucleus ventral and the smaller pregeniculate nucleus assuming a more or less dorsal or dorsomedial position, is caused by a great increase in size of the primate thalamus, which, in turn, results in a complex displacement during the phylogenesis and ontogenesis of the laminated nucleus in a lateral, posterior, and downward direction (*see* Környey 1928; R. A. Pfeifer 1930; Le Gros Clark 1932).

According to the ontogenetical and phylogenetical investigations of the lateral geniculate nucleus from the lowermost Mammals to the highest, including Man, by Le Gros Clark (1932), the dorsal laminated nucleus differentiates out of the lateral portion of the ventral nuclear mass of the thalamus proper.

The ventral nucleus is a more primitive visual center, showing a progressive reduction in the Higher Mammals (*cf.*, however, sec. 10 [1], this chapter). It appears to be a differentiated lateral segment of that part of the *pars ventralis diencephali* which is called the subthalamus (in Gilbert's terminology "ventral thalamus"). This is indicated by its topographical relations, the similarity of its nerve cells, its gradual grading into *zona incerta* (*zi* in Fig. 209), all features noticeable both in primitive Mammals, such as the Tree Shrew, and also in the Tarsier, and likewise seen both during human ontogenesis and in the mature human brain (Figs. 212, 214, 215).

The ventral nucleus, accordingly, is phylogenetically an old subthalamic visual center with tegmental connections (*see* sec. 10 [2], this chapter, on connections). In the Primates the ventral nucleus is preserved in the pregeniculate gray nucleus, *griseum praegeniculatum* or *substantia grisea praegeniculata*, of O. and C. Vogt (1909). In the adult human and simian brain

this nucleus remains permanently continuous with the subthalamus. (*Cf. also* S. Ingvar 1923, 1925; M. S. Gilbert 1935; E. R. A. Cooper 1945.)

The lateral geniculate nucleus, with the medial geniculate nucleus, which is a subcortical station of the auditory pathway, forms the *metathalamus* or hind part of the thalamus proper, from which both nuclei became differentiated (*cf.*, however, Kuhlenbeck 1935 36).

The laminated geniculate nucleus is anatomically, functionally, and trophically closely related both to the infranuclear and to the supranuclear divisions of the visual system. Its nerve cells, irrespective of whether they belong to the neuron variety with a long axon (Golgi type *I*) or have a short axon (Golgi type *II*), are closely trophically dependent on the optic nerve fibers under whose exclusive influence they are ("monopoly of afferent relationship"). When separated from them, they atrophy or die completely, a phenomenon known as "transsynaptic or transneuronal degeneration." This is a reverse of a process of retrograde degeneration taking place, e.g., in the ganglion cells of the retina in consequence of their separation from the laminated nucleus.

A similar, though less intimate, relationship is possibly present between the pregeniculate nucleus and the optic nerve fibers and their cells of origin in the retina; this, however, requires further study.

In another sense the trophic interdependence of the infranuclear and nuclear neurons differs markedly. Whereas the cells of the laminated nucleus degenerate when they are cut off from their afferent influences, the retinal ganglion cells show but a slight reduction of staining properties in experiments where the supranuclear division of the visual system (the visual radiation or the striate area) is damaged, provided that no damage is done to the terminations of the optic nerve fibers in the laminated nucleus or to the latter's blood supply (*see* the author's observations in Klüver's paper 1937, p. 388; *cf. also* Lauber 1927 and Kolmer & Lauber 1936).

The axis cylinders or axons of the larger or principal nerve cells of the laminated lateral geniculate nucleus represent the visual radiation which terminates in the striate cortex of the occipital lobe of the cerebral hemisphere (*see* chap. VII, 1 [2]). When these fibers are interrupted or their terminations in the striate cortex are cut off or in any way seriously interfered with, their cells of origin in the laminated nucleus show signs of irritation, which finally ends in their complete wasting or disappearance or retrograde degeneration.

To what extent the geniculate nerve cells in an adult state are capable of regeneration or what is the maximum of interference to their axons and teledendrons after which anatomical integrity and normal functioning still can be restored remains an open problem. Experimental evidence points with certainty toward a delicate adjustment, in which any mechanical interference with the terminations in the striate cortex is followed by degeneration and complete disappearance of the entire neuron.

In a severe insult, e.g., a complete interruption, not only the principal cells whose axons are severed but also the association cells of the laminated nucleus degenerate. The process of retrograde degeneration of the nervous parenchyma is accompanied by an increase of neuroglial elements. (*Cf.* chaps. VII and XII.)

The cells of the pregeniculate nucleus do not seem to suffer in consequence of an interference with the visual radiation. This, owing to an absence of cortical connection in this nucleus, is understandable. (*See* sec. 10 [2], this chapter.)

2. SHAPE AND TOPOGRAPHICAL RELATION OF THE LAMINATED LATERAL GENICULATE NUCLEUS.—The shape and the lamellated structure of the lateral geniculate nucleus proper in the various primate species are similar, even though they vary in detail (*cf.* Le Gros Clark, *Brit. J. Ophth.*, v. 16, 1932; also 1941, 1942; *see also* Solnitzky & Harman 1943; and Harman & Solnitzky 1944). In the Lower Monkeys, e.g., a Rhesus Macaque, the shape of the nucleus in the customary coronal sections resembles that of a horseshoe, with its apex or convex extremity pointing dorsolaterally, and its lower indented side facing down (Figs. 186, 210, 211). In the Anthropomorphous Apes (Fig. 214) and in Man (Figs. 209, 215) the nucleus is more or less club-shaped, with its bulky end turned medially and its short, attenuated handle extending in the lateral direction and down, although compact

forms of the human nucleus are also found occasionally.

The axial line by which the lateral geniculate nucleus may be divided into two fairly symmetrical halves is inclined laterally with its upper end, this line inclosing, with the horizontal line, an angle of approximately 45° (Fig. 211). The ventral notch or hilum (*h*) and the terisk in Fig. 200, sketches *C–G;* Figs. 210, 211; Fig. 214, sketches *E, F;* Fig. 215, sketches *G–I*).

The two nuclei are separated from each other by a thick, curved fiber lamina, the "circumgeniculate capsule" (*cgc*), which incases the entire circumference of the laminated nucleus. On anterior levels this capsule is largely made up of the incoming retinal fibers from the optic tract.

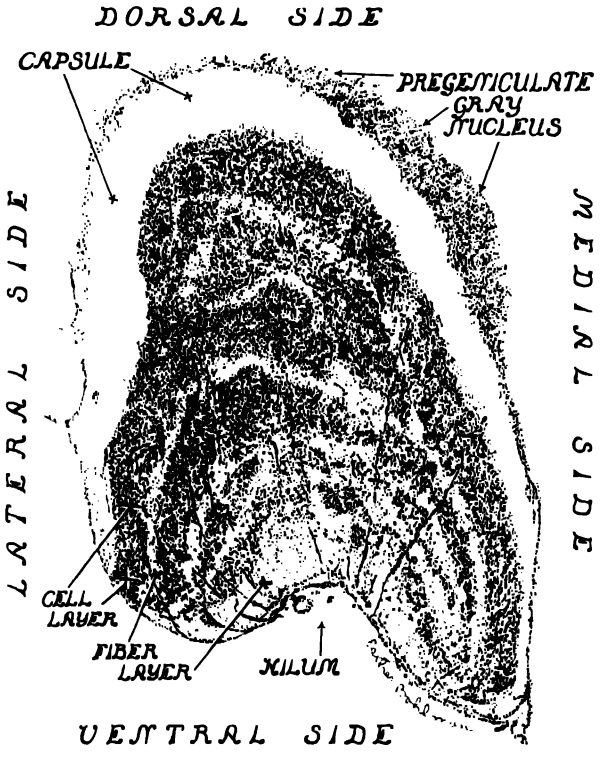

FIG. 210.—Lateral geniculate nucleus of a Rhesus Macaque, showing cell laminae in a Nissl-stained section through the middle third of the anteroposterior extent of the nucleus. Note the fiber layers, relatively free from cells, by which the cell laminae are separated, and the much thicker fiber capsule, entirely free from cells, by which the caplike pregeniculate nucleus is separated from the laminated nucleus. (*Cf.* preceding and following figures.)

two ventral extremities flanking it are part of the basal cerebral surface, the rest being imbedded in the substance of the brain. Dorsomedially, on anterior levels, much of the lateral geniculate nucleus is surrounded by the pregeniculate nucleus (*pgn* or marked by an as-

On posterior levels, especially above the apex of the nucleus, the circumgeniculate capsule consists mostly of the outgoing geniculate axons that form the initial portion of the visual radiation. Here this capsule increases in thickness, forming an area somewhat triangular in shape,

called the "field of Wernicke" (*W* in Fig. 213); from it a long, narrow strand of obliquely cut fibers extends along the lateral face of the thalamus (Fig. 230).

Other important structures adjoining the lateral geniculate nucleus are the posterior thalamic nuclei on its dorsal and dorsomedial sides (*Th* or *th* in Figs. 209, 213), the subthalamus (*STH* or *sth* in Figs. 209, 215), the medial geniculate nucleus or body (Figs. 181, 183) or the cerebral peduncle on the medial side (*PP* in Figs. 209, 230), and the posterior extremity of the internal capsule of the brain on its lateral side. The lateral geniculate nucleus is separated from the hippocampal gyrus of the temporal lobe by a cleft, the chorioid fissure, which belongs to the space outside the brain (Fig. 230). Between the nucleus and the inferior horn of the lateral ventricle are the *fimbria* and *taenia* of the *hippocampus*, the blood vessels, and the chorioid plexus of this region (Fig. 230).

3. Lamination of the lateral geniculate nucleus.—The nerve cells and fibers which constitute the laminated lateral geniculate nucleus in the Monkey, Ape, and Man are assembled into several parallel and alternating cell and fiber layers or laminae.

In the Macaque the laminae are "everted," that is, bent in a semicircular fashion around a ventral notch, the hilum (Fig. 200; also *h* in Figs. 210, 211). In the Anthropomorphous Apes and in Man the eversion or ventral curving, with the concavity facing down, is less pronounced and is noticeable, if at all, only in the anterior or rostral half of the nucleus (Fig. 214, *D–F;* Fig. 215, *E, H*).

In the posterior or caudal portion the "inversion" or curving, with the concavity facing up, is more pronounced (Fig. 214, *A–C;* Fig. 215, *A–D*). In the posterior tip of the nucleus, in fact, this inverted curving alone is present (Fig. 214, *A, B;* Fig. 215, *A–D*).

This particular feature of the principal or laminated lateral geniculate nucleus found in the phylogenetically highest Primates resembles the arrangement found in the Lower Primates, the Lemurs, and in the insectivorous relative of the primate ancestors, the Tree Shrew *Tupaia* (*cf.* Le Gros Clark in *Brit. J. Ophth.*, v. 16, Fig. 6, 1932, and lower photo in Fig. 213; *see also* sec. 6 [6], this chapter).

The number of the cell laminae of the laminated lateral geniculate nucleus and their arrangement vary somewhat in detail in different primate species. They also vary on different levels of the geniculate nucleus of the same species. In the anteriormost portion, at the anterior pole of the nucleus, where the fibers of the optic tract enter, there are four cell laminae in all simian species and in Man (Fig. 200, *G;* Fig. 214, *F;* Fig. 215, *H*).

Of these, the lower two magnocellular laminae are narrow and composed mostly of large nerve cells, the largest in the nucleus, though fewest numerically. The first or lowermost magnocellular lamina, *1c*, is related to the decussating optic nerve fibers from the nasal half of the contralateral retina, as discussed in detail in section 6 (5), this chapter. The next layer, *1i*, also magnocellular, is related to the nondecussating fibers from the temporal half of the ipsilateral retina.

The two upper parvocellular laminae, much thicker and made up of smaller but more numerous nerve cells, are also terminals of fibers from the same homonymous retinal halves: *2i* of the nondecussating ipsilateral and *2c* of the decussating contralateral.

In the much larger posterior portion of the nucleus the number of the laminae increases by a further subdivision of each of the parvocellular laminae into two, which makes four parvocellular and two magnocellular laminae. Of these, the *1i*, *2iα*, and *2iβ* are related to the ipsilateral fibers, and *1c*, *2cα*, and *2cβ* are related to the contralateral.

In the middle third or so of the longitudinal extent of the nucleus in the Monkey, however, the six laminae are found only in the intermediate foveal-areal segment (*see* Fig. 200, e.g., *E* or *F*). In the medial and lateral segments of the nucleus, where fibers from the upper and lower extramacular quadrants terminate (*see* Fig. 225 and sec. 7, this chapter), the number of the laminae in the Monkey remains limited to four or five.

In the Chimpanzee a sesquilaminal differentiation is present in the entire medial segment, in most of the posterior two-thirds of the nucleus (Fig. 214, *A–D*). In the medial extra-areal

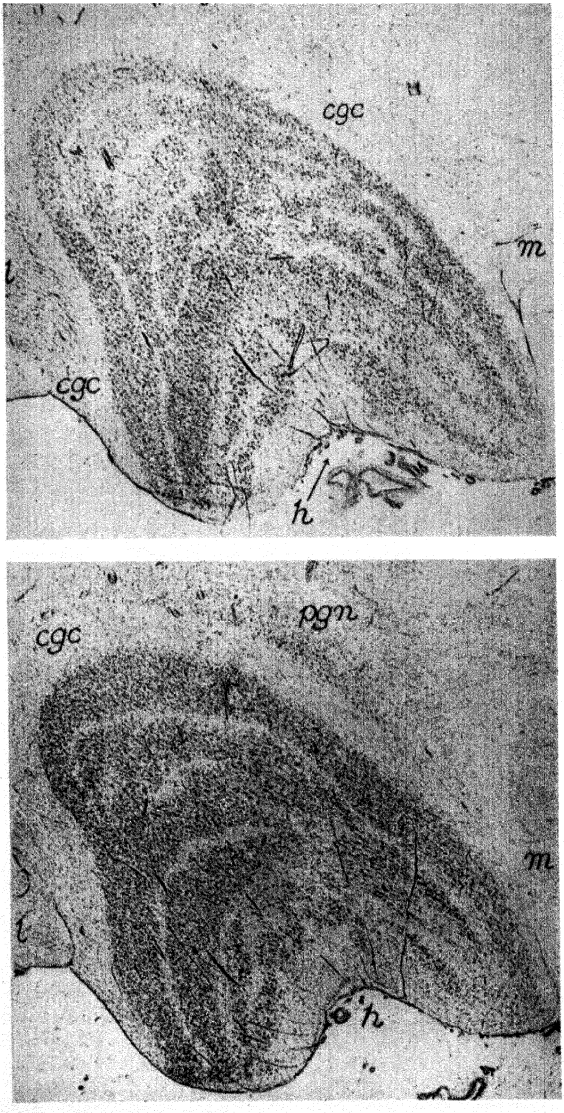

FIG. 211.—Microphotographs of Nissl-stained sections of the lateral geniculate nucleus of a Rhesus Macaque, showing the arrangement of cell laminae, separated from one another by fiber laminae relatively free from nerve cells. The upper photo is from a more posterior level through the nucleus than the lower photo; hence the pregeniculate nucleus is found only in the latter. For a complete presentation of the laminar pattern changing from level to level *see* Figs. 200, 214, 215. *Labeling: cgc*, fiber lamina surrounding the laminated nucleus and, in the lower photo, separating it from the pregeniculate nucleus; *h*, hilum of the nucleus; *l*, lateral face; *m*, medial face; *pgn*, pregeniculate nucleus. (*Cf.* Fig. 210.)

segment in the Monkey, in particular, the limitation to four basic laminae remains throughout the length of the geniculate nucleus. In the extreme posterior tip alone, in the Macaque, the differentiation of the four into six cell laminae is complete or almost so (Fig. 200, *A*).

In Man, in the entire posterior third of the nucleus (Fig. 215, *A–C*), in the Chimpanzee in the posterior tip only (Fig. 214, *A*, left), the number of the laminae is again reduced to the original four, the two thin lower laminae containing large cells and the two thicker upper ones composed of small cells.

In the Macaque, an ill-defined supplemental lamina of scattered medium-sized cells is also found in the closest proximity to the ventral

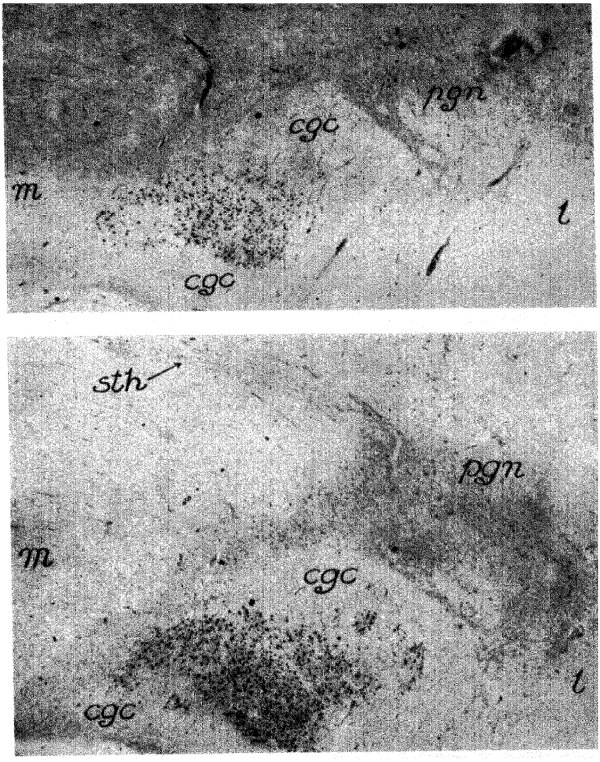

FIG. 212.—Microphotographs of the lateral geniculate nucleus of Man, showing, in Nissl-stained sections passing through anterior extremity, both portions of the nucleus: the larger laminated one made up of large, intensively stained nerve cells, enveloped by a thick fiber lamina (*cgc*) free from cells, and a paler, diffusely outlined pregeniculate gray nucleus (*pgn*) containing a great number of minute, fusiform cells which continue along a strand into subthalamus (*sth*), whence they have migrated during phylogenesis and ontogenesis, as shown in Fig. 209. The levels of these photos pass through the anterior extremity of the nucleus, where the pregeniculate nucleus is well developed, the same nucleus gradually disappearing on posterior levels shown in Fig. 213. Medial and lateral sides indicated by *m* and *l*. (*Cf.* also Fig. 215.)

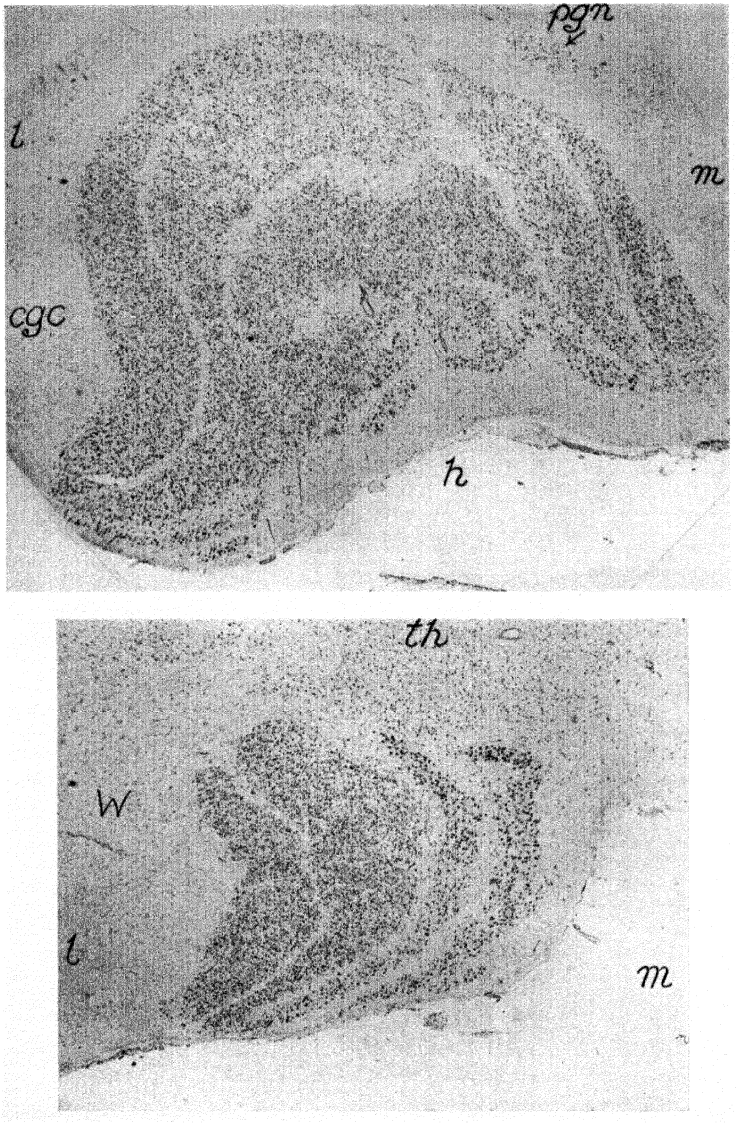

FIG. 213.—Microphotographs of human lateral geniculate nucleus, showing on posterior levels the laminated portion fully developed and the pregeniculate nucleus (*pgn*) much decreased before its final disappearance. In the lower photo, which shows a section through the posterior extremity of the nucleus, only four cellular laminae are present, two made up of small cells, the other two of large cells. This photo represents a level where the entire nucleus belongs to the fovea and may be considered a "geniculate fovea," its exquisite function being reflected in its regular arrangement and the great number of cells. (*Cf.* Fig. 215.)

surface at the hilum (Figs. 210, 211). A vestige of this formation, in Man and in the Ape, is the few stray nerve cells imbedded in the ventral portion of the circumgeniculate fibrous capsule at the hilum of the nucleus.

The intertwining of the secondary and tertiary extensions of the cell laminae in all species is most pronounced in the middle third of the longitudinal extent of the nucleus, in the intermediate areal-foveal segment, while the two magnocellular laminae are in many places broken up into discontinuous rows of larger and smaller groups and islands of cells.

A considerable difference in detail is found in individual specimens, even though the underlying basic quadri-, quinque-, and sesquilaminal pattern is always apparent. This is especially noticeable in human geniculates. In some individuals the cell laminae are smooth, evenly outlined, and regularly arranged, resembling the relatively uncomplicated pattern of the Macaque, while in others, e.g., Figure 215, the original simple pattern is much complicated by the secondary twisting and intertwining. (*See* sec. 6 [6], this chapter, and chap. VII, 3, for the functional significance of lamination of the lateral geniculate nucleus.)

4. Varieties and distribution of nerve cells of the lateral geniculate nucleus, in general. The bodies of the neurons which make up the laminated lateral geniculate nucleus have, in general, a more or less spherical or globular shape. Some, however, resemble a short spindle or are irregular. The majority of the cells are multipolar. The large cells, measuring in Man up to 20 × 30 microns, constitute the two lower or ventral, magnocellular laminae (*1c*, *1i*), while the upper or dorsal, parvocellular laminae (*2i*, *2c*) and their derivatives (*2ia*, *2iβ*, *2cα*, *2cβ*) are made up of cells half the diameter of the larger ones.

In the magnocellular laminae, in addition to the larger cells which are in the majority, there are also smaller cells similar in size and shape to those filling the parvocellular laminae. In the latter, close scrutiny reveals that the size of the cells also varies, with the medium-sized elements predominating. Occasionally an exceptionally large solitary cell is found here also. Small groups and clusters of larger cells resembling those in the magnocellular laminae are found in places along the medial and lateral fringes of the nucleus close to or among the smaller cells.

All cells of the laminated lateral geniculate nucleus, large and small, stain intensively with toluidine blue and thionin modifications of the Nissl method (Figs. 210, 211, 212, 213). In this respect they contrast with the somewhat paler cells of the adjoining portions of the thalamus, and considerably more with the even paler cells of the pregeniculate nucleus (Fig. 212).

At low magnification the entire cell body appears to be rather uniformly and diffusely stained. High magnification reveals the presence of numerous minute granules, threads, and specks of Nissl's chromophile substance filling the cytoplasm of the entire pericaryon or cell body. Most intensively stained are the rod-shaped granules in the immediate vicinity of the nuclear membrane. In all cells, large and small alike, in the adult human and anthropomorphous simian specimens, abundant yellowish-brown pigment is found.

The conspicuous difference in cell size between the dorsal parvocellular laminae (*2c*, *2i*; or *2cα*, *2cβ*, *2iα*, *2iβ*) and the ventral magnocellular laminae (*1c*, *1i*) is apparently an expression of their different functional character. Again, the fact that in places there are four or more parvocellular laminae (*2cα*, *2cβ*, *2iα*, *2iβ*) indicates further differentiation of cells of the two original parvocellular laminae (*2c*, *2i*) into two or more distinct neuron varieties, one in *2cα* and *2iβ*, and another in *2iα* and *2cβ*.

According to this concept, each laminated lateral geniculate nucleus is made up of two sets of neurons, one ipsilateral (*1i*, *2i*; or *1i*, *2iα*, and *2iβ*), and the other contralateral (*1c*, *2c*; or *1c*, *2cα*, and *2cβ*). Each set of neurons, in turn, is represented by two, three, and possibly more distinct neuron varieties, depending upon the number of cell laminae in the particular locality of the nucleus. The arrangement is such that the same neuron varieties are found in each two adjacent laminae, one ipsilateral and one contralateral, e.g., *1i* and *1c*; *2i* and *2c*; or *2iα* and *2cβ*; and *2cα* and *2iβ*.

All the neuron varieties in question represent Monakow's "principal cells" (*cf.* chap. IV, 5 [4]). The axis cylinders of these cells form the

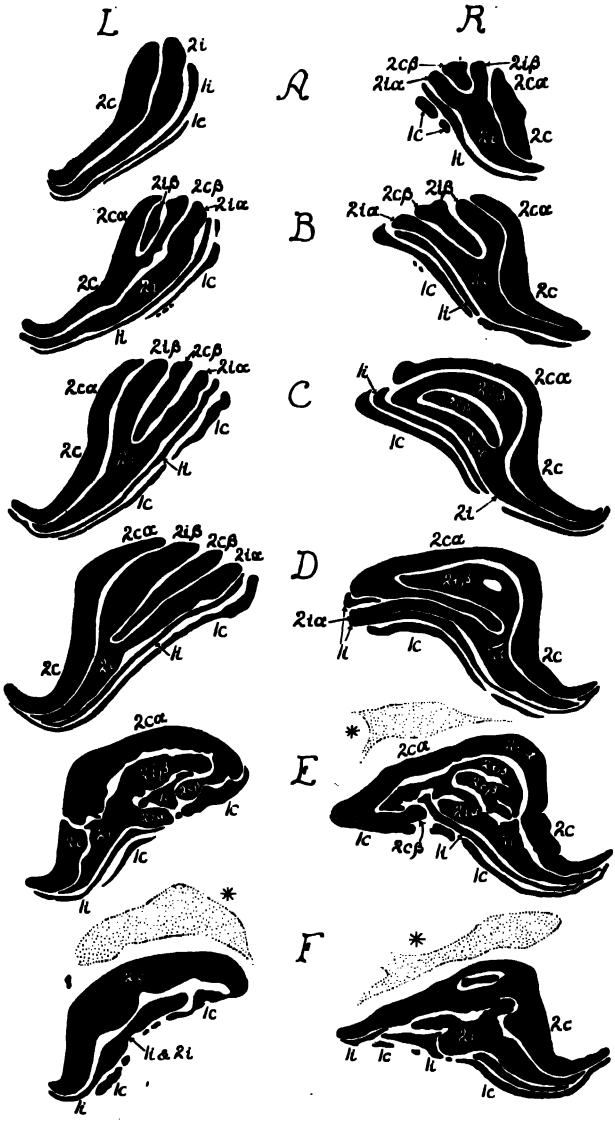

FIG. 214.—Lateral geniculate nuclei of an adult Chimpanzee showing the laminar pattern at approximately equal spacing from the most posterior extremities (*A*) to the anterior ends of the nuclei (*F*). *L* and *R* columns represent serially arranged levels through the left and right nucleus. The layers where the nondecussating ipsilateral retinal fibers terminate are *1i*, *2i*, *2iα*, *2iβ*; the layers where the contralateral decussating fibers terminate are *1c*, *2c*, *2cα*, *2cβ*. The pregeniculate nuclei, given in stippling, are marked by asterisks (*). (*Cf.* Figs. 200, 215.)

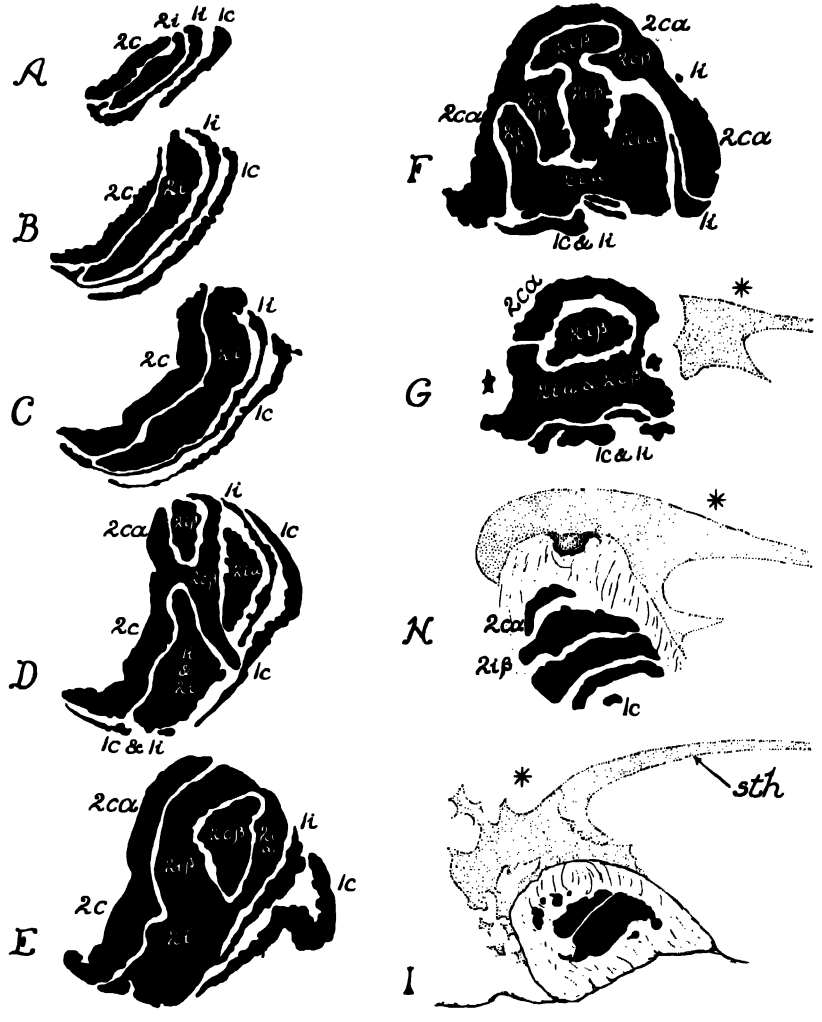

FIG. 215.—Coronal sections through the normal human lateral geniculate nucleus of the left side, arranged at approximately equal intervals from the posterior tip (*A*) to the anterior extremity of the nucleus (*I*). The layers where nondecussating ipsilateral retinal fibers terminate are *1i*, *2i*, *2iα*, *2iβ*; the layers where contralateral decussating fibers terminate are *1c*, *2c*, *2cα*, *2cβ*. The pregeniculate nucleus, given in stippling, is marked with asterisk (*). Compare the complex laminar pattern in this specimen, which was of an eminent microscopist of superior visual performance (Dr. F. B. Mallory), with simpler arrangement in the Chimpanzee (Fig. 214) and in the Ithesus Macaque (Figs. 210, 211), and see photos of the same specimen in Figs. 212, 213. Note the large size of the pregeniculate nucleus, its elaborate structure, and its connections with the subthalamus (*sth*). (On the brain of the same case *see* chap. XII, 10.)

visual radiation, which terminates in the striate cortex of the occipital lobe. They are, therefore, representative of Golgi type *I*, or neurons with a long axon. In addition to the neurons mentioned, however, there are smaller nerve cells in every one of the several laminae whose axis cylinders divide into teledendrons within the nucleus itself. These are representatives of Golgi type *II*, or neurons with a short axon (*see* following sec. 9).

In experiments and in pathological cases where one eye is removed, both types of neurons undergo transsynaptic or transneuronal degeneration. Also, they both degenerate when the visual radiation is interrupted or the striate cortex destroyed. The neurons with short axons or "association cells," as they may be called, are present in the simian lateral geniculate nucleus (*see* sec. 9 [3], this chapter), and have also been found in the Infraprimate Mammals, such as the Cat and Rabbit (O'Leary). This trophic interdependence is indicative of the intimate and exclusive anatomical and physiological relationship between these two neuron varieties. (*See* chap. IV, 5 [4] on Monakow's "intercalated cells"; *see* sec. 6 [6], this chapter, on functional interpretation of neuron varieties.)

5. TERMINATION OF OPTIC AND OTHER NERVE FIBERS IN THE LATERAL GENICULATE NUCLEUS.

The optic nerve fibers enter the laminated lateral geniculate nucleus by continuing the sagittal course they pursue in the optic tracts. How they are distributed in the various segments of the nucleus according to their particular origins in the retina has been dealt with in section 7 of this chapter.

In general, in the core of the laminated nucleus the entering optic nerve fibers spread in the manner of a fan, dividing into several thin sheets or fiber laminae, each composed of numerous minute bundles and each separating two adjoining cell laminae. In coronal sections the fiber laminae appear curved in the same general sense as the cell laminae, in conformity with the general outline of the nucleus. In sagittal sections the fiber laminae are fairly straight, with the fibers running in the anteroposterior direction. The fiber laminae, alternating with the cell laminae, are mostly not solid but made up of numerous small bundles. Their numerical distribution on transverse coronal sections also varies, more fibers being assembled closer to the periphery of the nucleus than in its core, with the medial and ventral margins composed of a solid mass of fibers.

The shape, extent, arrangement, place, synaptical relationships, and other particulars of the terminal arborizations of the optic nerve fibers, in Man and in the Simians, are described in section 9 [4, 5], of this chapter.

SEC. 9. MINUTE STRUCTURE OF THE PRINCIPAL OR LAMINATED LATERAL GENICULATE NUCLEUS AS REVEALED BY HISTOANALYTICAL METHODS

1. INTRODUCTORY REMARKS. —The constituent structures of the laminated lateral geniculate nucleus as revealed by the Golgi method of staining go a long way toward amplifying those which can be demonstrated by the routine methods of hematoxylin and eosin, Van Gie-

son, and the like, and by some selective methods, such as those of Weigert and of Nissl. They show this nucleus to be more complex in its intrinsic makeup than is commonly assumed. In fact, in the light of the information furnished by histoanalytical methods, the lateral geniculate nucleus appears to be, not a simple "relay station" included in the visual pathway, but a true subcortical center, where a certain amount of reciprocal influencing of the constituent neurons takes place.

The histological elements of the simian and human laminated lateral geniculate nucleus are represented by several categories. First are the larger nerve cells whose bodies make up the bulk of the cellular layers: the principal nerve cells. Next are the smaller neurons interspersed among the larger ones: the association cells. The third element is represented by various terminations of optic nerve fibers or axis cylinders of the retinal ganglion cells. Still another category of terminations are those whose cells of origin are unknown (they possibly reside in the brain). Interspersed between the elements mentioned, which constitute the nervous parenchyma proper, is the stroma or supporting framework made up partly of neuroglia, which is ectodermal in origin, and partly of the interstitial connective tissue and blood vessels, which are mesodermal.

2. Review of preceding histoanalytical investigations.—The investigations of the lateral geniculate nucleus of Mammals with the histoanalytical method of Golgi are few in number and incomplete. Ehrlich's vital methylene blue method was never used.

As far as the available record goes, Koelliker (1896) was first to apply the Golgi method to the lateral geniculate nucleus. Thereafter Tello (1904), S. Ramón y Cajal (1899–1904, 1909–11), Henschen (1925, 1926, 1931), Taboada (1927–28), Balado & Franke (1937), and O'Leary (1940) used this technique. Additional information was obtained with the reduced silver stain by Barris, Ingram & Ranson (1935), Glees & Clark (1941), and Glees (1942). Mention may also be made of the numerous publications by P. Ramón y Cajal (1890–1943) and by C. J. Herrick (1914–48) dealing with the brain stem, including the visual pathways and centers of the Inframammalian Vertebrates. In the following, the essential results of these studies are briefly summarized.

Koelliker described the cells in the dorsal nucleus of the Rabbit and Cat as the "shrub variety" (*Buschzellen*), with a round body and with rather short dendrites. These cells resemble in appearance the "principal cells," which have a long axon, according to the present classification. The other smaller category found in the Mouse had a short axon. The "radiating cells" (*Strahlenzellen*), which Koelliker found in the ventral nucleus, are typical of that structure. Some of the large radiating cells located in the optic tract discharge an axon which, with or without collateral branches, joins the tract fibers. These neurons, he guessed, are homologous to those which, according to P. Ramón y Cajal, Van Gehuchten, and Koelliker, are the origin of the centrifugal fibers of the retina. (Judging from their appearance, these neurons may also be the principal cells of the ventral or superficial lamina whose axons enter the visual radiation.) In the human geniculate Koelliker mentions only the shrub variety. He also describes and depicts a dense plexus in the thalamus and lateral geniculate nucleus of afferent optic nerve fibers made up of terminal tufts and of several collaterals.

Tello (1904), besides correctly identifying the dorsal and the ventral geniculate nuclei of the Cat, gave additional information. He described three series or tiers of terminations in the dorsal nucleus of this species resembling cypress trees, corresponding to the three cellular laminae (Fig. 216). There is apparently an overlapping of the adjoining terminal tufts belonging to the individual optic nerve fibers. The nerve cells vary in size and shape, and all categories are distributed uniformly over the entire nucleus. Judging by the length of the axon, two varieties are present: neurons with a long axon and numerous dendrites, some with, others without, "spines" (Golgi type *I*), and neurons of Golgi's type *II*, of small size, with an axon which divides not far from the cell body into a scattered terminal ramification. Since both neuron varieties are enveloped by the terminal plexus of the incoming optic nerve fibers, the short-axon neurons cannot be interpreted as Monakow's "intercalated cells" mediating the transmission of

impulses from the fibers to the principal neurons and farther to the cortex. Finally, Tello also described certain terminals which he regards as arising from the cells residing in the cerebral cortex.

The principal object of Taboada (1927–28) in his study of the simian lateral geniculate nucleus was to determine the exact relationship of the cell laminae to one another. His observation corroborated Minkowski's opinion of the existence of a laminar independence against the objections of Henschen (1925) and of Brouwer & Zeeman (1926). In addition, Taboada found cells closely packed into glomeruli, or nests, with a denser intercellular substance in the center. The cells are of multipolar type, with three to four and even five to six dendrites, all belonging to the same variety. The dendrites are always confined to the same lamina where the body resides. Moreover, the processes of all cells that form a glomerulus remain within its territory. This, in his view, indicates that each glomerulus functions as a unit and receives terminal arborizations of a group of optic nerve fibers. In the ventral magnocellular laminae, each glomerulus consists of from 12 to 15 cells; in the middle laminae, from 30 to 40; and in the upper laminae at the convexity of the nucleus, from 60 to 100. In the thinner ventral magnocellular laminae the glomeruli correspond to segments passing through their entire thickness; in the dorsal parvocellular laminae, especially in the intermediate "macular" portion, the glomeruli take up only a fragment of the thick lamina. The capillary network is denser in the cellular than in the fiber laminae. The association neurons, seen by Koelliker and Tello, and the terminations of fibers, Taboada did not discuss.

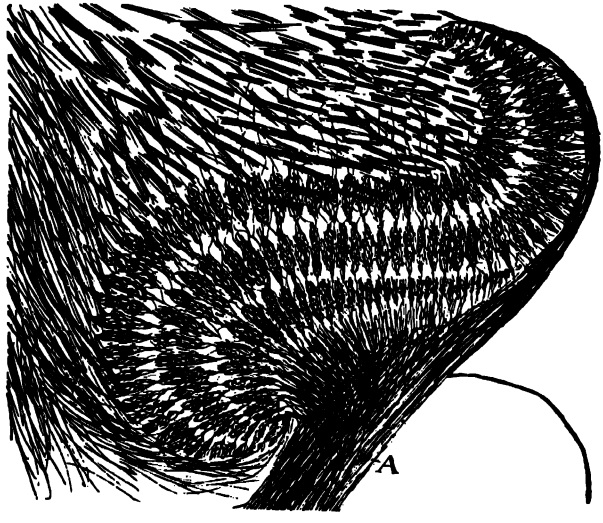

Fig. 216.—Structure of the lateral geniculate nucleus of the Cat stained with the Golgi method. *A*, optic tract entering the nucleus from underneath, its fibers forming terminal arborizations around the cells arranged in regular, parallel layers. From J. F. Tello, "Disposición macroscópica y estructura del cuerpo geniculado externo," Trab. del lab. de invest. biol. Madrid, v. 3, p. 39, 1904. (*Cf.* Figs. 192, 217, 218.)

The most complete and most careful analysis of the structural makeup of the lateral geniculate complex was made in the Cat, by O'Leary (1940). In the dorsal nucleus, he found, as Koelliker and Tello had before, two categories of nerve cells present in all laminae. The larger principal cells give origin to axons, which, usually without emitting any or only a few initial collaterals, leave the nucleus and become the visual radiation or geniculostriate fiber tract.

The axons of the smaller cells are short and terminate within the same lamina of the nucleus in which their cell bodies reside.

There are apparently two short-axon varieties of neurons: one with a loose, scattered teledendron, the other terminating in baskets enveloping the bodies of the principal cells. There are several categories of the principal cells also: the axons of the large cells do not have the initial collaterals, whereas such are present in the medium and small cells. Some axons of the principal cells may pass over to the midbrain (this interpretation is clearly contradicted by the experimental observation showing all geniculate cells undergoing degeneration, thus indicating their dependence on the cortex; *see* chap. VII, 1, 3). The neurons of the ventral nucleus, of smaller size, send their axons, with collaterals, either in the anterior direction or to the optic tract.

The thick afferent optic nerve fibers terminate in the dorsal nucleus. The thin fibers give off collaterals to the ventral nucleus, in which they form a dense tangle, whereas their principal branches probably pass over to the superior colliculus (*cf.* S. Ramón y Cajal 1904 or 1911; *also* secs. 5, 7, 10, this chapter). Other categories of fibers may possibly also terminate in the ventral nucleus.

All thick fibers bifurcate into two branches, one thick, one thin. Each thick branch arborizes in the dorsal nucleus, with secondary terminals, whereas the thin branches may terminate elsewhere. Occasional brushlike collaterals are found just before the terminal arborization. In the thin laminae the terminal teledendrons extend across the entire thickness, in the thick laminae over only a part of the lamina.

It is an important observation that no single optic nerve fiber produces terminal tufts for more than one lamina (which is in agreement with Minkowski's separate termination of the ipsilateral and contralateral fibers in discrete laminae and with a similar observation made by Taboada).

It is probable that each principal geniculate cell is synaptically related to several afferent axons (*cf.* following subsection). There is probably abundant synaptical contact, both on the cell bodies and on the dendrites (unfortunately not illustrated). A dense tangle of overlapping terminal arborizations, both of the exogenous optic nerve fibers and of the endogenous short axons of association neurons, envelops the cells. Short axon arborizations deriving from the adjoining laminae suggest a reciprocal influencing (*see* par. 4, this section).

The connections of the ventral nucleus are apparently more complex than expected. Its

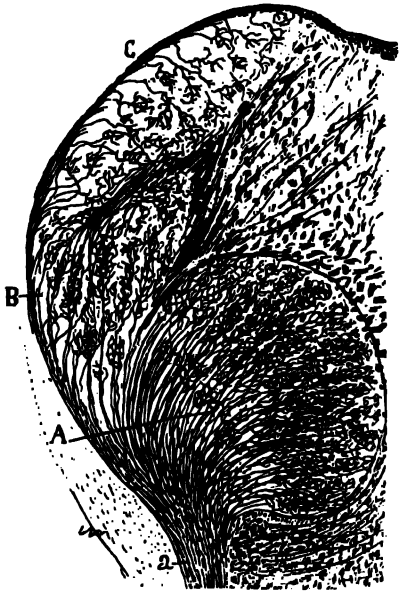

FIG. 217.—Coronal section through the lateral geniculate nucleus of a Cat a few days old, stained with the Golgi method, showing elaborate terminal arborizations of optic nerve fibers of retinal origin around the cells of the nucleus. *A*, inferior, *B* and *C*, superior segments of the nucleus; *a*, optic tract. From S. Ramón y Cajal, *Histologie du système nerveux*, v. 2, 1911. (*Cf.* Figs. 216, 218.)

cells are enveloped by a dense tangle of the afferent collaterals of a thin variety of optic fibers, to which tangle neither the collaterals of the thick fibers terminating in the dorsal nucleus nor the short-axon association cells residing in the latter nucleus contribute. These thin afferent fibers of the ventral nucleus apparently belong to a special variety of the retinal neurons instead of being the branchings of the thick fibers terminating in the dorsal nucleus. (This

is of interest because it reverses an earlier belief expressed by Gudden [1889] and Westphal [1898], according to which the thin fibers represent a cortical pathway, the thick that of the pupillary reflex circuit; *see* Kolmer in Möllendorff's *Handb. d. mikr. Anat.*, v. 4, p. 494.)

In the dorsal nucleus there is no rich plexus of the afferent collaterals, but, significantly, one of the short-axon terminations. Since the afferent optic nerve fibers are related directly both to the bodies and to the dendrites of the principal cells, the short-axon cells are not interneurons in the sense of Monakow (*see* chap. IV, 5 [4]). Judging from the synaptical connections, both the principal long-axon neurons and the short-axon association neurons receive retinal impulses simultaneously via the afferent optic nerve fibers. The short-axon cells may function as synchronizers of the groups of related principal cells (*see* O'Leary 1937; O'Leary & Bishop 1938).

Finally, O'Leary believes his work lends support to Lorente de Nó's concept of a "partially shifted overlapping" of the terminal arborizations of the tract fibers in the dorsal nucleus, denying the possibility that an individual axon has ever provided an exclusive relationship to a single principal cell or to a small group of such cells. The fact that the Cat has no true fovea, its photoreceptors being exclusively rods, the number of fibers in its optic nerve being only one-tenth of those in Man and Monkey, makes one wonder whether the synaptical arrangements not found in the feline visual system may

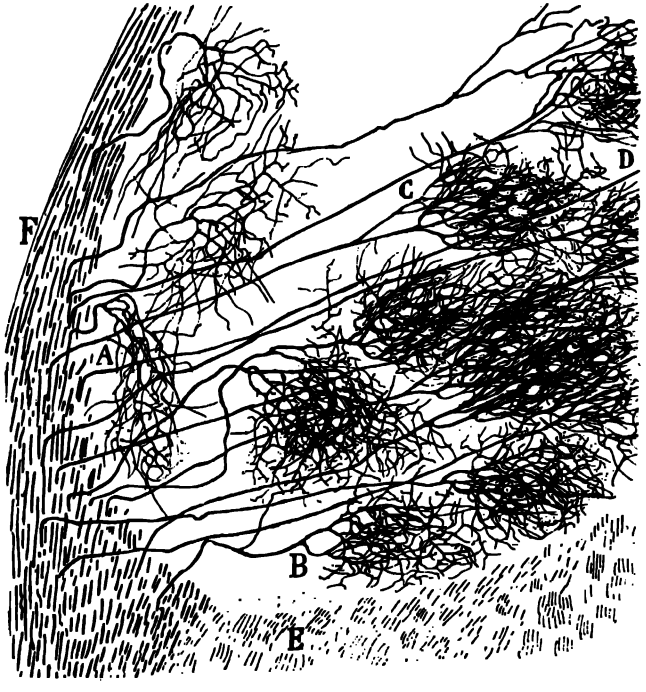

FIG. 218.—Portion of the "inferior segment" of the lateral geniculate nucleus of the Cat, showing at higher magnification terminal arborizations of optic nerve fibers of retinal origin stained with the Golgi method. *A*, superficial arborizations; *B*, *C*, *D*, similar arborizations located in deeper parts of the nucleus; *F*, superficial layer of nerve fibers arriving from the optic tract. well be a regular equipment of the Primates, whose visual acuity is far superior to that of the Cat (*cf.* sec. 3 [4], this chapter, and pars. 5–9, this section).

Glees & Clark (1941) and Glees (1941, 1942) investigated the form and mode of termination of the optic nerve fibers in the lateral geniculate nucleus of the Monkey, Rabbit, and Cat by means of reduced silver nitrate stain. They showed, in addition to the termination of the ipsilateral and contralateral fibers in discrete cell laminae, that each individual fiber terminates in an arborization related to half-a-dozen cells. The terminal nodules are attached to the cell bodies (axosomatic synapse), each cell being in contact with a single nodule. There seems to be no overlapping of the terminal arborizations. In the Cat, the terminal buttons are attached both to the bodies and to the dendrites, with the axodendritic synapses preponderating numerically over the axosomatic synapses. Glees was inclined to think that in the Cat each geniculate cell may be synaptically related to more than one optic nerve fiber, each cell having, altogether, about 40 of both kinds of synaptical contacts. Whether these contacts belonged to one or to several fibers, it was not possible to ascertain, even though the latter was probable. The optic nerve fibers do not terminate as free endings but in the form of nodules. More than ten cells may be related to a single optic nerve fiber, and each cell, in turn, may be related to more than one fiber, which indicates the presence of an overlap in the geniculate terminations. An absence of an overlap in the Monkey and the presence of such in the Cat may be interpreted as "an arrangement providing for the utmost precision in the recording" of the retinal image in the first species and as "an anatomical basis for a high degree of sensitivity in low intensities of illumination" in the latter species. In the Rabbit, both axosomatic and axodendritic synapses are present. The number of the first is about ten to each cell. An overlap is probable.

3. PRINCIPAL NERVE CELLS.—The bulk of the cellular elements of the laminated lateral geniculate nucleus in Man and in the Monkey is represented by the larger nerve cells. When these cells are stained completely in Golgi preparations, including all their dendrites, they have the appearance of typical multipolar neurons.

From a more or less spherical body, commensurate in size and shape with the bodies seen in Nissl preparations, half-a-dozen stout principal dendrites arise and soon divide into secondary, tertiary, and further branches. These branches are all of approximately the same length, radiating in all directions, thus giving the cells an asteriform or star-shaped appearance. Cells along the periphery of the cellular laminae are exceptions; their dendrites are all turned inward, in this way avoiding the extralaminar territory. Only occasionally does a dendrite penetrate into the circumgeniculate fibrous capsule or into one or another fiber layer separating the cell laminae. The rule is, however, that each cell spreads its dendrites in the cell lamina where its body resides.

The dendrites carry a moderate number of typical "spines," giving a dendritic branch the appearance of a more or less twisted twig of a thorny bramble. The "spines" are all of approximately the same length and usually carry minute spherical nodules at their ends.

The diameter of the dendritic spread of a large nerve cell is, on the average, from 300 to 500 microns or from $\frac{1}{3}$ to $\frac{1}{2}$ mm. across, the size of the spread being commensurate with the size of the cell body. A reciprocal overlapping of dendrites of the adjoining principal cells amounting to half the spread, more or less, is the rule throughout the nucleus. A preferential orientation of dendrites is not noticeable, except in small cells of the parvocellular layers at the apex of the nucleus, whose dendrites somewhat follow the lines vertical to the surface of the nucleus—an arrangement apparently caused by the emergent bundles of fibers of the visual radiation.

A single axis cylinder emerges directly from the cell body, usually with a typical "hillock," and is soon lost in the surrounding fiber layers. Its direction is toward the circumgeniculate fiber capsule.

4. ASSOCIATION CELLS.—The cell body of this category of neurons of the laminated nucleus of Man and Monkey is of a spherical or oval shape, approximately half the diameter of that of the larger principal cells of the immedi-

ate neighborhood, which are in the majority (Fig. 219). From one side of the body one or a few main dendrites arise and gradually divide into half-a-dozen secondary branches, altogether forming a loose, tree-shaped arborization, spreading over a territory which includes about fifty nerve cells. The dendrites carry a relatively small number of terminal twigs and spines, some twigs forming minute clusters or baskets. Most of the terminal twigs and spines are swollen into minute spherical "gemmules" or nodules at the very ends. These are the terminal varicosities.

A single, relatively thin, axis cylinder originates at the opposite pole of the body, dividing into half-a-dozen secondary branches, which, by further subdivision, produce a loose teledendron. The terminal twigs of this teledendron, all provided with nodules and a terminal varicosity, twist in various ways between the cells for which they form baskets, closely adhering to the surface of their bodies, in this way undergoing the axosomatic synapses. The number of principal cells synaptically related to an association cell approximates one dozen, all cells belonging to the same cellular lamina in which the body of the association cell resides.

5. General remarks on axonal terminations.—The terminal arborizations in the simian and human laminated nucleus, revealed by Golgi's silver bichromate method of staining, produce, by repeated division in the nucleus, an exceedingly rich and dense plexus surrounding the cells and their expansions.

This plexus is made up of coarser and finer terminal branches and twigs variously bent and twisted, many carrying varicosities of different shapes and sizes. Such varicosities or protoplasmic swellings may be found either along the course of the fibers or at the end of the terminal twigs, or the terminal "spines" may be without a swelling. Again, the terminal branches and twigs may stand alone, or they may be assembled into groups or clusters touching the surface of the body of a related geniculate cell, or they may be clasping a dendrite of a cell, or in some other way be attached to it.

In every case the terminals of the retinal fibers are in direct contact with the surface of the related geniculate neuron. Altogether, the terminal branchings or teledendrons of retinal origin produce an exceedingly dense plexus around the cells and their expansions, resembling, when stained completely, baskets that practically envelop the cells in shell-like casings.

A careful analysis of this terminal intercellular plexus reveals it to be made up of individual constituents belonging to teledendrons of different types, originating from distinct varieties of retinal and other ganglion cells, and of distinct functional significance.

Several varieties of terminal ramifications of the afferent optic nerve fibers may be distinguished, according to type, as far as it was possible to determine by number and distribution of terminal twigs, size and shape of the spread, and the orientation relative to the cell and fiber laminae of the geniculate nucleus.

From the well-established fact of the presence of several distinct varieties of retinal ganglion cells described in chapter V (5), several distinct categories of terminal ramifications may be expected in the laminated lateral geniculate nucleus. The difficulty in solving this problem arises, however, not only because of the "fickle" character of the Golgi technique, but even more because of the great distance intervening between the cells of origin of the fibers residing in the retina and their terminals in the brain. (This difficulty was largely absent in the study of retinal neurons, because of the shortness of their axons.) Unfortunately, there are no sure criteria by which a particular type of termination could be assigned to a definite variety of nerve cells as its probable origin. The only way, therefore, by which such identification may be attempted consists of circumstantial evidence.

Experience shows that in the nervous system in general, each particular neuron variety has a certain "character" with which all parts of that neuron variety, by and large, agree. As an example may be cited the parasol (*m*) and midget ganglions (*s*) of the retina. The first possess a rather large body with several robust dendrites dividing into a considerable number of short twigs, which, together, form a compact treetop of limited extent. The teledendrons of this ganglion variety may, accordingly, be expected also to be of rather robust appearance and of limited size. In the case of the midget ganglion

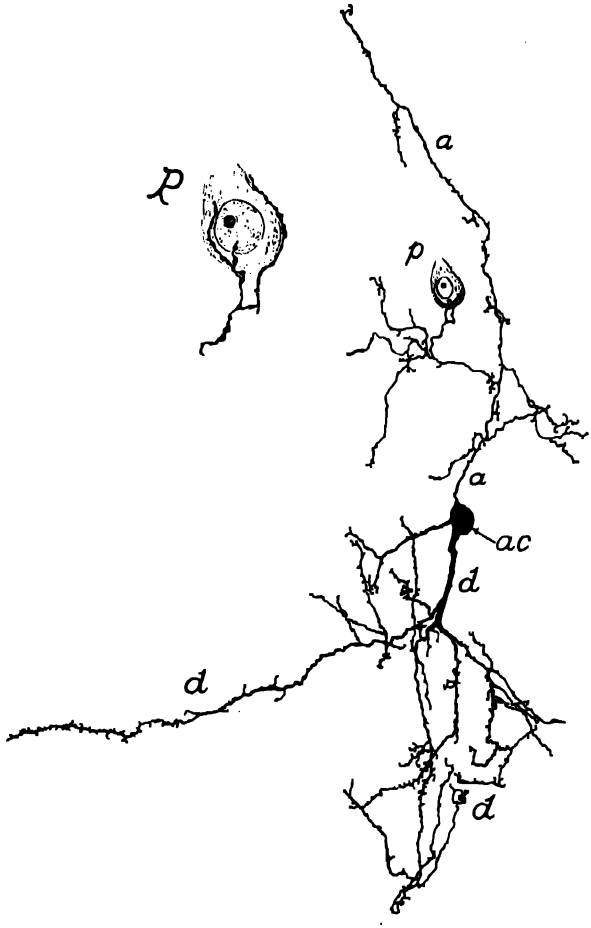

FIG. 219.—An "association cell" (*ac*) from the laminated lateral geniculate nucleus of a Rhesus Macaque, with the expansions completely stained. The axis cylinder or "nerve fiber" (*a*) arises from a spherical body and soon divides into a terminal arborization made up of a limited number of branches, each provided with a few short branches carrying terminal twigs and varicosities or swellings. Some varicosities are also found along the course of the branches themselves. All such terminal arborizations of axis cylinders form loose baskets, spreading in the cell lamina of the nucleus where the cell body resides. The terminal twigs and varicosities undergo synaptical contacts with the bodies of the "principal nerve cells" of the same lamina, as shown in the upper left corner at a higher magnification (*P*): a terminal branch embracing the body of a principal cell with several twigs, its smaller and larger varicosities adhering to the surface of the cell body. From the other end of the body of the association cell (*ac*) arise two dendrites (*d*), one shorter and thinner and the other much thicker, both dividing into an elaborate dendritic arborization. This dendritic arborization, formed by more numerous and more robust branches than those of the axonal arborization, is also provided with short terminal twigs which carry terminal varicosities or swellings. The dendritic arborization also spreads in the same cell lamina where the body of the association cell resides. The probable function of association cells is to condition in some way the groups of the principal cells around them, possibly under the influence of terminal teledendrons of retinal optic nerve fibers or also of fibers whose origin is somewhere in the brain, possibly in the striate area. Golgi method; larger sketch magnified 280×, detailed sketch 660×.

cells the teledendrons may also be expected to be of small dimensions and of delicate appearance. Again, the location and the relative number of a particular ganglion variety in a particular locality or region of the retina may be a clue to its identity. Since the midget ganglions represent the greater majority of ganglion cells in the central area, it is legitimate to expect their terminations to prevail numerically in the portion of the lateral geniculate nucleus, where, according to the experiments described in section 7 of this chapter, the central fovea and area are represented.

Lastly, the location and orientation of the terminal ramifications may be an important indicator concerning the identity of fiber terminations. As the experiments described in section 7 of this chapter show, no retinal fibers are to be found in the apical segment of the circumgeniculate lamina, with the exception of delicate fibers terminating in the pregeniculate nucleus (which nucleus is limited to about the anterior third of the laminated nucleus). Any robust fiber entering from the internal capsule of the brain, in the posterior third of the nucleus, and spreading in it, is likely to be of nonretinal origin.

Using the preceding and other less explicit morphological criteria which long experience with the method of Golgi suggests and always bearing in mind the tentative character of the interpretation, in the following subsections an attempt is made to classify the various types of terminal arborizations in the simian and human laminated geniculate nucleus, and their probable functional significance is discussed.

6. TERMINATIONS OF AXONS OF UMBRELLA OR PARASOL GANGLIONS (*M*).—This type of terminal arborization conforms to the classical concept of a teledendron (Fig. 220, *a*, *t*). A relatively stout axon fiber usually emerges either from the ventral portion of the circumgeniculate fiber capsule at the hilum of the nucleus or from one of the several fiber laminae. Such fibers terminate in one of the adjoining cell laminae by dividing into a few dozen of rather short and twisted secondary, tertiary, and further branches and twigs, in many places swollen into spherical or irregular varicosities and nodules, and altogether forming a crude terminal arborization. The ultimate twigs usually terminate with a minute spherical nodule. A single teledendron of this type spreads over the territory of a compact group of nerve cells of the particular lamina. Two dozen or more cells are to be found in such a group in the parvocellular laminae, next to the axis of the geniculate nucleus.

The size and appearance of the teledendron vary somewhat, depending upon the portion of the nucleus in which it is found. In the intermediate segment, corresponding with the representation of the central area and fovea, the size is more restricted and the twigs are more delicate than in the ventral magnocellular layers, where the extra-areal retinal periphery is represented. Some of the branches are oriented vertically with regard to the cell lamina, others meander in all directions.

The size and arrangement of the terminal twigs suggest basket-shaped synapses applied to the bodies of the laminar nerve cells, each pericellular basket being formed by the branches contributed by a number of individual teledendrons of the same variety.

The synapses formed by this variety of terminal arborization are of an axosomatic type; the terminal varicosities, or short terminal twigs carrying such varicosities, are closely applied to the surface of the body of the related cell.

Whether this arborization found in the entire laminated geniculate nucleus truly represents a single variety or whether similar, though functionally slightly different, types of the same variety of teledendron are present in the several laminae of the two sets, the crossed and the uncrossed, possibly indicating a different function in each lamina, it is not possible to determine on morphological grounds alone.

7. TERMINATIONS OF AXONS OF SHRUB GANGLIONS (*N*).—A conspicuous, although very delicate, variety of termination is the axons arranged according to the radii of the laminated nucleus (Fig. 220, right-hand sketch). At moderate magnification they appear as long, fine, and rather straight threads passing up and down the layers, their lower ends pointing toward the hilum. Oil-immersion objectives reveal them to be very thin, but otherwise typical,

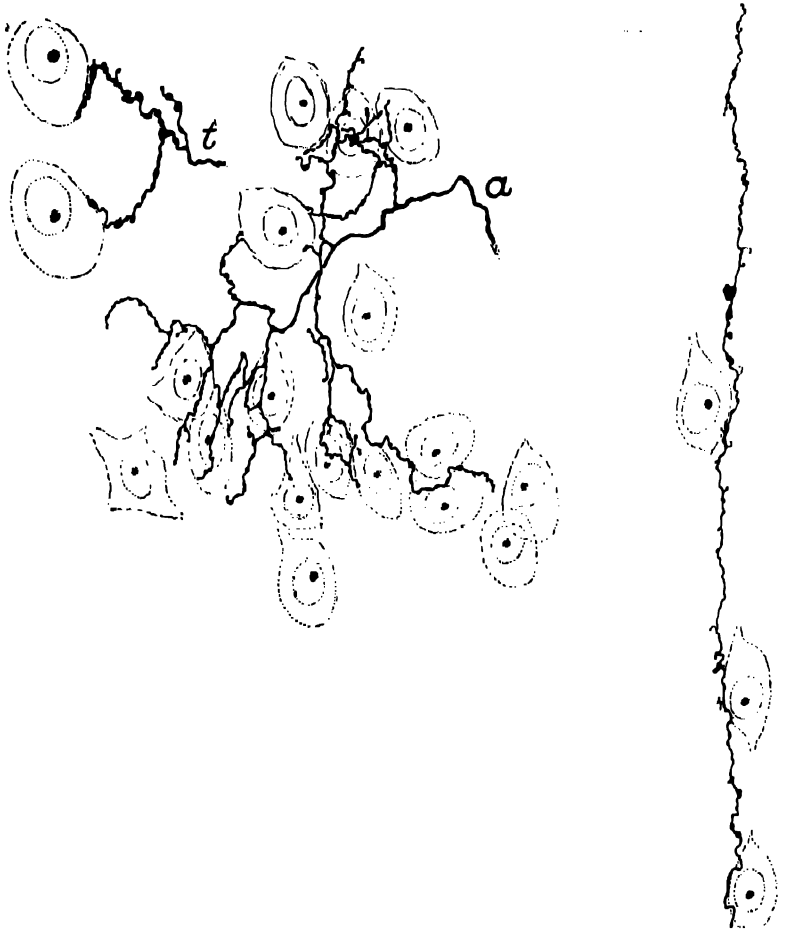

FIG. 220.—Terminal arborizations of optic nerve fibers in the laminated lateral geniculate nucleus of a Rhesus Macaque made visible with the Golgi method of staining: *a*, an elaborate arborization of a single nerve fiber, apparently of retinal origin, made up of branches, gradually dividing into terminal twigs, each in places swollen into varicosities and each terminating with a larger or smaller varicosity, each arborization terminating around a nest of "principal nerve cells" within a single lamina of the nucleus, whence the axon fibers of visual radiation originate; *t*, a single terminal twig of an arborization at a higher magnification with outlines of two principal cells showing in profile the attachment of varicosities to the surface of the bodies of cells, together forming an axosomatic type of synapse. The right-hand sketch represents the termination of a single afferent nerve fiber of unknown origin, possibly also retinal, of very thin diameter and long, straight course, arranged according to the radii of the laminated nucleus, with numerous minute terminal twigs and varicosities attached to the surface of principal nerve cells, the cells, interconnected in this way, forming narrow functional segments or columns passing through several cell laminae. There are indications of still other types of termination in the laminated nucleus, some probably of cerebral origin, altogether showing this nucleus to be an elaborate center wherein retinal impulses are processed in many ways before they are dispatched to the cerebral cortex. Camera lucida drawings, Leitz *Ultropak* oil-immersion objective 60×, transillumination, approximate magnification: center and right-hand sketch 270×, left upper sketch 450×.

terminal axons exhibiting numerous minute twists and curves, with an occasional minute varicose swelling in their course or with such a varicosity attached to the fiber. An occasional varicosity may be of much larger size than the average. A few minute twigs or "spines," usually curved in the form of a hook and with an infinitesimal budlike swelling at the usually undivided ends, are found along the fiber.

The remarkable fact about this variety of terminals is their length and the mode of their synapsing. Whereas the *M* and *S* terminals contact a compact cluster of cells roughly spherical in shape, occupying a minute area anywhere in one of the several cell laminae, the *N* terminals freely pass in a straight course from one cell lamina across the fiber lamina to the next cell lamina. In this way the cells of the adjoining laminae, independently related to the *M* and *S* terminals, are again joined with one another across the separating fiber laminae by means of the connecting *N* terminals.

The synapses of the *N* terminals are made by direct contact with the surface of the bodies of a string of nerve cells nearest to them.

8. TERMINATIONS OF AXONS OF MIDGET GANGLIONS (*S*).—This variety of terminal ramifications somewhat resembles the *M* variety, though much richer and composed of much more delicate branches and twigs. The space taken by it is likewise roughly spherical, representing but a tiny area of a cell lamina. The terminal twigs are variously contorted, forming dainty baskets for the bodies of the laminar cells with which they form axosomatic synapses.

9. TERMINATIONS OF FIBERS OF CEREBRAL ORIGIN (*X*).—A variety of terminal arborizations differing from the preceding in appearance, location, and orientation possibly belongs to axons of neurons residing in the brain itself. These rather thick fibers enter the laminated nucleus anywhere along its convex dorsal, dorsomedial, or dorsolateral aspect. Within the territory of the nucleus each fiber divides into a few fairly thick, long branches parting in opposite directions. The branches, thickened in places into small varicosities, carry a moderate number of terminal twigs and "spines," each terminating with a minute nodule. The area over which this type of arborization spreads is large and may be populated by several hundreds of nerve cells of a given lamina. This variety of teledendron is present in all parts of the laminated nucleus, mingling indiscriminately with the terminations described earlier as possibly those of the retinal fibers. Because of the fact that the *X* terminations do not arise from fibers of the optic tract, it is a fair guess that they originate from neurons residing in the brain, probably somewhere in the occipital cortex.

10. SUMMARY OF THE INTRINSIC ORGANIZATION OF THE PRIMATE LAMINATED LATERAL GENICULATE NUCLEUS.—Because of the incompleteness of our knowledge of the actual structures, any plan of the intrinsic makeup or functional organization of the laminated lateral geniculate nucleus of Primates must be made with emphasis upon its tentative character.

Beginning with the nerve cells of the nucleus, it is certain that, in general, these resemble the neurons in the remainder of the central nervous system. Each cell has a body, several protoplasmic dendrites, and a single axis cylinder or axon. On the basis of whether the axon leaves the nucleus or terminates within its territory, two categories of neurons may be distinguished that conform to types *I* and *II* of Golgi. Strictly observable facts do not as yet permit us to go beyond this. At cursory examination, the principal neurons in all layers of the nucleus have about the same appearance. The only obvious difference is in dimension, which, in both Nissl- and Golgi-stained preparations, appreciably exceeds, in the ventral layers, the dimensions of the smaller cells making up the laminae closer to the rounded circumference of the nucleus.

True, mere size would not suffice as a criterion for further classification. Its consistent observance, making the neurons in the various layers oscillate around a certain mean size, however, indicates a specific functional differentiation. In other words, each cell lamina is made up of principal neurons which are functionally different from the principal neurons making up the other cell laminae of the same set. Since each nucleus contains two laminar sets, one set related to the ipsilateral, and the other to the

contralateral optic nerve fibers arising from the two homonymous halves of both retinae, both sets must contain, in the homodynamic laminae, e.g., in *1c* and *1i* or in *2ca* and *2iβ*, neurons capable of reacting in the same way. There must be, in the binocular portion of the nucleus, at least two, and close to the fixation point not less than three, neuron varieties, crossed and uncrossed, arranged on a cross-section vertical to the longitudinal axis of the nucleus according to the retinotopical principle. In the extreme flanks of the nucleus representing the monocular portions of the contralateral retinae, there may be a single variety only of the principal neurons. (*Cf.* sec. 6 [6], this chapter.)

Before proceeding further in our attempt to understand the functional organization of the geniculate complex, it will be useful once more to emphasize the structural independence of the homolateral from the heterolateral set of the cellular laminae, first revealed by Minkowski (*see* chap. IV, 6 [6]). Henschen (1925, 1926, 1930, 1931), until his death, refused to accept such independence, even though his evidence was based upon defective preparations, as Tuboada (1927-28) correctly pointed out. Minkowski's observation and interpretation have since been corroborated beyond reasonable doubt and are well illustrated by the experiment presented in Figure 200.

According to present knowledge, the four (in the extra-areal binocular flanks) or six (in the intermediate foveal-areal segment) cell laminae of the nucleus are arranged alongside one another in a way permitting the closest possible approach of the two sets of neurons related through the optic nerve fibers to the "corresponding" or "homodynamical" points of both homonymous retinal halves. This fact indicates the necessity of some sort of reciprocal influencing or co-operation of the two sets of neurons (counterbalancing the other factor, that of separation, because of which the cellular laminae became segregated from an original homogeneous matrix).

When two "corresponding points" of both retinae, for example, a and a_1 or b and b_1, are stimulated by two identical or almost identical stimuli—because of an automatic direction of lines of view of both eyes toward the same object in the normal act of vision—the impulses converge upon the single "corresponding point" either of the left or of the right lateral geniculate nucleus. Here, depending upon the proximity to, or distance from, the "fixation point" and the "principal vertical meridian" (*F*), a minute segment of the nucleus is activated. This segment passes through all four or six cell laminae, narrow in the two ventral magnocellular laminae (*1c*, *1i*) and gradually widening toward the thicker laminae filled with smaller cells along the convexity of the nucleus (*2i*, *2c*, or *2iα*, *2cβ*, *2iβ*, *2cα*). From the particular segment of each lamina arises a bundle of axon fibers, which passes over into the visual radiation, eventually terminating in the striate area of the same cerebral hemisphere.

Each bundle of the visual radiation is, accordingly, made up of two sets of fibers, one set originating in the laminae related to the temporal half of the ipsilateral retina, the other originating in the laminae related to the nasal half of the contralateral retina. The constitution of the elementary conducting units, beginning with those related to the foveal center, is increasingly simplified toward the monocular periphery, where the units are probably made up of neurons and axons of a single variety, related only to the contralateral retina.

The problem of why the two sets of the geniculate laminae—the ipsilateral and the contralateral—are neatly juxtaposed, the "corresponding" or "syndynamical" points of one set exactly matching the "corresponding mates" of the other set, has been discussed by a few investigators. Minkowski (1920) believed that there must be some relationship of a "reciprocal inhibitory nature" (in Sherrington's sense) between the ipsilateral and contralateral laminae, perhaps mediated by the "intercalated cells." This, in his opinion, would agree with the (1) binocular contrast, (2) struggle of the fields of view, (3) above all, the binocular color mixing of Hering (1879, 1905). According to this, the hue and the brightness of the resulting subjective experience is always an intermediary between the two monocular impressions, between which it may oscillate, approaching now the one, now the other, without ever becoming a simple addition or superposition, as is the case with monocular mixing when the lights of different hues act upon the same retinal point.

Observations by R. W. Pickford (1947) are of importance in this connection. In binocular combinations, no color pairs completely fail to fuse or give perfect combinations when each eye is stimulated by a separate color; all colors show a strong combination tendency when presented independently to each eye in pairs; complementaries are very difficult to combine; bright colors are difficult to combine with dark; red and green can be combined to a certain extent, but only with considerable difficulty.

All this gives little support for the trichromatic theory of color perception of Young & Helmholtz but clearly sustains the four-color theory of Hering and Houston, according to which the opposite colors combine by a "neutralizing process" in one eye but not when presented separately to both eyes, whereas neighboring colors would combine readily in either way. "The fact that complementary colours are extremely difficult to combine when presented separately one to each eye, but very easy to combine in one eye alone, also throws doubt on the theory that all colour combinations take place in a single locus of the brain, and not in the retina. It is more likely that complementaries combine in the eye, though neighbouring colours may combine in the brain."

From the experiences of physiologists it appears that the principal portion of the visual mechanism instrumental in color mixing is the retina. Certain mixing also takes place in the brain. The cerebral mechanism responsible for this may, to some extent, be the laminated lateral geniculate nucleus; the final arbiter, however, is the striate cortex. The presence of geniculate connections relaying the ipsilateral and contralateral homonymous cell laminae of that nucleus makes such interpretation mandatory. This indicates that, contrary to prevalent belief, the laminated geniculate nucleus may play some role in color perception, just as it does in the other basic function -visual perception of space. In fact, the laminar organization of this internode appears, in primate vision, to be essential for both functions, as discussed elsewhere. (*Cf.* sec. 6 [6], this chapter.)

SEC. 10. THE PREGENICULATE GRAY NUCLEUS AND THE PUPILLARY REFLEX PATHWAY

1. THE PREGENICULATE NUCLEUS, ITS STRUCTURE AND RELATIONSHIPS. The primate pregeniculate gray nucleus (*pgn* or * in Figs. 200, 209-15) is an accumulation of mostly small nerve cells along the upper extremity and medial margin of the principal laminated lateral geniculate nucleus. It has also been named *corpus geniculatum laterale ventrale, corpus praegeniculatum,* and *substantia grisea praegeniculata* by various investigators (*see* Koelliker 1896; C. Vogt 1909; Friedemann 1911–12; Minkowski 1920; Ariëns Kappers, Huber & Crosby 1936). It is a homologue of the phylogenetically older ventral nucleus, the pars ventralis, of the primitive Mammals, as discussed in section 8 (1) in this chapter (*v* in Fig. 191).

The pregeniculate nucleus of Primates is smaller than the laminated nucleus, even though it is not insignificant or "vestigial," as one might judge from the literature. Topographically it is closely related to the principal laminated nucleus, which is a homologue of the dorsal and phylogenetically younger portion of the lateral geniculate complex of primitive Mammals (*d, pars dorsalis,* in Fig. 191; *cf.* secs. 1 [3] and 8 [1], this chapter).

The shape of the pregeniculate nucleus is roughly triangular, resembling a skullcap, and irregular on anterior levels. The nucleus extends from the anterior tip of the principal laminated nucleus to a varying distance in the posterior direction. In the Rhesus Macaque (Fig. 200) the posterior limit lies as far back as the boundary between the caudal two-fourths. In the

Chimpanzee (Fig. 214) and in Man (Fig. 215) this nucleus extends not quite to the midlength of the laminated nucleus. Everywhere the pregeniculate nucleus closely applies to the laminated nucleus, or rather to the latter's thick fibrous circumgeniculate capsule. On coronal sections the position of the pregeniculate gray nucleus varies. On the anterior levels it covers the top or the apex, in Man the lateral side of the laminated nucleus also, and becomes more posteriorly displaced along its medial margin.

The pregeniculate gray nucleus, as its name implies, is made up chiefly of nerve cells and their unmyelinated fibrous processes. A number of minute bundles of thin myelinated fibers found in it are arranged singly, in groups or in short rows (*pgn* in Fig. 187, sketch *A;* also Fig. 221). A row of thin bundles marks the upper boundary toward the internal capsule and subthalamus. By far the greater majority of its nerve cells are small, more or less fusiform in shape, and with little cytoplasm (*pgn* in Figs. 210, 211, 212). Owing to a less-developed chromophile substance and apparently also to a lesser chemical affinity of that substance for aniline dyes, such as toluidine blue, the cells appear pale in preparations treated with routine modifications of the Nissl method, in contrast with intensively stained cells of the laminated nucleus. Hence, especially in improperly treated material, the pregeniculate nucleus may easily be overlooked or its considerable size underestimated. The irregular shape, poor staining qualities, and peculiar arrangement of cells in intertwining rows and strands, which sometimes undermine and disrupt the adjacent fibrous substance in the manner of the "reticular substance," all make the pregeniculate gray nucleus markedly resemble sympathetic or vegetative nuclei elsewhere, e.g., in the "lateral gray columns" of the spinal cord.

From the medial edge of the pregeniculate nucleus (Fig. 209, *PGN*) a thick strand composed of similar oblong, pale, and mostly fusiform cells directly continues into the subthalamus of the betweenbrain (*STH*), where it may be followed as a continuous band between the ventral margin of the thalamus proper (*TH*) and the cells of the *substantia nigra* (*SN*) almost as far as the lateral margin of the red nucleus (*R.V*). This strand, observed by Koelliker (1896, p. 544) and Minkowski (1920) and well presented also in Figure 212, *sth*, and Figure 215, *I*, marks the road traveled by the pregeniculate nucleus during phylogenesis and ontogenesis from its origin in the *zona incerta* to its final location on the lateral face of the subthalamus. (For this, *see* Le Gros Clark in *Brit. J. Ophth.*, v. 16, 1932; and M. S. Gilbert in *J. Comp. Neurol.*, v. 62, 1935.)

In addition to the smaller elements described, a few somewhat larger and more intensively stained nerve cells are found singly or in clusters in the pregeniculate nucleus. Some of these cells may reach proportions exceeding those of the cells that make up the parvocellular layers of the laminated nucleus. Owing to the well-developed Nissl granules, these large solitary cells stain intensively. Other medium-sized cells, usually of multipolar shape, are scattered in fair numbers between the smaller fusiform cells. Their chromophile granules are well developed; but they, too, apparently because of their small chemical affinity for dyes, appear paler than the intensively stained cells of the laminated nucleus.

The large size of the pregeniculate gray nucleus in human specimens is surprising (Fig. 215, stippled areas marked with *; *pgn* in Fig. 212). This is contrary to what one would expect from the literature on comparative anatomical investigations, where a gradual decrease in the relative size of this nucleus in the ascending phylogenetical scale of Mammals and its absence in Man have been claimed (Woollard 1926; Le Gros Clark 1932; Tonerav & Krieg 1946; and others). The imposing size of this nucleus in Primates in general and in Man, in particular; the number of its nerve cells, which, owing to their small size, may not be much below that of the laminated portion; and their variety, as well as the connections with the midbrain tegmentum dealt with in the following paragraph, all indicate the important function that this nucleus performs in the central visual mechanism.

The several varieties of the nerve cells in the pregeniculate nucleus, furthermore, are indicative of its complex structure. In Man a small oval nest of minute, tightly packed cells lodged in a notch in the tip of the thick circumgenicu-

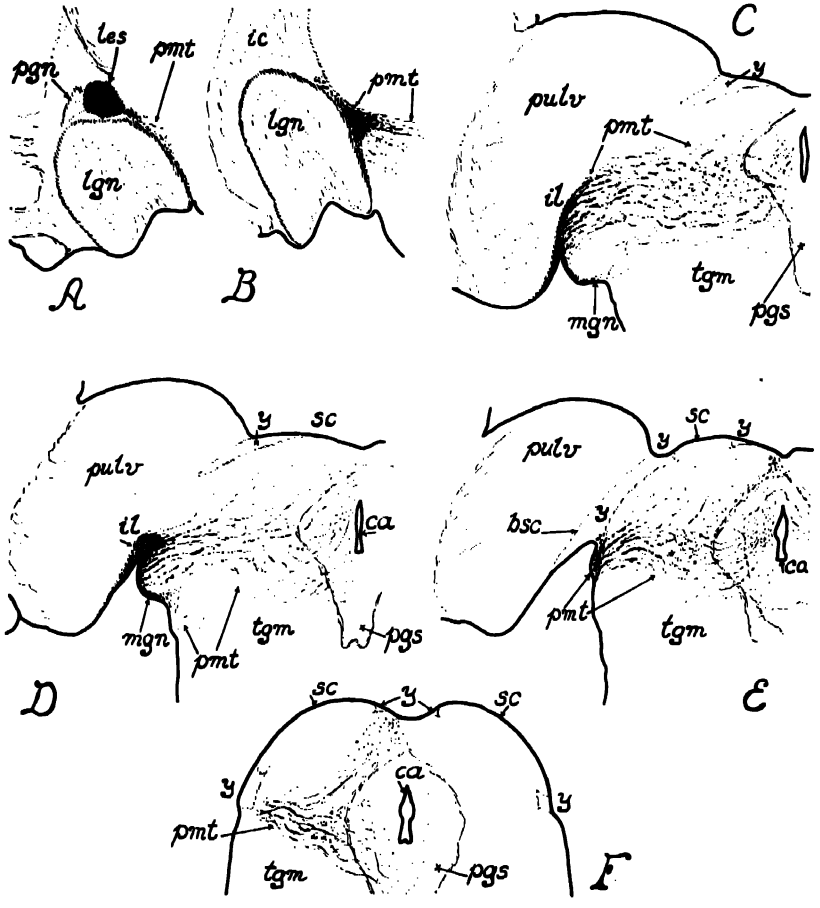

FIG. 221.—Origin, course, and termination of the pregeniculo-mesencephalic or indirect optomesencephalic tract (*pmt*), as revealed by experiment in a Rhesus Macaque. A minute lesion, *les* (*shaded area* in sketch *A*) was made with an electrocoagulating stereotaxic instrument of Horsley, Clark & Ranson in the cap-shaped pregeniculate nucleus (*pgn*). The degenerated nerve fibers, indicated by stippling and broken lines, stained with the Marchi method, enter partly into the hypothalamus (sketch *B*), with the majority forming the intergeniculate lamina (*il*, in sketches *C* and *D*) tucked between the pulvinar (*pulv*) and the medial and lateral geniculate nuclei (*mgn*, *lgn*), thence passing through the substance of the midbrain tegmentum (*tgm*), finally to reach the periaqueductal gray substance (*pgs*) around the nuclei of the oculomotor or third nerve of the brain (sketches *C*, *D*, *E*, *F*). Very few of these fibers enter into superficial layers of the superior colliculus (that was shown to be in part a terminal station of the direct optomesencephalic system, in Fig. 187), and only a few of them may decussate to the opposite half of the periaqueductal gray substance. It is probable that this system represents a central link in the pathway of the pupillary light reflex and that, when interrupted, it causes partially "frozen pupil" or Argyll-Robertson's symptom. *Labeling:* *ca*, cerebral aqueduct; *bsc*, brachium of superior colliculus; *ic*, internal capsule; *les*, lesion; *lgn*, laminated lateral geniculate nucleus; *mgn*, medial geniculate nucleus; *pgn*, pregeniculate nucleus; *pulv*, pulvinar of thalamus; *sc*, superior colliculi; *y*, system of direct optomesencephalic fibers, which in this experiment remained normal but degenerated in the experiment illustrated in Fig. 187. (*Cf.* Figs. 222, 223; and *see* W. H. Magoun & S. W. Ranson in Arch. Ophth., v. 13, p. 791, 1935.)

late fiber lamina which surrounds the principal laminated nucleus is a conspicuous feature (Fig. 215, sketch *H*). Such a pronounced structure in the approximate place where the horizontal meridian must be looked for is likely to be concerned with some particular function, e.g., constriction of the pupils during fixation.

The appearance of the neurons of the pregeniculate nucleus in Golgi preparations is shown in Figure 222. The relatively large size of some of its nerve cells is remarkable; the majority, however, are small. Another peculiarity is the confinement of dendritic expansions to the territory of the nucleus. The dendrites carry a considerable number of short "spines" with minute globules at the ends. Along these run long, fine threads, apparently teledendrons of collateral branches originating from the axons of retinal origin whose principal terminals are in the laminated nucleus. Each cell of the pregeniculate nucleus gives off a single axis cylinder, which turns in the median direction, toward the subthalamus and intergeniculate fiber lamina.

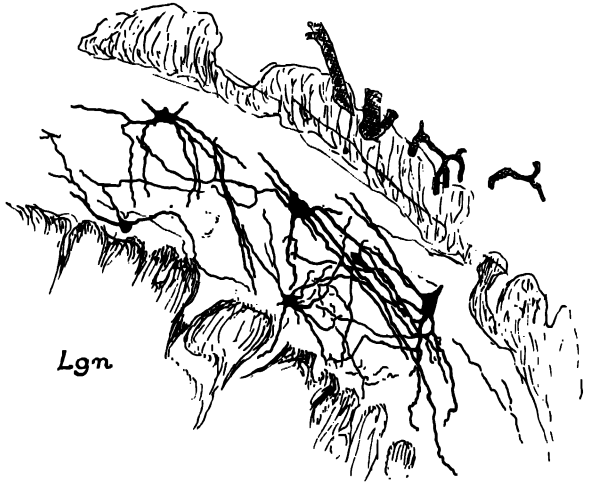

FIG. 222.—Pregeniculate nucleus of a baby Rhesus Macaque showing nerve cells and their expansions, stained with the Golgi method. A few blood vessels along the upper margin are also impregnated. *Lgn*, dorsal extremity of the principal or laminated portion of lateral geniculate nucleus. (*Cf. pgn*, in Figs. 210, 211.)

2. CONNECTIONS OF THE PREGENICULATE NUCLEUS.—The avenue by which the retinal impulses reach the pregeniculate gray nucleus is represented by delicate myelinated fibers which enter it, partly directly from the optic tract and partly by way of the subjacent laminated lateral geniculate nucleus (*pgn* in Figs. 186, 202–5). These fibers emerge from the intermediate foveal-areal segment of the tract and geniculate nucleus, as described in section 4 (4). The origin of these afferent fibers is almost exclusively in the pit of the central fovea of both eyes, ipsilateral and contralateral, and in the region next to the fovea, as evidenced by experiments described in section 7 (5), in this chapter. In spite of their great numbers, in view of the observations of O'Leary (1940), these collateral branches apparently belong to the axons of special retinal neurons whose principal termination is in the laminated nucleus (*see also* S. Ramón y Cajal 1899–1904 [Figs. 576, 577]; and Tello 1904). Whether the pregeniculate nucleus receives additional afferent or efferent fibers from other parts of the nervous system, e.g., from the somatosensory, somatomotor, auditory, and so forth, including the cerebral cortex, is not known.

The efferent connections of the pregeniculate

gray nucleus are revealed by experiment (Fig. 221, sketch *A; cf.* Fig. 187). When, in a monkey, a minute lesion (*les*) is made in this nucleus, for example, by means of an electrocoagulating needle attached to a stereotaxic instrument of Horsley and Clarke (*see* Clarke & Henderson and Ranson & Ingram), the axis cylinders of the nerve cells of this nucleus degenerate, making it possible to follow them in Marchi preparations along their course as far as their termination.

The "pregeniculo-mesencephalic" or "indirect optomesencephalic tract" (*pmt*), revealed in this way, consists of fibers noticeably thicker than the very fine direct optomesencephalic fibers mentioned in the preceding paragraph and described in sections 4 (4) and 7 (5), in this chapter. Close to the origin, both systems of fibers, direct and indirect (*pmt* and *x* & *y*), partly commingle in the narrow "intergeniculate lamina" (*il*) squeezed between the lateral geniculate nucleus and the pulvinar, on the one hand, and the medial geniculate nucleus, on the other hand. Soon, however, the thicker fibers of the pregeniculo-mesencephalic tract leave the common roadbed and pursue their own course. The anteriormost turn at once medially into the subthalamus along the subthalamic strand of nerve cells described in one of the preceding subsections (*pmt* in Fig. 221, sketches *A*, *B; cf. PGN* in Fig. 209, and *sth* in Figs. 212, 215, sketch *I*). Their direction is oblique-medial and at the same time posterior. Eventually, these fibers reach the pretectal region, in front of and below the anterior exit of the cerebral aqueduct (*ca*). Whether anywhere along their course these fibers give off collaterals and undergo synapses with the cells of the subthalamus, and especially of the pretectal region, is a problem which must be solved with the help of histoanalytical methods like Golgi's.

The remaining pregeniculo-mesencephalic fibers, apparently the majority, for a while follow a more direct caudal course in the "intergeniculate fiber lamina" (*il* in sketch *C*, in Fig. 221). They enter the zonal-like fiber layer which coats the exposed lateral and ventral face of the medial geniculate nucleus (*mgn*). From this fibrous layer they successively turn in the medial direction, pushing in scattered bundles through the plain substance of the medial geniculate nucleus and farther on through the substance of the midbrain tegmentum (*tgm*) underlying the superior colliculus (*sc*) and as far as the posterior end of that structure (back of sketch *F*). Whether these fibers undergo synaptical connections anywhere along their passage through the medial geniculate nucleus and tegmentum could not be determined by the method used.

Some of the pregeniculo-mesencephalic fibers reach from underneath the base of the superior colliculus (*sc*) of the same side, where they probably terminate (in sketches *D*, *E*, *F*). They do not enter the collicular brachium (*bsc*) or the circular zone in the superficial caplike portion of the colliculus (*y*, *y* in sketch *F*), where much finer direct optotectal fibers, referred to in section 4 (4), terminate (*y*, *y* in sketch *F*, in Fig. 187). The bulk of the indirect pregeniculo-mesencephalic fibers proceed to the central gray substance (*pgs*) surrounding the cerebral aqueduct (*ca*). In it they are found as far as the mid-line, with a few penetrating for a short distance beyond this line, within the periaqueductal gray substance, above and below the aqueduct. Also, only a few of these fibers may, by this route, reach the base of the contralateral superior colliculus. A small region on the ipsilateral side just lateral to the aqueduct appears best supplied with these pregeniculo-mesencephalic fibers. The nests of cells, both of the somatic and of the vegetative or Edinger & Westphal's divisions of the oculomotor nucleus, seem less well provided with these fibers, with none spreading as far as the inferior colliculus and nucleus of the trochlear nerve.

The number of fibers of the pregeniculo-mesencephalic tract coincides fairly well with the number of the nerve cells in the pregeniculate gray nucleus. The course and termination of this tract, since it remains subcortical throughout, explain the observation that the cells of the pregeniculate nucleus are unaffected in experiments or pathological cases where extensive portions of the parieto-occipital cortex have been destroyed (Minkowski, Polyak, A. E. Walker).

From the description of the course and termination of the optic nerve fibers which directly, without synaptical interruption, reach the midbrain, as given in section 4 [5], it is evident that the retinal fibers are not directly

related to the nuclear complex of the oculomotor nerve. Such a connection, as described in this section, is established indirectly, through the pregeniculo-mesencephalic system, with the synapses in the pregeniculate nucleus. (*Cf.* Figs. 180, 223.)

3. PROBABLE FUNCTION OF THE PREGENICULATE NUCLEUS AND OF THE PREGENICULO-MESENCEPHALIC FIBER SYSTEM.—Unlike the fiber systems originating in the laminated lateral and medial geniculate nuclei, in the pulvinar, and in most parts of the thalamus (A. E. Walker, Le Gros Clark), the fibers from the pregeniculate nucleus do not reach the cortex. The pregeniculo-mesencephalic system represents a subcortical side track to the great corticopetal afferent visual pathway. Terminating, as it does, in the closest proximity to the oculomotor nuclei, it is most appropriate to consider it a central link in the circuit of the pupillary light reflex, especially concerned with constriction.

Such an interpretation appears well substantiated by the close agreement between the origin, course, and termination of this tract and the faradic plotting of stimulable points from which the pupillary constriction may be elicited experimentally (Magoun, Atlas, Hare & Ranson 1936; *see also* Ranson & Magoun 1933; Hare, Magoun & Ranson 1935; Magoun & Ranson 1935; Magoun, Ranson & Mayer 1935; *cf. also* Karplus & Kreidl, who in their faradic experiments in 1913 unknowingly severed precisely this fiber tract on both sides of the oculomotor nuclei and described pupillary constriction in a medial cut and an absence of such constriction of the pupil in a lateral cut).

The observations presented in section 7 (5) of this chapter, showing that most, if not all, afferent fibers from the optic tract to the pregeniculate nucleus originate in the central fovea and area of the retina, precisely the region from which a constriction of the pupils may most promptly be elicited on direct stimulation with light (C. von Hess 1907, 1908, 1916; Gasteiger 1934), agree well with the interpretation of this tract as a central link in the pupillary reflex pathway. Also in agreement with this interpretation are those experiments which indicate that the superior colliculus of the midbrain is not indispensable for the maintenance of the pupillary reflex, showing its pathway to have a location below the tectum, that is, in the subjacent tegmentum of the midbrain (Magoun 1935; *see also* Knoll 1869; Bechterew 1883; Ferrier & Turner 1901; Levinsohn 1904, 1909; Bernheimer 1909; Keller & Stewart 1932; Ranson & Magoun 1933).

4. PREGENICULO-MESENCEPHALIC TRACT AND THE PATHOLOGY OF THE PUPILLARY REFLEX.—Ever since the value of the pupillary reflex to light stimulation in the clinical diagnosis of syphilitic and metasyphilitic affections of the central nervous system became known by Argyll Robertson (portrait, Fig. 224), innumerable attempts have been made to discover the anatomical basis of this reflex.

As the anatomical mechanism responsible for the transmission of light stimuli from the retinal photoreceptors to the sphincter muscle of the iris of the eye became better known, the problem was gradually limited to the stretch of the reflex pathway intervening between the termination of the optic nerve fibers in the brain and the oculomotor nuclei of the midbrain.

During the past few decades this gap has been bridged by numerous investigations, mostly physiological-experimental, such as those of Karplus & Kreidl (1913), of Lenz (1927, 1929), and especially of Ranson & Magoun (1933) and of Magoun & Ranson and their associates (1935, 1936).

This section of the pupillary reflex circuit, as revealed by electrophysiological plotting, in the Cat and Monkey passes beneath the base of the superior colliculus, through the upper zone of the midbrain tegmentum, from the brachium of the superior colliculus laterally, to the pretectal nucleus medially. The superior colliculus is apparently not related to the constricting phase of the pupillary reflex, whereas the posterior commissure, though of some importance, seems not to be a major structure involved.

This gratifying agreement still left two specific questions to be answered. The first concerns the precise linking of the optic fibers to the plotted pupillary tract in the midbrain. The other deals with the exact relation of the pupillary tract to the sphincter nucleus of the oculomotor nerve. Finally, in order to produce convincing evidence, the pupillary tract of the mid-

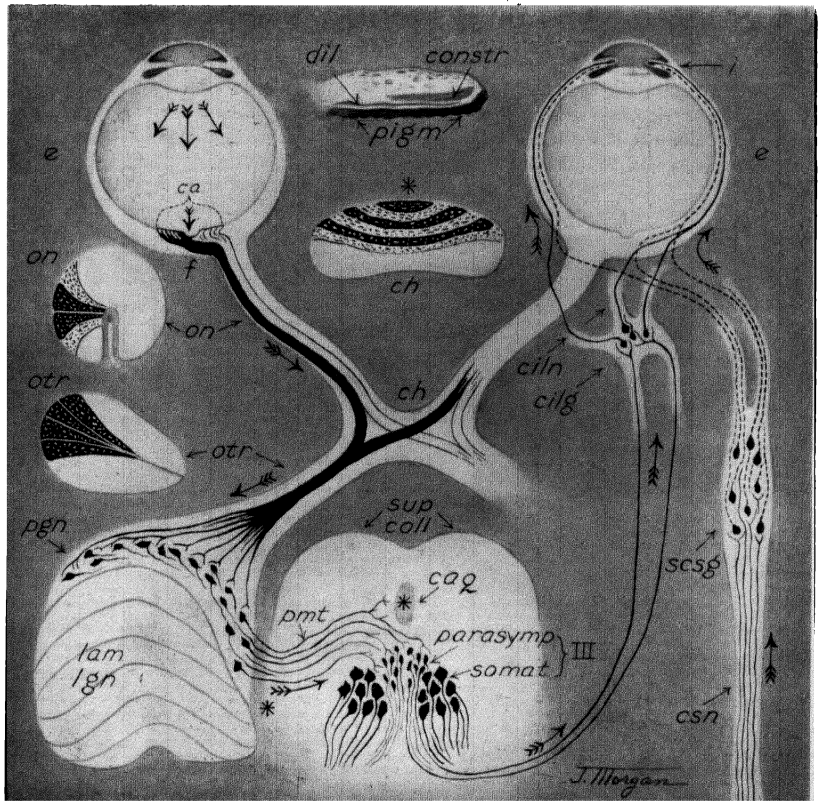

FIG. 223.—Diagram of the pathway of pupillary light reflex as revealed by pathological investigation, anatomical and physiological experiments, and clinical experience. The light that enters the eye (*e*, in *upper left*) stimulates the retina, principally the central fovea (*f*) and area (*ca*). These impulses are transmitted along decussating and nondecussating optic nerve fibers to the lateral geniculate nuclei of both sides, where they enter the pregeniculate nuclei (*pgn*). From here the impulses are further transmitted along the pregeniculo-mesencephalic tract (*pmt*) through the midbrain tegmentum to the central gray substance around the Sylvian aqueduct (*caq*), where they are synaptically related to the small-celled parasympathetic Edinger & Westphal portion of the oculomotor nucleus (*parasymp III*), and along its delicate axon fibers to the ciliary ganglion (*cilg*). After once more synapsing, the impulses finally reach, via short ciliary nerves (*ciln*), the smooth-muscle fibers of the pupillary constrictor in the margin of the iris (*constr*, in *upper center*), cutting down the amount of light entering the eyes. The superior colliculi of the midbrain (*sup coll*), situated above the pregeniculo-mesencephalic tract (*pmt*), and the large-celled somatic portions of oculomotor nucleus (*somat III*) apparently do not take part in a direct pupillary light reflex. The sympathetic fibers, originating in the lower segments of the cervical portion and the upper segments of the thoracic portion of the spinal cord, pass up the cervical sympathetic trunk (*csn*) to the superior cervical sympathetic ganglion, whence fibers arise which, by devious ways, reach the eyeball via long ciliary nerves and finally the smooth radially arranged muscles of the pupillary dilator (*dil*, in *upper center*). *Labeling: ca*, central area and fovea; *caq*, Sylvian aqueduct; *ch*, chiasma; *cilg*, ciliary ganglion; *ciln*, ciliary nerve; *constr*, constrictor or sphincter of pupil; *csn*, cervical sympathetic nerve or trunk; *dil*, dilator of pupil; *e*, eyeballs; *f*, central fovea; *i*, iris; *lam lgn*, laminated geniculate nucleus; *on*, optic nerve; *otr*, optic tract; *parasymp III*, parasympathetic or Edinger & Westphal nucleus; *pgn*, pregeniculate nucleus; *pigm*, pigment layer of iris; *pmt*, pregeniculo-mesencephalic tract; *somat III*, somatic portion of oculomotor nucleus; *sup coll*, superior colliculi; *scsg*, superior cervical sympathetic ganglion; *, points at which pupillary reflex pathway is most exposed to noxious agents. The arrows indicate the course of impulses from the retina via the oculomotor motor center to the sphincter or constrictor muscle of the pupil.

sible for pupillary miosis. (For other details *see* F. B. Walsh 1947.)

The ventral nucleus is a constant constituent of the lateral geniculate complex, beginning with the lowest and including the highest Mammals. In Man, although much smaller than the laminated nucleus, it is by no means "vestigial," that is, on the verge of being eliminated.

It may be pertinent to inquire whether the regulation of the amount of light to be admitted into the eye chamber exhausts the function of the pregeniculate nucleus and of the pregeniculo-mesencephalic pathway, or whether some other similar function associated with vision is also to be attributed to it. This question is particularly pertinent with regard to the Lower

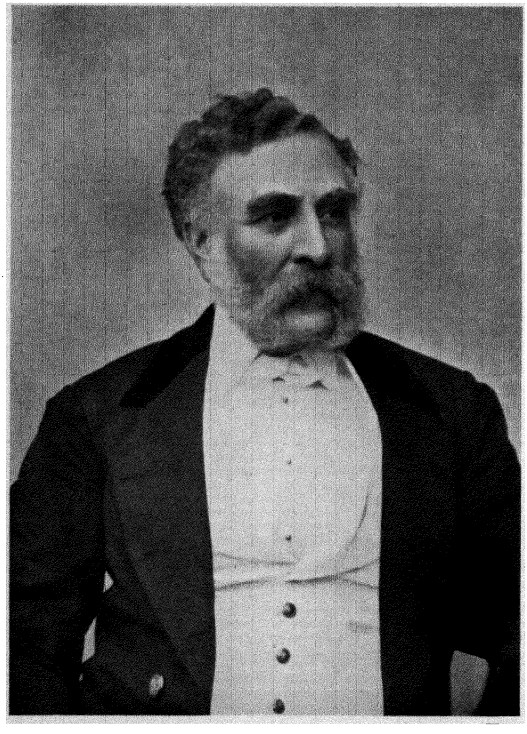

FIG. 224.—Douglas Argyll Robertson (1837–1909), Scottish ophthalmologist. Disciple of A. Graefe and of W. P. Bowman. Discovered "Argyll-Robertson's sign or symptom," or partially "frozen pupil," one of the most important tests in clinical neurology. In his own words, this symptom consists in the following: "Although the retina is quite sensitive, and the pupil contracts during the act of accommodation for near objects, yet an alteration in the amount of light admitted to the eye does not influence the size of the pupil" (Edinburgh M. J., v. 14, p. 696; v. 15, p. 487, both 1869). Portrait from J. Hirschberg, in Graefe & Saemisch, *Handb. d. ges. Augenh.*, 2d ed., v. 14 (4), p. 414, 1914. *See* obituary by G. Mackay in Klin. Monatsbl. f. Augenh., v. 1, p. 308, 1909. Biography in Haymaker & Baer, *The Founders of Neurology*, 1953.

Its good development in all Primates is understandable in the light of the foregoing interpretation as a link in the pathway of the pupillary light reflex.

Mammals, in which the ventral nucleus is relatively larger than in the advanced Mammals. Its subthalamic origin, connections, and relatively large size indicate that this nucleus may

be essentially vegetative in nature, serving a more complex function in the vision of primitive Mammals. (*See* Fig. 191.)

SEC. 11. SUMMARY OF THE INTRINSIC ORGANIZATION OF THE INFRANUCLEAR AND NUCLEAR DIVISIONS OF THE VERTEBRATE VISUAL SYSTEM

1. Retinal origin of optic nerve fibers.—The infranuclear or peripheral division of the visual system by which the photogenic impulses arising in the retinae of the eyes reach the brain is represented by the photoreceptors and other neurons residing in the retina itself and by the optic nerve fibers or axis cylinders of the retinal ganglion cells. In the retina, whose ninth layer they form, these optic nerve fibers, in general, pursue a radiating course as they converge upon the optic papilla or disk. In the region of the central area and temporal to it, the fibers from the upper and the lower quadrant are separated from one another by a horizontal division line, the raphé or "seam." In this locality the two sets of fibers are not arranged in straight radial lines but describe arches above and below the central area and fovea.

The optic nerve fibers in Man and other Higher Mammals normally do not possess myelin sheaths along the stretch in the eye; they obtain these sheaths after leaving the eyeball through the numerous small openings in the cribriform or sievelike lamina of the scleral tunic. In Rodents, e.g., the Hare and the Rabbit, a portion of the intraretinal section of the optic nerve fibers is normally provided with myelin sheaths.

2. Course and arrangement of optic nerve fibers in the retina, papilla, and optic nerve.—The optic nerve fibers preserve a certain stable order while still in the retina. In general, each small bundle which originates from a limited territory keeps its relative position, to some extent, with respect to other bundles that originate from adjacent areae. A certain degree of interchange and displacement, however, occurs, especially because of the arch-like course in and around the central area.

The "papillomacular bundle," a broad stream of delicate fiber bundles arising from the central area and fovea, passes over to the papilla in a rather straight horizontal course or in slight arches, being surrounded above and below by bundles of thicker fibers from the extra-areal portions of the two temporal quadrants and from the adjacent zone of the nasal quadrants.

At the temporal margin of the papilla the arrangement is similar, with the areal and foveal fibers located next to the horizontal meridian and flanked from above and from below by the upper and lower extra-areal temporal fibers (Fig. 225, *optpap*). Along the nasal margin of the papilla the arrangement is less complicated, each wedge-shaped retinal segment sending its

bundles directly to the nearest point at the papilla.

In the optic nerve close to the eyeball, essentially the same arrangement is preserved. Here the foveal-areal quadrants are located along the horizontal meridian between the temporal margin and the central blood vessels, flanked above and below by the extra-areal temporal fibers and surrounded nasally by the fibers from the nasal extra-areal quadrants, including those from the extreme peripheral monocular crescent.

Farther away from the eyeball, in the optic nerve, the foveal-areal fibers become central and are surrounded on all sides by the extra-areal fibers of the four quadrants (Fig. 225, *optn*). Close to the chiasma the optic nerve seems to be rotated around its axis, resulting in a tilting of its temporal, and a lowering of its nasal, margins.

3. Course of optic nerve fibers in the chiasma and in the tracts.—The first great change takes place in the chiasma or junction of the optic nerves (Fig. 225, *chiasma*). This is accomplished by the crossing of fibers originating from the somewhat larger nasal halves of both retinae and joining the respective uncrossed fibers in the contralateral optic tracts originating from the somewhat smaller temporal retinal halves. In spite of the apparent confusion during their decussation, the fibers preserve a modicum of stable order: those from the central areae and foveae being in the upper portion of the chiasma, the monocular fibers in the lower portion, while the remainder from the binocular extra-areal portions of the two nasal retinal halves are arranged in between.

The cleavage line along which the fibers from the nasal half of the retina separate from those of the temporal half is, accordingly, entirely extraretinal, being caused by a partial decussation in the chiasma. Although not visible in a normal retina, this cleavage line is nevertheless real, as manifested by the visual field defects in various types of hemianopia and by experiment. Whereas each optic nerve contains all fibers from the corresponding eye, the middle portion of the bridge of the chiasma is made up of decussating nasal fibers of both eyes, and the optic tracts of decussating nasal fibers of the opposite eye and of the nondecussating temporal fibers of the eye of the same side. The lateral portions of the chiasma contain nondecussating temporal fibers, the right portion from the right eye, the left portion from the left eye. Functionally, the middle part of the chiasma represents the nasal halves of the two retinae; in its two lateral portions it represents the right and the left temporal halves. The tracts, being composed both of the crossed nasal and of the uncrossed temporal fibers, functionally represent the homonymous halves of both retinae: the right tract the right halves, and the left tract the left halves.

In the fields of vision—the eye being a camera obscura or dark chamber, where only the crossed rays of light are utilized—the effect is reversed: in the chiasma the middle portion represents the two temporal halves, and the two lateral ends represent the right and the left nasal half of the two fields of view. For the same reason, each optic tract represents the two homonymous contralateral halves of the two monocular fields of view, an ipsilateral nasal and a contralateral temporal. Essentially the same anatomical arrangement and functional representation as in the tracts remain in the lateral geniculate nuclei and in the supranuclear division of the afferent visual pathway.

4. Retinotopical organization of the optic tracts and lateral geniculate nuclei.—As soon as the decussating fibers pass the lateral portion of the chiasma, they spread over the entire thickness of the initial portion of the tract (Figs. 195, 199). Here they meet the nondecussating bundles, which spread in the same fashion over the entire tract. In this way the two systems of fibers meet, each decussating bundle joining its nondecussating homonymous functional mate (Fig. 225, *r.opt.tr.*, *l.opt.tr.*). In the tracts, after mingling, the fibers are rather uniformly distributed over the cross-section.

Through this arrangement the right and the left homonymous synergical fiber bundles arising from the "corresponding points" of the homonymous halves of both retinae come to lie very close together. The fiber bundles are arranged in an orderly way, bundle by bundle, according to the homodynamical quadrants, or parts thereof, in the retinae and in the fields of view, with some qualification.

In the dorsomedial sector of each tract and

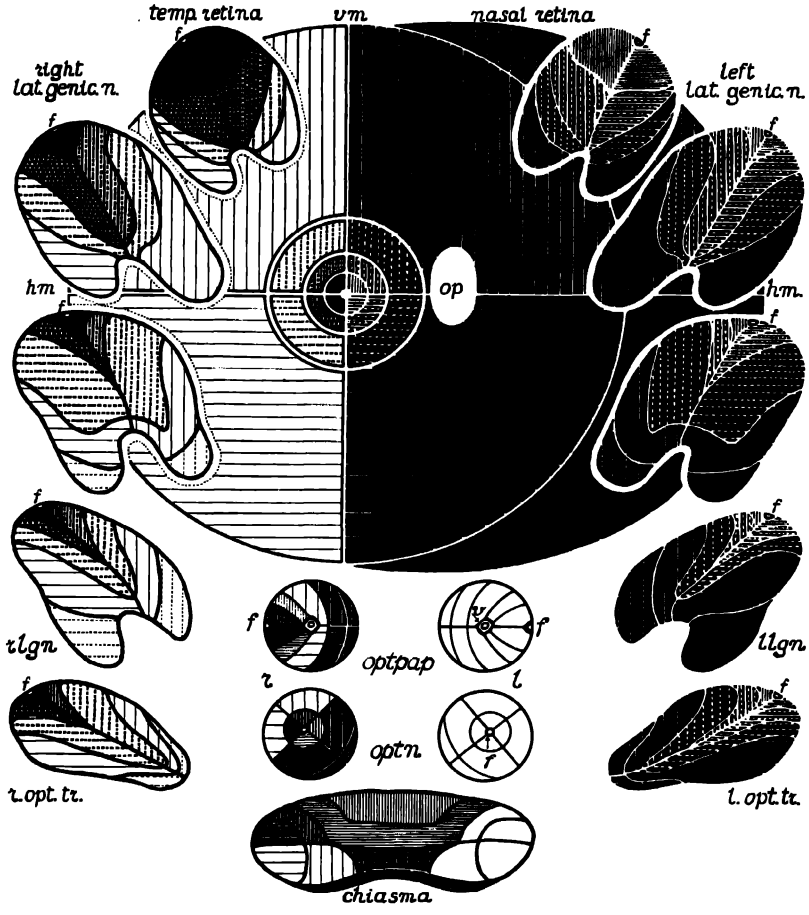

FIG. 225.—Topographical representation or "projection" of the retinal surface of the right eye in the infranuclear and nuclear divisions of the visual system of a Rhesus Macaque, determined in experiments described in section 7 of chapter VI, in this book. In the upper center the surface of the right retina is presented facing the observer, with the nasal half black and the temporal half white. Right-hand sketches represent, in black with white shading, cross-sections through the left optic tract and laminated lateral geniculate nucleus; the left-hand sketches represent, in white with black shading, the same of the right tract and the geniculate nucleus. The sketches in lower center show cross-sections through the optic papillae, optic nerves, and the chiasma, with the left papilla and nerve (*right* in the diagram) given only in outlines. The various patterns of the retinal belts or zones are carried throughout the visual pathways and centers and may be followed as far as the cortical visual centers (*see* Figs. 259, 260). In the center of the retina a small white circle indicates the fixation point. First circle surrounding it, divided into four quadrants, shows the foveola; the second circle, the periphery of the central fovea; the third circle, the remainder of the central area; and the fourth and largest complete circle, the extra-areal binocular portion of the retina, with the semilunar zone, which has no counterpart in the temporal half, representing the monocular nasal portion (corresponding to monocular temporal crescent in the field of view). By following variously shaded patterns from the right optic papilla (*optpap*) through the right optic nerve (*optn*) and the chiasma to both tracts and geniculate nuclei, it is possible to locate in this figure each belt or quadrant of the retina at any point in the visual pathway, including the supranuclear division. *Labeling: f*, fixation point; *hm*, horizontal meridian; *l*, left optic papilla or nerve (*optpap*, *optn*); *llgn*, left lateral geniculate nucleus; *l.opt.tr.*, left optic tract; *op*, optic papilla or disk; *r*, right optic papilla or nerve (*optpap*, *optn*); *rlgn*, right lateral geniculate nucleus; *r.opt.tr.*, right optic tract; *v*, central blood vessels; *vm*, vertical meridian.

lateral geniculate nucleus, the binocular portions of the upper ipsilateral homonymous retinal quadrants or of the lower contralateral homonymous field quadrants are represented. In the ventrolateral sectors of the tracts and geniculates, the binocular portions of the lower ipsilateral homonymous retinal quadrants or of the upper contralateral homonymous field quadrants are represented.

The fibers originating from the homonymous halves of the two central areae and foveae, both decussating and nondecussating, are assembled according to their homodynamic quadrants between the above-mentioned two extra-areal segments in an intermediate wedgelike segment of the tract and geniculate, whose sharp lower end points ventromedially and whose bulky end forms the dorsolateral convexity of the tract or geniculate. In the fields of view this intermediate segment represents the contralateral homonymous halves of the foveal or central field quadrants (*cf.* Figs. 202, 203).

At the inner or ventromedial extremity of the cross-section of the tracts, the monocular fibers from the extreme nasal portion of the contralateral retina are assembled in a narrow, superficial zone, the upper quadrantic fibers above, the lower ones below, representing the lower and upper portions of the contralateral monocular field of view. In the lateral geniculate nucleus the same fibers terminate in the two lowermost extremities on both sides of the hilum.

The long, slanting axis of the cross-section of the tract represents the horizontal meridians in the ipsilateral homonymous halves of both retinae or in the contralateral homonymous halves of both fields of view. The point at which the axis touches the upper contour of the tract is the fixation point (*f*). The fibers originating along the principal vertical meridians (*vm*), which divide the right from the left homonymous hemiretinae, are strung along the lateral margin of the tracts. In the lateral geniculate nucleus the principal vertical meridians and fixation points have a similar location.

The relative position of the superimposed homonymous quadrants in the tracts and geniculates is, accordingly, essentially the same as in the retinae, except for certain adjustments necessary to accommodate the fibers to the changed shape of the tracts and geniculates when compared with the homonymous retinal halves. A slight displacement of the areal-foveal bundles seems also to take place along the horizontal meridian, inasmuch as the sharp wedge of the intermediate areal-foveal segment is pushed deep into the nucleus toward its ventromedial extremity, or hilum, in the posterior half of the nucleus completely separating the upper from the lower extra-areal segment. Or, in other words, the homonymous halves of the two central areae and foveae, the "hemimaculae," which in the retinae are located practically in the central corners of the upper and lower quadrants, in the optic tracts are somewhat, and in the lateral geniculate nuclei completely, displaced and are squeezed between the upper and the lower extra-areal quadrants, in this way in the tract nearly, and in the geniculates entirely, splitting up the raphé into a "gap" which they fill.

The peculiar topographical arrangement of the quadrants in the tracts, resembling a complete separation of the upper from the lower extra-areal fiber bundles by the "papillomacular bundle" close to and in the temporal margin of the optic papilla of the eye, remains essentially the same in the laminated lateral geniculate nucleus and also farther up in the visual radiation, where the separation of the two extra-areal quadrants by the intercalated areal-foveal quadrants becomes complete (*see* Figs. 259, 260, *LVR* and *RVR*). In the striate cortex, the extra-areal quadrants again join each other (*LSA* and *RSA*, in same figures).

5. Representation of the central fovea or "macula" in the infranuclear and nuclear divisions of the visual system.—The fovea or "macula" of each eye is represented in the infranuclear division of the visual pathway and in the laminated lateral geniculate nucleus according to the same general principle that holds for the extrafoveal parts of the retina (Fig. 225).

Each fovea is divided by a vertical meridian into a nasal and a temporal half, a hemifovea, owing to a partial decussation in the chiasma. The fibers from the ipsilateral temporal and the contralateral nasal hemifovea join in the tract and geniculate nucleus. Furthermore, as in the

peripheral extrafoveal fibers, the foveal fibers are also subdivided into an upper and a lower homonymous hemifoveal quadrant. The two foveal quadrants are separated by a virtual axial line representing the horizontal meridians (*hm*), the line terminating at a point of the upper margin where the fixation points are represented (*f*).

The indications are that the representation in the foveal segments of the optic tracts, and even more so in the geniculates, is extremely minute or detailed and that it may, in fact, approach the theoretically postulated elemental conductor units, each represented by only a few neurons. In the greater portion of the optic tracts and geniculates such units are double, being composed of both the ipsilateral and the contralateral synergical or homodynamical fibers. In the monocular portion of the tracts and lateral geniculate nuclei the elementary conductor units are made up of decussating fibers only.

This view is supported by a similar shape and location of the areas of degeneration in the two tracts and geniculates in experiments where the retinal lesion similarly affects the two symmetrical localities on both sides of the principal vertical meridian, or where it straddles that meridian. It also agrees with and, in turn, explains in terms of anatomical factors the congruous boundaries of the functional defects in cases of homonymous hemianopias and hemianopic scotomas in complete and incomplete unilateral lesions of the optic tract (*see* chaps. XI, XII). Sharp boundaries observed in minute zones of degeneration in the lateral geniculate nucleus in experiments with monkeys, where small lesions were made in the visual cortex in one half of the brain, likewise support this view (chap. VII, 5).

The fact that the two sets of the homonymous fibers terminate in different cell laminae of the lateral geniculate nucleus indicates that, even though the two constituents of the elemental units, the "corresponding points," are close together, a certain measure of independence is preserved. By means of this arrangement, the fusion of the two similar homonymous retinal impressions in the infranuclear division and in the subcortical centers is merely prepared, its consummation, however, taking place in the striate cortex of the occipital lobes.

Chapter VII

Visual Radiation

SEC. 1. INTRODUCTION; GENERAL REMARKS CONCERNING THE SUPRANUCLEAR DIVISION OF THE VISUAL SYSTEM

1. Relation of nuclear to supranuclear divisions of the visual system.—The optic nerve fibers, which originate in the ganglion cells of the retina, terminate in several nuclei or subcortical visual stations of the brain, as described in the preceding chapter. Structurally, the most elaborate of these is the laminated lateral geniculate nucleus, or body, where the bulk of the optic fibers terminate (Fig. 180, *lgn*). Next in importance is the smaller pregeniculate gray nucleus, which is the terminal station of the delicate optic nerve fibers or their collateral branches (*pgn*). The superior colliculi of the midbrain (*cols*) also receive numerous delicate optic fibers, while a few of these fibers may possibly enter the pulvinar of the thalamus (*pulv*). (*See* chap. VI, 4, 5, on other terminal structures of the visual system, in particular in the Infraprimates.) From the nerve cells of each of these four structures, one of each in each half of the brain, originate fiber systems along which the impulses generated in the two retinae of the eyes are further propagated and distributed to the various parts of the brain.

2. Visual radiation—its origin, course, and termination.—Only the tract or fiber system originating in the laminated lateral geniculate nucleus may be considered an avenue along which the visual impulses are transmitted to the highest brain center of vision—the striate area. This tract is the visual or optic radiation (*radiatio optica, vis rad* in Fig. 180), also called the geniculo-calcarine tract and Gratiolet's radiation (*see* chap. III, 5 [5]). The tracts which originate from the three other subcortical visual stations remain outside the scope of the present topic: the indirect pregeniculo-tectal system and the fibers that originate from the superior colliculi, because they are wholly subcortical (*see* chap. VI, 10), and fibers of the pulvinar of the thalamus to the cortex, because few optic nerve fibers, if any, enter that part of the brain and because there is, so far, no positive experimental, clinical, and pathological evidence to show that the pulvinar is a link in the afferent visual pathway.

The visual radiations of Gratiolet are systems of fibers of considerable magnitude which form part of the white fibrous core of the posterior portion of the cerebral hemispheres (Fig. 180, *vis rad*). They are made up of axis cylinders or nerve fibers of the principal cells of the laminated lateral geniculate nuclei of the betweenbrain. In the occipital lobe the fibers of the visual radiation are included in the thick fiber lamina known as the sagittal fiber layer (Figs. 226, 227).

Each visual radiation originates in the lateral geniculate nucleus and terminates in the striate area of its own cerebral half or hemisphere. The striate area of G. Elliot Smith (1904) *stra* in Fig. 180, one in each hemisphere) is that portion of the superficial gray cortical lining in and around the calcarine fissure and the pole of the occipital lobe, distinguished by a thin, whitish line, the stripe of Gennari and Vicq-d'Azyr, visible on a cut surface through the cortex (Figs. 226, 227). Other terms for it are "field *17*" (Brodmann), "visuo-sensory area" (Campbell), and "area *OC*" (Economo).

3. General characteristics of visual radiation.—The visual radiation in its general makeup, its subcortical origin, its course within the fibrous core of the cerebral hemisphere, its termination in the occipital cortex, its blood supply, its minute structure, and its elemental functional properties resembles other great af-

ferent fiber systems of the brain, especially the somesthetic and auditory pathways. Its specific function in normal conditions and its reaction in disease are the expression of several factors: its minute structure and the innate properties of its living nervous substance, its blood supply, its topographic relationships, and its intrinsic functional organization. In the following sections of this chapter the basic facts of the anatomy and physiology of the visual radiation are discussed, the rest being treated in chapter VIII.

SEC. 2. MENINGES AND THE INTERNAL MAKEUP OF THE CEREBRAL HEMISPHERES—THEIR RELATION TO THE VISUAL PATHWAY IN GENERAL AND TO THE VISUAL RADIATION IN PARTICULAR

1. Brain envelopes or meninges.—The brain consists of various tissues arranged in a definite, characteristic way. These tissues and their arrangement are revealed by cutting the brain into slices and by careful examination of the exposed structures. An instructive way is to cut the entire brain by horizontal section at about the level of the posterior extremity of the lateral fissure or fossa of Sylvius—Flechsig's cut (Figs. 226, 227). Another way is to make coronal sections (Figs. 228–33). Such preparations permit general orientation concerning the various parts of both hemispheres, their appearance, size, shape, location, and relative arrangement.

The outermost of the various cerebral structures are the meninges or tunics, in which the brain is enveloped. There are three of these. The outermost is the *dura mater*, or *pachymeninx*, a thick, tough, fibrous membrane, which adheres to the cranium. The dural membrane also forms two firm partitions. The more conspicuous, placed between the two hemispheres, is the *falx*, or "sickle," of the cerebrum (Fig. 228). In the posterior portion of the cranial cavity the falx is continuous with another similar, tough, fibrous partition, the *tentorium*, or tent, placed transversely and separating the larger anterior forebrain above it from the smaller cerebellum, or little brain, below and behind. These two partitions, firmly attached at one end to the inside of the skull, form a secure support which holds the various parts of the brain in place. By splitting into two sheets along the lines where they are attached to the bony wall of the cranium, the dural partitions form the venous sinuses through which the blood leaves the brain and skull.

The other two meningeal tunics within the dura are thin and soft and are therefore called *leptomeninges* (sing. *leptomeninx*). The one closer to the dura is the arachnoid membrane. It does not carry any blood vessels, and it adheres to the innermost tunic by means of numerous delicate threads and trabeculae. The space between the dura and the arachnoid is the subdural space.

The third tunic, the *pia mater*, is the innermost, closely adhering to the surface of the gyri and sulci of the brain. It penetrates all dents and depressions of the cerebral surface, everywhere carrying both large and small blood vessels, from which numerous branches penetrate into the cerebral substance. The pia mater is the principal avenue by which the nutritive blood reaches the brain, especially the more superficial parts. The space between the pial and arachnoid membranes is the subarachnoid space.

Both the subdural and the subarachnoid spaces in the living are filled with a watery cerebrospinal fluid, as are the inner cavities, called the *cerebral ventricles*, where the fluid is produced by the chorioid plexus. The cerebrospinal fluid, by filling the ventricular cavities and by providing a cushion upon and in which the brain floats, is an important mechanical factor maintaining the normal conditions necessary for the existence and function of the brain.

2. Gray and white substance of the brain.—The first feature noticeable on a cut surface of a brain specimen is that it is composed of two kinds of substance: the darker, gray matter and the white matter (Figs. 226, 227, 228).

In a freshly prepared specimen the color of the gray substance is grayish-brown, with a slight tinge of reddish, or ocher. This color is caused by countless bodies and by innumerable protoplasmic expansions or dendrites of the nerve cells and by a dense network of minute blood vessels and capillaries, the principal constituents of the gray substance. The nerve fibers possessing myelin sheaths here are relatively few.

The white substance, on the contrary, consists principally of axis cylinders or nerve fibers, mostly enveloped in myelin sheaths of varying thickness, arranged in sheets, laminae, and sys-

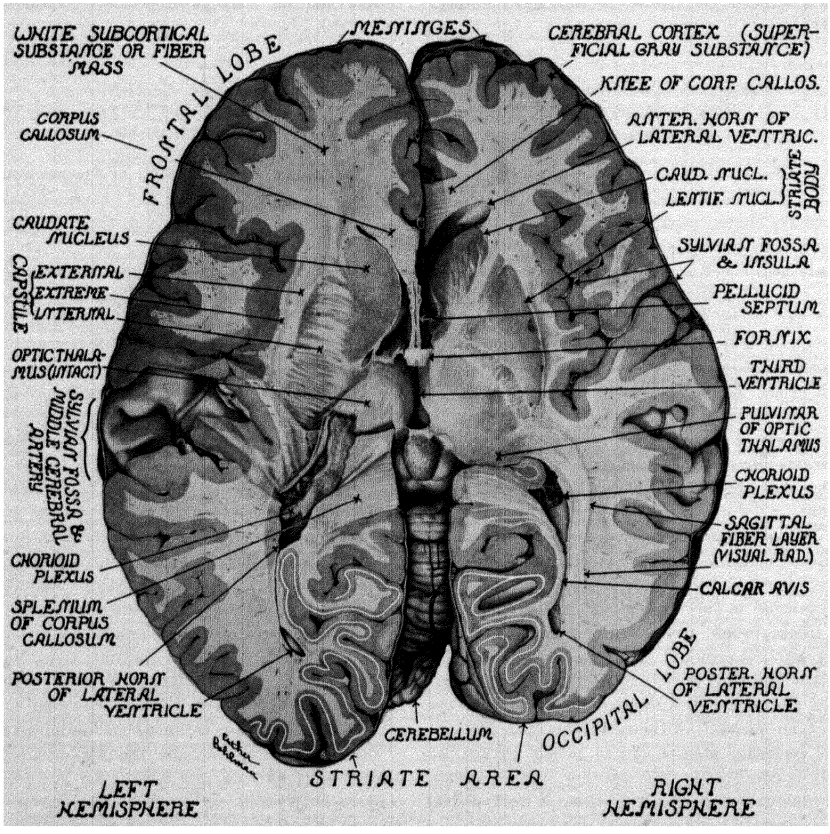

Fig. 226.—Human brain with upper parts of the hemispheres removed by a horizontal section to show the various structures which compose it. The cut through the right hemisphere is carried through a deeper level than on the left side. The superficial gray layer, the cerebral cortex or "rind," lines all gyri and sulci or furrows in between and varies in thickness. The deepest pocket is the Sylvian fossa or pit. Note the third ventricle in the center and close to it the two lateral ventricles extending from the frontal to the occipital lobes; pineal body and quadrigeminal colliculi in mid-line; white lines in the occipital cortices indicate the striate areae or visual cortical centers in both occipital lobes; the visual radiation, a thick whitish fiber lamina extending from the thalamus to the striate area, may be seen in the right occipital lobe.

tems. There are blood vessels in the white substance also, but their network is less dense. It is this fibrous composition, the myelin content, the absence or scarcity of the cell bodies, and the relative scarcity of blood vessels that impart a white coloring to the subcortical substance of the cerebral hemispheres. The same – the supporting neuroglia, a special nervous interstitial tissue—is present in both the gray and the white matter.

The distribution of gray and white substance in various localities of the brain varies, the two usually being segregated from each other. Most of the gray matter forms a relatively thin super-

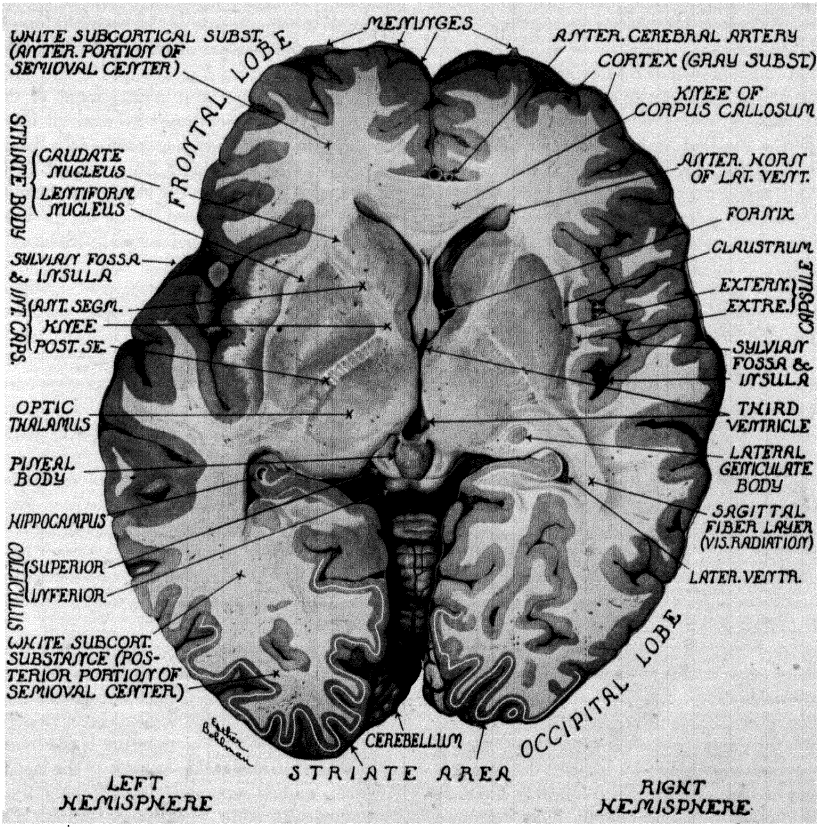

FIG. 227.—Horizontal section through human brain at a slightly lower level than in the preceding figure. On the right side the initial portion of the visual radiation and a part of the lateral geniculate nucleus are visible. The striate areae, marked by white intracortical lines, are clearly visible in both occipital lobes.

factors are also responsible for the varying appearance of different localities of the core of the brain, the brain stem, the cerebellum, the spinal cord, and the peripheral nerves and ganglions in the rest of the body.

The third constituent of the brain substance ficial coating, which lines all convolutions or gyri and all furrows or sulci of the brain—the cortex, "rind," "bark," or "crust," of the brain. The thickness of the cortex varies considerably, depending upon the locality, partly because some of the gyri and sulci are cut more or less

tangentially and partly because of the varying thickness of the cortex in different localities. On close examination one or more thin, and usually faint, whitish stripes may be observed in the cortex with the unaided eye. The most prominent of these is the stria of Gennari and Vicq-d'Azyr, found along the inner sides and at the poles of the occipital lobes, which, as mentioned, indicates the striate areae or the cortical visual centers.

The remainder of the gray matter is chiefly accumulated in the center of the brain in several solid masses, called *basal nuclei* (Figs. 226, 227)—the *thalami*, which flank the third ventricle, and the *striate bodies*, each of which, in turn, is made up of a *lentiform* and a *caudate nucleus*.

The white subcortical mass or substance of the brain (white in Figs. 226, 227, and dark in Fig. 230) forms the core of the two hemispheres —the semioval center of Vieussens. It also passes into every gyrus, of which it forms the central ridgelike portion. Sheets and segments of the white substance also separate the basal ganglia from one another and from the cortex: the internal, the external, and the extreme capsule.

The internal capsule is one of the best-known and pathophysiologically most important localities of the white subcortical core of the brain (Figs. 226, 227). It is a thick sheet resembling the letter **V**, with the point, the *genu*, or "knee," facing toward the third ventricle. The anterior limb or segment of the internal capsule separates the caudate nucleus, the posterior limb or segment separates the thalamus, from the lentiform nucleus.

The internal capsule contains important fiber tracts: the great corticobulbar and corticospinal or "pyramidal tracts" for skilled, detailed voluntary movements (which frequently are damaged in cases of cerebral hemorrhage, thrombosis, or "stroke," producing motor paralysis of the opposite half of the body); the great corticonigral and corticopontine tracts for the semiautomatic and postural movements of the limbs and body; the abundant fiber systems connecting various nuclei of the thalamus with most of the cortex and largely serving the transmission of somesthetic impulses from the body to the somesthetic areas of the cortex; and others.

3. Sagittal fiber layers of the occipital lobes.—In the posterior portion of the white subcortical core, corresponding with the parietal, occipital, and adjoining parts of the temporal lobes, a thick fiber lamina becomes apparent which may be traced from the posterolateral extremity of the thalamus along the posterior horn of the lateral ventricle in the direction of the tip or pole of the occipital lobe—the sagittal fiber layers of H. Sachs (Figs. 226, 227).

The exact number and arrangement of the fiber sheets which compose the sagittal layer may be examined more accurately in a brain whose posterior ends have been cut off (Fig. 228). In such a specimen the surface of the cuts through the two occipital lobes shows fiber bundles obviously arranged sagittally, or lengthwise, in the center of the white subcortical core. Because of their uniformly compact arrangement and the fact that they have been cut across, these bundles are somewhat grayish in color and have a texture somewhat different from the remainder of the white fibrous core.

The shape of these particular fibrous sagittal layers varies from plane to plane, usually somewhat resembling an irregular horseshoe (*see* Figs. 229, 231–33). The two ends of the horseshoe point inward, toward the medial face of the hemisphere, the horseshoe inclosing in its concavity the more or less collapsed posterior horn of the lateral ventricle (*v*), together with a deep furrow—the calcarine sulcus or fissure (in Fig. 229 marked with *).

Attentive examination of the sagittal fiber tracts reveals that they are composed of three parallel layers or strata (Fig. 228): an external, an internal, and a medial sagittal layer or *tapetum* (H. Sachs 1892). The tapetum is the innermost, closest to the posterior horn of the lateral ventricle, and is separated from it only by a microscopically thin ependymal lining. The thin, white fibrous coating on the medial side of the posterior horn is the subcortical layer of the calcarine fissure—the calcarine layer, or *stratum proprium*, coating the *calcar avis*.

In horizontally cut or dissected specimens this structure is noticeable as a curved, white bulge in the medial wall of the lateral ventricle, for which reason it was named *calcar avis*, or "bird's claw," the *hippocampus minor* of Vicq-d'Azyr (*cf.* Figs. 226 and 229). The lateral or

collateral eminence of Meckel caused by the collateral sulcus is another bulge in the floor of the lateral ventricle, but lateral to the one just mentioned.

Of the several sagittal, longitudinally arranged fiber layers of the posterior portion of the hemisphere, the external stratum is chiefly afferent, containing practically all geniculo-**calcarine fibers** or the actual visual or optic radiation (for evidence, *see* secs. 3 and 4, this chapter, and accompanying figures).

From the early period of modern anatomy until recently, this conspicuous tract was thought by some investigators to be a system of long association fibers: the lower portion the inferior longitudinal bundle, *fasciculus longitudinalis inferior* of Burdach supposedly connecting the occipital with the parietal lobe; the upper portion the superior longitudinal bundle, *fasciculus longitudinalis superior* supposedly uniting the occipital with the parietal lobe (*see* chap. III, 5 [3]; chap. IV, 3 [2], 7 [4]).

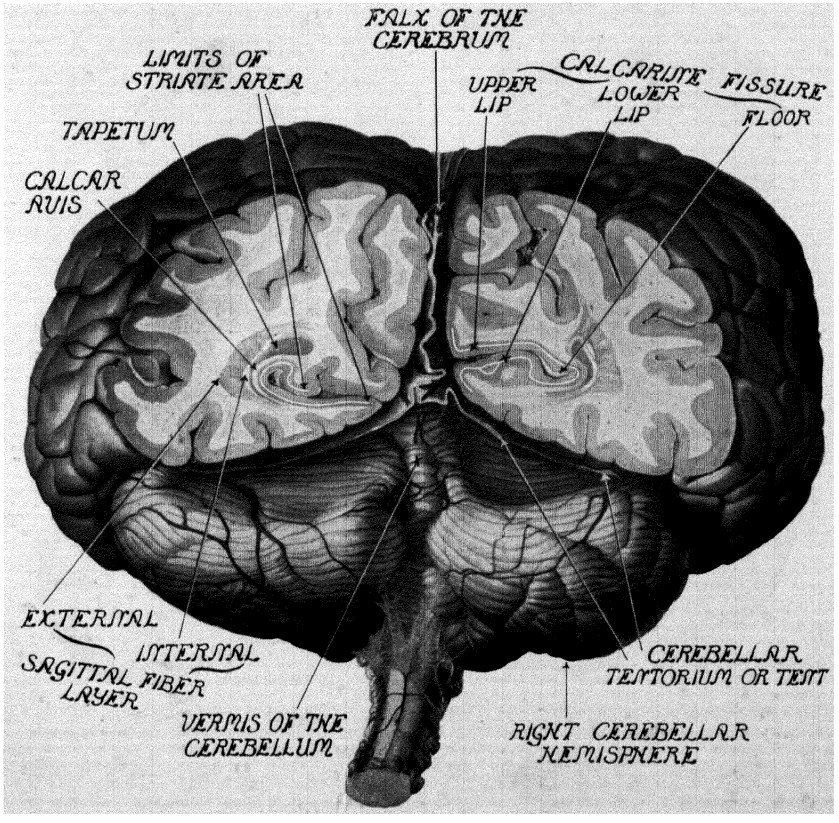

FIG. 228. Back view of the human brain, with the caps of both occipital lobes cut off by a vertical section, in order to show on the cut surface the shape, size, and position of both calcarine fissures, the extent of the striate areae marked by white intracortical stripe of Gennari and Vicq-d'Azyr, the position of the sagittal fiber layers, which include the visual radiations, and other details. The *falx* or "sickle" of the dura mater of the brain's meningeal envelopes, and the tentorium of the cerebellum, both somewhat distorted, are left *in situ*. The translucent arachnoid and pial membranes covering the oblong medulla are also left in place. (*Cf.* preceding and following figures.)

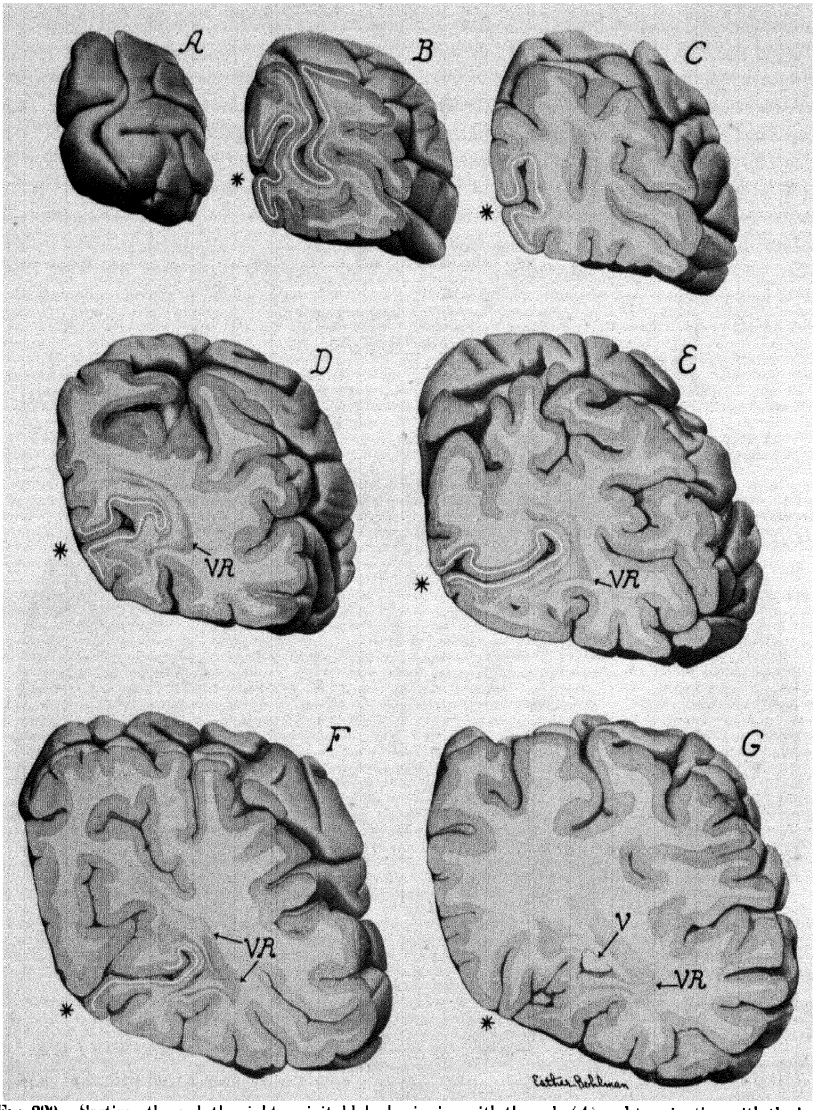

FIG. 229.—Sections through the right occipital lobe beginning with the pole (*A*) and terminating with the level passing through the posterior horn of the lateral ventricle (*G*). Note the calcarine fissure, marked with asterisks (*), representing in *G* a rather shallow sulcus medial to the lateral horn (*v*), not as yet lined by striate cortex; same fissure in *F* becoming quite deep and lined in its lower lip and floor with the striate cortex (identified by Gennari's white line), which extends from *E* on into the upper lip of the calcarine fissure and further expands over the lateral face of the occipital pole (in *B*, *A*), where it also lines the vertically placed lateral or posterior calcarine sulcus. *Labeling: v*, lateral ventricle; *vr*, saggital fiber layers which include the visual radiation. (*Cf.* Figs. **231, 232, 233, 271, 278, 288.**)

The intermediate or internal sagittal stratum is composed largely of the efferent, or corticofugal, fibers arising in the para-peristriate area of G. Elliot Smith, or fields *18* and *19* of Brodmann, of the parieto-occipital lobes; it terminates in the subcortical centers, in part in the cap of the ipsilateral superior colliculus of the midbrain (*see* Fig. 268). The tapetum is made

The layer covering the calcar avis contains various fiber systems entering into, or leaving, the striate cortex, including the short subcortical association fibers of that and the adjoining cortical areae (Fig. 238).

The external sagittal stratum, in the anatomical sense, is not a pure afferent system, since efferent fibers of the internal stratum and also

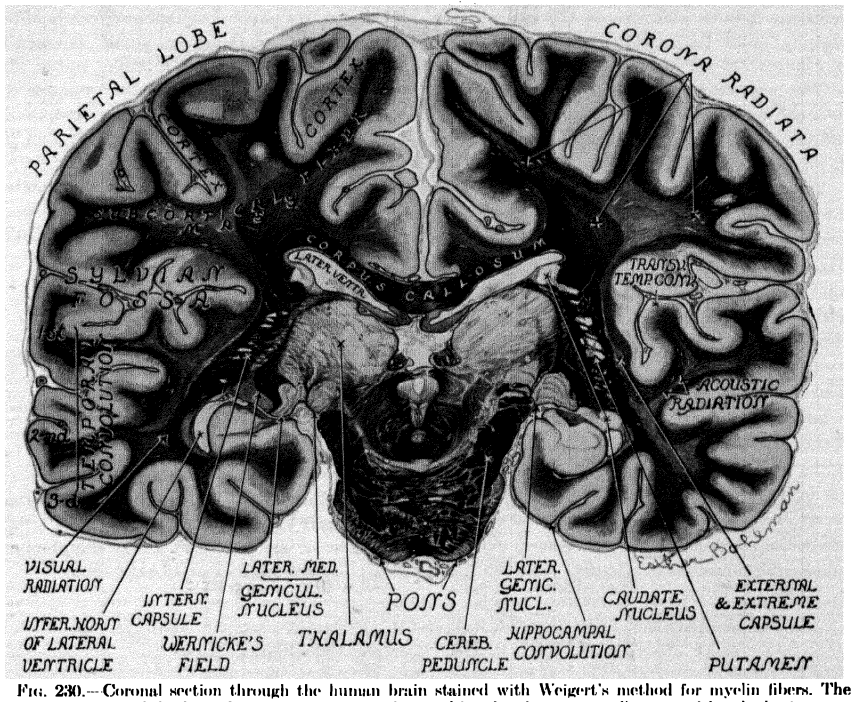

FIG. 230.—Coronal section through the human brain stained with Weigert's method for myelin fibers. The plane passes through both cerebral hemispheres, held in mid-line by the corpus callosum and by the brain stem. The parts of the visual system which are visible are the two lateral geniculate nuclei (next to the medial geniculate bodies, thalamus, cerebral peduncles, and internal capsule) and the visual radiations contained in the sagittal fiber layers of the temporal lobes (above and lateral to the inferior horns of the lateral ventricles). Note the meningeal covers; the gyri and sulci of the brain, lined with cerebral cortex, the core of the brain and of the gyri, made up of fiber systems, one of which is the visual radiation; the pronounced lamination of the lateral geniculate nuclei; and the topographical relations of the visible parts of the visual system. (*Cf.* following figures.)

up entirely of the ipsilateral and contralateral commissural fibers passing through the splenium of the corpus callosum from the occipital lobe of one hemisphere to that of the other (Fig. 267). A fourth layer, *stratum sagittale extremum*, just lateral to the external sagittal layer, has been distinguished by R. A. Pfeifer (1925).

the callosal fibers of the tapetum and numerous association fibers pass between its bundles to and from the respective points of the cortex which lines the upper, lateral, and lower faces of the parietotemporo-occipital region. The same is also true of the internal sagittal stratum, through which pass bundles of the callosal

fiber system of the tapetum on their way to and from the cortex. (For further details on the visual radiation *see* the following sections in this chapter.)

The striate area, or the visual cortical center in the limited sense, recognizable without magnification by a sharp, whitish, intracortical stripe—the stria of Gennari and Vicq-d'Azyr or the outer stripe of Baillarger—is found in the calcarine fissures and around the poles of the occipital lobes. Its location and extent are given in Figures 226–29 and 231–33.

The position and extent of the striate areae over the occipital poles, in this case asymmetric, are shown in Figure 288. (*See* chap. VIII, 1 and 2, for further details on striate area.)

The two spacious cavities of the brain—the lateral ventricles, one in each hemisphere—are oriented longitudinally (Figs. 226, 227; *cf. also* Fig. 269). The rostral extremities of the lateral ventricles, called anterior horns, are close together and are separated from one another by a thin partition only—the pellucid septum—and by the anterior portion of the corpus callosum. The posterior extremities—the posterior horns—located in the occipital lobes, on the contrary, diverge from one another. The third expansion of the ventricular cavities—the inferior horns—are in the temporal lobes (Fig. 230). At the anterior ends, underneath the fornix, the lateral ventricles communicate by means of two passages—the foramens of Monro—with the third ventricle, placed in the middle between the two thalami (Fig. 226). The third ventricle, in turn, communicates through the narrow, tubelike cerebral aqueduct of Sylvius with the fourth and hindmost of the cerebral cavities (*see* Fig. 269).

The cerebrospinal liquor or fluid, secreted by the chorioid plexuses, chiefly in the two large lateral ventricles, passes through the foramens of Monro to the third ventricle. From here the fluid enters through several small openings in the wall—the foramens of Luschka and of Magendie—in the subarachnoid space outside the brain, from which it is resorbed by Pacchioni's granulations into the venous blood system. In the living, the secretion of cerebrospinal fluid is continuous, and the ventricles are in a moderately expanded state. In an anatomical specimen, unless specially prepared, the ventricular cavities are often found collapsed, if they are not pathologically extended. (*See* Fig. 269 for the topography of cerebral ventricles in the living person.)

SEC. 3. ORIGIN, COURSE, AND TERMINATION OF THE VISUAL RADIATION IN GENERAL

1. ORIGIN OF THE VISUAL RADIATION IN THE LAMINATED LATERAL GENICULATE NUCLEUS.—The visual or optic radiations take their origin from the principal nerve cells of the laminated lateral geniculate nuclei of the betweenbrain (Fig. 180).

The details concerning the initial portion of the axis cylinders close to the geniculate cells, particularly whether or not they possess collateral branches and what course they take, where the termination of such collaterals may be, and also whether there is more than one variety of axis cylinder in the visual radiation—all unfortunately remain unsolved problems.

Only by circumstantial evidence—an absence of certain retrograde degeneration of nerve cells in the laminated nucleus in experiments and in human pathological cases where parts of the brain other than the visual radiation or the striate cortex were damaged—may the inference be drawn that there are no such collaterals or that, if present, they are short and probably terminate not far from the nerve cells in the nucleus itself.

The same experiments and pathological cases may also be adduced as evidence that the laminated lateral geniculate nucleus is the sole origin of the visual radiation and that the striate area

is its exclusive terminal territory in the cerebral cortex. From the same evidence it is also apparent that the visual radiation, from its subcortical origin to its cortical termination, is strictly unilateral, no part of it crossing by way of the corpus callosum to the contralateral cerebral hemisphere. (For evidence *see* subsec. 4, this section, and secs. 4 and 5, this chapter; *see also* chap. XI, 8, 9.)

2. COURSE OF VISUAL RADIATION AND ITS TOPOGRAPHICAL RELATIONSHIPS.—The initial portions of the axon fibers of the radiation at first pass through the layers of the lateral geniculate nucleus. Most of them emerge along its upper and lateral contours, a few along its medial contours, and apparently none along its lower contour (*cf.* chap. VI, 4 [3]).

After leaving the confines of the nucleus, the

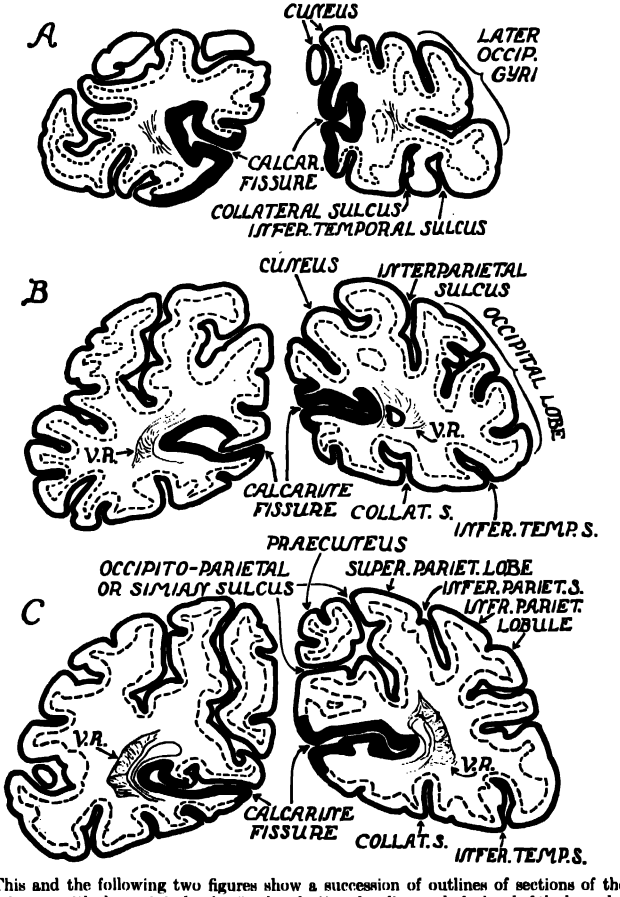

FIG. 231.—This and the following two figures show a succession of outlines of sections of the human brain, ¼ inch apart, beginning with the occipital poles (in sketch *A*) and ending with the level of the lateral geniculate nuclei (in sketch *H* in Fig. 233). Note the position, size, and general topographic relations of the calcarine fissures of both sides and of the two striate areae (given in *solid black*), showing the extent and location of the same areae in the fissures; note also the topography of visual radiations (*V.R.*), from their beginnings in the lateral geniculate nuclei (in sketch *H*, in Fig. 233) to their terminations in the striate areae of the occipital lobes, and also the relation of the radiations to the lateral ventricles (*L.V.*) and to the gyri and sulci of the temporal lobes.

fibers fan out in various directions, mostly dorsally, laterally, anteriorly, and posteriorly, as they stream over to the posterior portion of the internal capsule. Here they form an almost complete circle around the lateral geniculate nucleus: perigeniculate fiber lamina. The broad dorsolateral segment of this fibrous ring is known as the triangular field of Wernicke (Fig. 230, left).

Posterior to its exit from the geniculate nucleus, in the *carrefour sensitif*, or "crossroad of the sensory pathways," of the French authors, the radiation is in immediate proximity to other important fiber systems (Fig. 237). One is the auditory radiation (*ar*), which, originating from the medial geniculate nucleus, slips just above and somewhat in front of the lateral geniculate nucleus on its way to Heschl's transverse temporal gyri (*Ttr*) of the Sylvian fossa (*FS*). The other is the somesthetic radiation (*sr*), which emerges from the lateral side of the thalamus and passes through the internal capsule to the cortex around the central sulcus of Rolando (*C*).

In this locality, where the three principal pathways are close together, they may all be easily damaged by a single lesion, e.g., a hemorrhage or encephalomalacia, resulting in an impairment of all three important functions: vision, audition, and bodily sensation; whereas closer to the cortex, where the three fiber systems are far apart, they may be damaged individually, if the lesion is small enough.

Outside the lateral geniculate nucleus the fibers of the visual radiation, assembled into bundles, are arranged in a thick, compact lamina in the posterior segment of the posterior limb of the internal capsule (Figs. 226–33). The position of this fiber lamina in the fibrous core of the temporal lobe is on the lateral side of, and somewhat slanting along, the inferior horn of the lateral ventricle (*V* and *L.V.*). The inferior margin or edge of this fiber lamina (*V.R.*) is bent in, with the concavity facing inward and parallel to the curve of this part of the ventricle. The bent-in lower edge of the lamina thins out into a narrow fiber sheet, which slips medially underneath the ventricle and becomes the core of the hippocampal gyrus (Fig. 230). It is very probable that the most inferior and medial bundles of this fiber lamina of the temporal lobe are in no way concerned with the visual function.

In any case, the inferior margin of the sagittal fiber system of the temporal lobe comes to lie quite close to the floor of the inferior temporal and collateral sulci. The inferior segment of the visual radiation may, therefore, be easily damaged by any local pathological process spreading on the inferior face of the temporal lobe, involving an interference with its blood supply by a tumor, hemorrhage, encephalomalacia, abscess, mechanical injury, or other pathology (*cf.* sec. 8, this chapter, and chap. X).

In the occipital lobe the thick fiber sheet or lamina of the visual radiation, the most external of the three sagittal strata of Sachs, identical with Burdach's "inferior longitudinal fascicle," is found lateral to the posterior horn of the lateral ventricle (Figs. 228, 229). In coronal sections the external stratum includes in its concavity both inner sagittal strata, the tapetum, closest to the ventricle, and the internal —in fact, middle —sagittal stratum in between, which, together with the posterior horn of the lateral ventricle, are encircled by it from above, from below, and from the lateral side. To these must be added the deeper portion of the calcarine fissure and the fiber layer which covers that fissure on the ventricular side—the calcar avis.

The shape of the visual radiation changes considerably from level to level, resembling either an irregular horseshoe, a triangle, or a crescent with its concavity facing inward. It may be subdivided roughly into two or three segments: more posteriorly, close to the posterior limit of the ventricle, there is an upper and a lower segment; more anteriorly, through the occipital lobe, an upper, an intermediate, and a lower segment or branch are distinguishable.

The calcarine fissure, again, may be divided into an "upper or dorsal lip" and a "lower or ventral lip" (Fig. 228). The junction of the two lips is the "floor" of the fissure. It is this deepest portion, coated with a fiber layer, which protrudes into the ventricle and which, because of its peculiarly curved shape, noticeable in specimens cut horizontally or dissected, has been named calcar avis.

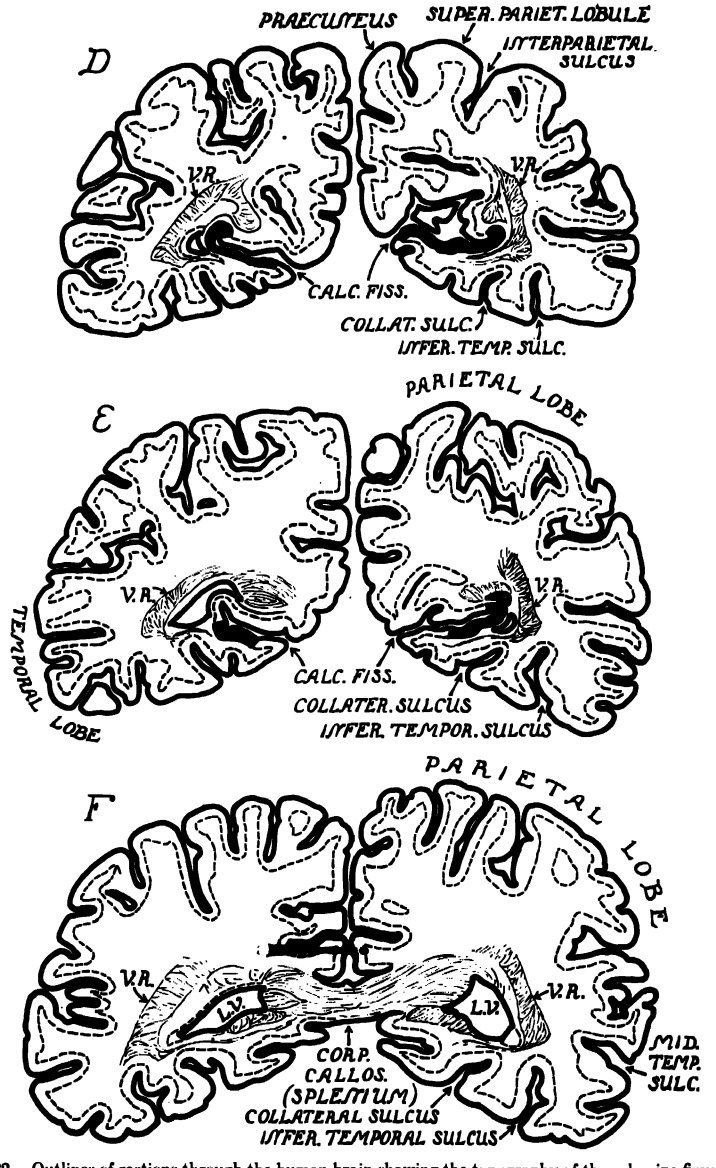

FIG. 232.—Outlines of sections through the human brain showing the topography of the calcarine fissures (*Calc. Fiss.*), striate areæ (*solid black*), and visual radiations (*V.R.*) in the brain, and especially their relation to the posterior horn of the lateral ventricle (*L.V.*). (*Cf.* preceding and following figures.)

3. Functional segmentation of visual radiation.—An attentive examination of the coronal sections through the human or simian occipital lobe, stained for myelinated fibers, e.g., by Weigert's method or one of its modifications or according to Marchi's technique, reveals further details concerning the arrangement and course of the visual radiation (Figs. 235, 236; and *see* par. 6, this section).

Those bundles which make up the upper segment of the external sagittal stratum gradually become medially displaced as the more posterior levels of the lobe are reached. After turning the upper corner of the lateral ventricle,

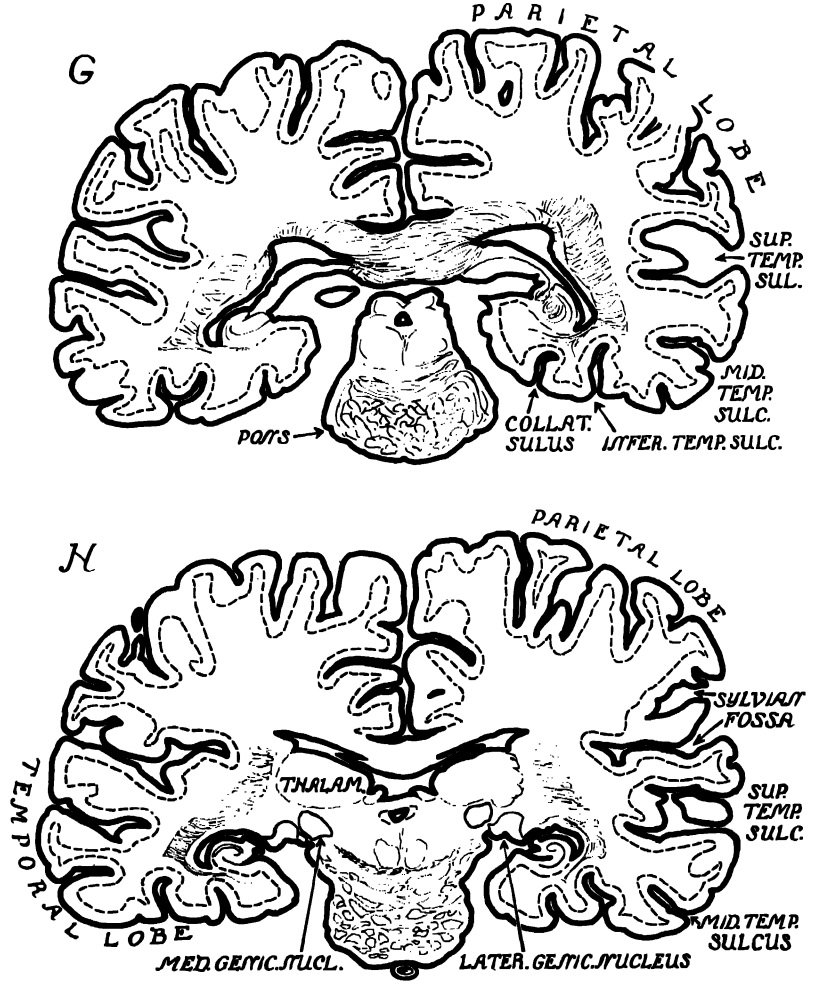

Fig. 233.—Outlines of sections through the human brain showing the topography of visual radiations, lateral geniculate nuclei, and lateral ventricles. (*Cf.* two preceding figures.)

these bundles finally slip into the upper lip of the calcarine fissure. A similar course is pursued by those bundles which form the lower segment of the radiation, except that they turn underneath the ventricle and thus pass beneath it into the lower lip of the calcarine fissure. The other fibers, those which are directly lateral to the ventricle and on most sections seemingly have no connection with the calcarine fissure, may be followed beyond the tip of the ventricle toward the pole of the occipital lobe.

The visual radiation, accordingly, is made up of several segments: the upper segment, which supplies the upper lip of the calcarine fissure; the lower segment, which supplies the lower lip; and the intermediate segment, which takes a more direct course along the lateral side of the ventricle to the occipital pole. As is apparent, the anterior portion of the striate area, closer to the splenium of the corpus callosum, is supplied by fibers which constitute the upper and lower segments of the radiation, while the intermediate segment of radiation supplies the striate cortex in the posterior portion of the calcarine fissure close to, and around the pole of, the occipital lobe.

Additional facts, especially those obtained experimentally, described in section 4, suggest a comparison of the visual radiation with a fan made up of many parallel ribs, each represented by a minute fiber bundle or segment of the radiation and each segment with a stable position relative to the other segments. The uppermost and the lowermost bundles of the fan are the first to turn medially around the lateral ventricle and enter the anteriormost portion of the striate area. The next upper and lower bundles, also turning above and below the ventricle, reach the next successive and somewhat more posterior segments of the striate cortex in the upper and lower calcarine lip, respectively; and so on. The intermediate bundles, which represent the axis of the fan, proceed directly to the farthest, posteriormost portion of the striate cortex at the occipital pole. Along the greater part of the calcarine fissure, bundles which turn above the ventricle and those which turn below meet in the fiber layer which coats the calcar avis along a line more or less corresponding to the floor of the calcarine fissure.

A simple principle of the "vertical articulation" just described, according to which the visual radiation is organized, in spite of the apparent irregularities and confusion, is strictly observed both in the Monkey and in Man. In the latter, however, this arrangement has to be somewhat qualified concerning the afferent fiber supply of the anteriormost portion of the striate area. Here the upper lip on a short stretch usually does not contain the striate cortex, this being confined to the lower lip alone (thus in Figs. 228, left side; 229, *F;* and 232, *D, E*).

Contrary to expectation, this portion of the striate cortex receives fibers not only from the lower segment of the visual radiation but also from the upper. The disagreement with the proposed scheme, however, is only apparent, as close study reveals: the fiber bundles deriving from the lower segment reach the inner half of the striate cortex closer to the inner edge of the lower calcarine lip, whereas the fibers from the upper segment of the radiation descend through the fiber layer coating the calcar avis and reach the outer half of the striate cortex closer to the floor of the calcarine fissure in the same lip. If the striate cortex be imagined as displaced in such a way that equal parts come to lie in both lips, the typical condition present in most of the calcarine fissure described in the preceding paragraphs would be restored.

The peculiar supply of the anterior portion of the striate area in Man, just described, makes possible an interruption of its afferent fibers by a single pathological focus, e.g., one situated underneath the lower calcarine lip or one destroying this lip directly, causing a defect in the extreme part of the contralateral field of view both above and below the horizontal meridian. (*See* sec. 8, this chapter, and chap. VIII, 3, for additional topographical details; *see also* chaps. XI, XII.)

4. UNILATERALITY OF VISUAL RADIATION.—The visual radiation is anatomically a unilateral fiber system, precisely as are the other great afferent fiber systems of the brain: the thalamocortical, auditory, and pyramidal-motor (*see* Polyak 1932). That is, no part of the radiation passes over to the contralateral hemisphere by way of the corpus callosum. The *fasciculus corporis callosi cruciatus* of Niessl von Mayendorf, R. A. Pfeifer, and others, does not exist. The

evidence in support of this view is experimental, pathological, and clinical.

When, in a monkey, one occipital lobe is removed, only the lateral geniculate nucleus of the same side degenerates in the retrograde sense, and it does so completely, with the contralateral geniculate nucleus retaining its normal appearance (Fig. 234). Also, whenever any portion of the radiation is interrupted experimentally, it can be followed to the occipital cortex of the same side only (Figs. 238–43). Functionally, however, because of a partial decussation of the optic nerve fibers in the chiasma, the visual radiation of each side represents ipsilateral homonymous halves of both retinae or contralateral homonymous halves of both fields of view. (*See* chaps. XI, 8, 9; XII; and XIII, 3, for the physiological and clinical implications, especially the cortical representation of the central fovea.)

5. Terminal area of the visual radiation in the cerebral cortex.- The terminal area of the visual radiation in the cerebral cortex is identical with the striate area of G. Elliot Smith, with Brodmann's field *17*, or with Economo's occipital area *OC*.

The evidence in support of this statement is

Fig. 234.—Sections of the lateral geniculate nuclei and thalami of a Rhesus Macaque stained with the Nissl method to show the origin of the visual radiation. The upper photo shows, at low magnification, the effect of the retrograde degeneration upon the nerve cells of the right-hand nucleus on the side where the occipital lobe, together with the striate area, was amputated and the visual radiation interrupted. On the opposite side, left, where no damage was done, the nucleus remained normal. The two lower photos show, at a somewhat higher magnification, on the left side the laminae of the lateral geniculate nucleus filled with normal cells, whereas on the operated right side the cells have been reduced in size and in their staining properties, the layers, in addition, being filled with greatly increased neuroglial cells. From S. Polyak, "A contribution to the cerebral representation of the retina," J. Comp. Neurol., v. 57, p. 541, 1933. (*Cf. also* Fig. 251.)

manifold (*see* Polyak, *The Main Afferent Fiber Systems of the Cerebral Cortex in Primates*, 1932). In experiments with monkeys, whenever a portion of the radiation was interrupted, degenerated fibers, without exception, entered the striate cortex, and that alone. The limits of the cortex supplied by the fibers of the visual radiation are sharp and are indicated by the stripe of Gennari and Vicq-d'Azyr (Figs. 238–43). In other experiments a retrograde degeneration in the laminated lateral geniculate nucleus of the same side was found exclusively when the striate area was damaged completely or in part (Figs. 252–58, and secs. 4, 5, this chapter; *also* Polyak 1933).

Observations of suitable human pathological cases agree with these experimental results (chap. XII). In these, the laminated lateral geniculate nucleus was found degenerated completely or in part only when the visual radiation or the striate area of the same side was affected by a pathological process. In cases where the para-peristriate areae were damaged without the involvement of the striate area, the lateral geniculate nucleus remained intact, the zones of degeneration having been found in the pulvinar of the thalamus.

6. Presentation of the visual radiation by dissection. A useful method of demonstrating not only the origin, course, and termination of the visual radiation but also its basic internal or functional organization is a careful dissection or "teasing" of well-fixed and hardened brain specimens. Such "old-fashioned" preparations go a long way toward solving problems of long standing, which, by modern methods of serially stained sections, could be answered only by laborious plastic reconstruction.

The dissection method, used as a routine technique during the early period of modern brain research by Vicq-d'Azyr, Gall, Reil, Arnold, Foville, Gratiolet, Meynert, J. Henle, J. Stilling, and others, became largely outdated through the development of modern microscopy. A number of investigators, however, applied this method in modern times to the study of various fiber tracts of the brain, including the visual radiation: Trolard (1906), A. Meyer (1907, 1911), J. B. Johnston (1908), Curran (1909), H. J. H. Hoeve (1909), E. B. Jamieson (1909), Herrick & Crosby (1918), L. E. Davis (1921), S. W. Ranson (1921), H. Cushing (1922), Tandler (1926-29), Büttner (1927), C. Elze (1929), J. W. Hultkrantz (1929, 1935), and J. P. Martin (1937).

Lately the dissection method has been used by Rasmussen (1943) for a restudy of the question of the "temporal loop" of the visual radiation. According to the classical presentation by Flechsig (1896, 1920), repeated by A. Meyer (1907), Cushing (1922), R. A. Pfeifer (1925), and Elze (1929), those bundles which constitute the inferior segment or margin of the radiation, after emerging from the lateral geniculate nucleus, first turn anteriorly, toward the pole of the temporal lobe, before turning back to the occipital pole, describing, in Flechsig's designation, a "temporal knee" or, in A. Meyer's terminology, a "temporal loop" (*see* chap. IV, 3 [2]).

Confirming these and a similar observation of La Salle d'Archambault (1909), Rasmussen found the fibers of the visual radiation in the temporal lobe to extend anteriorly as far as the lateral surface of the amygdaloid nucleus and the vicinity of the anterior commissure and "almost as far anteriorly as the extreme tip of the inferior cornu of the lateral ventricle, in the roof and lateral wall of which they are located." The recurrent detour of the visual radiation proceeds anteriorly fully 2 cm. or almost 1 inch before again turning in the posterior direction.

The visual radiation and, in fact, the sagittal fiber layers of the posterior half of the human brain are a very definite anatomical entity, easily demonstrable by careful dissection of hardened specimens (Figs. 235, 236). In a lateral aspect, after scraping off most of the cortical substance from the lateral face of the hemisphere below the Sylvian fissure (*Sylv*) and the intraparietal sulcus (*is*), but leaving intact the cortex around the occipital pole, and after gradually peeling off the sheets of various systems of short association fibers which make up the core of that portion of the hemisphere, the visual radiation may be demonstrated in its entire extent.

The visual radiation—the classical "inferior longitudinal fascicle" of Burdach—appears as a broad, though relatively thin, lamina, composed

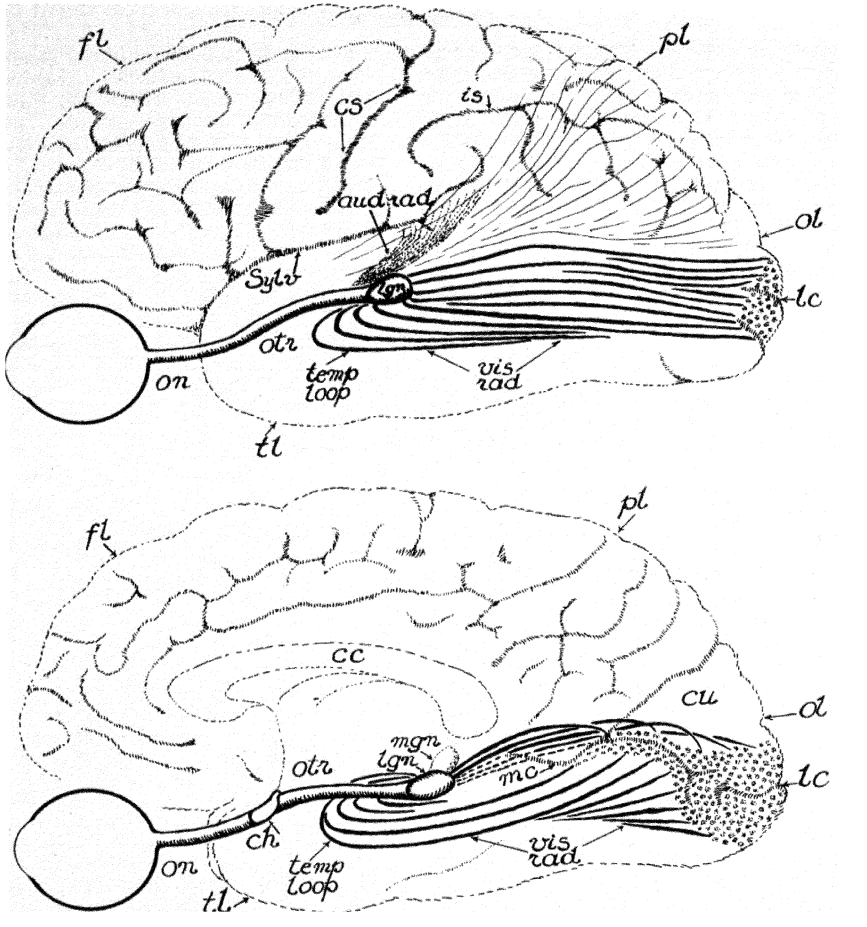

FIG. 235.—Visual radiation (*vis rad*) of the human brain revealed by dissection of a fixed and hardened specimen. Upper diagram represents a lateral aspect of the left hemisphere, lower diagram a medial aspect of the right hemisphere. Visual radiation given in thick lines, striate area in stippling. In the upper diagram bundles of fibers making up the radiation are arranged parallel to one another. They mostly follow a straight course from the lateral geniculate nucleus to the striate area at the occipital pole (*lc*). Lower bundles describe a detour of almost 1 inch, first being directed toward the pole of the temporal lobe (*tl*), then turning back again toward the occipital lobe: "temporal loop" of Flechsig and A. Meyer. The forming of a "temporal loop" and its entire course from its origin in the lateral geniculate nucleus to its termination in the lower lip of the calcarine fissure are shown in the lower diagram. Fibers that form the upper bundles of the visual radiation, not visible in the upper diagram, are seen in the lower diagram. They are shorter, have a straighter course, and terminate in the upper calcarine lip, in the cuneus (*cu*). Most of the striate area spreads over the medial face of the hemisphere along the calcarine fissure (*lower diagram*), only a small portion spreading over the occipital pole (*upper diagram*). Nonvisual radiations of the posterior half of the brain are indicated by thin lines, the auditory radiation by thin broken lines (*aud rad*). Note that the area of visual radiation, when projected on the lateral face of the hemisphere, remains well below the level of the Sylvian fissure (*Sylv*). (*Cf.* Figs. 182, 228–33, and especially Figs. 236, 269, and 271.) *Labeling: aud rad*, auditory radiation; *cc*, corpus callosum; *ch*, chiasma of optic nerves; *cs*, central sulcus; *cu*, cuneus; *fl*, frontal lobe; *lc*, lateral or posterior calcarine fissure; *lgn*, lateral geniculate nucleus; *mc*, medial or anterior calcarine fissure, separated in this specimen from the lateral calcarine fissure by a cuneo-lingual gyrus; *ol*, occipital lobe; *on*, optic nerve; *otr*, optic tract; *pl*, parietal lobe; *Sylv*, Sylvian fissure; *temp loop*, temporal loop of visual radiation; *tl*, temporal lobe; *vis rad*, visual radiation.

of a considerable number of rather thin, parallel fiber bundles (Fig. 235, upper diagram). The bundles extend in a fairly straight course from the region of the thalamus to the occipital pole, the length of the radiation amounting to considerably more than the posterior half of the length of the entire cerebrum. Anteriorly, the radiation approaches to within less than 1 inch from the anterior pole of the temporal lobe, whereas its lower margin is nowhere more than ½ inch, and in the occipital lobe even less, from the inferior surface of the cerebral hemisphere. The uppermost bundles of the radiation, determined according to their point of origin in the lateral geniculate nucleus and their termination in the striate cortex, slightly bulging about midway of their longitudinal extent, remain well below the horizontal level of the Sylvian fissure.

The origin, course, and termination of each particular segment of the visual radiation or of the individual constituent bundles may be revealed more easily and more instructively by dissection than by serial sections. Such a preparation (Fig. 235, upper diagram) shows the lateral segment of the radiation, best seen from the lateral side, to be made up of bundles which pursue a fairly straight anterioposterior course. This segment, situated on the lateral side of the lateral ventricle, contains fibers related to the central fovea and area of the retina ("the macular bundle").

The lower bundles of the radiation, however, as they emerge from the lateral geniculate nucleus, are first seen directed anteriorly, toward the temporal pole. Slipping above the anterior horn of the ventricle, the bundles make a sharp turn laterally and backward—the "temporal loop"—and in this way come to lie on the lateral face of the ventricle. Gradually, these bundles slip underneath the ventricle and pass over to the lower lip of the calcarine fissure (Fig. 235, lower diagram).

Those bundles that form the upper segment of the radiation pursue a similar spiral course above the ventricle to reach the upper lip of the calcarine fissure. The only difference is that they do not form a "loop" but pursue a straight course back from their origin, bending only a little medially as they enter the upper calcarine lip (Fig. 235, lower diagram).

Altogether, the visual radiation can be seen to resemble a fiber fan made up of a great number of minute bundles exhibiting a remarkably orderly arrangement, with individual bundles arranged parallel to their neighbors and with hardly any mixing or intertwining of the bundles.

The fibers of the visual radiation are a part of the sagittal fiber system of the brain, with which they are continuous. The "inferior" and "superior longitudinal bundles" of the parieto-temporo-occipital lobes of the older anatomists as they appear in macroscopically dissected specimens are a single, solid fiber lamina, precisely as it appears in microscopic sections stained for fibers (Fig. 230). There are no visible features by which parts of this lamina belonging to the visual system may be distinguished from those serving other functions. The only criterion for such differentiation is the origin of a particular segment of this lamina in a subcortical nucleus with a known function, e.g., the lateral geniculate nucleus, and its termination in a cortical area whose functional significance is ascertained, e.g., the striate cortex. (*See* sec. 4, this chapter, for experiments on the functional organization of the visual radiation; *see* sec. 8, this chapter, for additional topographical data.)

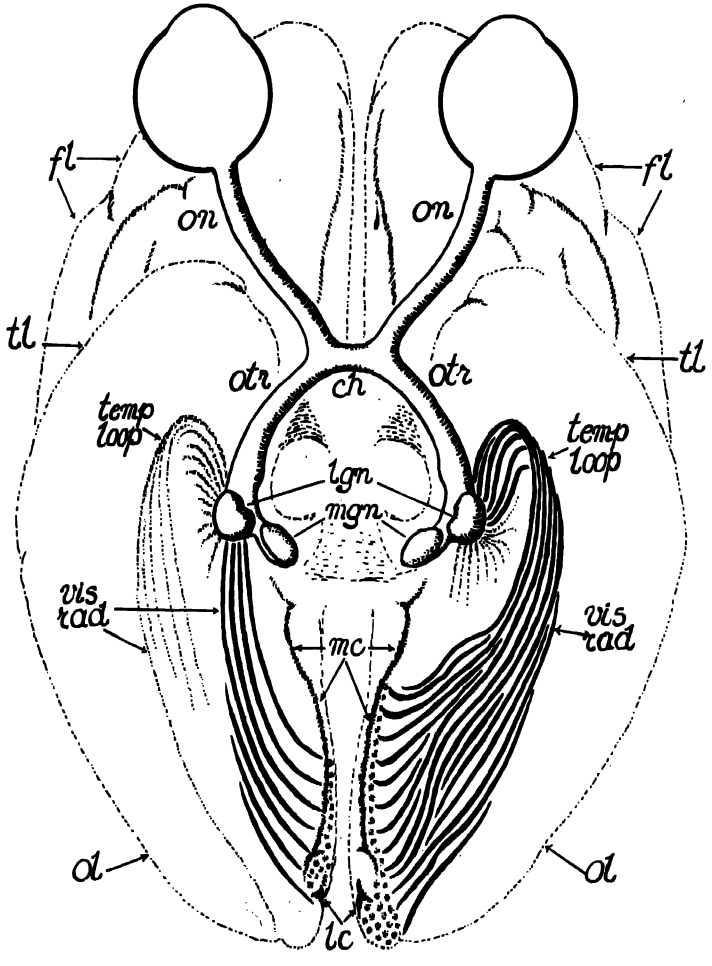

FIG. 236.—Visual radiations, dissected from a fixed and hardened human brain, in ventral aspect. In the right hemisphere (*left* in the figure) solid lines represent upper bundles of the right radiation originating from the medial segment of the lateral geniculate nucleus, pursuing a straight course and terminating in the upper calcarine lip. The lower bundles, which form the middle and lower segments of the radiation, are merely indicated by stippled lines. These bundles, which in part form Flechsig-Meyer's "loop" or "temporal detour," originating from the lateral and intermediate segments of the lateral geniculate nucleus, are drawn in solid lines in the left hemisphere (*right* in the figure), where they are seen to terminate in the lower calcarine lip and around the occipital pole. In each calcarine fissure only the lip or portion of the striate area supplied by the solidly drawn bundles of the radiation is indicated by stippling. Note straighter and shorter bundles supplying the upper lip (in the *left half*), and longer, detouring bundles supplying the lower calcarine lip (*right half* of the figure). (*Cf.* Figs. 182, 228–33, and especially Figs. 235, 269, and 271.) *Labeling: ch*, chiasma of optic nerves; *fl*, frontal lobe; *lc*, lateral or posterior calcarine fissure; *lgn*, lateral geniculate nucleus; *mc*, medial or anterior calcarine fissure; *mgn*, medial geniculate nucleus; *ol*, occipital lobe; *on*, optic nerve; *otr*, optic tract; *temp loop*, temporal loop of visual radiation; *tl*, temporal lobe; *vis rad*, visual radiation.

SEC. 4. FUNCTIONAL ORGANIZATION OF THE VISUAL RADIATION AND OF THE STRIATE AREA

1. TOPOGRAPHICAL PROJECTION, OR QUADRANTIC REPRESENTATION, OF THE RETINA IN THE SUPRANUCLEAR DIVISION OF THE VISUAL SYSTEM.—The surface of the retinal membranes is represented in the visual radiations and in the cerebral cortex according to a topographical

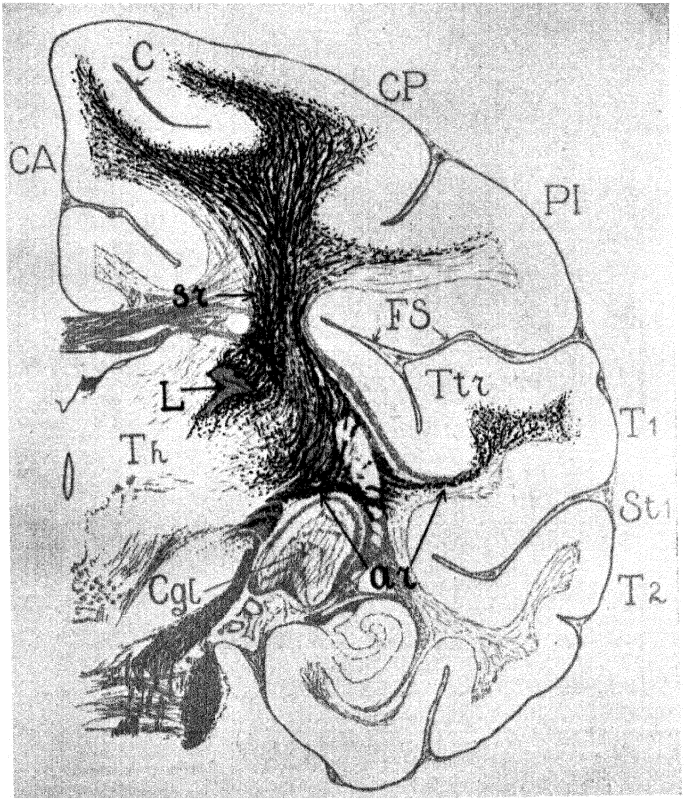

FIG. 237.—Section through the cerebral hemisphere of a Rhesus Macaque, where, in an experiment, a lesion *L* interrupted parts of the somesthetic (*sr*), auditory (*ar*), and visual radiations (*vr*, latter to be seen in subsequent sections), and the degenerated fibers were made visible by Marchi stain. *Labeling: ar*, auditory radiation; *C*, central sulcus of Rolando; *CA*, anterior central gyrus; *CP*, posterior central gyrus; *Cgl*, laminated lateral geniculate nucleus; *FS*, Sylvian fissure; *PI*, inferior parietal gyrus; *sr*, somesthetic radiation; *St1*, superior temporal sulcus; *Th*, thalamus; *T1*, *T2*, first and second temporal gyri; *Ttr*, transverse temporal gyrus of Heschl. This and the following Figs. 238–43 taken from S. Polyak, *The Main Afferent Fiber Systems of the Cerebral Cortex in Primates*, Berkeley, 1932.

principle or plan. According to this view, each minute area of the retina has its own discrete representation in the visual radiations and in the visual centers of the cerebral cortex, the striate areae of the occipital lobe.

The mode of the "projection" of the retinal surfaces in the infranuclear and nuclear divisions of the visual system was described in chapter VI, 7. Detailed evidence was also given in support of the concept of "retinotopical projection." In section 3 (preceding), anatomical evidence was adduced in support of the theory of the retinotopical organization of the visual radiation. Abundant clinical and pathoanatomical evidence in support of the same theory is presented in chapters XI and XII.

The accumulated evidence, anatomical and experimental, including cases of congruous homonymous hemianopic defects of the fields of view, particularly the quadrantic, and the "scotomas" or "blind patches" caused by unilateral injuries to the visual radiation or to the cortical center of vision, makes mandatory the acceptance of the concept of the detailed retinotopical organization of the visual system.

How this idea originated and the opposition it met with, until it became generally recognized, was dealt with in the preceding pages (*see* chap. II, 6 [2], 10 [2], 11 [2, 6]; chap. III, 2 [4], 6 [2], 8 [4], 9 [7–9]; chap. IV, 1 [7], 4–7; chap. VI, 7).

The evidence from gross anatomical investigation which suggests a "vertical functional articulation" of the visual radiation was presented in section 3. Even more important is the evidence furnished by observation of human clinical cases in conjunction with the study of pathological material (*cf.* Part III, this book).

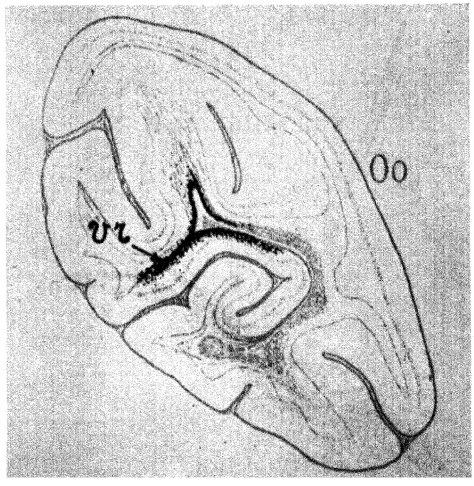

FIG. 238.—Cross-section of the occipital lobe of a Rhesus Macaque, showing the degenerated upper horizontal branch of the visual radiation (*black*), entering the upper lip of the calcarine fissure. Same experiment, Marchi stain. Note the extent of the striate cortex marked by a stippled line, supplied by the afferent visual fibers as far as its medial limit. *Labeling: Oo,* occipital operculum or occipital lobe; *vr,* visual radiation. (*Cf.* preceding figure.)

The anatomical and physiological experiments with monkeys and apes, of which a few are described in the following subsections, are of decisive importance because of the clarity of the procedure, which permits a detailed analysis of the visual pathway (for a complete presentation *see* Polyak 1932, and papers 1933 and 1936).

In these experiments both the visual radiation and the striate area were damaged in various ways. The resulting degeneration was then determined with the help of two technical pro-

cedures. In one, the degenerated fibers of the radiation, stained selectively by the Marchi method, were followed from the point of lesion, where they were interrupted, to the respective area in the cortex where they terminated; or a damaged portion of the radiation, after degenerated fibers had disappeared, was determined in serial sections treated by the Weigert method or one of its modifications for staining normal myelin fibers. The other procedure aimed at producing restricted lesions in the striate cortex, with subsequent study of the resulting zones of retrograde degeneration in the laminated lateral geniculate nuclei, stained by the Nissl method.

In this way it was possible to determine for each major segment of the visual radiation, and thus indirectly for each retinal quadrant, its subcortical origin, its location and course within the fibrous core of the parietotemporo-occipital lobes, and its cortical termination in the striate area.

2. ORIGIN, COURSE, AND TERMINATION OF THE UPPER SEGMENT OF THE VISUAL RADIATION.—When, in a monkey, a definite segment of the laminated lateral geniculate nucleus is destroyed, a well-defined portion or segment of the visual radiation degenerates. The degenerated fibers may be followed in serial sections as

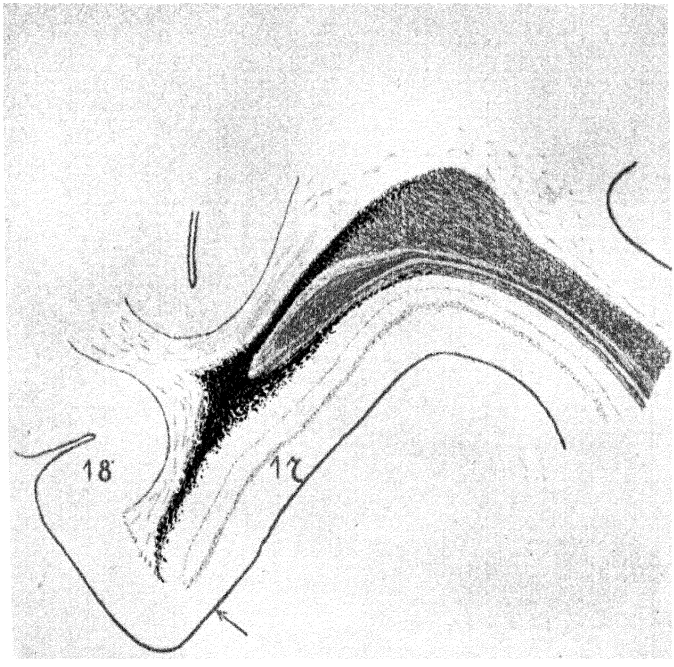

FIG. 239.- Upper lip of the calcarine fissure of a Rhesus Macaque showing the afferent fibers of visual radiation, made to degenerate experimentally, entering into that lip from the sagittal fiber layers of the occipital lobe. Marchi stain. Note the degenerated fibers passing over into the striate area as far medially (*to left*) as the stripe of Gennari (*stippled and marked with number 17*), beyond which point, marked with an arrow, no afferent degenerated fibers enter into the part of the cortex marked *18*, which is the parastriate area. Medium magnification. (*Cf.* preceding figures.)

far as the terminal segment in the striate area of the occipital lobe of the same side. If the lesion is limited, for example, to the medial segment of the nucleus, the same area where fibers originating from the upper extrafoveal homonymous quadrants of both retinae terminate (as found in experiments described in chap. VI, 7), the upper segment or upper horizontal branch of corner of the ventricle, then descend to the upper lip of the calcarine fissure, where they enter the striate cortex. The fiber bundles, which constitute the upper segment of the visual radiation, must accordingly describe a flat spiral turn above the posterior horn of the lateral ventricle, precisely as found in a dissected specimen of the human brain, in order to reach

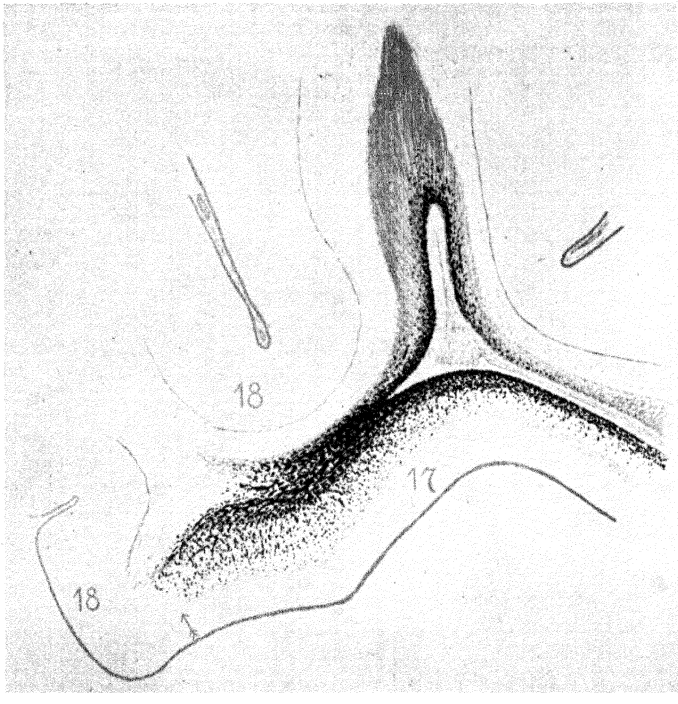

FIG. 240.—Similar experiment as in the preceding figure showing, in a Rhesus Macaque, degenerated fibers of the upper horizontal branch of the visual radiation entering the upper lip of the calcarine fissure. Note the abrupt cessation of fibers entering the striate area (*17*) at the point indicated by an arrow where the Gennari stripe ceases and the parastriate area (*18*) begins. Marchi method of staining, medium magnification. (*Cf.* preceding figures.)

the visual radiation degenerates (*vr*, in Figs. 238, 239, 240).

The degenerated fibers of this segment, stained black by the Marchi method and thus contrasting with the normal fibers, which remain unstained, gradually turn around the thick upper margin of the internal sagittal layer and of the tapetum, and around the upper the upper lip of the calcarine fissure from their origin in the lateral geniculate nucleus (*see* Figs. 235, 236).

Since these bundles originate in the medial geniculate segment and since the destruction of the upper calcarine lip produces, in both Man and Monkey, a contralateral inferior quadrantic homonymous hemianopia, sparing the cen-

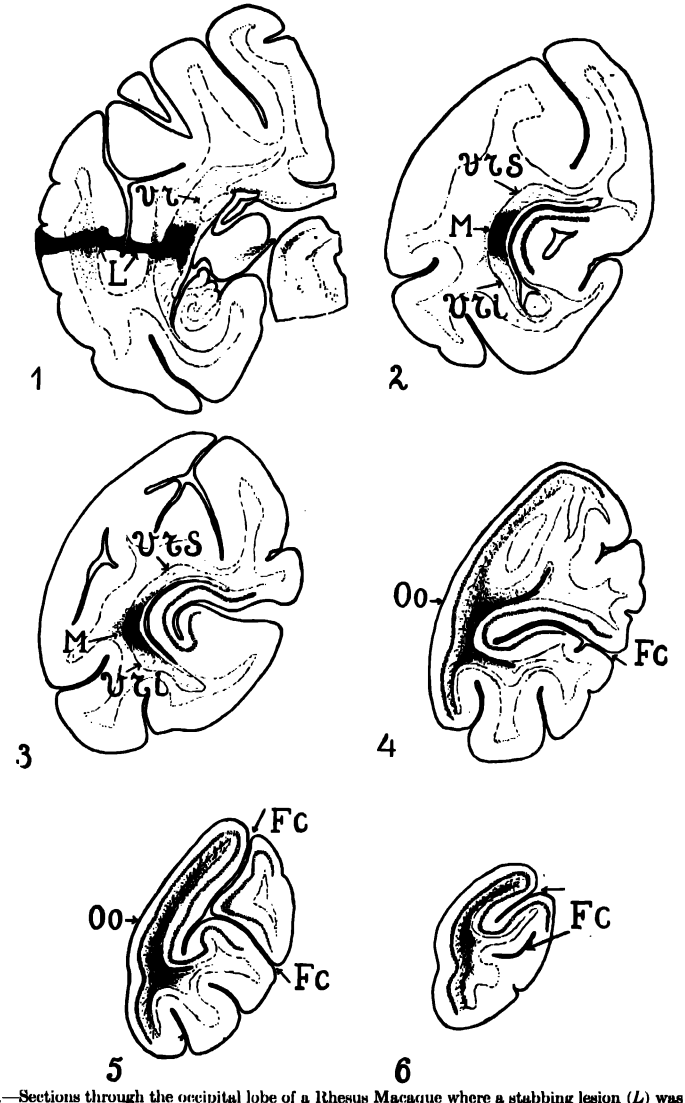

FIG. 241.—Sections through the occipital lobe of a Rhesus Macaque where a stabbing lesion (*L*) was made with Graefe's knife in one hemisphere at level *1*, which interrupted the intermediate foveal-macular segment (*M*) of the visual radiation. Note on subsequent posterior levels *2–6* the degenerated fibers passing over exclusively to the striate cortex on the lateral face of the occipital lobe (*Oo, left* in the figures), corresponding to the foveal-macular projection, leaving the upper and lower horizontal branches of the radiation (*vrs, vri*) and the two lips of the calcarine fissure (*Fc*) entirely free. The extent of the striate area or visual cortical center is indicated by the intracortical stripe of Gennari or Vicq-d'Azyr (*stippled line*). This experiment shows the intermediate branch of radiation and the opercular portion of striate area to belong, in the Monkey, to the central area and fovea, while the extrafoveal periphery is represented in the upper and lower branches of the radiation and in the anterior portion of the calcarine fissure, facing medially (*to the right*, in the figures). (*Cf.* preceding figures.)

ters of the fields of view around the fixation points, the conclusion is warranted that the upper segment of the visual radiation represents the upper extrafoveal quadrants of both homonymous retinal halves.

A duplicate of this experiment, with exactly the same result, may be attained when the lesion is located in the upper tier of the postvisual radiation; the adjoining parastriate area, or field *18*, beyond the limits of the stripe of Gennari and Vicq-d'Azyr, receives none (Figs. 239, 240).

When, in another experiment, the lesion, because it is in a slightly different location, interrupts a segment of the radiation somewhat closer to the axis of the fiber "fan," while leav-

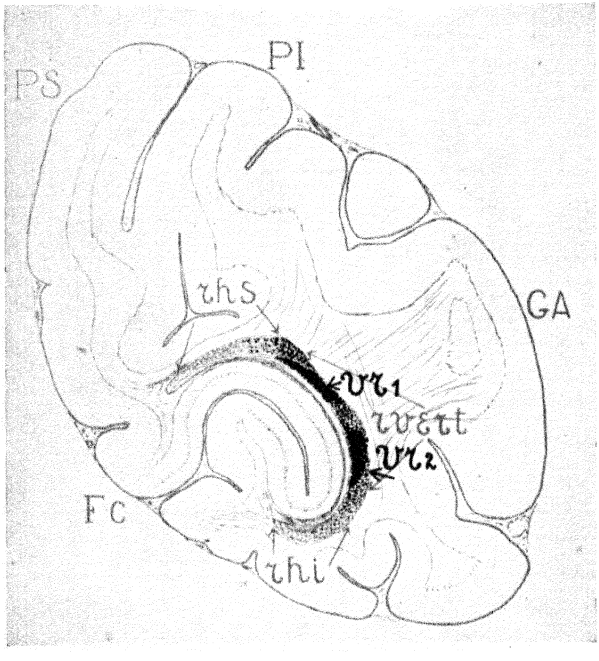

FIG. 242.—Another experiment in a Rhesus Macaque where two stabs were made with Graefe's knife in the intermediate or foveal-macular branch of the visual radiation (*rvert*), causing the degeneration of two fiber bundles (*vr1*, *vr2*), which could be separately followed to two distinct regions on the lateral face of the occipital lobe (*see* following figure). This experiment shows the composition of the visual radiation of nearly parallel fiber bundles which originate from distinct segments of the laminated lateral geniculate nucleus and terminate in distinct parts of the striate area. (*Cf.* Fig. 235). *Labeling: Fc*, calcarine fissure; *GA*, angular gyrus; *PI*, inferior parietal gyrus; *PS*, superior parietal gyrus; *rhi*, *rhs*, inferior and superior branches of the visual radiation; *rvert*, intermediate or vertical branch of the visual radiation. Marchi stain; low magnification. (*Cf.* preceding figures.)

terior limb of the internal capsule at some distance from the lateral geniculate nucleus. Here, too, the upper segment of the visual radiation alone degenerates and may be followed as far as the upper lip of the calcarine fissure.

These experiments, incidentally, also demonstrate that only the striate cortex, or Brodmann's field *17*, is supplied by the fibers of the visual radiation; the adjoining parastriate area, or field *18*, beyond the limits of the stripe of Gennari and Vicq-d'Azyr, receives none (Figs. 239, 240).

When, in another experiment, the lesion, because it is in a slightly different location, interrupts a segment of the radiation somewhat closer to the axis of the fiber "fan," while leaving the marginal segment intact, the degenerated fibers are seen to stream to the posterior portion of the calcarine fissure around its ascending prong (Fig. 238). In the anterior portion of the fissure, only a narrow zone close to the floor receives degenerated fibers, whereas the marginal zone in the upper lip receives none. This experiment also shows that when a seg-

ment of the striate area on more posterior levels of the occipital lobe becomes marginal, the afferent fibers strictly observe the boundary of the striate cortex (*17*), marked by the stripe of Gennari and Vicq-d'Azyr (indicated in Fig. 239 by an arrow).

3. ORIGIN, COURSE, AND TERMINATION OF THE INTERMEDIATE OR AXIAL SEGMENT OF THE VISUAL RADIATION.—When a lesion (*L*, Fig. 241, sketch *1*) interrupts the intermediate or axial segment of the visual radiation (*M*), that segment alone degenerates, whereas the upper (*vrs*) and the lower (*vri*) segments remain normal. In such an experiment the degenerated fibers of the intermediate segment may be followed continuously to the occipital operculum (*Oo*).

Since, on the basis of comparative anatomy (*see* chap. VIII, 2, 3) and from the experiments described in the remainder of this and the following sections, the opercular portion of the striate area in the Monkey is homologous with the posterior or polar portion of the human brain, it is apparent that the intermediate or axial segment of the visual radiation is related to both ipsilateral homonymous hemifoveae and central hemiareae of the retinae.

By the same token, the upper and lower segments of the radiation that flank the intermediate or axial segment, which in this experiment remained unaffected, represent the extrafoveal and extra-areal parts of the homonymous halves of the two retinae. The similarity thus revealed between the position of the foveal-areal fibers in the radiation and the position of the "papillomacular bundle" of the retina, flanked from above and below by the arching extrafoveal bundles, found close to the optic papilla or disk, becomes apparent (*cf.* chap. VI, 2).

When, in another similar experiment, two small bundles not far from each other (*vr1* and

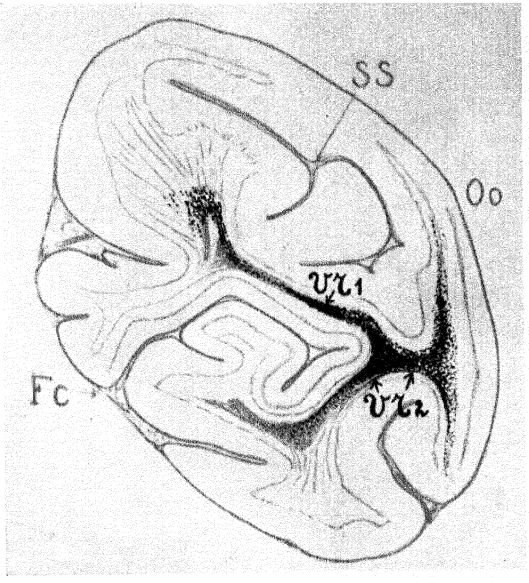

FIG. 243.—Section through the occipital lobe in the same experiment as in the preceding figure showing, on posterior levels, the Marchi-stained inferior degenerated fiber bundle (*vr2*) passing over to the lower segment of the striate area on the lateral face of the occipital lobe or operculum (*Oo*), while the upper bundle (*vr1*) reaches its destination in the upper segment of the same cortex, to appear on levels farther back. (*Cf.* preceding figures.)

vr2) are interrupted in the intermediate or axial segment of the radiation (*rvert*), they may be followed separately to two different localities of the occipital operculum (*Oo*), placed one above the other (Figs. 242, 243). As in the preceding experiment, here, too, no degenerated fibers pass to either lip of the calcarine fissure on the medial face of the hemisphere (*Fc*).

the lower lip of the calcarine fissure is underneath the lateral ventricle (Fig. 244).

When, in the Monkey, one temporal lobe is removed and the inferior segment of the visual radiation is interrupted, the ventrolateral segment of the laminated lateral geniculate nucleus is found to be degenerated (Fig. 244, *d*, in upper sketches; *cf. also* experiments in chap. VI, 7).

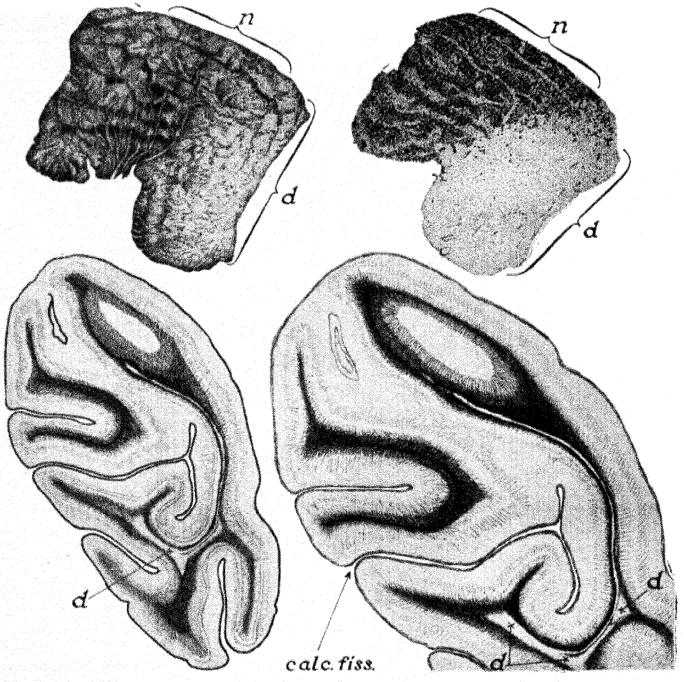

FIG. 244.—Sections through the lateral geniculate nucleus (*upper figures*) and through the occipital lobe (*lower figures*) of the brain of a Rhesus Macaque, where the temporal lobe of the same side was removed and the lower horizontal branch of the visual radiation was cut. As a consequence, the ventrolateral segment of the nucleus, *d* in upper sketches, degenerated in a retrograde sense, and in the occipital lobe the lower horizontal branch of the radiation, *d* in lower sketches, degenerated secondarily toward the striate cortex, specifically extending into the lower lip of the calcarine fissure (*calc.fiss.*). This experiment shows the origin of the lower horizontal branch of the visual radiation in the ventrolateral segment of the lateral geniculate nucleus and its termination in the striate cortex of the lower lip of the calcarine fissure.

4. ORIGIN, COURSE, AND TERMINATION OF THE LOWER SEGMENT OF THE VISUAL RADIATION.—Another experiment shows that the lower segment of the visual radiation originates in the ventrolateral segment of the laminated lateral geniculate nucleus and that its course to

The intermediate and dorsomedial segments of the geniculate nucleus, where the foveal-areal and upper extrafoveal fibers of the retinae terminate, are found to be normal (*n*). In the occipital lobe the lower segment of the external sagittal fiber layer is found to be devoid of

fibers as far as the inferior calcarine lip (*d*, lower sketches, same figure).

5. ADDITIONAL EXPERIMENTS ON THE RETINOTOPICAL ORGANIZATION OF THE VISUAL RADIATION.—Another and technically easier experimental method of analyzing the internal make-up of the supranuclear division of the visual pathway is to remove portions of the striate cortex of various sizes and from different locations and study the segments of the lateral geniculate nucleus showing retrograde degeneration. In these experiments it is preferable to use the Nissl method of staining.

When, with this purpose in mind, two lesions are made in a monkey on the medial side of the occipital lobe, the larger lesion undermining a substantial part of the striate cortex in the lower calcarine lip (marked with * in Figs. 245, 246) and the smaller lesion superficially damaging the striate cortex in the upper calcarine lip close to the ascending prong of the calcarine fissure (marked with # in same figures), two zones are found in the laminated lateral geniculate nucleus of the same side where cells have degenerated in the retrograde sense (Figs. 247, 251, photo *1*). The larger zone is located in the ventrolateral (*), the smaller zone in the ventromedial (#), segment of the nucleus.

This observation confirms, on the one hand, the projection of the lower extrafoveal quadrants upon the ventrolateral segment and of the upper extrafoveal quadrant of the two homonymous halves of the retinae upon the ventromedial segment of the lateral geniculate nucleus, as described in chapter VI, 7 (Fig. 225). On the other hand, the same experiment also confirms the origin and termination of the various segments of the visual radiation, as determined by a different technique in experiments presented in the preceding subsections of this section.

The large intermediate segment of the nucleus, flanked by the two partly degenerated segments, is found intact. It is in this segment where the foveal and central-areal fibers of the two retinae terminate, as found in chapter VI, 7. This observation corroborates the fact that the striate cortex over the occipital operculum was not interfered with. The evidence favoring the striate area over the simian occipital operculum as the locality where the homonymous halves of the foveae and central areae are represented in turn corroborates its homology with the posterior portion of the human striate area close to, and at the pole of, the occipital lobe (*see* chap. VIII, 2, 3).

Positive evidence that the striate area, which lines the lateral convexity of the occipital lobe,

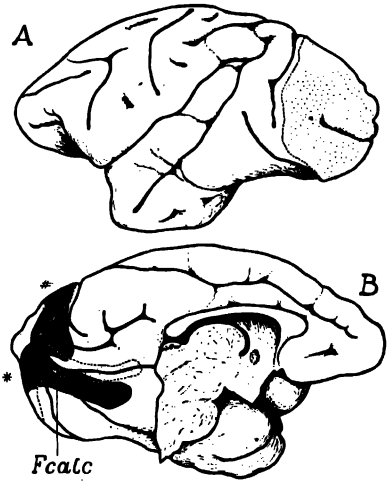

FIG. 245.—Lateral face (sketch *A*) and medial face (sketch *B*) of the brain of a Rhesus Macaque where both lips of the calcarine fissure (*Fcalc*) were undermined experimentally (*black*). The extent of the damage is presented in serial sections in the following figure, which shows the lesion in the lower calcarine lip, marked with an asterisk (*), larger than that in the upper lip (#). A larger and a smaller zone of retrograde degeneration in the ventrolateral and medial segments of the lateral geniculate nucleus of the same side were found, showing these segments to be related to the striate cortex of the two calcarine lips (*white stippling* in sketch *B*), while the occipital operculum (*black-stippled* area in *A*), where the foveal-macular fibers terminate, and the intermediate segment of the nucleus, where they originate, remained normal. (*Cf.* two following figures, and photo *1*, in Fig. 251.) (This and Figs. 246–58 taken from S. Polyak, "A contribution to the cerebral representation of the retina," J. Comp. Neurol., v. 57, p. 541, 1933.)

represents the homonymous foveal and central-areal halves of the two retinae is furnished by the following experiment.

A large portion of the cortex over one occipital operculum of a monkey was destroyed (Fig. 248, upper figure, lesion in solid black). There

was also some damage done to the underlying vertical or intermediate segment of the visual radiation (Fig. 249). In the lateral geniculate nucleus of the same side, the intermediate segment was found solidly degenerated, while the lateral and medial segments remained normal (Fig. 248, lower figure; Fig. 250, degeneration given in black; *also* photos *2* and *4*, Fig. 251).

In this way the chain of experimental anatomical evidence is completed. It demonstrates the same plan as in the Monkey. Here, too, the upper bundles arising from the medial portion of the laminated lateral geniculate nucleus terminate in the upper lip, and the lower bundles originating in the lateral portion of the geniculate nucleus terminate in the lower lip of the calcarine fissure. Those bundles which arise from the intermediate segment of the nucleus and represent the axis of the radiation terminate in the posterior portion of the striate area

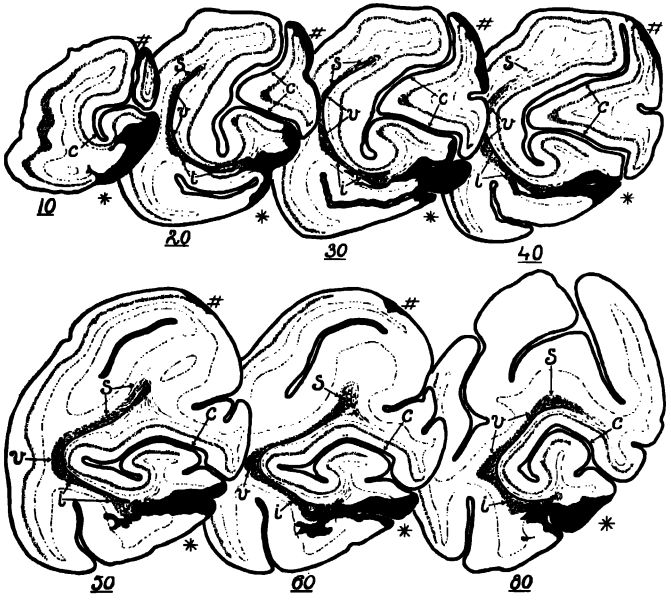

Fig. 246.—Coronal sections through the occipital lobe of a Rhesus Macaque, approximately equally spaced, showing the two lesions in the upper and lower lips of the calcarine fissure (*c*) made experimentally (* and #; *see* preceding figure). The lesion in the lower lip (*i*) is more extensive than that in the upper lip, the first also undermining the lower horizontal branch of the visual radiation, the other damaging only superficially the striate cortex, recognizable by the stippled intracortical stripe of Gennari. The upper (*s*) and the vertical branches (*v*) of the radiation remained undamaged. As a consequence, a larger (*) and a smaller zone (#) of retrograde cell degeneration were found in the lateral geniculate nucleus of the same side, showing the relationship of the two cortical and geniculate localities to each other. (*Cf.* following figure.)

a discrete representation, by quadrants, of the extrafoveal periphery of the homonymous retinal halves and of the central foveae, both in the visual radiation and in the visual cortical center, the striate area of the occipital lobes (Figs. 259, 260).

In Man the gross arrangement of the segments of the visual radiation follows essentially at the occipital pole. A study of carefully dissected brain specimens (Figs. 235, 236), with the analysis of the pathological cases described in Part III of this book, does not leave any doubt on this point.

As an over-all result, the positive evidence indicates that the two peripheral receptor surfaces—the retinae—are represented in the two

striate areae and in no other territory of the cerebral cortex. They are here represented not *in toto*, as O. Foerster (1929) imagined, but according to a strictly topographical principle; each single point of the monocular portion of one retina and each two "corresponding points" of the binocular portions of both retinae are represented in a single locality of either the one or the other striate area.

Outside the striate area the retinae are not represented either globally or in detail. This must be especially emphasized in connection with the central fovea-area, or "macula," for which a "second representation" outside the striate area, possibly outside the occipital lobe, has been claimed (Monakow, Balado *et al.*, Hyndman, Putnam, Fox & German, and others). The evidence reveals the fovea to be represented, like the remainder of the retina, in its own discrete segment of the striate area, namely, at the occipital pole. (*See* chap. XI, 8, 9, and chap. XII, 10, for additional discussion of the prob-

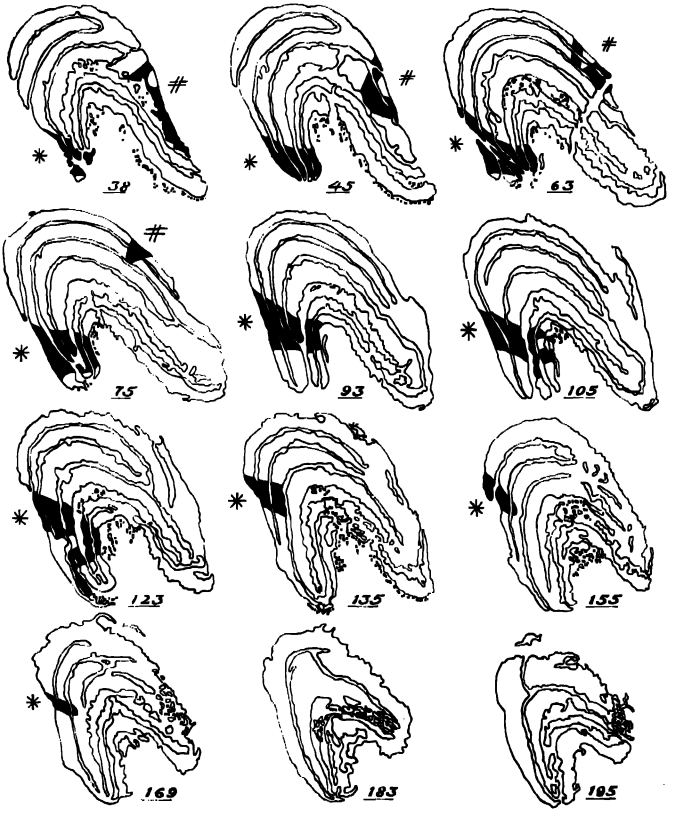

FIG. 247.—Serial sections through the lateral geniculate nucleus of the same cerebral hemisphere where two lesions were made, the larger in the lower lip and the smaller in the upper lip of the calcarine fissure (*see* preceding figures). In the lateral geniculate nucleus two zones were found where the cells degenerated in a retrograde sense: a more extensive one in the ventrolateral segment (*) and a smaller one in the medial segment (#). This experiment, where a different method was used, shows a topographical relationship of the upper and lower calcarine lips to the medial and lateral segments of the lateral geniculate nucleus, demonstrating a discrete cortical representation of the retinal surface in the striate area of the occipital lobes. (*Cf.* Figs. 237–44.)

lem of cortical representation of the fovea-macula.)

SEC. 5. ELEMENTAL COMPOSITION OF THE VISUAL RADIATION AND THE TRANSMISSION OF RETINAL IMAGES TO THE CEREBRAL CORTEX

1. GENERAL EVIDENCE IN SUPPORT OF DETAILED RETINOTOPICAL ORGANIZATION OF THE VISUAL RADIATION.—In the preceding sections

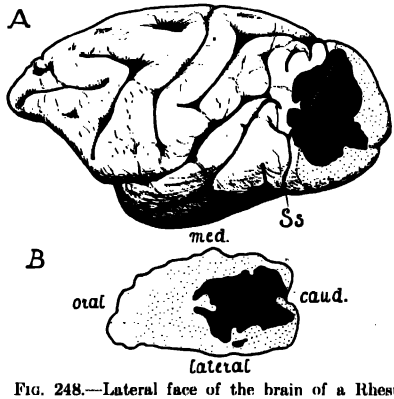

FIG. 248.—Lateral face of the brain of a Rhesus Macaque (sketch *A*), where a single lesion, shown in black, was made in the striate area (*stippled*) of the occipital operculum along the simian sulcus (*Ss*). In the lateral geniculate nucleus of the same side a zone of retrograde cell degeneration (*black*) was found in the intermediate or foveal-macular segment, shown serially in Fig. 250, whose dorsal view is given in sketch *B*. This experiment shows the projection of the intermediate segment of the nucleus, and hence of the fovea-macula, upon the portion of the striate area located on the lateral face of the occipital operculum, a homologue of the occipital pole in the human brain. (*Cf.* following figures.)

of this chapter experimental anatomical evidence has been adduced in substantiation of the claim that the upper and lower extrafoveal quadrants of the homonymous halves of both retinae and also the homonymous halves of both central foveae and areae are separately represented in the visual radiation and in the striate area. It is now necessary to examine whether the representation of the surface of the two retinae in the laminated lateral geniculate nuclei, in the visual radiations, and in the striate areae is more than roughly quadrantic, and, if so, whether the minuteness or the "grain" of the cortical representation approaches the one theoretically postulated. (*See* chap. IV, 4, on the problem of retinal representation in the brain.)

A general indication that the retinal representation in the visual radiation and in the striate area is more than "global" or roughly quadrantic is evidenced by a sharp linear demarcation between the normal and degenerated fiber segments in the radiation or between the zones of the normal and degenerated cells in the laminated lateral geniculate nucleus. This is the rule, no matter what the size and location of the segments or zones, provided that the lesions in the radiation or in the striate area are well defined. Such localized and sharply outlined zones of degeneration as those depicted, e.g., in Figs. 251 (*2, 4*) and 255, are difficult to reconcile with the hypothesis of a diffuse, haphazard arrangement of the conductor units. They agree, however, with the concept of an orderly two-dimensional or "spatial" arrangement both of the nerve cells and of their axis cylinders or fibers on a cross-section through the supranuclear division of the visual pathway, in a way similar to that found in the infranuclear division (chap. VI, 7).

2. EXPERIMENTS ON DETAILED ANATOMICAL REPRESENTATION OF THE RETINAL SURFACE IN THE VISUAL RADIATION AND IN THE STRIATE AREA.—In order to determine experimentally how detailed the intrinsic organization of the visual radiation was, several minute lesions were made in the striate area of a monkey on the convex, lateral aspect of the occipital lobe, the "occipital operculum" (*a, b, c, d,* in Fig. 252, upper figure). The lesions were small enough to be confined to the cortex without involving the subcortical fiber substance and were separated from one another by strips of normal cortex (Fig. 253). They varied somewhat in shape and in size, which facilitated the identification of the resulting zones of degeneration.

In the laminated lateral geniculate nucleus of the same side, cut serially, four minute zones of degeneration were found, each passing through all six cell layers (Fig. 254; *also* Fig. 255). These zones closely correspond with the four lesions in size and location. Zone *a* was closest to the posterior extremity and in the ventrolateral half of the nucleus (sketches *2–5*). Beyond the gap of forty sections there were three other zones (*b, c, d*) running almost parallel with one another and at somewhat varying distances from one another: the distance between *b* and *c* was only half that between *c* and *d*. Also, all four zones were located in the somewhat smaller posterior half of the nucleus (secs. *264–390*), the anterior half of the nucleus showing no degeneration (secs. *391–600*).

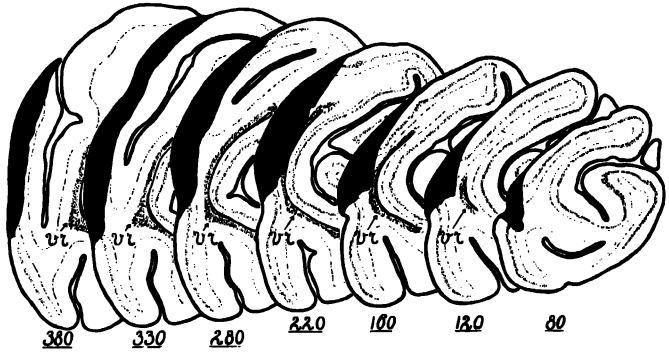

FIG. 249.—Serial sections through the occipital lobe or operculum of a Rhesus Monkey shown in the preceding figure, to demonstrate the extent of the lesion (*black*) and the damage done to the striate area (*stippled*) and to the visual radiation (*vr*). Since in this experiment the opercular portion of the striate area, or its fibers in the vertical branch of the radiation, alone suffered damage, the zone of retrograde degeneration also was confined to the intermediate or foveal-macular segment of the lateral geniculate nucleus. The striate area is identified by the stippled intracortical stripe of Gennari. (*Cf.* preceding and following figures.)

The principal feature of each lesion was its location in the striate area. Of the four lesions which in this particular experiment produced recognizable zones of retrograde degeneration in the laminated lateral geniculate nucleus, the smallest lesion (*a*) was closest to the anterior boundary of the striate area along the simian sulcus (*Ss*). The other three lesions (*b, c, d*) were all farther back and at about the same distance from that sulcus. The largest of these (*b*) was close to the superior margin of the hemisphere. The distance separating it from the middle lesion (*c*) was smaller than the distance

Considering the topographical relationship between the retinal surface and the laminated lateral geniculate nucleus found in the preceding experiments (chap. VI, 7) and the relationships between that nucleus and the visual radiation and striate area described in sections 3 and 4 in this chapter, the interpretation of this experiment offers no difficulties. The confinement of all four zones of degeneration to the posterior

half of the nucleus is obviously because all four lesions are located in the external, opercular portion of the striate area, which, in the Monkey, represents the homonymous halves of the central areae and foveae, as pointed out in section 4 (3) in this chapter, and in chapter VIII, 2, 3.

Zone *a*, closest to the posterior tip of the nucleus, shown in the right lower sketch in Figure 252, standing alone, in its relationships resembles lesion *a* close to the "anterior," but, actually, the posterior, limit of the striate area which represents the vertical meridians. Zones *b*, *c*, and *d* are all found at approximately the same distance from the caudal tip of the nucleus, just as the corresponding three lesions are located at about the same distance from the "posterior" boundary of the striate area along the simian sulcus *Ss*. The relative distances between these three zones and their relative sizes are also an accurate copy of the sizes and distances between the three lesions in the striate area. Taking all these facts together, it is obvious that the zones of degeneration in the lateral geniculate nucleus in this experiment are, in all particulars, an accurate copy of the lesions made in the striate area of the same side.

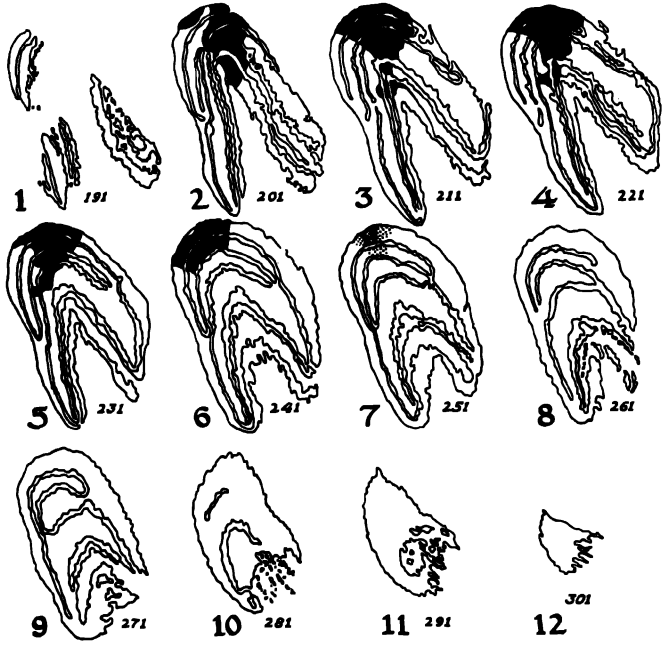

FIG. 250.—Serial sections through the lateral geniculate nucleus from its posterior (*1*) to its anterior extremity (*12*), from the experiment with a Rhesus Macaque where a single lesion was made in the occipital operculum of the brain (Fig. 248). A single zone of solidly degenerated nerve cells was found in the intermediate segment of the nucleus, showing this locality and the operculum to be related to the foveal-macular, or "central," vision. (*Cf.* preceding figures, and photos *2* and *4* in the following figure.)

The foregoing experiment and other similar experiments clearly suggest a stable two-dimensional arrangement of the minute fiber bundles in the visual radiation, beginning with their geniculate origins and extending to their respective terminations in the striate area. The principle which seems to be strictly observed is that the fibers which originate from the adjoining cell groups in the geniculate nucleus also ter-

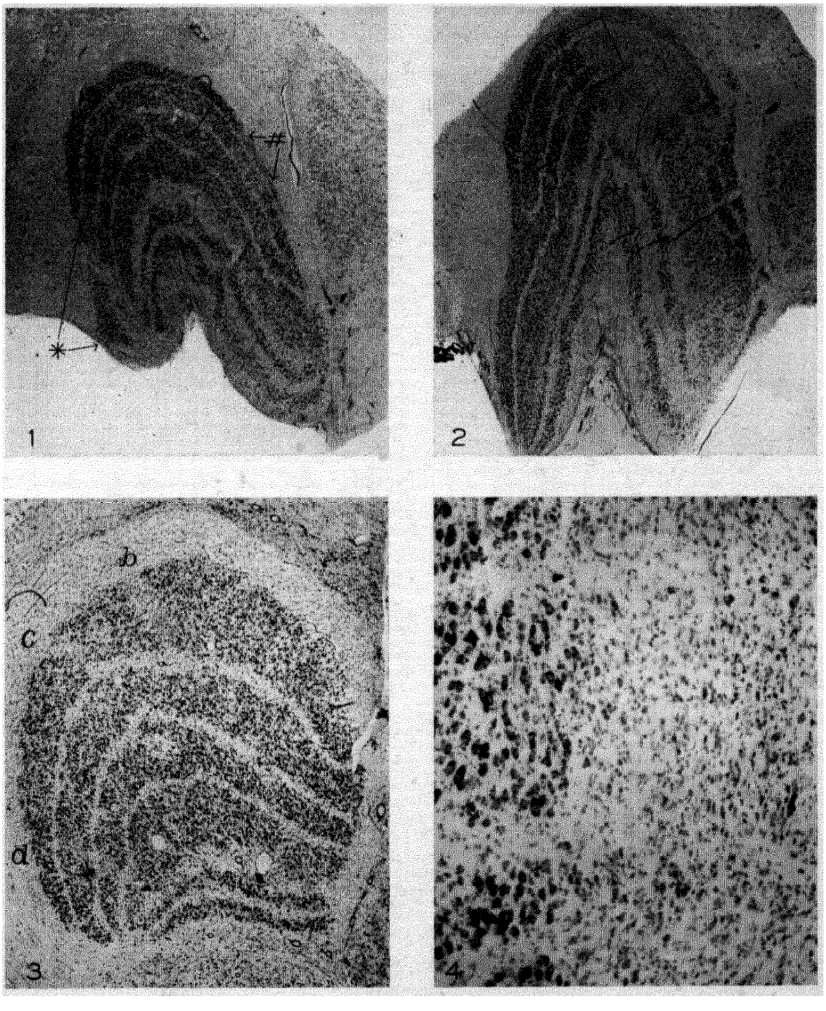

FIG. 251.—Microphotographs of Nissl-stained sections of the lateral geniculate nuclei from experiments with variously located lesions in the visual system of the Rhesus Macaque to show the resulting zones of retrograde cell degeneration. Photo *1* from the experiment where two lesions were made in the calcarine fissure, resulting in two degenerated zones, a larger one in the ventrolateral segment (*) and a smaller one in the medial segment (#) of the nucleus (*cf.* Figs. 245, 246, 247). Photos *2* and *4* show a single zone in the intermediate segment at low and high magnification; note shrunken and poorly stained nerve cells and increased neuroglial nuclei (*cf.* Figs. 248, 249, 250). Photo *3* shows three of the four minute zones of retrograde degeneration in the lateral geniculate nucleus (*b*, *c*, *d*) of a Rhesus Macaque, where the opercular striate area was slightly damaged in four places (*cf.* Figs. 252–55). Note the remarkably straight, almost linear, demarcations of the zones of degeneration.

minate close together in the striate area. Since exactly the same arrangement, except for the crossing of the nasal fibers in the chiasma and their doubling-up in the tracts with the uncrossed fibers, is present in the infranuclear and nuclear divisions of the visual system, the conclusion cannot be avoided that the distribution of the functional units in the striate areae resembles their distribution in the retinal membranes.

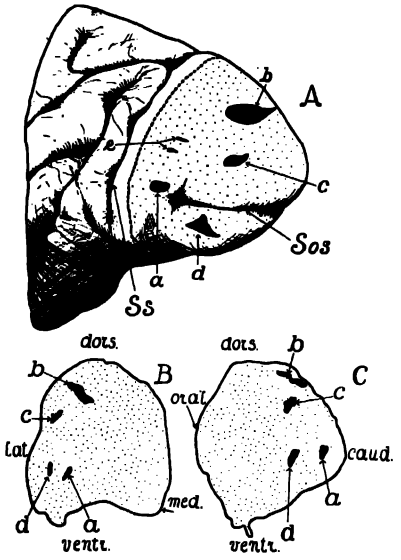

FIG. 252.—Upper figure *A* shows a lateral aspect of the left occipital lobe or operculum of a Rhesus Macaque with four small lesions (*a*, *b*, *c*, *d*) made in the foveal-macular portion of the striate area (*stippled*), its boundary parallel to the simian sulcus (*Ss*), the occipital lobe showing a slight horizontal dent: the incipient lateral calcarine sulcus (*Sos*) further discussed in chap. VIII. The four lesions caused cells to degenerate in four minute zones of the lateral geniculate nucleus of the same side which, in their size and topographic arrangement, were a replica of the four cortical lesions. The two additional lesions *e*, because of their almost microscopic size and superficial location, however, did not reveal themselves by a noticeable retrograde degeneration. Sketch *B* shows a posterior aspect, sketch *C* a lateral aspect, of a plastic model of the left lateral geniculate nucleus, with the surface arrangement of the four degenerated zones as follows: zone *a*, smallest of the four zones, was located close to the posterior tip of the nucleus, since lesion *a* was close to the anterior limit of the striate area; the larger three zones, *b*, *c*, and *d*, were located in front of it and arranged in a straight line, as were the three larger lesions in sketch *A*. (*Cf.* following four figures.) *Labeling: caud*, caudal or posterior extremity of lateral geniculate nucleus; *dors*, dorsal or upper extremity of same; *lat*, lateral side of same; *med*, medial side of lateral geniculate nucleus; *oral*, oral or anterior extremity of same nucleus; *Sos*, lateral calcarine sulcus; *Ss*, simian sulcus; *ventr*, ventral or inferior face of lateral geniculate nucleus. (For further details *see* S. Polyak, "A contribution to the cerebral representation of the retina," J. Comp. Neurol., v. 57, p. 541, 1933.)

The only points in which the fidelity of the cortical representation of the retinae, in addition to the doubling-up of the ipsilateral and contralateral homonymous fibers, needs to be qualified are the relative sizes of the units and their slight shifting or displacement in order to become adapted to a different surface configuration in the cortex.

In the retina, owing to the compelling physical factor—the nature of light—the foveal units are very small, especially in the central fovea, gradually increasing in size in the extrafoveal regions. In the striate area, where space is less severely restricted and function obviously demands a greater mass of the nervous substance in each unit, exactly the opposite is true, the units gradually increasing in size toward the fixation points. The mass of the functional units and the number of constituent cells are very much greater in the central nervous system than in the peripheral.

3. EXPERIMENTAL ANATOMICAL EVIDENCE FOR A TRANSMISSION OF "FIGURES" FROM THE LATERAL GENICULATE NUCLEUS TO THE CEREBRAL CORTEX.—In order to verify the correctness of the deduction made from the preceding experiments, various lesions, resembling simple figures, were made in the occipital operculum in a number of monkeys. Due consideration was given, first, to the blood supply, also that the lesions remained cortical, and, finally, that they were not complicated by damage to the intervening cortex.

In the following experiment the "cortical figure" resembled a reversed letter *C* (Fig. 256, upper figure *A*). When the occipital operculum of the simian brain is imagined turned back and the striate area spread in one plane, a condition is created resembling that normally found in the human brain. In this case, the C-shaped lesion was located in the posterior foveal-areal portion of the striate area, the concavity of the letter

facing the corpus callosum (lower sketch C).

In the lateral geniculate nucleus of the same side, in the posterior half, a complex zone of retrograde degeneration was found (Fig. 258). In spite of its complexity, when taking into account the information obtained from the preceding experiments it was possible to make an accurate correlation between various parts of the cortical lesion and the geniculate zone of degeneration.

Particularly striking was the similarity between the lesion in the striate area and the zone of degeneration in a model of the lateral geniculate nucleus. Presented in this way, the zone of degeneration, in its location and shape, appeared as only a slightly distorted replica of the cortical lesion (Fig. 256, middle sketch *B*).

The result of this experiment shows that the arrangement of the cell and fiber units which compose the supranuclear division of the visual system is very detailed, permitting an accurate transmission of two-dimensional retinal "figures," greatly varying in shape, size, and location, via the laminated lateral geniculate nucleus to the striate area of the same side. This agrees with clinical experience and recent physiological experiments.

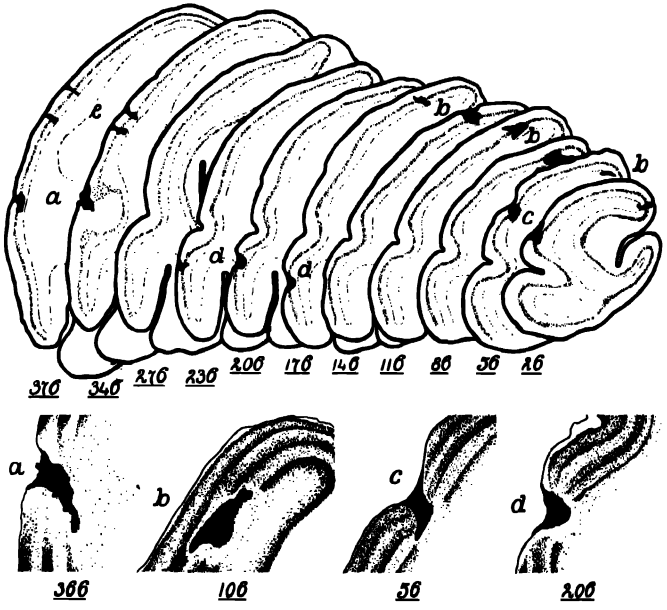

Fig. 253. – Upper diagram shows serial sections through the left occipital lobe of a Rhesus Macaque (Fig. 252), with the four small lesions of the striate area, *a*, *b*, *c*, and *d*, resulting in four minute zones of retrograde degeneration in the lateral geniculate nucleus (Fig. 254), and the two almost microscopic lesions *e* whose zones could not be detected. The four sketches in the lower row show, slightly magnified, the four lesions where they attain their maximum size. Note the smooth boundaries of the lesions and their almost strict limitation to the cortex. (*Cf.* preceding and following figures.)

SEC. 6. SUMMARY OF THE INTRINSIC ORGANIZATION OF THE SUPRANUCLEAR DIVISION OF THE VERTEBRATE VISUAL SYSTEM

1. GENERAL REMARKS.—The visual system of Man and other Primates and of the Vertebrates in general is a well-defined and elaborately organized system of neurons (Fig. 180). It is composed of three subdivisions, an infra- and a supranuclear and an intermediate linking the two.

The infranuclear division is represented by the photoreceptors and other nerve cells that constitute the retinal membranes, including the axis cylinders of the retinal ganglion cells, commonly called optic nerve fibers. These fibers form the two optic nerves, their junction, or the chiasma, and the two optic tracts. The chiasma, specifically its middle portion, is made up of decussating fibers which originate in the larger nasal halves; its lateral parts consist of the non-decussating fibers originating from the smaller temporal halves of the two retinae. The optic tracts, accordingly, are mixed, each tract con-

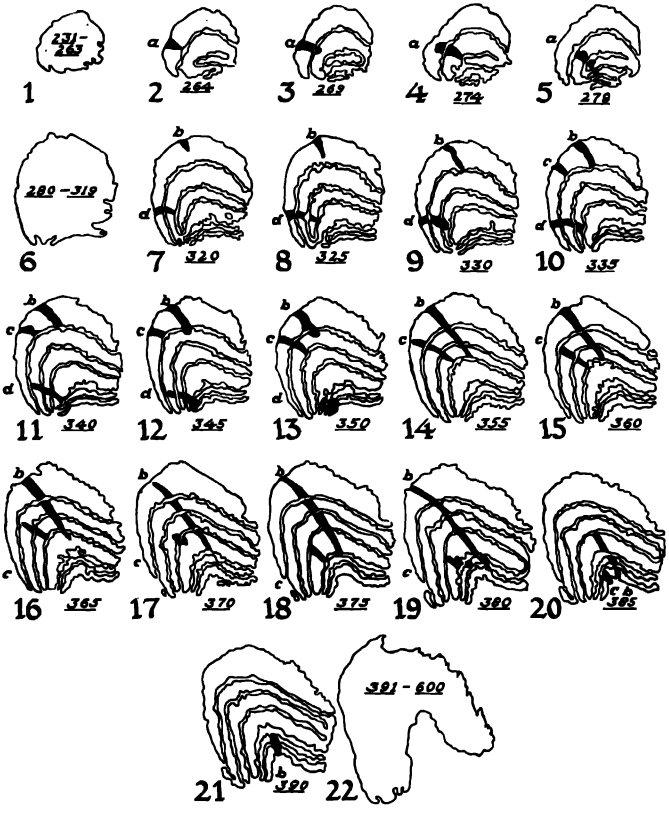

FIG. 254.—Serial sections through the lateral geniculate nucleus of a Rhesus Macaque from its posterior tip (*1*) to its anterior extremity (*22*), showing the four retrograde zones of degeneration caused by the four minute lesions made in the striate area of the occipital operculum (Figs. 252, 253). The size and the location of the zones are in fair agreement with those of the four lesions shown in the preceding figures.

taining both decussating and nondecussating fibers originating in the ipsilateral homonymous halves of both retinae.

The optic nerve fibers terminate in the subcortical visual centers of the brain stem, which represent the intermediate or nuclear division of the visual system. There are at least four such centers in each half of the brain: the laminated lateral geniculate nucleus or body, which is the principal station; the gray pregeniculate (and parageniculate) nucleus; the superior colliculus of the midbrain; and the pulvinar of the thalamus. In the laminated lateral geniculate nucleus, the identical homonymous decussating and nondecussating fiber bundles terminate close to each other in segments of two sets of separate but adjacent cell laminae.

The supranuclear division of the visual system is represented by the axis cylinders originating from the nerve cells of the laminated lateral geniculate nuclei. Other extensive fiber systems which originate in the pulvinars of the thalami, as far as is known, are not concerned with the direct transmission of unmodified visual impulses to the cerebral cortex and may therefore not be regarded as parts of the afferent

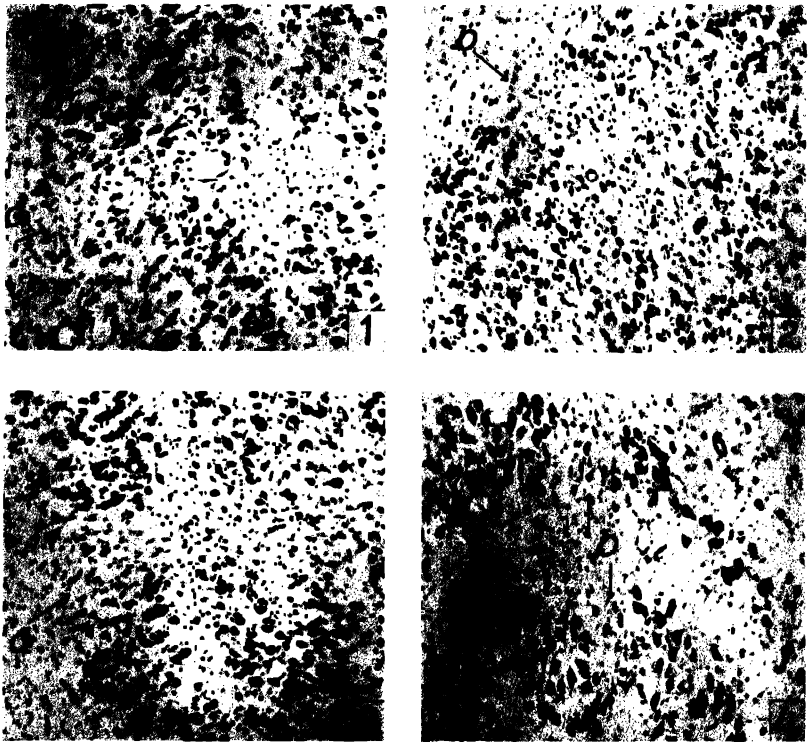

FIG. 255.—Microphotographs of three of the four minute zones found in the lateral geniculate nucleus of a Rhesus Macaque where the nerve cells degenerated in a retrograde sense, in an experiment where four small lesions were made in the striate area of the occipital operculum. Note advanced state of shrinkage of the nerve cells, straight boundaries of the zones, their passage through several cell laminae, and an increase in neuroglial nuclei in the zones. This experiment shows the detailed "projection," or representation, of very small territories of the retinal surface upon the striate area, or visual center, of the brain. (*Cf.* Fig. 251, photo *3*, and Figs. 252, 253, 254.)

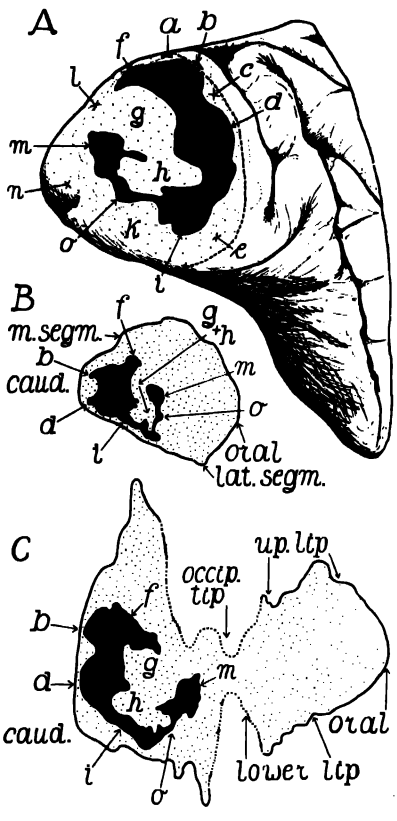

FIG. 256.—Upper sketch *A* shows a lateral view of the posterior portion of the right hemisphere of the brain of a Rhesus Macaque with the C-shaped lesion (*black*) made in the striate area (*stippled*) of the occipital operculum. Lower sketch *C* shows the entire right-sided striate area spread in a single plane, showing the position of the C-shaped lesion in the posterior opercular portion of the area. The middle sketch, *B*, shows the upper aspect of a plastic model of the right lateral geniculate nucleus, with the location of the retrograde degeneration, caused by the lesion in the striate area. The lettering, identical in all three sketches, shows the various details of the lesion or of the degeneration. Note great similarity between the lesion and the zone of degeneration (which, however, are inverted in sketches *B* and *C*). This experiment furnishes evidence in support of the "point-to-point representation" of the retinal surface in the visual cortical center, which makes possible an accurate transmission of images from the eyes to the brain. (*Cf.* following figures.) *Labeling: caud*, caudal or posterior extremity; *lat.segm.*, lateral segment of lateral geniculate nucleus; *lower lip*, lower lip of calcarine fissure; *n.segm.*, medial segment of lateral geniculate nucleus; *occip.tip*, *o.t.*, pole of occipital lobe; *oral o.*, anterior extremity of lateral geniculate nucleus; *up.lip*, upper lip of calcarine fissure.

visual pathway in the usual restricted sense. The pregeniculate nuclei and the superior colliculi give rise to fibers which do not pass over to the cerebral cortex.

The fibers which originate in the laminated lateral geniculate nuclei form the visual radiations contained in the external sagittal fiber layers of the parietotemporo-occipital lobes. Each visual radiation is strictly a unilateral system, no part of it crossing to the contralateral hemisphere by way of the corpus callosum. The "decussating callosal bundle" of Heine, Niessl von Mayendorf, Pfeifer, and others does not exist.

The fibers of the visual radiation terminate in the cortex, which lines the calcarine fissures as far as the poles of the two occipital lobes. The terminal areae coincide with the striate areae, distinguished by the white intracortical stripe of Gennari or Vicq-d'Azyr. No portion of cortex outside the striate areae receives afferent visual fibers.

2. RETINOTOPICAL ORGANIZATION OF THE SUPRANUCLEAR DIVISION OF THE VISUAL SYSTEM.—From its origin in the laminated lateral geniculate nuclei to its termination in the striate areae of the cerebral cortex, the supranuclear division of the visual system is elaborately organized topographically. In this way the detailed two-dimensional representation or "projection" of the retinal surfaces is continued as far as the striate areae (Figs. 259, 260; *cf.* Fig. 225).

The arrangement or representation of the retinal quadrants on various levels is as follows: the right upper extrafoveal-areal homonymous binocular quadrants of both retinae (black with white shading in *LR* and *RR*, Fig. 259) are in the dorsomedial segment; the right lower extrafoveal-areal quadrants of the retinae are in the ventrolateral segment; the corresponding homonymous quadrants of the central foveae and areae are in the intermediate segment; the extreme nasal monocular portion of the left retina

is in the lower inner edge, of the right optic tract (right *OT*).

In the right laminated lateral geniculate nucleus (right *LGN*) the arrangement is the same, except that the lateral and medial extrafoveal-areal segments decrease, while the intermediate foveal-areal segment increases in size toward the posterior extremity of the nucleus. Topographical representation is also present in the pregeniculate nucleus and in the superior colliculus.

In the right visual radiation (right *VR*) and in the calcarine striate area of the right occipital lobe (*RSA*) the upper and lower right homonymous retinal quadrants are represented in a similar way: the upper extrafoveal-areal quadrants in the upper segment, the lower extrafoveal-areal quadrants in the lower segment, and the foveal-areal quadrants in the intermediate or axial segment of the radiation, flanked by the two extrafoveal-areal segments.

The foveal-areal fibers, accordingly, fill in the "anatomical interval of radiation" of G. Holmes (1918, 1931) in the same way as the "papillomacular bundle" does in the retina, as suggested by H. Rønne (1919).

In the striate area of the right calcarine fissure, the upper lip approximately represents the upper, the lower lip the lower, right homonymous retinal quadrants. The zones or belts of the right homonymous halves of both hemiretinae are arranged in succession along the right half of the horizontal meridians, approximately corresponding to the floor of the calcarine fissure of the right occipital lobe (*f HM* and *f hm*).

The most peripheral nasal monocular portion of the left retina (in *LR*) is represented in the anteriormost segment (close to the right-hand *HM* or *hm*, in *RSA*), the foveal centers in the posteriormost, polar portion (next to *f*), with the remainder arranged in an orderly manner, zone after zone, in the rest of the right striate area.

The fixation points are at the occipital pole (*f*), the right halves of both horizontal retinal and field meridians (*HM*, *hm*) approximately along the floor of the right calcarine fissure, whereas the principal vertical meridians are identical with the posterior boundary of the striate area at the right occipital pole (*VM*, *vm*).

The left homonymous halves of both retinae (lightly shaded in *LR* and *RR*) are symmetrically represented in the same way in the optic tract, lateral geniculate nucleus, visual radiation, and striate area of the left cerebral hemisphere (left sketches in Figs. 259, 260).

The representation of the surface of the reti-

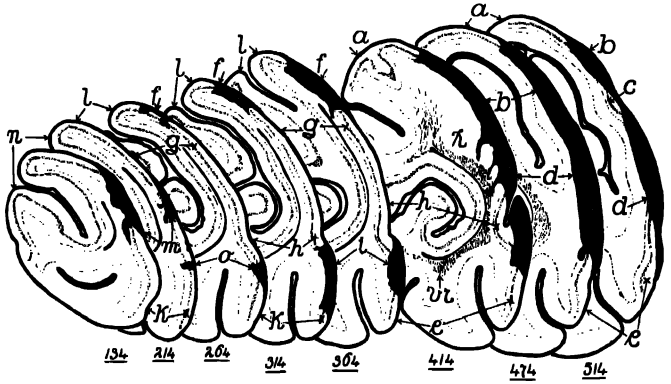

FIG. 257.—Serial sections through the occipital lobe of the preceding figure, to show location and extent of the lesion (*black*) in the striate cortex indicated by the presence of a stippled cortical stripe of Gennari or Vicq-d'Azyr. Note that in only a few localities the lesion extends as far as the sagittal fiber layers containing visual radiation, *vr* (thus at *x* in section *4/4*), remaining in other sections confined to the striate cortex and its immediate vicinity. (*Cf.* preceding and following figures.)

nal membranes in the visual pathways and centers, however, is not merely by quadrants but is much more detailed, approaching, in fact, a physiologically postulated point-to-point representation. The entire afferent visual system may be compared to a complex cable made up of individual conductors arranged throughout the whole system essentially according to the same plan.

small, numerous, and close together. Farther away they are larger and separated by larger intervals. The keys in each keyboard are grouped from the center to the periphery along the meridians, each having its own definite space value in the two-dimensional plane of the keyboard.

In the initial portion of the system, in the two optic nerves, the same approximate relative

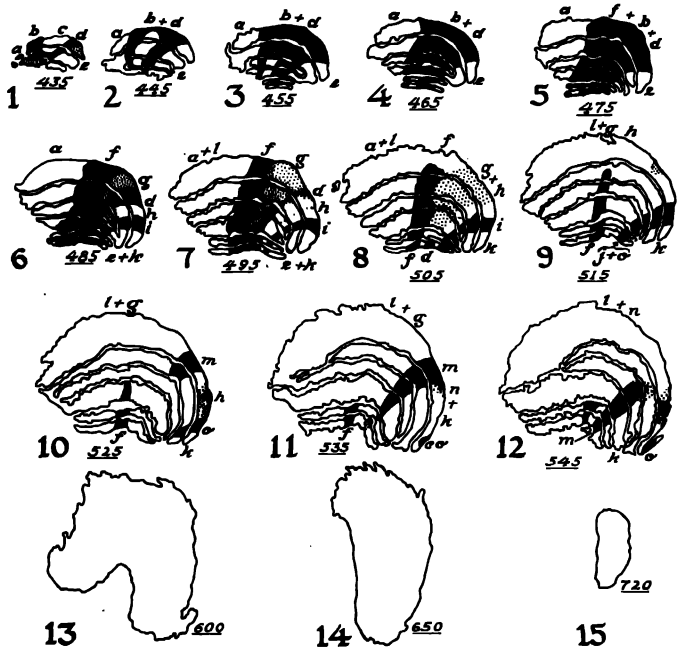

FIG. 258.—Serial sections through the lateral geniculate nucleus of the right side from its posterior (*1*) to its anterior extremity (*15*), to show the location and extent of the complex zone of retrograde degeneration caused by the C-shaped lesion in the occipital operculum. The lettering makes possible the identification and correlation of the various parts of the zone and of the lesion. Note the passing of the zone (*black*) through all cell layers of the nucleus down to the hilum, and its confinement to the posterior half of the nucleus (from section *435–545*). (*Cf.* preceding two figures.)

The two peripheral photoreceptors—the retinae—may be compared in this respect with two large keyboards made up of hardly less than one hundred thousand keys each. Every key is connected by its own independent conductor to the subcortical intermediate station and, through it, to the terminal station in the cortex. In the centers of the keyboards the keys are very

arrangement as in the retinal keyboards obtains. This is also true of the next section, the optic tracts, except for the decussation of the nasal fibers and their joining with the fibers which do not decussate.

In the subcortical relay stations—the lateral geniculate nuclei—the isodynamic or synergical bundles of fibers originating from the "corre-

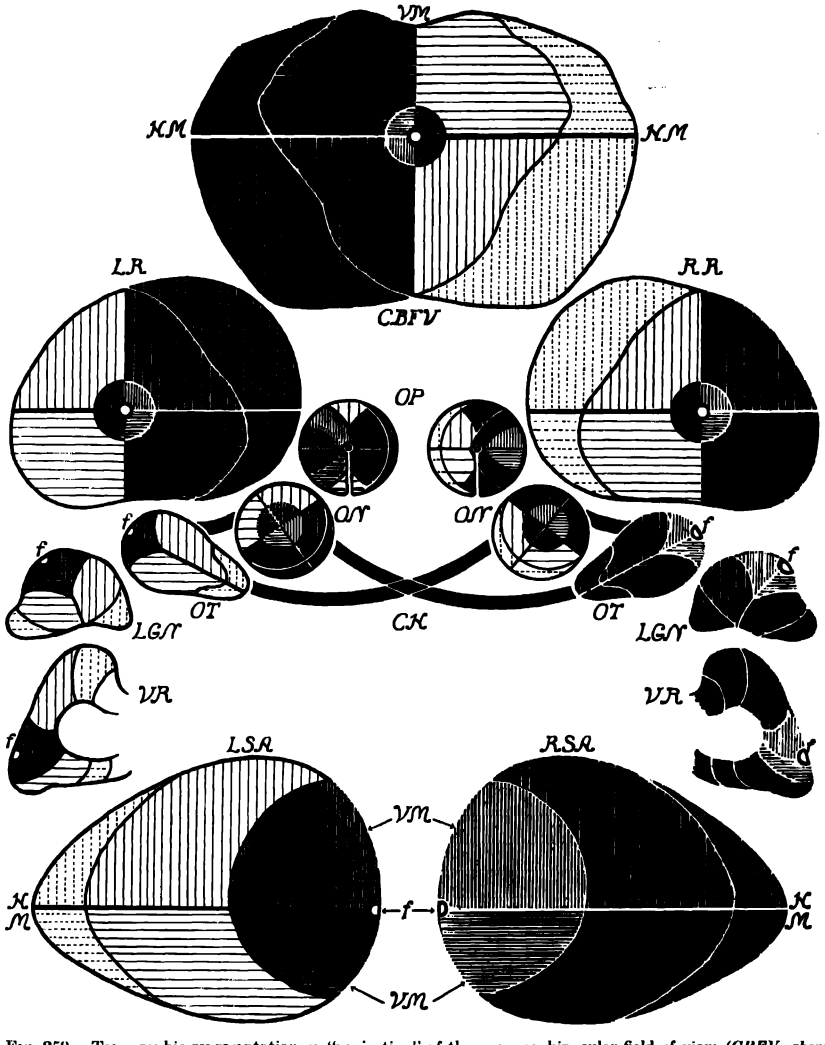

FIG. 259.—Topographic representation or "projection" of the common binocular field of view (*CBFV*, *above*), and of the left and right retinal surfaces (*LR*, *RR*) in the visual pathways and centers of the brain, in Man and in other Primates. The two monocular fields of view, superimposed over each other as in the normal binocular vision, are divided by a vertical meridian (*VM*) into a right and a left half, and again each half is subdivided by a horizontal meridian (*HM*) into an upper and a lower quadrant. A small white circle in the very center indicates the point of fixation. The next circle surrounding it, divided into four small quadrants, represents the central fovea (relatively much enlarged). The largest complete circle represents the extrafoveal parts of the binocular field of view. It is flanked on each side by the monocular temporal crescents. Each half and each quadrant are marked in the same way throughout the entire scheme: in the two retinae (*RR*, *LR*), optic papillae or disks (*OP*), optic nerves (*ON*), chiasma (*CH*), optic tracts (*OT*), lateral geniculate nuclei (*LGN*), visual radiations (*VR*), and the striate areae of the brain (*RSA*, *LSA*). The position of the fixation points (*f*), vertical and horizontal meridians, their approximate orientation in each locality, and the relative size of each quadrant are also indicated. (*Cf.* Figs. 125, 260. 381.)

sponding points" of the homonymous halves of the two peripheral keyboards—the retinae—come very close together, even though they still preserve their identity.

In the supranuclear division, the arrangement of the units on cross-section through the conductor cables—the visual radiations—remains essentially the same.

On the two central screens—the striate areae—the individual conductor units are similarly arranged. The terminal cortical pattern closely repeats the pattern of the retinal receptor keyboards, except for the nonessential displacement required by a somewhat different shape and surface configuration of the cerebral hemispheres.

There are, however, also some important differences. Whereas in the peripheral organs—the eyes—there are two recipient retinal keyboards, in the central terminal station in the cortex there is only a single screen; for each striate area represents only half, though of both retinae. If the common binocular field of view, as present in the normal physiological visual act, be considered (*CBFV*, in Fig. 259), each striate area (*LSA*, *RSA*) sees only the contralateral half of this field. Both striate areae together, therefore, represent a complete binocular field of view (Fig. 439).

Since the two eyes, directed by a delicately adjusted visuomotor mechanism, always work in unison, they function somewhat in the manner of a single median "cyclopean eye" of appropriate size. It is therefore logical to consider the two striate areae also as a single complete cortical center—in fact, as a single "cerebral eye." (*See* chap. XIII, 3, for further details.)

Another difference concerns the relative size of the functional units. In the peripheral receptor keyboards of the two retinae—because of the peculiar character of the physical stimulus, light, to be responded to—the smallest units are in the central foveae; in the terminal cortical screens, on the contrary, the largest functional units are found in those portions of the striate areae where the hemifoveae are represented. In the striate areae the foveal portions appear to be relatively larger and expanded, in comparison with the extra-areal periphery, which is relatively reduced in size. This again raises the question of the importance of the mass, or volume, of the nervous substance in the working of the visual system and of the brain in general. The apparent functional superiority of the foveal cortex as manifested in the "fixation points" last to become extinguished in general narcosis, and so probably also in death, may be based upon the much larger size of the foveal cortex and its relatively greater resistance, which results from a much better blood supply (*cf.* chap. X, 6, 8, and chap. XI, 8, 9).

3. PHYSIOLOGICAL IMPLICATIONS OF THE RETINOTOPICAL ORGANIZATION OF THE VISUAL SYSTEM.—The foremost functional consequence of the elaborate intrinsic organization of the visual system described in the preceding subsections and sections of this chapter and in chapter VI, 7, is that whenever a single point or, in the binocular visual act, two syndynamical "identical or corresponding points" of both retinal keyboards are stimulated, a message arrives, and a signal flashes in a single, definite locality of the central screen, always in precisely the same point (mostly in one of the striate areae).

The position of the signal is fixed, being determined by the relative position of the activated key or keys with respect to the center or centers, the fixation points, and the meridians of the two peripheral receptor keyboards as the points and lines of reference.

Briefly, the number, arrangement, size, shape, and position of messages flashed upon the "cerebral eye" will be fairly accurate copies or replicas of the "figures" painted on the two retinal keyboards. Whatever other structures there are to serve special visual functions, such as an eliciting of special reflexes and a reciprocal influencing of the receptor and conductor units, the intrinsic organization of the afferent visual pathway makes possible a maximum of fidelity of the figures transmitted from the retinae to the visual centers of the cerebral cortex.

The other and hardly less important functional consequence of the intrinsic organization of the afferent visual pathway is the automatic fusion of both images, separately caught on the two retinae, into a single image painted upon the cyclopean cerebral eye. (*See* chap. XIII, 3, for further elaboration of this theme.)

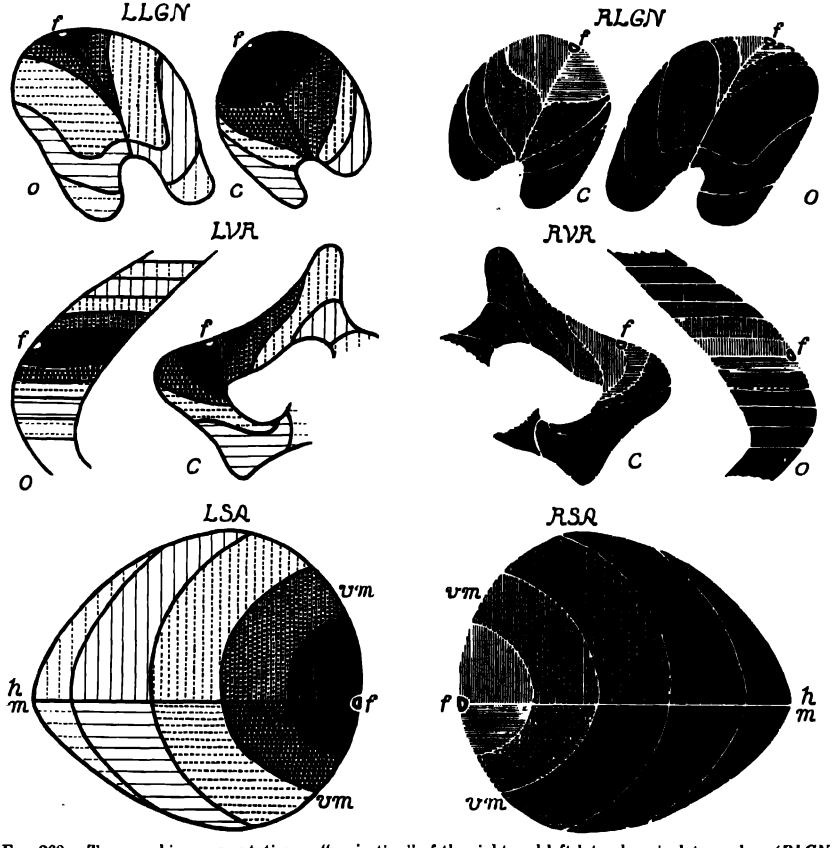

FIG. 260.—Topographic representation or "projection" of the right and left lateral geniculate nucleus (*RLGN*, *LLGN*) in the right and left visual radiation (*RVR*, *LVR*) and in the right and left striate area (*RSA*, *LSA*) in the brain of a Rhesus Macaque, determined experimentally. Shading of the quadrants similar to that in Figs. 225, 259. In the nuclei and in the radiations two levels are represented, an oral or anterior (*o*) and a caudal or posterior (*c*). In the striate areae the pointed extremities at *hm* are oral or anterior, the blunt ends facing each other correspond to the posterior extremities next to the simian sulci or, in Man, at the poles of the occipital lobes, where fixation points (*f*) and vertical meridians (*vm*) are represented. The central foveae around the fixation points (*densely shaded*) have a distinct representation next to the central areae (next zones, shaded with straight and broken lines). Note the relatively large size of the central foveae and areae on all levels, in comparison with the extra-areal peripheries, and a relative shrinkage of the inferior halves, in comparison with the upper halves of the fields.

SEC. 7. CONNECTIONS OF THE STRIATE AREA OR VISUAL CORTEX WITH OTHER PARTS OF THE BRAIN

1. GENERAL REMARKS.—The impulses generated in the peripheral photoreceptor organs of the visual system—the retinal membranes of the eyes—are transmitted along the optic nerves, chiasma, and tracts to the laminated geniculate nuclei of the betweenbrain, and from these nuclei, traveling along the visual radiations, they eventually reach the striate areae of the occipital lobes of the brain. The striate areae, accordingly, are the "gateways" through which the retinal impulses enter the cortex and

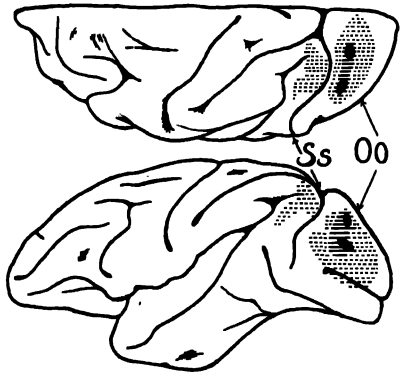

FIG. 261.—Upper and lateral views of the left hemisphere of the brain of a Rhesus Macaque, where two small and strictly cortical lesions in the striate area (*black oval patches*) were made experimentally, in order to determine the territories which receive association fibers: the larger shaded area indicates the portion of the striate area, the smaller shaded area indicates the portion of the para-peristriate areae relayed to the two localities destroyed. *Labeling: Oo,* occipital lobe or operculum; *Ss,* simian sulcus. For the course and termination of fibers *see* Figs. 262–66. From S. Polyak, *The Main Afferent Fiber Systems,* etc., Berkeley, 1932.

from which they are further distributed to other cortical areae and regions.

Other visual subcortical stations—the hypothalamus, the pregeniculate gray nucleus, the pulvinar of the thalamus, the superior colliculi, and possibly the adjoining parts of the midbrain—do not participate in the transmission of retinal impulses to the cortex, partly because of their scanty connections with the visual system (pulvinar) and partly owing to the fact that their connections remain subcortical (pregeniculate nucleus, superior colliculus). The various sidetracks supposedly connecting the laminated nucleus to the thalamus, described by some investigators (Ferraro 1926; Klossowski 1930), have also not been substantiated either by the normal anatomical methods of investigation or by experiment.

From the evidence adduced in this and the preceding chapter it is fairly certain that the only avenue by which retinal impulses reach the cerebral cortex is the visual radiation or that part of the visual system mediated by the laminated lateral geniculate nuclei and terminating in the striate areae along the calcarine fissures.

In order to pursue further the course of the retinal impulses, it is necessary to follow the connections of the striate cortex, or Brodmann's field *17*. From a general knowledge of the structural organization of the brain, the striate area may be expected to be connected with other parts as follows: (1) by short relays from neuron to neuron, this connection remaining wholly confined to the substance of the cortex, or intracortical; (2) by subcortical association fibers of various lengths arising from the nerve cells residing in the striate cortex and passing into the white subcortical fibrous substance, eventually terminating in the extrastriate cortical areae surrounding the striate area of their origin, and at different distances from it, all in the same cerebral hemisphere; (3) by commissural fibers arising in the striate cortex of one cerebral hemisphere and decussating by way of the corpus callosum to the opposite hemisphere, where they may terminate in the contralateral striate area, producing a "homotopical connection," or in any one or a group of the extrastriate areae, thus establishing a "heterotopic connection," or in both the striate and the extrastriate areae of the cortex; (4) by fibers arising in the striate cortex and descending to any one, or to several, of the many subcortical structures in the core of the brain and the brain stem, such as the caudate nucleus, the putamen and globus pallidus of the striate body, the thalamus and other parts of the betweenbrain, parts of the midbrain, especially the superior colliculi, and pos-

sibly elsewhere; (5) in the reverse, by association fibers arising in any one of the several extrastriate cortical areae of the same cerebral hemisphere and terminating in the striate area; (6) in the reverse, by the callosal commissural fibers originating either in the striate area or in the extrastriate areae or in both of the contralateral cerebral hemispheres; (7) in the reverse, by the fibers originating in one of the subcortical structures other than the laminated lateral geniculate nucleus and ascending to one or to both striate areae.

On the basis of probability, it may be expected that not all the possibilities mentioned are actually realized. The presence of some connections and the absence of others may give important indications as to which way the retinal impulses spread and what their functional significance may be.

In the following a single example based on experiments with monkeys is presented. A complete survey of the outgoing and incoming fiber connections of the striate area is a problem which, because of its magnitude, must remain outside the framework of the present book. Its importance should make it an attractive object of a special investigation.

2. Association fibers of the visual cortex.—When a few minute lesions are made in a Rhesus Macaque, measuring from 1 to 2 mm. in diameter and strictly localized to the striate cortex of one occipital lobe (black, in Fig. 261), a great number of short, thin myelinated fibers degenerate secondarily and may be followed to the point of termination in preparations stained according to the Marchi technique (Figs. 262–66). The caliber of the overwhelming majority of these fibers is fine to very fine, with a few of medium thickness interspersed, indicating that, for the most part, they originate from cells of small size.

In the striate cortex immediately adjoining the lesion, except in the lowermost layer, there are no degenerated fibers of any length to be seen coursing away from the lesions (Figs. 262, 263). In particular, the stripe of Gennari or Vicq-d'Azyr, indicated by stippling, approximately corresponding to the intragranular layer *4-b*, remains free from any degenerated myelin. This layer, though medullated, accordingly does not contain intracortical myelinated fibers of any appreciable length. All the long axon fibers originating from the nerve cells in the destroyed portions of the striate cortex (L_1, L_2) leave this cortex and enter the subjacent subcortical fiber substance, where they sort themselves into several categories.

The first variety, exceedingly numerous, are short association fibers. Immediately after entering the subcortex, these very fine fibers turn horizontally, keeping quite close to the striate

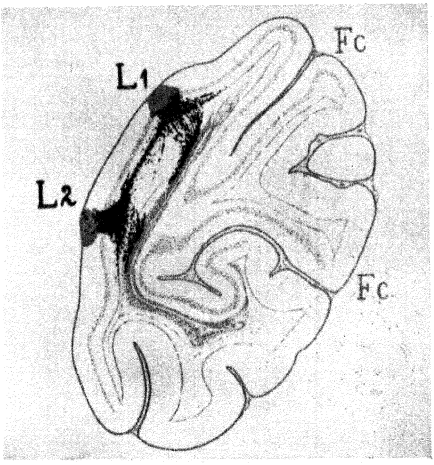

Fig. 262.—A section through the occipital lobe of a Macaque showing two small, cortical lesions (*L1*, *L2*) in the striate area (Fig. 261), whence fibers emanate to other regions of the brain. The stripe of Gennari or Vicq-d'Azyr, marked by stippling, indicates the striate area, partly buried in the calcarine fissure (*Fc*) and partly extending over the lateral face of the occipital lobe where the lesions were located. Note the great number of short association fibers (*black lines*) spreading below the cortex and within it, while others pass into the subcortical fiber substance. Marchi method of staining. (*Cf.* preceding and following figures.)

cortex, some re-entering its lowermost zone. A few of these fibers remain within the cortex, where they pursue a horizontal course in the lowermost zone next to the subcortex. The short association fibers are most numerous in the immediate vicinity of the lesion in an area measuring approximately 2 mm. across. From the vicinity of the lesion these short subcortical association fibers gradually and rapidly decrease

in number until, at an approximate distance of 5 mm. on all sides of the lesion, the last of them have disappeared. Their lateral spread, accordingly, amounts to a circular area, shaded in our figure, measuring approximately 10 mm. in diameter, or almost half the extent of the striate area covering the lateral face of the occipital operculum at this level (*cf. Oo*, in Fig. 261).

Anteriorly, along the simian sulcus (*Ss*), these short association fibers attain the limit of the striate cortex (in Figs. 263 and 264 the striate cortex is clearly indicated by a stippled interval). Here they are fitted (Figs. 262, 263). They are confined to the sagittal strata, the thicker ones with preference for the internal stratum and the thin ones entering the extreme stratum. They remain in these strata until they reach the level of the well-developed annectent gyri, where some terminate (Fig. 264). The remaining and slightly longer association fibers, the majority, continue for a short distance in the sagittal strata in the rostral direction, gradually entering the surrounding fibrous core of the occipital

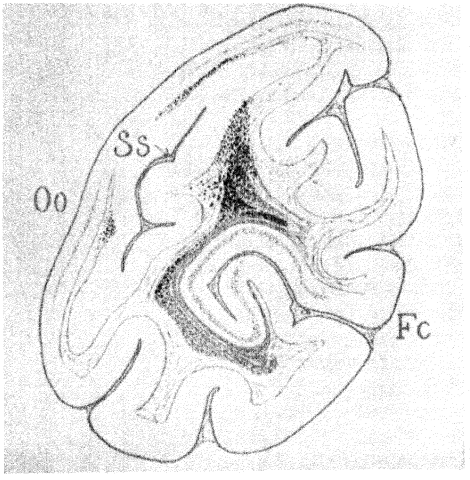

FIG. 263.—A section slightly anterior to the preceding one, located in front of the two small lesions, showing short association fibers passing in great numbers to the striate cortex immediately adjacent to the lesions, while other fibers pass over into the sagittal fiber layers underneath the cortex in the floor of the simian sulcus (*Ss*). *Labeling: Fc*, calcarine fissure; *Oo*, occipital operculum; *Ss*, simian sulcus. Marchi method. (*Cf.* preceding and following figures.)

tracortical line marking the extent of the stripe of Gennari). An attentive examination of the serial sections makes it appear probable that a zone of the adjoining parastriate cortex in the free lip of the simian sulcus also receives these short strio-parastriate association fibers as far as the floor of that sulcus (*Ss*).

In the second category the fibers originating in the striate cortex are longer. They are fewer in number, also mostly thin, although the caliber of some is slightly thicker. They descend in parallel, gently curved bundles directly to the lobe. This is especially evident on levels where the angular gyrus (*GA*) becomes fully developed (Figs. 265, 266). It is the cortex of this gyrus, particularly that part lining its exposed ridge, within which these longer association fibers terminate. They are worthy of attention on account of their remarkably regular course, bundles arranged along bundles. In the fibrous core of the occipital lobe, these fibers correspond to the bundles radiating from the sagittal strata in the center toward the cortex lining the surface of the hemisphere. A few thicker fibers do

not follow this course but curve away from the bulk, toward the cortex lining the anterior segment of the inferior occipital sulcus.

On levels in front of the angular gyrus, a few degenerated fibers are still found in the sagittal strata of the parietotemporal lobes (Fig. 266). Some of them, both thin and a few thicker ones, may be followed with some doubt through the pulvinar toward the superior colliculus of the same side. Similar, very fine, degenerated fibers possibly enter the tip of the lateral geniculate

Anterior to the level of the pulvinar of the thalamus (*Pulv*) no degenerated fibers could be found either in the fibrous core of the hemisphere or in the various gyri of the temporal and parietal lobes. Specifically, no long association fibers could be found in this experiment to the pre- and postcentral gyri (motor and somesthetic areas), to the orimental transverse temporal gyrus of the Sylvian fossa (auditory area), or to any other cerebral structure, cortical or subcortical. (*Cf.* Fig. 261.)

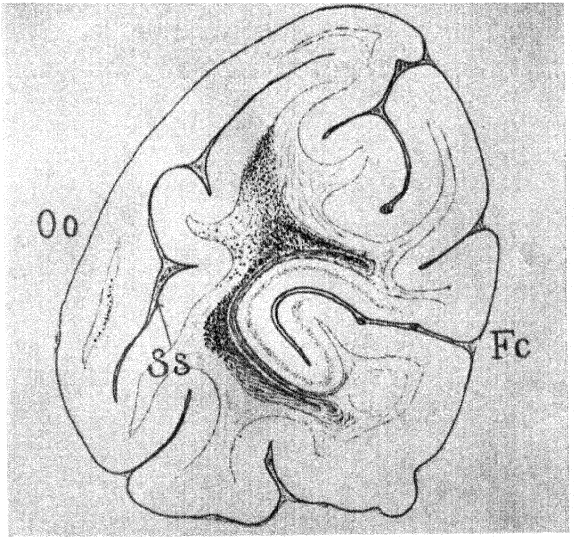

FIG. 264.—A section placed farther anteriorly through the occipital lobe and close to the lip of the simian sulcus (*Ss*), showing the reduced striate area and fewer short association fibers, whereas the somewhat longer fibers now begin to emerge from the sagittal layers to enter the cortex in the floor of the simian sulcus, including the annectent gyrus. *Labeling: Fc*, calcarine fissure; *Oo*, occipital lobe or operculum. (*Cf.* preceding and following figures.)

nucleus; either they are descending corticogeniculate fibers, or they are fibers of the visual radiation which, owing to some damage to their terminations in lesions L_1 and L_2, have undergone a retrograde degeneration. A few thin bundles of very delicate fibers could be followed in the poorly developed tapetum (*Tap*) all the way from the occipital lobe to the posteriormost segment of the splenium of the corpus callosum, and through it over to the contralateral hemisphere.

3. EVALUATION OF THE ANATOMICAL CONNECTIONS OF THE STRIATE AREA.—The remarkable fact which was demonstrated in this experiment is that most fibers undoubtedly originating in the striate area are short association fibers, terminating either within this area or in the areae of the cortex immediately adjoining it.

First are the short intracortical fibers originating from, and terminating around, the nerve cells residing in the striate cortex itself. Through these, each minute territory of the striate cortex

is connected by relays with the remainder of that cortex and thus with the entire cerebral cortex.

The others are short subcortical association fibers. These are noteworthy, in the first place, because of their great numbers. They represent the majority of all fibers which leave the striate area. The other noteworthy feature is their direction or pattern of spreading. From each minute locality a great number of them enter into the subjacent subcortical substance, immediately spreading to right and left, fore and aft, in order eventually to re-enter the same striate cortex.

In this manner each particular point of the striate cortex is interconnected both ways with a fairly large segment of the same cortex. According to a rough estimate, the functional units of this kind may amount to at least one-sixth of the entire striate area covering the external face of the occipital lobe of a monkey's brain (Fig. 261, shaded). The total number of short association fibers must be formidable. Through them, every point of the striate area is connected both ways with its immediate environment and, through this, by intracortical and subcortical relays, with the rest of the striate area and the remainder of the cerebral cortex.

The mechanism represented by the system of short association fibers makes the striate area an "integrated collective" or "aggregation of functional units." In this collective the most intimate and direct connection of any particular point is with its immediate neighborhood. The intimacy gradually fades toward the periphery, the connection with the remaining and much larger portion of the striate area being indirect, mediated through the next adjoining units.

The somewhat longer subcortical association fibers connecting the striate area with the paraperistriate areae lining the annectent gyri and the angular gyrus are also noteworthy because

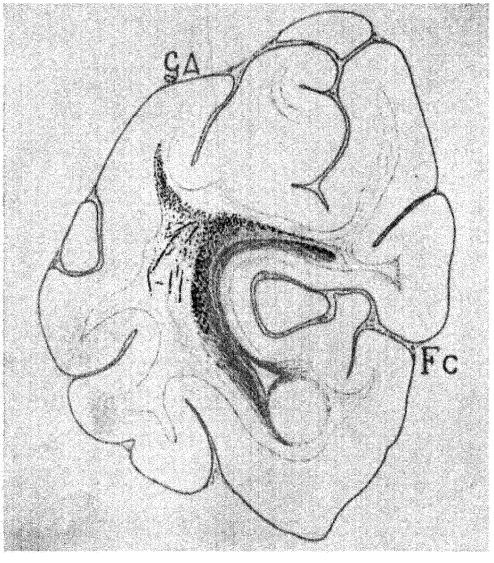

FIG. 265.—A section through the simian hemisphere in front of the occipital lobe, passing through the angular gyrus (*GA*), into which somewhat longer association fibers from the striate area enter, while others still remain in the sagittal fiber layers, with a few distributed to the near-by cortex of the parietal and possibly temporal lobes. *Labeling: Fc*, calcarine fissure. (*Cf.* preceding and following figures.)

of their abundance and orientation. The territory which they supply is closest to their point of origin in the striate area. Moreover, this territory is considerably larger in extent than the striate territory, whence they originate. As in the distribution of the short, subcortical, striate association fibers, the longer striopara-peristriate fibers also spread out at the place of their termination, indicating a collection of retransformed retinal impulses from the striate area reaches, as the next station, the para-peristriate areae, whence other influences may originate, which may further spread to more distant parts of the cortex and to the subcortex (Figs. 267, 268).

In any case, if the subcortical association fibers, because of greater thickness and better myelinization, indicate greater speed and vol-

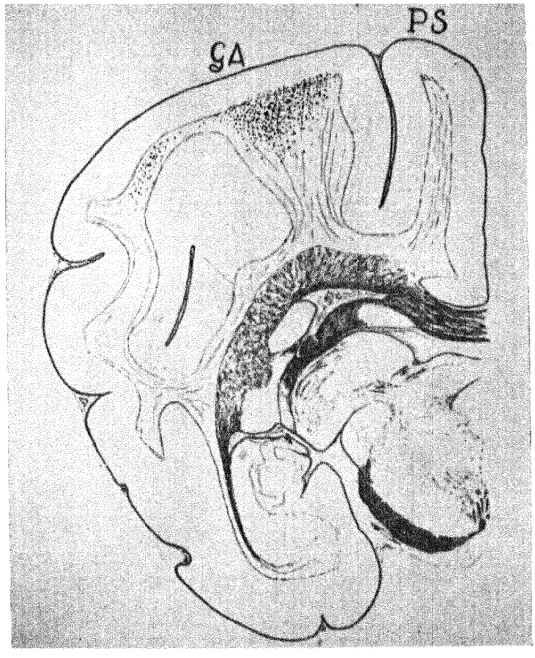

FIG. 266.—A section through the angular gyrus (*GA*), where it is fully developed, to show the distribution of the long association fibers originating in the striate area which enter that gyrus, as found in this experiment. It is doubtful whether similar fibers pass over to other parts of the brain. (*Cf.* preceding figures.)

ciprocally overlapping units. Briefly, each minute territory of the striate cortex is related by medium-long subcortical association fibers to a larger territory of the para-peristriate cortex, with a reciprocal overlapping of the adjoining units.

Since no other cortical areae of the same cerebral hemisphere receive association fibers originating from the striate cortex, it is permissible to conclude that the principal stream of ume or intensity of propagated impulses in comparison with the thinner and poorly myelinized, short, intracortical relays, the transformed retinal impulses may at first spread only as far as the para-peristriate areae.

A fair amount of localization is preserved in this spreading, since each point of the striate cortex transmits impulses to one particular territory of the para-peristriate areae, the remainder having no such direct connections with that

particular point. The fact, however, that each minute territory of the striate area transmits impulses to a much larger territory of the para-peristriate areae and that the areae of distribution overlap shows that, besides a possible point-to-point relationship, there is a much wider one of more diffuse character, owing to which a change in the dynamic state is brought about in a wide area.

Altogether, the evidence points toward a complex relationship between the striate and the para-peristriate areae in which many numerous structural and dynamic factors may work together. To identify these, a systematic investigation, both in the analysis of fine structural details of the striate cortex and by means of physiological experiments, is necessary.

The direct connections of the striate area with the contralateral hemisphere appear to be poorly developed, if possibly they are not entirely absent. This agrees with the very reduced tapetal stratum found in the posterior portion of the occipital lobe as a distinct fiber formation in a few localities only, as, for example, next to the upper and lower corners of the posterior horn of the lateral ventricle. Equally uncertain are direct connections of the striate area with the subcortical parts of the brain, especially the superior colliculus of the midbrain.

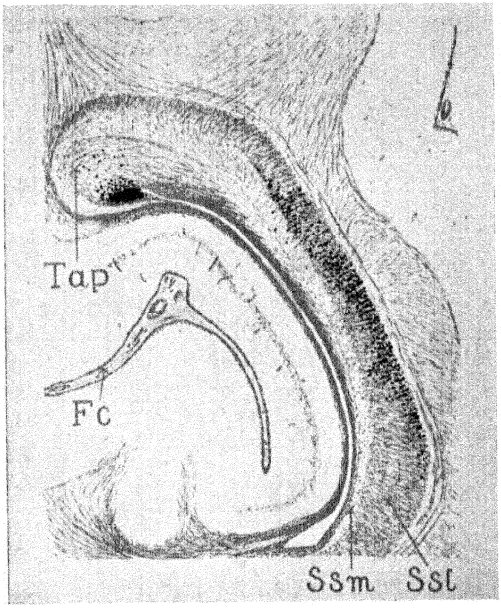

FIG. 267.—A section through the sagittal fiber layers of the occipital lobe of a Rhesus Macaque, where, in an experiment, a portion of the para-peristriate area was damaged, resulting in a secondary degeneration of two systems: a bundle in the tapetum (*Tap*), which eventually passes over to the contralateral hemisphere, and of other fibers descending to the superior colliculus of the midbrain (in *Ssl*). *Labeling: Fc*, calcarine fissure; *Ssl*, *Ssm*, lateral and medial sagittal layers; *Tap*, tapetum. (*Cf.* following figure.)

One of the unexpected results of the experiment described is an absence of truly long association fibers from the striate area to other principal sensory and motor regions of the same and contralateral hemispheres of the brain. Even more remarkable is a development so poor that it amounts to an absence of commissural callosal fibers by which the two striate areae of both occipital lobes would be con-

nected into a functional team. If there are such connections, they are not direct but are mediated through other nonstriate areae.

This contrasts with the manifest association of the two striate areae into a team by virtue of a partial decussation of the optic nerve fibers in the chiasma and a resulting welding of the two homonymous retinal sets into two twofold halves in the suprachiasmal portion of the visual system, as described in the preceding sections of this chapter and in chapter VI, 6. Hence the task of producing a single visuomental image in a common binocular visual act, resulting in single stereoptic vision, is a process commenced by the semidecussation in the chiasma, its consummation taking place in the striate areae of the two occipital lobes of the brain.

The extraordinary wealth of association fibers arising in the striate area of the occipital operculum and their termination in the adjoining parts of the para-peristriate areae is also of interest in still another respect, that is, because the operculum is a locality where the central foveae and areae of both retinae are represented. An abundant connection is here to be expected, in view of the functional supremacy of the fovea in visual space perception, especially in acuity. The central fovea and its immediate vicinity is a principal retinal gateway for the most detailed or epicritic visual impulses. Hence its cortical representation in the posterior or polar portion of the striate area not only is relatively the largest but is also well supplied with association fibers. Through these a broad avenue is kept open for the epicritic foveal impulses to pass over to the para-peristriate and other areae of the cortex, there to combine into composite traces of a higher order. (*Cf.* chap. VIII, 3.)

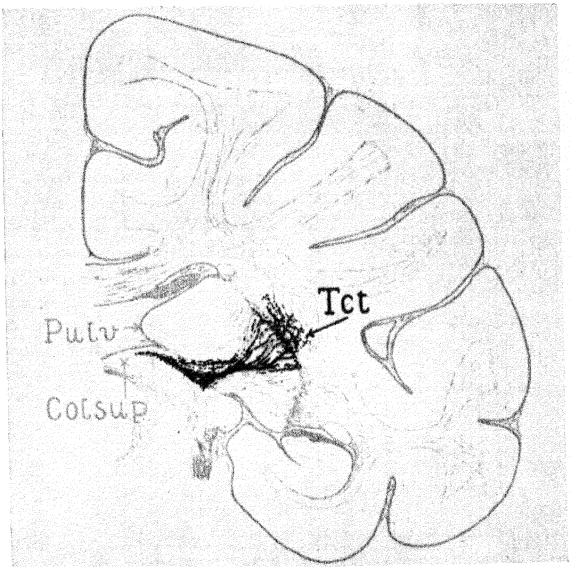

FIG. 268.—A section through the occipital lobe of a Rhesus Macaque, where a portion of the para-peristriate areae was damaged, resulting in a secondary degeneration of fibers descending through the pulvinar of the thalamus to the superior colliculus of the midbrain. *Labeling: Colsup,* superior colliculus of midbrain; *Pulv,* pulvinar of thalamus; *Tct,* occipital corticotectal tract.

SEC. 8. TOPOGRAPHICAL RELATIONSHIPS OF THE VISUAL SYSTEM

1. GENERAL REMARKS.—The visual system, beginning with the peripheral organs—the eyes—and terminating with the striate areae of the occipital lobes, extends along the longer axis of the head, from the anterior to the posterior limit. Throughout this long stretch it is topographically related to numerous structures: the bony parts of the cranium, parts of the brain, the nerves, blood vessels, and other structures. This close relationship, partly anatomical-functional, partly purely physical, makes knowledge about it important in theoretical as well as practical respects.

In surgical operations, by keeping at some distance from the visual pathways and centers, serious injury to vision may be avoided. Dangerous procedures—for example, the posterior puncture of the lateral ventricles and other similar techniques which are likely directly to damage parts of the visual radiations and of the striate areae—may thus be avoided.

2. TOPOGRAPHICAL RELATIONSHIPS OF EYEBALLS. The visual system is, in general, located close to the base both of the skull and of the brain (Fig. 269).

The eyes, sheltered in the orbital cavities, with the anterior poles of the corneae fairly accurately coinciding with the anterior poles of the cerebral hemispheres, are close beneath the overhanging frontal lobes. The distance between the upper pole of the eyeball and the orbital surface of the frontal lobe is but a few millimeters. This space is taken up by the muscles, glands, fat, and other tissues filling the orbital cavities; by the thin bony partition made up of the orbital portion of the frontal bone and of the *ala parva* or "small wing" of the sphenoidal bone; and by the cerebral meninges and meningeal spaces.

3. TOPOGRAPHICAL RELATIONSHIPS OF THE OPTIC NERVES.—The course of the optic nerve in the orbital cavity is not straight but meanders somewhat in three dimensions, thus allowing necessary excursions to the eyeball during the converging movements and the lateral and vertical shifting of the gaze.

The point where the nerve is implanted in the eyeball is at a slight distance nasal to the posterior pole, where the optical axis touches the fundus of the eye. In the orbital cavity or eye socket, the optic nerve is imbedded in, and surrounded by, various tissues, such as the extrinsic eye muscles, oculomotor and sympathetic nerves, glands, the plastic fatty tissue which functions as a "cushion," and abundant blood vessels that fill the remaining space.

At the posterior, narrow, funnel-shaped end of the orbital cavity, the optic nerve slips through a short bony channel which varies in length from individual to individual. This channel is the optic foramen, formed by the small wing (ala parva) of the sphenoidal bone, in which the optic nerve is firmly lodged, and thus reaches the cranial cavity, in particular, the middle fossa or pit. Viewed *in situ*, from below or from above, the two optic nerves form an angle of approximately 60°.

4. TOPOGRAPHY OF THE OPTIC CHIASMA.—As soon as the optic nerves have entered the cranial cavity, they unite, producing a short, bridgelike junction—the chiasma—by means of which they are firmly linked together. The chiasma, in turn, is loosely lodged in the chiasmal sulcus, a shallow groove in the middle portion of the sphenoidal bone at the base of the skull (Fig. 269).

Two paired protrusions—the anterior and posterior clinoid processes—surrounding a nichelike depression, in which the hypophysis or pituitary gland is lodged, together form a smooth socket, the *sella turcica*, or "Turkish saddle," from which locality the two optic tracts continue to the brain. Important cranial nerves, such as the oculomotor, abducent, trochlear, and trigeminal, and the internal ca-

rotid artery with its branches, essential for the nutrition of the brain, are in the immediate vicinity of the sella, which also is filled with, and surrounded by, a rich, spongy, venous network—the cavernous sinus.

The region of the sella and of the optic chiasma is in the closest proximity to the base of the brain, in particular to the hypothalamus, which contains important centers for the regulation of various vegetative functions of the organism growth, metabolism, temperature, reproduction, and emotional reactions.

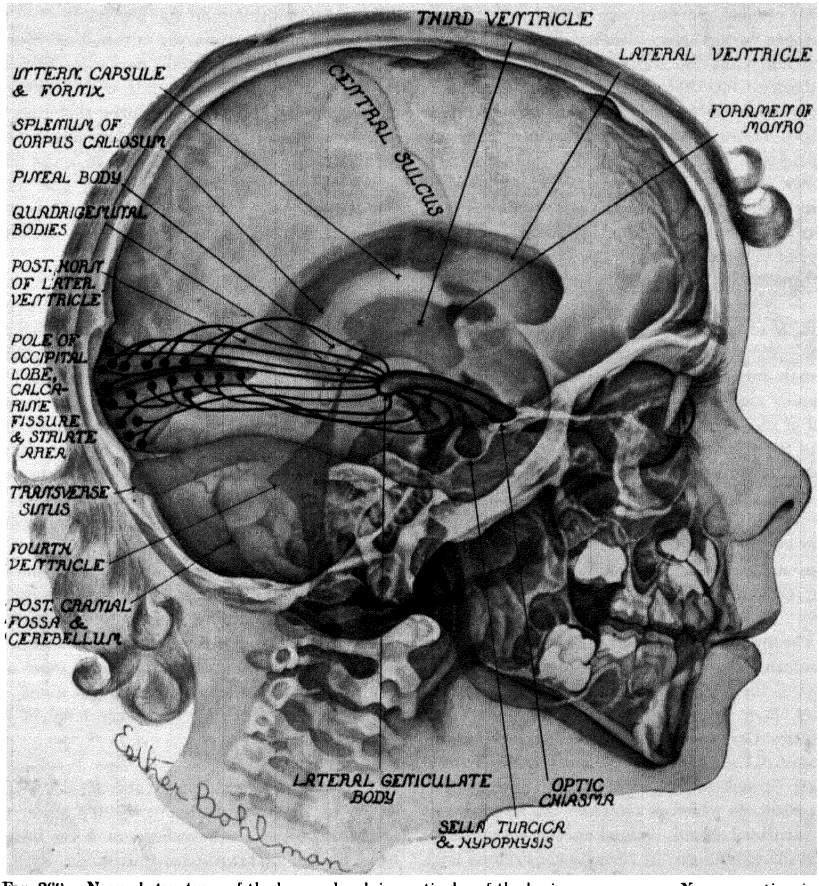

FIG. 269.—Normal structures of the human head, in particular of the brain, as seen on an X-ray negative, in a side view, of an eight-year-old child (University of Chicago Clinics No. 5074-9). Visual system drawn in its normal position: from the eye the optic nerve passes through the optic foramen of the orbit, extending through the chiasma and optic tract to the lateral geniculate body or nucleus, whence bundles of the visual radiation, indicated by thick lines, pass over to the striate area in the calcarine fissure of the occipital lobe, where they terminate (*black dots*). Note the topographic relations of the constituent parts of the visual system to the various parts of the skull and brain; the composition of the visual radiation of shorter upper bundles with a flatter curving course, terminating in the upper calcarine lip; of longer ventral bundles describing considerable detours, before turning back to the lower calcarine lip (so-called "temporal loop" of Flechsig and Meyer); and of intermediate bundles pursuing a straight course to the occipital pole.

On rare occasions the chiasmal junction is absent. In such cases each optic nerve continues as an optic tract on the side of the brain where it originates (for references, *see* chap. II, 8 [4]).

5. TOPOGRAPHY OF OPTIC TRACTS.—The optic tracts are dorsoventrally somewhat flattened central continuations of the optic nerves attached to the base of the brain. In particular, they surround the exposed parts of the hypothalamus from the lateral sides: the *tuber cinereum*, which continues as a narrow, funnel-shaped *infundibulum* and connects it with the *hypophysis*, and the two rotund mammillary bodies. In their further course, the tracts remain closely attached to the ventral and lateral sides of the two cerebral peduncles, along which they finally reach the parts of the betweenbrain and midbrain, where they terminate.

6. X-RAY TOPOGRAPHY OF THE VISUAL SYSTEM.—In a side view of a radiogram of the human head (Fig. 269) the optic foramen or channel appears as a small, oval opening at the end of the slanting roof of the orbit, not far behind the tip of the temporal lobe. Close behind the inner mouth of the optic foramen, in front of the anterior clinoid processes, the optic nerves unite and form the chiasma, determinable by the position of the sella turcica. From here on, the optic tracts take a slightly slanting, ascending course in the posterior direction.

There are several landmarks which may help determine the position of the structures at the base of the brain, useful in a region filled with thick fiber trunks and small interconnecting cavities. One, below the optic tract, is the round pocket of the sella. The other is the faintly outlined, funnel-shaped infundibulum and its slender stalk, to which is attached the hypophysis, or pituitary gland, lodged in the sellar fossa. The infundibulum, in turn, is continuous with the lower portion of the third ventricle, whose small supraoptic recess is well outlined at the coronal level of the anterior commissure (which, in turn, is found below and slightly in front of Monro's foramen).

Posteriorly, the shadow of the infundibulum continues into the gently sloping floor of the posterior portion of the third ventricle, which leads directly to the anterior orifice of the cerebral aqueduct of Sylvius and thus to the midbrain. In this locality the lateral geniculate nuclei or bodies and the initial portions of the visual radiations are found. Most of the third ventricle is located above the optic tracts, being outlined along its upper boundary by the arching internal capsule and the fornix.

The spacious and sharply outlined cavities of the lateral ventricles extend partly in the frontal lobes, where they terminate with blunt, expanded anterior horns. Posteriorly, they may be followed as a curved, semicircular shadow, descending partly as the inferior horns in the temporal lobes and partly as a shorter and more slender shadow—the posterior horns of the lateral ventricles, pointing toward the occipital poles.

The position of the lateral geniculate nucleus in a lateral view is at the anteroventral *tegmentum* of the midbrain, corresponding with the red nucleus. This location is much more anterior and more ventral than indicated in a model by Cushing (1922), whose location of the lateral geniculate at the pineal body is inaccurate. For this reason, the detour described by the ventral bundles of the visual radiation, the "temporal loop," is somewhat shorter than indicated in Cushing's model and in other similar presentations (*cf.* Figs. 235, 236).

The fiber complex of the visual radiation, except the "temporal loop," represents a rather straight anteroposterior tract. Its lower margin runs close to and fairly parallel with the inferior outline of the occipitotemporal lobes and not far from the transverse venous sinus, its upper margin reaching the lower level of the callosal splenium.

7. TOPOGRAPHY OF THE STRIATE AREA.—The shape of the striate area projected upon the lateral aspect of a roentgenogram of the human head is that of an elongated triangle, with its sharp end turned anteriorly (dotted area at the left end of the figure). The anterior limit of the striate area extends approximately to the middistance between the lateral geniculate nucleus and the occipital pole. Its polar end extends downward as far as the internal occipital protuberance and the transverse sinus, the outward landmark being the external occipital pro-

tuberance or *torus*. Its surface extent, projected onto the occipital poles, does not quite reach the lambdoid suture of the parieto-occipital bones.

Chapter VIII

Cortical Visual Centers

SEC. 1. EXTERNAL CONFIGURATION AND FUNCTIONAL ORGANIZATION OF THE CEREBRAL HEMISPHERES

1. General remarks concerning the vertebrate brain. The bulky nervous organ which fills the spacious cavity of the cranium is the brain or cerebrum. It is made up of countless nerve cells or neurons of varied shapes, sizes, types of expansions, and synaptical relationships, held together by supporting neuroglial tissue, blood vessels, and meningeal envelopes.

In all its complexity the brain is the product of a long process of phylogenesis. From modest beginnings in the fishlike ancestor of the Vertebrates, probably somewhat resembling the present-day Lancelet (*Branchiostoma* or *Amphioxus*), where the primitive *prosencephalon* or "brain" is merely a slight vesicular expansion of the anterior end of the neural tube or spinal cord, the brain has increased immensely in bulk and in its structural and functional complexity, until in Man and his nearest relatives it has become the dominant part of the organism (*see* figures in chap. XIV).

The development of the brain into the central nervous organ may be considered to be a result of the direct relation of the rostral end of the spinal cord to the principal sense organs, above all, to those of sight, followed in evolutionary chronology by those of gustation and olfaction. In further consequence of its special relation to the sources of stimuli, elaborate centers of locomotion and balance have developed in the brain. In a word, owing to its favored location at the head-end of the body, the brain has become the leading and dominant part of the central nervous system, the managing center of the entire organismic "individual." (*Cf.* chap. XIII, 2, 3.)

In the Lower Vertebrates such as Fishes and Urodele Amphibians (Salamanders), although unquestionably a leading or central organ, the brain is still small and of relatively simple external and internal makeup. In particular, the endbrain, from which the bulky cerebral hemispheres developed in the advanced Vertebrates, is still little more than a ganglion of olfaction. The cerebral cortex is still in its infancy at this evolutionary stage.

In the Anuran Amphibians (Frogs, Toads), Reptiles, Birds, and Lower Mammals the brain has increased considerably, with the cortex definitely beginning to evolve, though still exhibiting rather primitive features. The cerebral hemispheres, e.g., of the Bat, Mole, Mouse, Rat, Rabbit, or Shrew are lissencephalous, or smooth, without gyri and sulci. The phylogenetically older part—the *paleocortex*, related to the olfactory function, and the midbrain—is relatively larger than the *neocortex* of the *telencephalon* or front brain, which is concerned with the integration of somesthetic, auditory, and visual impulses (*see also* chap. XIV).

In the larger Rodents, Ungulates, and Edentates, and in practically all Carnivorous Mammals, the brain has attained considerable size, and the surface of the hemispheres has become complex, gyrencephalous, or folded into gyri.

The most complicated surface of the cerebral hemispheres is found in large Mammals such as the Whale and the Elephant and, in general, in the Primates, among Simians in the Anthropomorphous Apes, and most complicated of all in Man. Here the cortex has grown to a bulk much exceeding the total mass of the remainder of the gray substance of the entire brain and spinal cord. In complexity and local and individual variation of minute structure the cortex also

exceeds all other parts of the nervous system put together. (*See* chap. XIV for comparative data on the brains of various Vertebrates.)

2. EARLY OR PRIMORDIAL NEOPALLIAL SULCI AND FISSURES OF THE HUMAN FETAL BRAIN.—The conspicuous feature of the external surface of the adult human brain is the numerous furrow-like depressions called sulci and fissures, could otherwise not take place may be established between its neurons.

When one examines the human brain, the first impression is of great irregularity. A closer study, especially of a developing human fetal brain, and an acquaintance with the brains of monkeys and apes, however, help reveal the essential features of the complicated sulcal pattern and its relative stability.

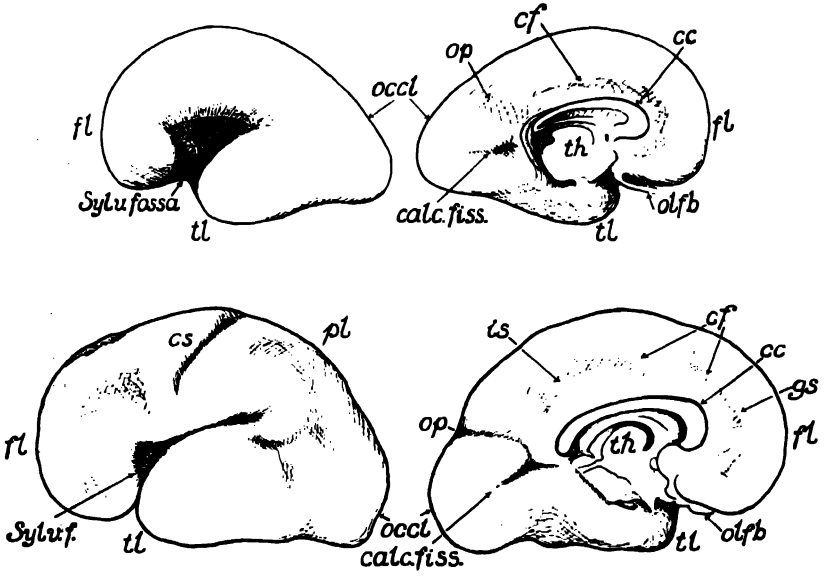

FIG. 270.—Lateral (*left-hand figures*) and medial aspects (*right-hand figures*) of the left cerebral hemispheres of human fetuses drawn while still fresh, in order to show the early development of sulci and gyri of the cortex. The upper figures of a fetus of an estimated age of four and three-quarters menstrual months, or nineteen to twenty weeks, the lower figures of a fetus of an estimated age of six and a half menstrual months, or twenty-six weeks. The lateral face of the younger brain is still perfectly smooth, lissencephalous, except for a wide-open Sylvian fossa, the brain at this stage markedly resembling that of a Tarsier (*cf.* Figs. 279, 516). The inner face, on the contrary, shows several quite shallow, barely perceptible principal or primordial sulci appearing first. In the older brain the primordial calcarine and Sylvian fissures are further deepened, owing to an expansion of the adjoining cortex, in addition to other sulci which appear now, some still vague depressions. At this developmental stage the brain somewhat resembles that of a Monkey (*cf.* Fig. 280). Slightly reduced. *Labeling: calc.fiss.*, calcarine fissure; *cc*, corpus callosum; *cf*, cingular or fornicate sulcus; *cs*, central sulcus (Rolando); *fl*, frontal lobe; *gs*, genual sulcus; *is*, intercalate sulcus; *occl*, occipital lobe; *olfb*, olfactory bulb; *op*, occipito-parietal or parieto-occipital sulcus; *pl*, parietal lobe; *Sylv.f.*, *Sylv.fossa*, Sylvian fossa or pit; *th*, thalamus; *tl*, temporal lobe.

separating the folds, called convolutions or gyri, from one another (Figs. 182, 271). In this way the area of organized gray matter of the cortex covering the hemisphere becomes much greater than if it were smooth, and the topographic and synaptical relationships which

During approximately the first half of the intrauterine development of the human fetus, no neopallial furrows in the proper sense of this word are seen, either on the lateral or on the medial face of a freshly examined specimen. In a ten-week-old human embryo, for example, the

lateral surface of a cerebral hemisphere is as smooth as in a lissencephalous Mammal, such as a Shrew, Bat, or Mouse. The only uneven locality on the otherwise unbroken surface is a wide, shallow depression from which the Sylvian fossa or pit, the "lateral fissure," later develops. This condition remains substantially unchanged until approximately the second half of the fifth fetal month (Fig. 270, upper left-hand sketch).

The various "transient fissures" supposedly developing during the early weeks of fetal life and described by some investigators as a normal feature are post mortem artifacts caused by the action of the fixing fluid in which the specimen is preserved. When, for example, a fresh brain of that age is placed in 10 per cent formalin solution, the surface that was perfectly smooth becomes disfigured within a few weeks by the appearance of crisscrossing furrows, even though a proper quantity of sodium chloride may have been added to make the solution isotonic.

The first true neopallial sulci or fissures normally appear on the medial face of the brain at about the twentieth intrauterine week (Fig. 270, upper right-hand diagram). One such short, shallow depression is the calcarine fissure (*calc. fiss.*), another, the parieto-occipital or occipitoparietal sulcus (*op*), both as yet independent of each other. The brain of a human fetus at this stage somewhat resembles the brain of an adult Mouse Lemur, a diminutive primitive Primate, and even more that of a Tarsier (*cf.* Fig. 279, *D*, *E*). A third shallow, smooth, and barely perceptible depression is the cingular or fornicate sulcus (*cf*), the posterior portion of which may be homologized with the intercalate sulcus, the anterior portion with the genual sulcus, of the Infraprimate Mammals.

The calcarine fissure, significantly, appears among the earliest neopallial furrows in the human fetal brain, just as this fissure is the first to appear during phylogenesis (*cf.* *c* in the brains of *Tupaia*, Lemur, Tarsier, Marmoset, and *Loris* in Figs. 279, 306, 307). Equally noteworthy seems the circumstance that, from its inception during human ontogenesis, that portion of the calcarine fissure appears first and quite independently of the other sulci which subsequently becomes transformed into a medial or anterior calcarine sulcus of the adult human brain (*mc*). The lateral or posterior calcarine sulcus (*lc*), which in the adult human brain forms the posterior extremity of the complete, fully developed calcarine fissural complex next to the occipital pole, appears much later during fetal development, duplicating ontogenetically its late appearance phylogenetically (for details *see* sec. 2, this chapter).

Other sulci and fissures begin to appear at a considerably later period, at a fetal age of six and one-half menstrual months (Fig. 270, lower diagrams). Some of these sulci form important boundaries by which the cerebral hemispheres are subdivided into major portions or lobes. On the lateral face the central sulcus of Rolando (*cs*) develops, separating the hemisphere of the brain into two almost equal halves, a frontal lobe anteriorly and a posterior portion (*cf.* *c* in Fig. 271). The posterior portion, in turn, is subdivided at this stage by the now much deeper, but narrower, lateral or Sylvian fissure (*Sylv. f.*) into an upper portion, the parietal lobe (*pl*), and a lower portion, the temporal lobe (*tl*). Posteriorly, both these lobes are directly continuous with the posteriormost portion of the hemisphere, the occipital lobe (*occl*). Several vague depressions identifiable as the incipient superior frontal, intraparietal, and other sulci at this stage become noticeable on the previously smooth surface.

On the medial face of the brain the most marked furrow is the calcarine sulcus or fissure (*calc. fiss.*). It is further deepened and lengthened and is now joined with the occipitoparietal sulcus (*op*). Toward the end of the prenatal period this simple fissural pattern of the human fetal brain is complicated by the appearance of secondary and tertiary sulci, which produce the final complex fissuration and gyration of the adult human brain (Figs. 182, 271).

3. Sulci and gyri of the adult human brain and the principal anatomical subdivisions of the cerebral hemispheres.—On the external or lateral face of the human cerebral hemisphere, five principal subdivisions, called lobes, are customarily distinguished (Fig. 271, upper diagram): frontal (*fl*), parietal (*pl*), temporal (*tl*), and occipital lobes (*ol*), and the

insula or "island" of Reil (concealed in the Sylvian fossa or pit, *Syl; see* Figs. 275, 301).

On the lateral face of the frontal lobe (*fl*) two principal furrows are usually found, the superior (*sfs*) and inferior frontal sulci (*ifs*), which separate three convolutions or gyri, the superior (*sfg*), middle (*mfg*), and inferior frontal gyri (*ifg*). The frontal sulci, however, extend only as far as the precentral sulcus (*precs*), which, usually broken up into several components, follows at some distance in front of and more or less parallel to the central sulcus (*c*), separating the anterior central, or precentral, gyrus from the rest of the frontal lobe. The orbital gyri (*og*) and the *gyrus rectus* or straight gyrus (*gr*, lower diagram), together with orbital sulci and the olfactory sulcus, in which the olfactory tract and bulb are lodged, form the inferior face of the frontal lobe (*see also* Fig. 272).

The parietal lobe (*pl*) is the region roughly outlined by the central sulcus (*c*) anteriorly, by the lateral or Sylvian fissure (*Syl*) inferiorly, and by an approximate vertical line beginning at the upper end of the parieto-occipital or occipital perpendicular sulcus (*po*) posteriorly. The convolution along the central sulcus—the postcentral gyrus—is more or less separated from the remainder of the parietal lobe by the postcentral sulcus (*pocs*), which, in turn, is usually broken up into a superior and an inferior component.

The rest of the parietal lobe, again, is subdivided by a horizontally placed or arching intraparietal sulcus (*ip*, in Figs. 271, 273; *ips*, in Fig. 272) into a superior and an inferior parietal lobule, the latter of which is composed of a supramarginal gyrus (*smg*, at the end of the lateral fissure) and an angular gyrus behind (*ag*). Sometimes a third, most posterior, division is distinguishable, the inferior posterior parietal gyrus of Retzius (*ippg*).

Below the parietal lobe and largely separated from it by a deep and spacious pocket of the lateral or Sylvian fossa or pit (*Syl*) is the temporal lobe (*tl*, in Fig. 271). This lobe is subdivided on the lateral face by a superior temporal, or parallel, sulcus (*sts*) and usually by a fragmented medial temporal sulcus (*mts*) into a superior (*stg*), middle (*mtg*), and inferior temporal gyrus (*itg*).

A large part of the cortex lies deeply hidden in the lateral fissure of Sylvius (*Syl*) beneath the overhanging surrounding parts, the frontal, parietal, and temporal opercula (Fig. 271). The deepest part or floor of the pit represents the insula or "island" of Reil, consisting of one long and several short gyri. The covered portion of the temporal lobe usually exhibits one long, broad convolution, placed obliquely, and one or two shorter ones in the posterior pocket of the pit. These are the transverse temporal gyri of Heschl (*H1* and *H2* in Fig. 274).

On the inner or medial face of the hemisphere (Fig. 271, lower diagram; also right diagrams in Figs. 272, 273), the gyrus next to the corpus callosum (*cc*, *gen*, *spl*) and encircling it from the front, from above, and from behind is the fornicate or cingular gyrus (*fcg*). The portion of the frontal lobe above it belongs to the superior frontal gyrus (*sfg*), here called marginal gyrus (*mg*). The paracentral lobule (*pcl*) is the medial extension of the anterior and posterior central, or precentral and postcentral, gyri. The quadrangular area just behind it is the precuneus (*precu*). The posterior boundary of the precuneus, and thus of the parietal lobe, separating the latter from the occipital lobe, is a deep furrow—in fact, a pit or fossa, the medial parieto-occipital fissure or sulcus (*po*), extending down to the calcarine fissure (*mc*).

The triangular area inclosed by the parieto-occipital and calcarine fissures is the *cuneus* or "wedge" (*cu*). The convolution just below the calcarine fissure which extends to the inferior face of the temporal lobe (*tl*) is the lingual gyrus (*lg*); its apparent continuation is the hippocampal gyrus (*hig*), terminating with the *uncus* or "hook" (*u*). Just outward to the latter gyri, also on the inferior face of the occipitotemporal region, is the fusiform or spindle-shaped gyrus (*fusg*), separated from the former by the collateral sulcus (*cols*). The furrow separating the fusiform gyrus from the inferior temporal gyrus (*itg*) is the inferior temporal sulcus (*its*).

Behind the parietal and temporal lobes, and only incompletely separated from them on the lateral face by the posterior descending extremity of the intraparietal sulcus, called the transverse occipital sulcus of Ecker (*tos*), and on the medial face of the hemisphere by the parieto-occipital sulcus (*po*), is the occipital lobe (*ol* in

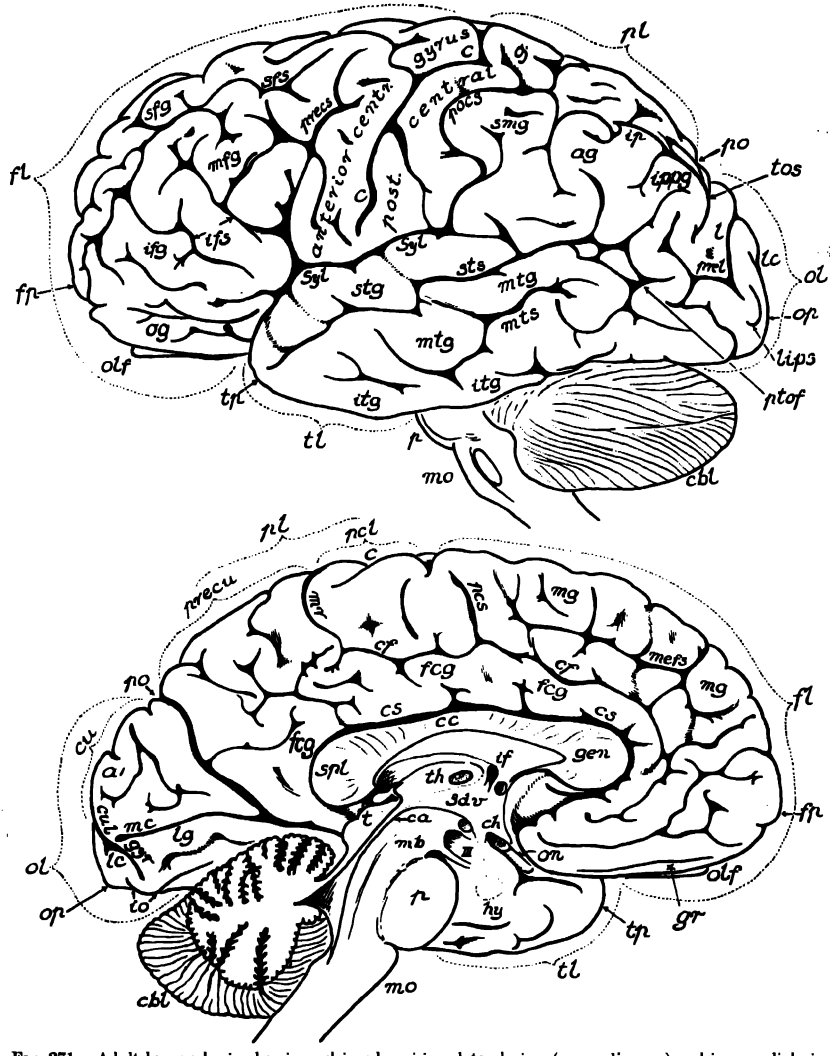

FIG. 271.—Adult human brain showing sulci and gyri in a lateral view (*upper diagram*) and in a medial view (*lower diagram*). *Labeling* for this and for the following Figs. 272, 273: *a1*, posterior cuneal gyrus; *c*, central sulcus of Rolando; *ca*, cerebral aqueduct of Sylvius; *cbl*, cerebellum; *cc*, corpus callosum; *cf*, cingular or fornicate sulcus; *ch*, chiasma of optic nerves; *cl*, cuneal or upper lip of calcarine fissure; *cs*, the sulcus of the corpus callosum; *cu*, *cun*, cuneus or "wedge"; *cul*, *cul gyr*, posterior cuneolingual gyrus of Cunningham, descending gyrus, or extreme lobule of Ecker; *fcg*, fornicate or cingular gyrus; *fl*, frontal lobe; *fp*, frontal pole; *fusg*, fusiform or occipitotemporal gyrus; *gen*, genu or "knee" of corpus callosum; *gr*, gyrus rectus or straight gyrus; *hif*, hippocampal fissure; *hig*, hippocampal gyrus; *hy*, hypophysis or pituitary gland; *if*, interventricular foramen of Monro; *ifg*, inferior frontal gyrus; *io*, inferior occipital sulcus; *ip*, *ips*, intraparietal sulcus; *ippg*, inferior posterior parietal gyrus or lobule of Retzius; *isth*, isthmus of fornicate or cingular and hippocampal gyri; *itg*, inferior temporal gyrus; *its*, inferior temporal sulcus; *l*, lunate or simian sulcus, *Affenspalte*; *lg*, lingual gyrus; *lc*, lateral or posterior calcarine sulcus; external calcarine sulcus of Cunningham; lateral calcarine sulcus of Ingalls and Kuh-

Fig. 271; *see also* Figs. 272, 273). The sulcal and gyral configuration of the occipital lobe frequently more or less resembles the conditions regularly present in the simian brain, its phylogenetic predecessor, with a lunate sulcus (*l*), a homologue of the simian sulcus or *Affenspalte*, and an occipital operculum (*op*) behind it (*cf.* Figs. 280, 282, 284, 286, 293, 294).

From the lunate sulcus a branch may extend for a varying distance into the parietal lobe. This is the prelunate sulcus (*prel*). If there is no lunate sulcus or if the lunate sulcus and the occipital operculum have been pushed back as far as the occipital pole, the lateral face of the occipital lobe is split by a number of short, twisted sulci into several irregular convolutions, the lateral occipital gyri (*og* in Fig. 296), the homologues of the annectent gyri of the simian brain, which have emerged onto the surface (*ag* in Figs. 282 and 284).

In many human brains, perhaps even in most of them, however, the original primate sulcal and gyral pattern can be revealed by careful examination. Such an examination will show the presence of a calcarine fissural complex, which, on comparative-anatomical and embryological grounds, may be subdivided into a medial or anterior calcarine sulcus (*mc*) and a lateral or posterior calcarine sulcus (*lc*), as will be discussed in detail in sections 2 and 3 of this chapter. Together, these three sulci form the classical posterior or horizontal occipital sulcus of Henle, better known as the calcarine sulcus or fissure of T. H. Huxley. A careful inspection of the external configuration of the occipital lobe in numerous specimens suffices to reveal the simian homologies of its components. In other complex and dubious instances the only safe criterion is the relation of the striate cortex or visual cortical area to the sulci and gyri in question.

4. Functional localization in the human cerebral cortex.—Since the observations and speculations of Francis Joseph Gall (1809, 1810–19, 1825) and of Jean Bouillaud (1825, 1839), but more definitely since the discovery of the motor speech center by Paul Broca (1861) and the presence of stimulable points by Fritsch and Hitzig (1870), the ancient concept of functional omnivalence of the entire cerebral cortex, rooted in the belief in a single, homogeneous, and indivisible transcendental "soul" or "mind," has been gradually replaced by another concept, that of the composite nature of cerebral functions. Just as the whole human organism is made up of numerous diverse parts and organs, each performing its own particular work, in harmony with other parts and organs, so each given locality, nucleus, cortical area, or any other accumulation of nerve cells possesses its own functional properties different from the properties of all other nuclei, areae, or foci of the brain.

The brain is an extremely complex organ, composed of diverse parts that possess their own functional properties, all parts being intricately interconnected to form a composite whole. The many efforts through which the present concept of functional cerebral organization was achieved are presented in Part I of this book, especially in chapter III, 3, 6, and chapter IV, 7, whereas the question of the basic organi-

---

lenbeck; triradiate sulcus of Landau; lateral intrastriate sulcus of Elliot Smith; ypsiliform sulcus of Ariëns Kappers; *lips*, lateral inferior paracalcarine sulcus; *ll*, lingual or lower lip of calcarine fissure; *lsps*, posterior superior paracalcarine sulcus; *mb*, midbrain; *mc*, medial or anterior calcarine sulcus; stem and posterior calcarine fissure of Cunningham; proper, limiting, or prestriate calcarine sulcus together with retrocalcarine sulcus of Elliot Smith; medial striate or intermediate portion of calcarine fissure of Kuhlenbeck (in part); *mefs*, medial frontal sulcus; *mfg*, middle frontal gyrus; *mg*, marginal gyrus; *mips*, medial inferior paracalcarine sulcus; *mo*, medulla oblongata; *mr*, marginal ramus of cingular or fornicate sulcus *cf*; *msps*, medial superior paracalcarine sulcus; *mtg*, middle temporal gyrus; *mts*, middle temporal sulcus; *og*, orbital gyri; *ol*, occipital lobe; *olf*, olfactory bulb and tract; *olfs*, olfactory sulcus; *on*, optic nerve; *op*, occipital pole; *p*, pons or "bridge"; *pcl*, paracentral lobule; *pcs*, paracentral sulcus; *pl*, parietal lobe; *pms*, paramedian sulcus of Elliot Smith; *po*, parieto-occipital sulcus; *pocs*, postcentral sulcus; *precs*, precentral sulcus; *precu*, precuneus or quadrate lobule; *prel*, prelunate sulcus; *ptof*, parietotemporo-occipital fossa or pit; *rhif*, rhinal fissure; *sfg*, superior frontal gyrus; *sfs*, superior frontal sulcus; *smg*, supramarginal gyrus; *spl*, splenium of corpus callosum; *stg*, superior temporal gyrus; *sts*, superior temporal or parallel sulcus; *S*, *Syl*, lateral fissure or pit of Sylvius; *t*, tectum or quadrigeminal bodies or colliculi of midbrain; *th*, thalamus; *tl*, temporal lobe; *tos*, transverse parietal or occipital sulcus; *tp*, temporal pole; *u*, uncus or "hook" of hippocampal gyrus; *3dv*, third cerebral ventricle; *III*, third cranial or oculomotor nerve.

zation of nervous tissue is dealt with in chapter I, 9, and in chapter IX.

The functional organization of the human brain, an organ which has been called "the most intricate living substance on this planet," is a problem which must still be regarded as far from solved. Much remains uncertain, even if we disregard the subtle question of the minute concatenation of the many types of nerve cells into complex associations and their interpretation in terms of function and limit ourselves to more or less gross functions. In the following, therefore, only those functions related to the principal senses and motility will be mentioned briefly, to serve as a background or framework for the function of vision, the principal theme of this book.

The *sense of vision*, or sight, is bound to the occipital lobes of both hemispheres of the brain (*Vision*, in Fig. 274; *cf.* Figs. 300, 301). The striate area or "striped cortex," so named by Elliot Smith because of a whitish line visible on a cross-section through it without magnification, or Brodmann's field *17*, lining the calcarine fissure on the medial sides and at the poles of the occipital lobes (given in close shading in the

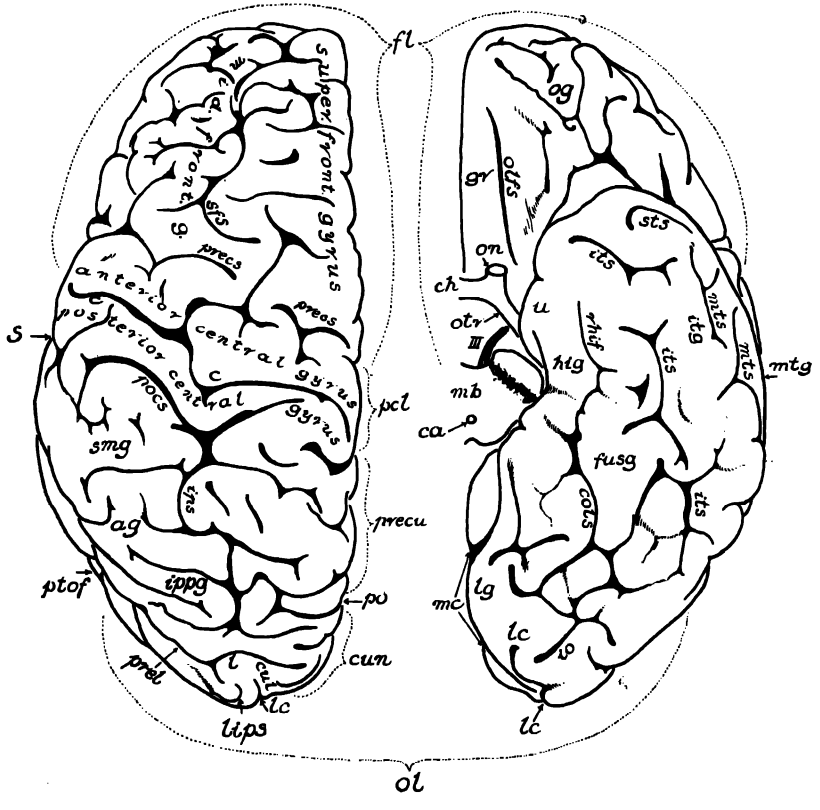

FIG. 272.—Left hemisphere of an adult human brain seen from above (*left diagram*) and from below (*right diagram*), showing major subdivisions besides sulci and gyri. Same specimen as the one represented in Figs. 271 and 273. (For *labeling see* legend of Fig. 271.)

same figure), is, as far as now known, the "gateway" for all impulses entering the cortex which originate in the retinae of the eyes. From here the impulses are further distributed into adjoining para- and peristriate areae of Elliot Smith, or Brodmann's fields *18* and *19*, and beyond.

The striate area appears to be a carrier of the visual sensations of a more elemental character, such as the perception of light, colors, and localization of external objects in space whence the stimuli arrive (*see ELEMENTAL VISUAL*

participation of the adjoining parts of the parietal, temporal, and occipital lobes in vision is even less clear, the indications being in favor of the localization of certain highly complex visual functions, such as reading and writing, in these territories (*cf.* also "Comment on Figure 274," this section).

The conjugate movements of the two eyes are also partly directed by the cortex of the occipital lobes, other similar centers being in the frontal lobe just in front of the precentral gyrus and apparently also in other localities,

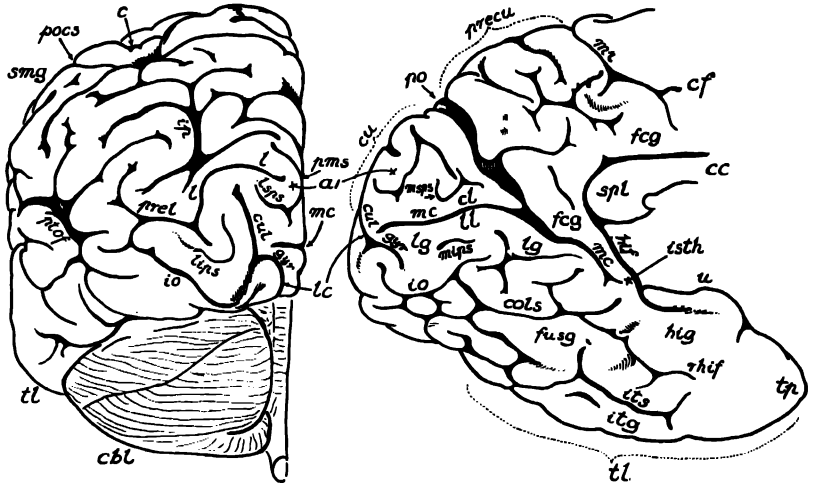

FIG. 273.—Left occipital lobe of the same human brain represented in preceding two figures, seen from behind (*left diagram*) and from a medial aspect (*right diagram*), showing the arrangement of sulci and gyri. (For *labeling see* legend of Fig. 271.)

SENSATIONS between sulci *l* and *lc*, in Fig. 275). The para-peristriate areae, in turn, seem to be a material repository of complex visual functions, such as visual memory of the shape, color, and movements of objects which have been observed and of the symbols or meanings of these objects or situations (*see 5*, in Fig. 274; and *COMPLEX VISUAL MEMORY* in Fig. 275).

To what extent these two categories of functions are tied to either the striate or the para-peristriate areae, or whether the first does or does not participate in the commemorative functions at all, remains an open question. The

such as the vicinity of the auditory center in the temporal lobe.

The *sense of hearing* is localized in the posterior pocket of the Sylvian fossa or pit and in the temporal lobe. Here again a projection area or "gateway" for the auditory impulses, identical with the termination of the auditory radiation, roughly coinciding with the transverse temporal gyri of Heschl (*H1*, *H2*), is distinguished from the surrounding spacious areae comprising most or all of the temporal lobe, with, perhaps, the adjoining portions of the Sylvian fossa and parts of the parietal and occipital lobes.

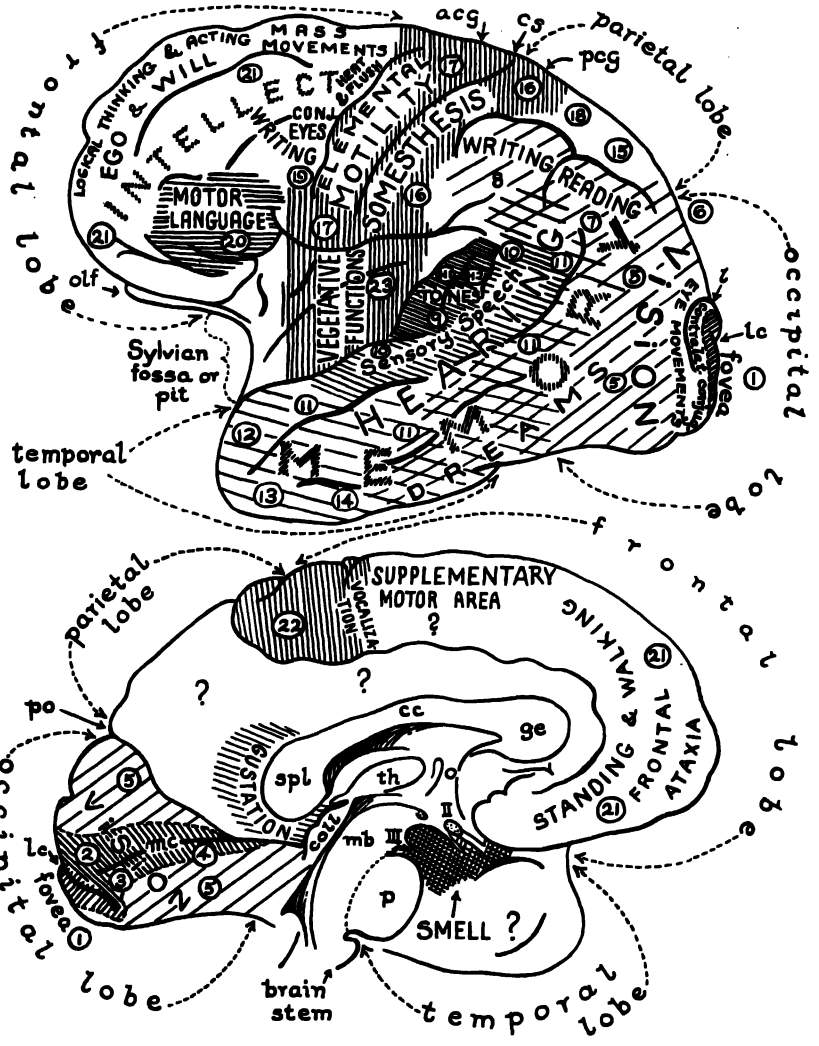

FIG. 274.—Principal functional centers of the human brain as determined by the physiological experiments, clinical observations, pathoanatomic investigations, and neurosurgical experience during the past hundred years (*cf.* chaps. III and IV). Upper figure represents the lateral face of the left cerebral hemisphere, with the opercular portions of the frontal and parietal lobes pulled away from the temporal lobe, in order to show the concealed parts of the Sylvian fossa. The lower figure represents the inner face of the left hemisphere. Sensory and motor centers are indicated by close shading. *Labeling: acg*, anterior central gyrus; *cc*, corpus callosum; *coll*, midbrain colliculi; *cs*, central sulcus; *ge*, genu or "knee" of corpus callosum; *H1*, *H2*, first and second transverse temporal gyrus of Heschl; *l*, lunate or simian sulcus; *lc*, lateral calcarine sulcus; *mc*, medial calcarine sulcus; *mb*, midbrain; *olf*, olfactory bulb; *p*, pons or "bridge"; *pcg*, posterior central gyrus; *spl*, splenium or "bandage" of corpus callosum; *th*, thalamus; *II*, chiasma of optic nerves; *III*, oculomotor nerve. (*Cf.* the following figure and Figs. 81, 115, 271, 272, 273, 300, 301; for further description and for the explanation of encircled figures and for the sources, *see* chap. VIII, 1 [4, 5].)

The cortex of Heschl's gyri apparently serves as a substratum of simple, elemental auditory perceptions, such as the intensity, pitch, and other tonal qualities of sound, the tones being arranged according to their proper position, from the highest to the lowest (Fig. 275). The temporal region appears to be a repository of the gnostic and commemorative qualities, such as auditory or vocal language or the recognition and understanding of spoken words and sentences and of their semantic meaning, including grammar and syntax, harmonies and melodies, and symbolic meanings of the various noises.

The *somesthetic sense*, the third principal faculty upon which human intellect is founded, is localized in and around the central sulcus (*cs*, in Figs. 274, 275). This sense may be subdivided into two categories, each with special localization. The one category comprises touch, especially "two-point discrimination," and also to some extent the sense of pain and thermal sense, or exteroceptive qualities with a subjective attribute of the externality; this category depends upon the posterior central gyrus (*pcg*), including the posterior wall of the central sulcus. The other category comprises sensations from the deeper parts of the body, particularly from the locomotor organs, such as the muscles, tendons, and joints of the limbs, which together contribute to the tridimensional sense of space or position of the limbs, or the so-called stereognostic sense; this faculty also depends, according to the latest neurosurgical experiences, upon the postcentral gyrus; but it may also be localized in the anterior central gyrus (*acg*), including the anterior wall of the central sulcus, and perhaps also to some extent in the adjoining parts of the frontal lobe. The numerous afferent fibers originating in the thalamus and terminating in the precentral gyrus and near-by parts of the frontal lobe indicate this (*cf.* Polyak 1932).

Closely allied with the somesthetic sense is the *somatomotor function*, represented by foci whence distinct movements on the contralateral side may be elicited by stimulation or paralysis may result from their damage. Such foci are chiefly in the precentral gyrus (*acg*). The postcentral gyrus directs only crude contralateral movements.

The exteroceptive sense of the bodily surface is represented in an orderly way, by segments and parts thereof, in the contralateral postcentral gyrus (*pcg*), with the mouth, tongue, and lips localized in the parietal *operculum* next to the Sylvian fossa, followed by segments representing the face, thumb, fingers, hand, arm, the trunk, leg, foot, toes, and *perineum* (Fig. 275). The parts which have more elaborate function, such as the tongue, lips, face, hand, and fingers, especially the thumb, have a proportionally larger areal representation than those where the sense is coarse, as on the trunk. In a similar way the numerous small muscles of the hand and arm, performing elaborate skilled movements, are represented in a more detailed way in a larger portion of the precentral gyrus (*cf.* motor and sensory *Homunculus*, in Figs. 9, 10, 22, 114, and 115, in Penfield & Rasmussen 1950).

The exteroceptive postcentral and the motor precentral representations are arranged fairly symmetrically on both sides of the central sulcus for each part or segment of the body. It is probable that this holds also for the proprioceptive qualities in the precentral gyrus.

Other motor centers, such as the frontal oculogyric center for the associated contralateral eye movements, are outside the somatomotor area proper in the frontal lobe, while the other similar optogyric foci for associated eye movements, distributed according to their spatial values, are located along the boundary of the striate area in the occipital lobe, with still other similar auditogyric eye foci attached to the auditory center in the Sylvian fossa and in the temporal lobe.

The other two faculties, the sense of *smell* and of *taste*, of capital importance on the lower levels of the vertebrate scale, in all Primates including Man are relegated in importance to a secondary role. The olfactory function, besides being localized in the olfactory bulb and tract (*olf*), is obviously served by those parts of the brain anatomically related to the first, particularly the prepyriform and periamygdaloid cortex. The gustatory sense is possibly related to the posterior portion of the fornicate or cingular gyrus and/or to the "island" of Reil in the Sylvian fossa.

Human *speech* or *language*, a function intimately related to Man's intellect, is a complex performance in which various parts of the cere-

bral cortex work together. Its two principal components are the auditory or sensory and the motor.

The sensory-auditory speech center of Wernicke is located in the superior temporal gyrus next to the terminal area of the auditory radiasentences, with pronunciation more or less preserved.

The other component of speech, the motor, is localized in the posterior portion of the inferior frontal gyrus, or Broca's area. The usually accepted view assumes the presence of Broca's

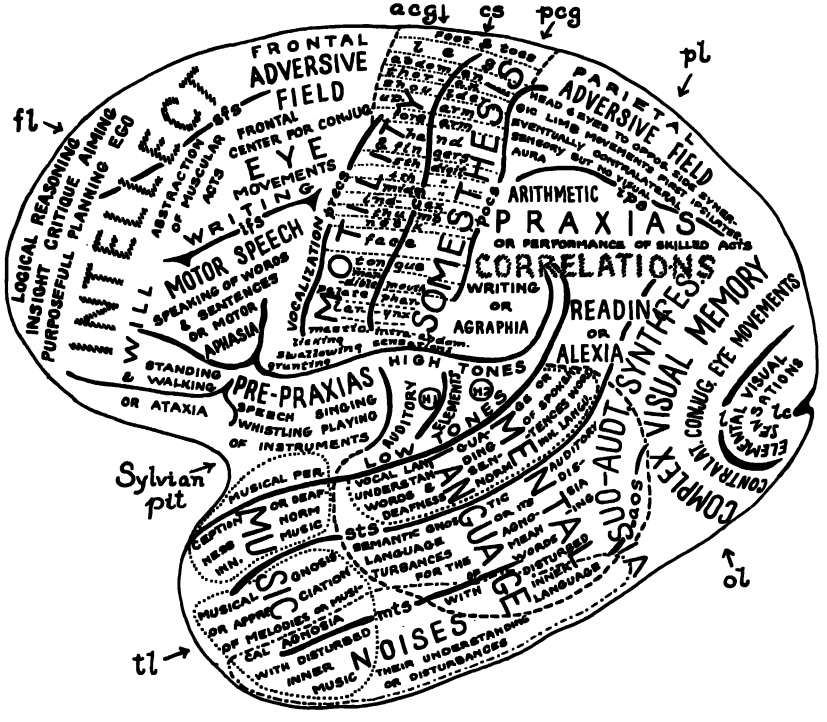

FIG. 275.—Functional map of the motor, sensory, and mental faculties in the human cerebral cortex based upon clinical observations, pathoanatomic investigations, and neurosurgical experiments. Lateral face of the left hemisphere of the human brain with Sylvian pit wide open. *Labeling: aos*, anterior occipital sulcus; *cs*, central sulcus of Rolando; *fl*, frontal lobe; *H1*, *H2*, first and second transverse temporal gyrus of Heschl; *ips*, intraparietal sulcus; *l*, lunate or simian sulcus; *lc*, lateral or posterior calcarine sulcus; *mts*, middle temporal sulcus; *ol*, occipital lobe; *pl*, parietal lobe; *pocs*, postcentral sulcus; *precs*, precentral sulcus; *sfs*, superior frontal sulcus; *sts*, superior temporal sulcus; *tl*, temporal lobe. (*Cf.* preceding figure and Figs. 115, 271, 272, 273, 300, 301; for further information *see* chap. VIII, 1 [4, 5].)

tion in the transverse temporal gyri of Heschl (*H1*, *H2*). It serves as a repository of complex auditory memory or auditory gnosis, or recognition and identification of verbal images and sentences. Its impairment results in an auditory word deafness or agnosia for heard words or

center in right-handed people in the left hemisphere of the brain, and in left-handed people in the right hemisphere. Whether this is valid for all or for the majority of individuals, whether perhaps there are exceptions, or whether the cerebral mechanism of language is essentially bi-

lateral, in analogy with the cerebral mechanisms of sight, audition, somesthetic sense, olfaction, gustation, and motility, future investigations alone may show.

5. COMMENT ON FIGURE 274 ON FUNCTIONAL LOCALIZATION IN THE CEREBRAL CORTEX.—Additional information on the functional localization in the human brain gathered from various sources is indicated by encircled numbers in this figure.

1. Representation of the central fovea and the points of fixation, where in stimulation experiments with conscious subjects various photomas, such as stars, placed straight ahead and standing still, frequently white, or in red, green, blue, and yellow colors, in the shape of diamonds, wheels, disks, or balls, or flashes of bright light, or visual aura of flame, were obtained; when this locality is damaged, homonymous scotomas in and around the points of fixation result, extending to the very dividing meridians (according to this author) or leaving central or "macular" sparing (*see* chap. XI, 8, 9, for the opinions of other authorities).

2. Scintillating photoma or a star moving from the contralateral side below toward the center.

3. Scintillation moving from the contralateral side above toward the center.

4. Lively scintillations or stars coming from the opposite side toward the center.

5. Substratum of complex visual memory; when artificially stimulated, producing either simple subjective sensations, such as lively photomas, bright stars, or balls, either colorless or in colors, flames, a sea of fire; or complex visual images, such as fog or black clouds moving toward the observer, various objects moving from the ipsilateral to the contralateral side, as, e.g., gaudy figures or butterflies coming from the opposite side toward the center, and changing rapidly one after another, or dancing lights; in stimulation experiments always associated with a strong deviation of eyes and turning of the head toward the contralateral side; in epilepsy frequently initiated by a complex visual aura; in damage followed by a contralateral loss of visual memory for shapes, colors, and the arrangement of visual objects, and/or a visual disorientation in space (possibly when damage also includes parts of the cortex labeled with encircled numbers *6*, *7*, *8*, and *15*).

6. Hallucination of being "far away," or of micropia or micropsia.

7. Repository of the visual verbal images; of the meaning and understanding of written language; when this locality is damaged, the inability to read, called *alexia*, results.

8. Ability to write or to perform kinetic hand and arm movements; a repository of engrams of "kinetic melodies" for writing; its loss results in agraphia or inability to write; a locality whose stimulation produces the inability to speak, or a parietal aphasic arrest.

9. Transverse temporal gyrus or gyri of Heschl (*H1*, *H2*), a cortical termination of the auditory radiation; the cortical auditory receptor area and distributor center of auditory impulses; when this area is destroyed, the result is central deafness (especially if bilateral); when stimulated, the result is turning of the eyes and the head and correspondingly co-ordinated movements of the body and limbs toward the opposite side; in auditory hallucinations it produces an auditory aura.

10. Wernicke's area, or auditory word transformer; this is the repository of auditory verbal images necessary for the understanding of spoken words and sentences; when it is impaired, perceptive word deafness results, without impairment either of motor or of inner language.

11. Repository of the meaning of auditory language or word semantics; substratum of auditory gnosis or understanding of words, of grammar and syntax; when this is destroyed, sensory aphasia of Wernicke, or agrammatism of Pick (1909), associative word deafness of Henschen, or commemorative word deafness results, with motor speech still possible, but with understanding of spoken language impaired and inner speech lost; when this locality is experimentally stimulated in a conscious human subject, inability to speak results, or the temporal area aphasic speech arrest of Penfield & Rasmussen; a probable localization of bodily vestibular balance; a substratum of complex auditory aura or hallucinations; the origin of Türck's fiber bundle.

12 and *13*. Repository of musical gnosis, or understanding of tonal qualities or pitch of single tones, of melodies, harmonies, or chords, and of rhythm and musical phrases; when damaged, lack of musical understanding results, or sensory amusia, or musical deafness, with inner music either preserved (when *12* destroyed) or impaired (when *13* damaged), with preserved tonal values and melodies, in spite of inability to understand them (musical agnosia); stimulation experiments are accompanied by fear and sensations in the abdomen, associated with movements of the hands.

14. Repository of the recognition or the meaning, or semantic values, of various noises.

15. Localization of the sensation of the position of the body in space; when stimulated, the sensation of dizziness or hallucination of falling results.

16. Center of bodily sense or somesthesis of the contralateral side, that is, of the superficial touch, including two-point discrimination, probably also partly of pain, temperature, and position of the limbs in tridimensional space, or stereognosis, in the opposite half of the body, face, head, and limbs, with the largest areal representation of the most used or most distal parts, such as lips, tongue, hand, fingers, and thumb; when damaged, numbness or hemianesthesia of the opposite half of the body, face, and limbs occurs; or the hallucination of numbness, tingling, pressure, or constriction in the corresponding half or parts results; a locality whence, when stimulated, crude movements of the opposite limbs may be elicited; but no lasting paralysis is produced when damaged.

17. Detailed action of individual muscles or groups of muscles of the contralateral side of the body and limbs or a transient complete contralateral hemiparalysis, with a return of crude movements of limbs and a residual lasting loss of detailed movements of the fingers and of the thumb, associated with spasticity or hypertonia on that side; or, when parts of the precentral gyrus alone are destroyed, resulting in monoplegia of the same character, limited to a particular muscular group or movement.

18. Parietal adversive field or area from which complex synergic movements of the contralateral limbs and eventually also of the ipsilateral ones may be obtained on stimulation, associated with turning of the eyes and head contralaterally; area where poorly localized sensations or sensory aura may be obtained in the contralateral limbs, but no visual aura.

19. Vocalization of inarticulate, nonverbal sounds *ah! oh! ugh!*, on stimulation of either hemisphere, which apparently stimulates the entire sound-producing apparatus, including the mouth, larynx, thorax, diaphragm, and abdomen.

20. Motor speech center; repository of the engrams of complex muscular movements, Monakow's "kinetic melodies" of speech, necessary for the enunciation of words and sentences and for singing, which may be possible, even though the auditory area of Wernicke (*10*) and its surroundings (*11*) may be damaged, resulting in Broca's motor aphasia, or inability to speak, with understanding of heard and written language still more or less preserved (provided that areae *7–14* and their connections escape injury); area whence interference with motor speech may be obtained on stimulation, or the frontal area of aphasic arrest.

21. Hypothetical substratum of abstract thinking; frontal center for equilibrium, or balance in standing, walking, and maintaining direction; when damaged, ataxia results, associated with change of character, irritability, moodiness, illogical thinking and acting, decrease of memory, eventually terminating in dementia.

22. Presumable motor and somesthetic centers for the contralateral leg and toes (according to Scarff 1940), or centers for the contralateral toes, for genitalia, and for the rectum (according to Penfield & Rasmussen 1950).

23. Centers for poorly localized sensations and involuntary movements of the alimentary system of organs and of intra-abdominal sensations (according to Penfield & Rasmussen 1950); centers for the regulation of blood pressure, respiration, and gastric motility (according to B. L. Hoffman 1951).

The preceding account and the diagrammatic representation of the present knowledge of the functional cerebral localization given in Figures 274 and 275 is a far cry from the "phrenology" of Gall, devised almost a century and a

half ago, discussed in the historical part of this book. In it the tremendous efforts of countless anatomists, physiological experimenters, and clinical and pathoanatomical observers are incorporated. Even so, as yet we have no more than a good foundation on which future investigators may build. In conclusion, it is fitting here to emphasize again the necessity for a thorough analysis of synaptical structures of the cerebral cortex, of which hardly a beginning has been made by S. Ramón y Cajal and a few other investigators, a work essential and indispensable to the proper understanding of the cortical mechanism (*cf.* sec. 7, this chapter).

Figures 274 and 275 represent a diagrammatic synthesis taken from several sources, chiefly from S. E. Henschen (*J. f. Psychol. u. Neurol.*, v. 22, 1918; *Ztschr. f. d. ges. Neurol. u. Psychiat.-Orig.*, vs. 47 and 52, 1919), Quensel & Pfeifer (*Zentralbl. f. d. ges. Neurol. u. Psychiat.*, v. 30, 1922; *Deutsche Ztschr. f. Nervenheilk.*, v. 77; *Ztschr. f. d. ges. Neurol. u. Psychiat.*, v. 81, 1922–23), O. Foerster (*J. f. Psychol. u. Neurol.*, v. 39; *Arch. Neurol. & Psychiat.*, v. 24, 1929), Foerster & Penfield (*Brain*, v. 53, 1930; *Ztschr. f. d. ges. Neurol. u. Psychiat.*, v. 125, 1930), J. M. Nielsen (*Agnosia*, etc., 1946), and Penfield & Rasmussen (*The Cerebral Cortex of Man*, 1950).

SEC. 2. GROSS ANATOMY OF THE CORTICAL VISUAL CENTERS

1. Morphology of the human calcarine fissure.—The calcarine sulcus or fissure, described and named by T. H. Huxley (1861; portrait, Fig. 276), also called the calcarine or striate fossa or pit by G. Elliot Smith (portrait, Fig. 277), is a locality of the cerebral cortex di-

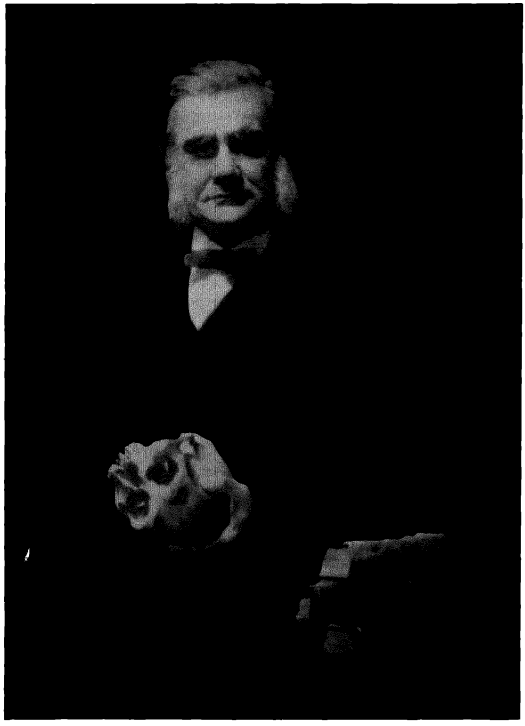

Fig. 276.—Thomas Henry Huxley (1825-95), professor of physiology in London. A notable biologist and foremost advocate of Darwin's "theory of evolution." First described and named the "calcarine sulcus" of the occipital lobes of the primate brain. From Stirling, *Some Apostles of Physiology*, Waterlow & Sons, London, 1932.

rectly related to the visual function. The evidence in support of this view is given in chapter VII and is further discussed in chapters IV, XI, and XII.

The calcarine fissure is a long furrow extending on the medial face of the occipital lobe in a roughly horizontal direction from the isthmus (*isth*) of the fornicate or cingular gyrus (*fcg*) below the splenium of the corpus callosum (*spl*) about as far as the tip or pole of the occipital lobe (*mc* and *lc* in Figs. 271, 273). The anterior portion is rather shallow, the posterior stretch is a deep and spacious pocket that includes a considerable area of the cortex (Fig. 278). The reverse situation is occasionally found in individual cases, with the anterior portion much more roomy than the posterior or polar portion.

The human calcarine fissure embodies morphological features common to all advanced Primates, Monkeys, Apes, and Man, in addition to those that must be considered specifi-

cally human. It is an evolutionary product, frequently sketchy and incomplete, of a merging or fusion of two distinct sulcal components arising within the territory of the striate area: (1) the medial or anterior calcarine sulcus (*mc*) between the fornicate-hippocampal isthmus and the posterior cuneolingual gyrus; and (2) the lateral or posterior calcarine sulcus behind the posterior cuneolingual gyrus (*lc*); (*cf.* par. 2, this section, and sec. 3, this chapter).

cipital pole. Usually it is curved, making one or more arches, with their convexities facing up or down. Also, either the fissure may be close to the lower margin of the medial face of the occipital lobe, making for a large cuneus, or the arches of the fissure may be considerably pushed upward, reducing the cuneus to half its usual size.

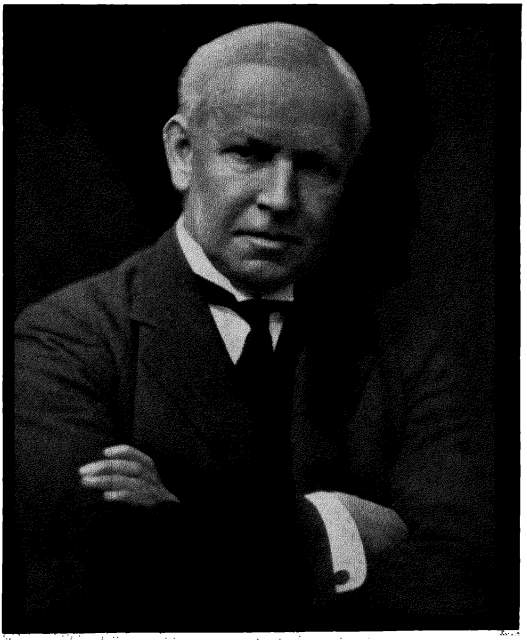

Fig. 277.—Grafton Elliot Smith (1871–1937), professor of anatomy at the University College of London, a lifelong student of the brain, especially of the cerebral cortex and of the visual center ("striate area," "lunate sulcus"), and an imaginative investigator of Man's origin (from J. Anat., v. 71, 1937). Courtesy J. Anat., and F. W. Schmidt, photographer, Manchester, England. *See*, for biography, Haymaker & Baer, *The Founders of Neurology*, 1953. For Smith's contributions to neurology *see* H. H. Woollard, in J. Anat., v. 72, p. 280, 1938.

The configuration of the calcarine fissure varies much in individual brains and in each hemisphere of a particular brain. It is rarely a single, fairly straight, horizontally placed furrow running from the isthmal region to the occipital pole, or may be short of

The calcarine fissure usually meets the medial parieto-occipital fissure (*po*) at a point about one-third the distance between the callosal splenium and the occipital pole, or farther away from the splenium. The posterior end of the calcarine fissure, often forked, may be precisely at the occipital pole, or may be short of

it, or may turn for a shorter or longer stretch around it onto the posterolateral face, or may be turned up or down.

Two lips—an upper cuneal or cuneofornicate (*cl*, dorsal *labium*) and a lower or lingual lip (*ll*, ventral *labium*)—are distinguished along most of the stretch of the calcarine fissure (Fig. 273, right diagram; Fig. 278). Frequently these lips are separated from the remainder of the cuneus and the lingual gyrus by secondary sulci running more or less parallel with the calcarine sulcus: the medial and lateral superior and inferior paracalcarine sulci (*msps*, *mips*, *lsps*, *lips*, in Figs. 273, 293).

When the lips of the calcarine fissure are drawn apart, the details of its floor, otherwise concealed, become visible (Fig. 278). In the anterior or precuneal portion, one or two small curved gyri are found hanging from the upper lip and oriented somewhat parallel to its margin: the cryptocalcarine gyri. Frequently, the anterior, attenuated, wedgelike portion of the cuneus continues in the anterior calcarine fissure, as an extension of the upper or cuneal lip, for quite a distance beneath the overhanging posteriormost gyrus of the precuneal cortex of the parietal lobe.

In the cuneal portion of the fissure one or more short, more or less vertical, or slanting gyri are found connecting the cuneus with the lingual gyrus: the anterior and posterior cuneolingual gyri of Cunningham. (According to Cunningham, one or the other gyrus is absent in from 8 to 10 per cent of brain specimens; according to others, these gyri are less frequent; according to our own experience, these gyri or their vestiges are present in most brains, the posterior one being a more stable feature.)

In some brains, or hemispheres, the cuneolingual gyri are not submerged and are visible on the medial surface, breaking up the calcarine fissure into two or more segments, the original constituents of the fissure (*cula*, *culpo*, in Fig. 295). Usually the posterior cuneolingual gyrus alone is on the surface, separating the anteromedial (*mc*) from the posterolateral (*lc*) calcarine sulcus (*see* right diagram, in Fig. 273). On occasion there are two anterior cuneolingual gyri, an upper one hanging from the upper lip and a lower one situated slightly more anteriorly, both gyri fitted to one another like the teeth of two cogwheels (Fig. 295, lower diagram). In still other cases no cuneolingual gyri whatever are found, and the entire calcarine fissure is a continuous, deep, smooth furrow (Fig. 293, lower diagram).

Altogether, the configuration of the calcarine fissure shows almost an infinity of individual variation of essentially the same sulcal and gyral pattern, in close association with, and dependence upon, the development of the adjoining regions of the occipital, parietal, and temporal lobes. No two brains and no two hemispheres of the same brain are exactly alike in all details of the calcarine fissural complex, although specimens are occasionally encountered in which the configuration in both hemispheres attains a remarkable degree of similarity. (*See* Zuckerkandl 1906; G. E. Smith; and Antoni, for additional data on the calcarine fissure.)

Hidden in the calcarine fissure is the calcarine artery, a branch of the posterior cerebral artery (Fig. 278). It gives off several twigs of various sizes for the two lips and for the cuneus. These arteries, in part, emerge with their terminal branches upon the cuneus, lingual gyrus, and the surface around the occipital pole. The same calcarine artery usually also gives off a large branch for the parieto-occipital sulcus, the posterior parietal artery. Another branch passing to the collateral sulcus—the collateral artery, a branch of the posterior temporo-occipital artery spreads over the ventral face of the occipital lobe. (*See* chap. X, 5, 6, 8, and corresponding figures, for additional information on blood supply.)

2. Morphology of the simian calcarine fissure.—In the simian brain the calcarine fissure has, in general, the same position on the inner or medial face of the occipito-parieto-temporal lobes as in the human brain. In the Indian Rhesus Macaque (Fig. 280), for example, and also in most other Monkeys its posterior extremity regularly forks into an ascending and a descending ramus or branch (*mc*, in *D* and *G*, in same figure; *see also* Connolly 1936, 1950).

The similarity of configuration of the simian and human calcarine fissure, however, is only apparent. In reality, the calcarine fissure of the Monkey is homologous only with approxi-

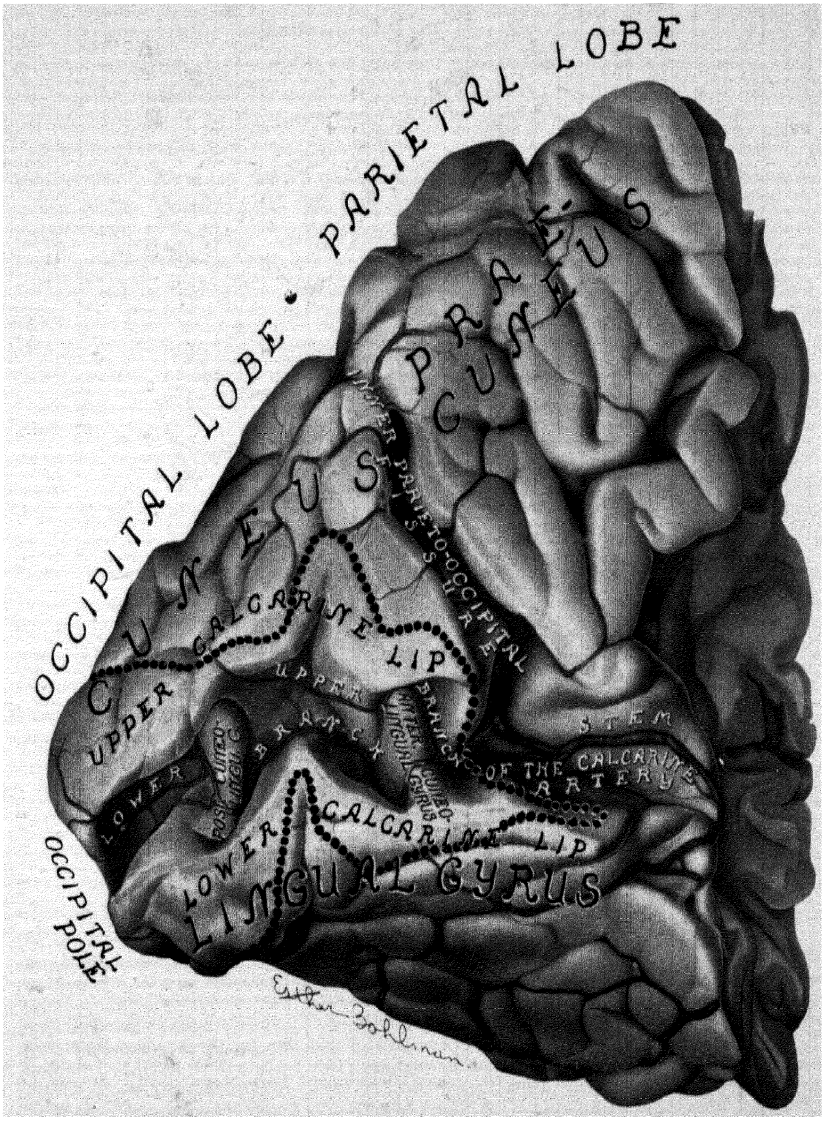

Fig. 278. Left occipital lobe viewed from the medial side. Lips of the calcarine fissure pulled apart in order to show the inner configuration, in particular the two cuneo-lingual gyri, and the distribution of the calcarine artery. Dotted line indicates the boundary of the striate area. (*Cf.* Figs. 288, 290, 293, 294, 295, 296.)

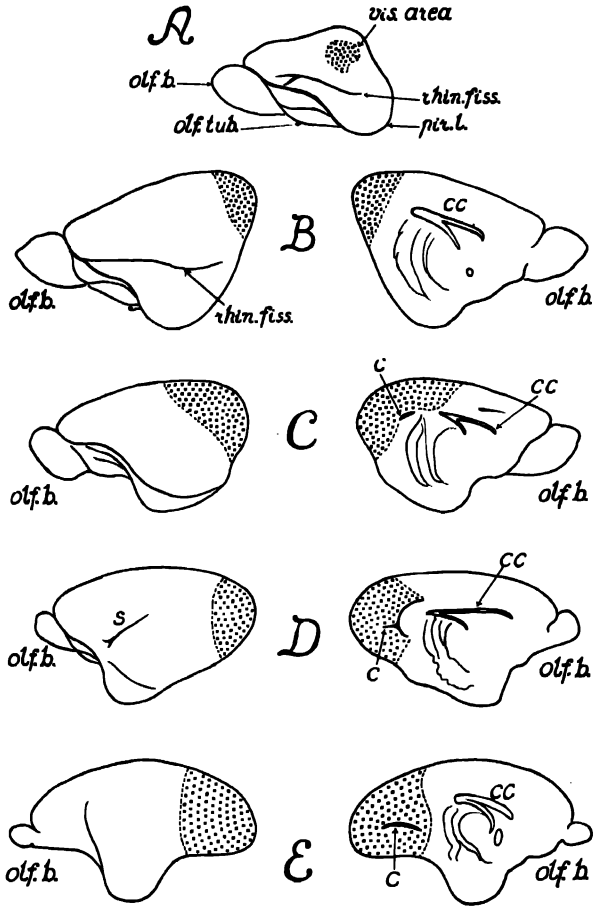

FIG. 279.—Composite drawing showing successive increase in size and change in shape and position of the cortical visual center, the striate area (*stippled*), in the forerunners and in the early representatives of the Primate Mammals, in dependence upon the mode of life: *A*, Jumping Shrew (*Macroscelides;* Africa; terrestrial, diurnal, moderately macrosmatic, large eyes, large anterior colliculi, but small and structurally poorly differentiated striate area; figure from Le Gros Clark 1928); *B*, Pen-tailed Shrew (*Ptilocercus lowii;* Borneo, Sumatra, Banka; arboreal, nocturnal, with small eyes and small, poorly differentiated striate area; figure from Le Gros Clark 1926); *C*, Tree Shrew (*Tupaia minor;* Malaya; mostly arboreal, diurnal, insectivorous, and fructivorous; rather large eyes; well-differentiated striate area spreading over a large part of hemisphere, on inside as far as calcarine sulcus, *c*, phylogenetically first to appear here; figure from Le Gros Clark, 1931); *D*, Mouse Lemur (*Microcebus murinus;* Madagascar; thoroughly arboreal, nocturnal, insectivorous, and fructivorous; eyes large; large striate area partly lining the calcarine fissure, *c*, which is here further extended in comparison with the Tree Shrew; figure from Le Gros Clark 1931, represents the "most primitive type of lemuroid brain"); *E*, Tarsier (*Tarsius spectrum;* Malaya; arboreal, nocturnal, subsists on insects, lizards, and other small animals; eyes very large, owl-like, relatively largest of all Mammals; striate area, comprising almost one-third of the cortex, surrounds and lines the calcarine fissure, *c;* figure from Woollard 1926). Note the gradual recession of olfactory parts (*olf.b., olf.tub., pir.l.*) as the striate area expands. *Other labeling: cc*, corpus callosum; *olf.b.*, olfactory bulb; *olf.tub.*, olfactory tubercle; *pir.l.*, piriform lobe; *rhin.fiss.*, rhinal fissure; *vis. area*, striate area. (For further information on Jumping Shrew, Tree Shrew, and Tarsier *see* chap. XIV, 10, 12.)

mately the anterior two-thirds or so of the human fissure, exactly from its anterior extremity at the fornicate-hippocampal *isthmus* or "neck" (*isth*, Fig. 273) to about midway or a little more of its cuneal stretch, or precisely as far back as the posterior cuneolingual gyrus (*cul gyr*). This portion corresponds to the "stem" and the "posterior calcarine fissure" of Cunningham; to the "proper," "limiting," or "prestriate calcarine sulcus," together with the "retrocalcarine" of G. E. Smith (*see* G. E. Smith, Tr Linn. Soc. 1902, p. 386); or to the "medial striate" or "intermediate portion of the calcarine fissure" of Kuhlenbeck. In the terminology adopted in this book this portion of the calcarine fissure of the simian brain and its human homologue, for reasons dealt with in the subsequent pages, is called the *medial* or *anterior calcarine fissure* (*mc* in the accompanying illustrations).

In the Monkey, the portion of the cortex homologous with the posterior third or so of the human calcarine fissure (*lc*, in Fig. 273), the "external calcarine sulcus" of Cunningham, is still located on the lateral, convex face of the cerebral hemisphere. It is not yet included in the fissure, and it still remains wide open: the occipital operculum of the simian brain (*oo*), largely identical with the simian occipital lobe (*ol*, in Fig. 280, *A*, *B*, *C*, *E*, *F*).

In most Old World Monkeys —for example, in large specimens of the Macaque—there is found an incipient invagination of the opercular striate cortex, from which the human polar calcarine fossa or pit (*lc*) behind the posterior cuneolingual gyrus develops (Fig. 280). This invagination is usually indicated by a shallow, but well-marked, sulcus, less often merely by a slight depression, on the lateral face of the occipital lobe (*lc*, same figure). This is the "superior" or "horizontal occipital," "occipital diagonal," "lateral intrastriate," or "opercular sulcus," more correctly called the "external calcarine sulcus" by Cunningham and "lateral calcarine sulcus" by Ingalls.

Occasionally, there may be two short and shallow lateral sulci arranged in succession, one close to the simian sulcus, the other curving around the occipital pole and embracing the inferior prong of the medial calcarine sulcus from beneath, obviously an intermediate arrangement indicating a beginning of the merging into a complete lateral calcarine sulcus of the simian brain. In still other cases only a short dent beneath the inferior prong of *mc*, with or without a slight depression close to *l*, indicates the very beginnings of the formation of a lateral calcarine sulcus.

Because of the usual three-pronged, shamrock-like formation of the lateral calcarine sulcus in the Anthropomorphous Apes (*lc*, in Figs. 284, 286), it was named "triradiate sulcus" by Landau, "ypsiliform sulcus" by Ariëns Kappers, "sulcus *x*" by others, and, because it is located within the lateral portion of the striate area, "lateral intrastriate sulcus" by G. Elliot Smith. For reasons to be discussed subsequently, this sulcus is simply called "lateral or posterior calcarine sulcus or fissure" (*lc*) in this book.

Except for this "oriment," or phylogenetical beginning, of what, during further evolutionary stages, develops into a posterior, foveal-areal segment of the human calcarine fissure at the occipital pole, in contrast with the complicated configuration of the human hemisphere, the lateral face of the occipital lobe is rather smooth in most of the Lower Simians, especially the Catarrhines.

Also, in the catarrhine Simians the occipital lobe is sharply separated from the rest of the hemisphere by a deep furrow or cleft, the lateral or external parieto-occipital sulcus or fossa, called the "external or perpendicular fissure" by Gratiolet and by Huxley, and known since Rüdinger (1882) as the "simian sulcus or fissure," *sulcus* or *fissura simialis* or *f. simiarum*, and *Affenspalte* or "monkey cleft or slit" (*l*, in Figs. 280 86).

How the "calcarine sulcal complex" of the advanced Simians and of Man developed from these original component oriments of the simian brain is treated in section 3, in this chapter.

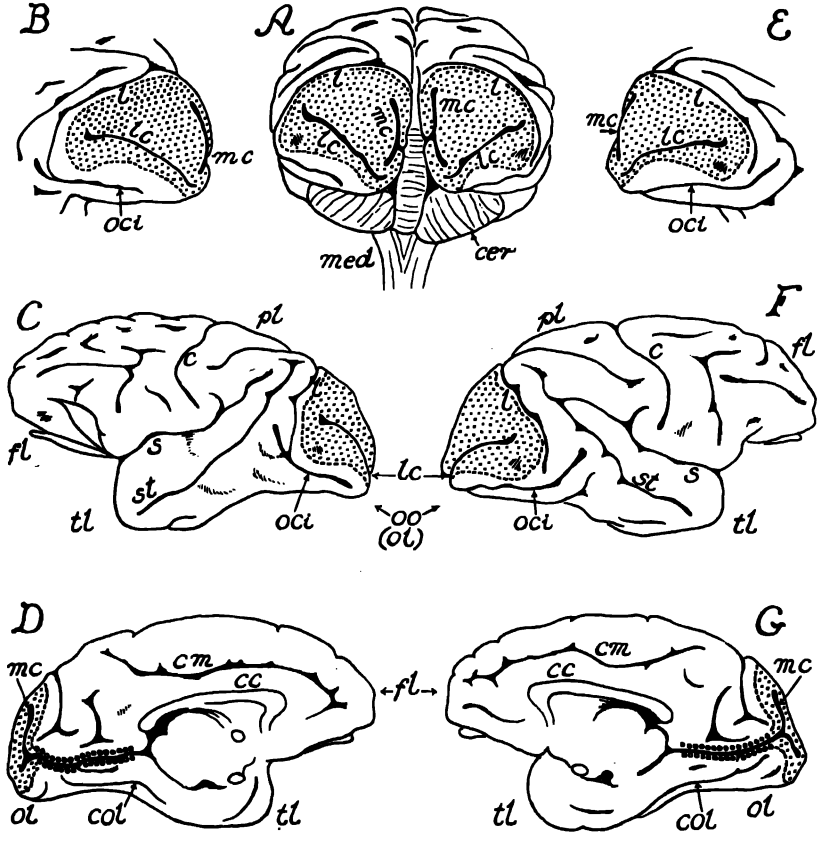

FIG. 280.—External configuration of the brain of a Rhesus Macaque showing the extent and location of the visual cortex, or striate area (exposed portion stippled; concealed portion marked by circles). *A*, posterior view of both hemispheres showing two occipital lobes in relation to each other and to the rest of the brain; *B*, posterolateral aspect of left occipital lobe (operculum); *C*, lateral, *D*, medial views of left hemisphere; *E*, posterolateral aspect of right occipital lobe (operculum); *F*, lateral, *G*, medial views of right hemisphere. *Labeling: c*, central sulcus of Rolando; *cc*, corpus callosum; *cer*, cerebellum; *cm*, callosomarginal sulcus; *col*, collateral sulcus; *fl*, frontal lobe; *l*, lunate or simian sulcus; *lc*, lateral calcarine sulcus; *mc*, medial calcarine sulcus; *med*, medulla oblongata; *oci*, inferior occipital sulcus; *oo* (*ol*), occipital operculum or occipital lobe; *pl*, parietal lobe; *S*, Sylvian fissure; *st*, superior temporal sulcus; *tl*, temporal lobe. Reproduced slightly reduced. Note the relatively large size of the striate area compared with the rest of the cortex; the occipital lobes are almost entirely taken over by the striate cortex.

SEC. 3. PHYLOGENY OF THE HUMAN CALCARINE FISSURE AND THE STRIATE AREA

1. Origin of the human calcarine fissure and of the striate area from the visual centers of Infrahuman Mammals.—The peculiar anatomical features of the calcarine fissure of the fully developed, mature human brain and the topography and functional organization of the human striate area can be understood only if due consideration is paid to all those phases of the long process of phylogenesis which isfactory phylogenetical explanation. This is the more necessary in view of the otherwise detailed retinotopical homology of the striate area of Man and his lesser relatives, the Monkeys and the Apes, abundantly demonstrated both by experimental investigations and by clinical and pathological-anatomical observations. (*See* in chap. VI, 7; chap. VII, 4, 5, 6; and Part III this book.)

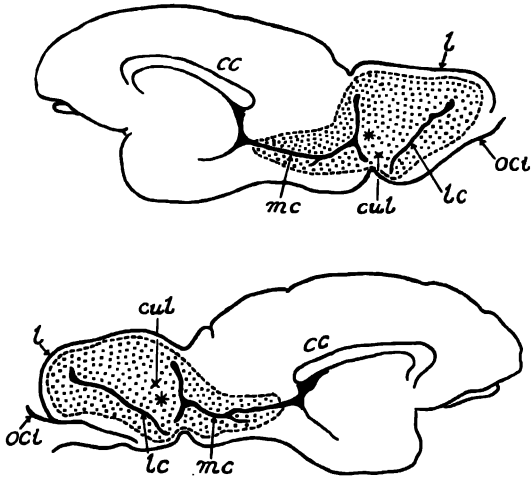

Fig. 281.—Right (*upper diagram*) and left cerebral hemisphere (*lower diagram*) of an adult Rhesus Macaque, with the occipital opercula represented turned back in order to align the lateral calcarine sulcus (*lc*) with the medial calcarine sulcus (*mc*), to conform to the condition usually found in the human brain. Both striate areae are represented in flat view. *Labeling: cc*, corpus callosum; *l*, lunate or simian sulcus; *oci*, inferior occipital sulcus. Asterisks (*) mark the position of the original occipital poles serving as hinges around which, during the process of phylogenesis, the simian occipital opercula rotate backward and medialward. Note the extraordinary relative length of the calcarine sulcal complex (*lc* and *mc*) and of the striate area (*stippled*), equaling two-thirds of the entire hemisphere. Compare with the conditions in Ateles (Figs. 282, 283), Chimpanzee (Figs. 284, 285), Gorilla (Fig. 286), and Man (Figs. 289–96). Reproduced at less than natural size.

have brought into existence the human cortical centers of sight.

Above all, the striking fact that in Man almost the entire striate area is found buried in a long and deep calcarine fissure wholly, or almost wholly, located on the medial face of the hemisphere, whereas in the lower Primates not less than half of the striate area is spread over the lateral face of the occipital lobe, requires a satisfactory phylogenetical explanation. This is the more necessary in view of the otherwise detailed retinotopical homology of the striate area of Man and his lesser relatives, the Monkeys and the Apes, abundantly demonstrated both by experimental investigations and by clinical and pathological-anatomical observations. (*See* in chap. VI, 7; chap. VII, 4, 5, 6; and Part III this book.)

The complete retinotopical homology of that portion of the striate area which covers the simian occipital operculum, or the "primitive occipital lobe," with the posterior third or so of the human calcarine fissure is clearly supported by the experiments already referred to.

Other evidence also supports this thesis, for example, the obvious fact that almost the entire cortex of the occipital operculum of the

lesser Primates belongs to the striate area (Fig. 280) and, above all, the mechanics of the phylogenetical process, because of which the striate area was gradually dislocated backward in the Primates, from the lowest to the highest.

The use in this connection of phylogenesis as evidence appears permissible, at least as an illustration of the probable stages of an evolutionary process through which the human cortical center of vision has passed, even though the now living and the known extinct representatives of the various suborders of Primates may not represent a "true phylogenetical series," since they may not be in every respect identical with the direct lineal ancestral links which preceded Modern Man. (*See*, for the phylogeny of Primates, Charles Darwin 1859, 1871 and subsequent editions; E. Haeckel 1866, 1891, 1894–96; Chapman 1904; G. Elliot Smith 1919, 1927, 1930; Le Gros Clark 1925, 1934, 1935, 1947; Regan 1930; Gregory 1934, 1935, 1951; Zuckerman & Fulton 1934; Parker & Haswell 1940;

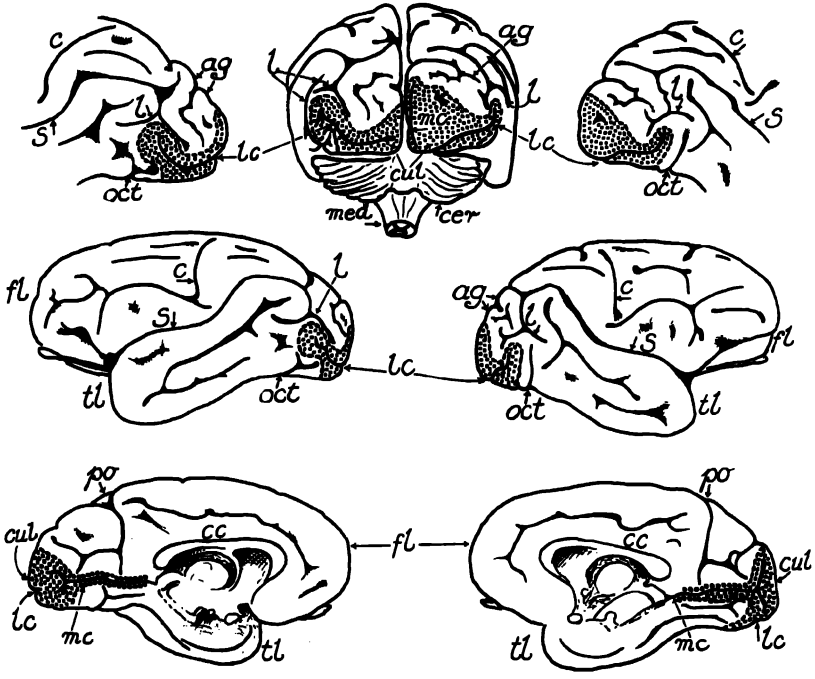

FIG. 282.—External configuration of the brain of a Red Spider Monkey (*Ateles paniscus?*; *cf.* preceding figure). This type represents the phylogenetical advancement in the evolution of the calcarine sulcal complex and striate area, compared with the Rhesus Monkey (Figs. 280, 281) and approaches somewhat the Anthropomorphous Apes (Figs. 284, 286). Arrangement and designation of diagrams same as in preceding figures. Lateral calcarine sulcus (*lc*), now fully developed, includes much of striate cortex that spreads less over exposed face of occipital lobe. In this way a condition is prepared which is realized in the brain of Anthropomorphous Apes. Another notable difference in comparison with the Macaque is an areal expansion of the cortex adjoining the striate area manifested by an emergence of annectent gyri (*ag*) and an anterior displacement of parieto-occipital sulcus (*po*) over the medial face. In addition, there is a general increase in area and in sulcal-gyral elaboration of the entire brain, bringing the Spider Monkey in this respect closer to the Anthropomorphous Apes, an advancement reflected in higher mental capacities resembling those of the Chimpanzee (Klüver). *Labeling: ag*, annectent gyri; *c*, central sulcus; *cc*, corpus callosum; *cer*, cerebellum; *cul*, cuneolingual gyrus; *fl*, frontal lobe; *l*, lunate sulcus; *lc*, lateral calcarine sulcus; *mc*, medial calcarine sulcus; *med*, medulla oblongata; *oct*, occipitotemporal sulcus; *po*, parieto-occipital sulcus; *S*, Sylvian fissure; *tl*, temporal lobe. Reproduced below natural size.

Romer 1943, 1945; G. G. Simpson 1949; and especially W. L. Straus, Jr. 1949; *see also* corresponding sections of chaps. XIV and XV.)

2. CORTICAL VISUAL CENTERS OF THE TREE SHREW, LEMUR, TARSIER, AND THE LOWER MONKEYS.—The probable course of phylogeny, which, starting from the original "basal primate stock," the primitive Prosimians or Protopriae or Lemurs of warm parts of Asia and of Africa, especially Madagascar (Lemuroidea, Fig. 279, *D;* Fig. 307). In these families, because of the gradual change from a terrestrial to an arboreal mode of life, increased use of the visual organs caused an expansion of the striate area in comparison with that of their subprimate precursors, the nonarboreal Insectivorous Mammals, exemplified by the Soricide Shrews,

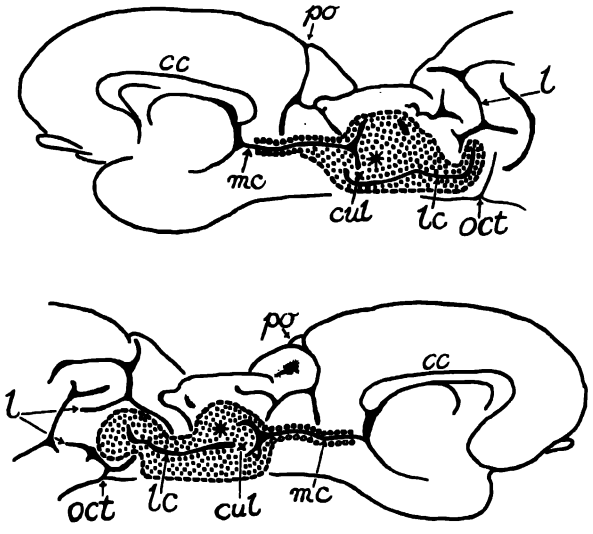

FIG. 283.—Calcarine fissural complex and its relation to the striate area and adjoining sulci and gyri in the brain of a Red Spider Monkey (*Ateles paniscus?*), presented in the same way as in Fig. 281. Right (*upper diagram*) and left cerebral hemisphere (*lower diagram*). Exposed parts of the striate areae stippled, parts buried in the calcarine fissures indicated by circles. Both striate areae presented in a flat view. Note a slight decrease of striate cortex in proportion to the remainder of the cerebral cortex, compared with the Rhesus Macaque. Most of the striate cortex is still along and in the lateral or posterior calcarine sulcus (*lc*), and at the occipital pole (*), and only a little along and in the medial or anterior calcarine sulcus (*mc*). However, both segments of the calcarine sulcus (*lc* and *mc*) are better aligned than in the Rhesus Macaque in preparation for the next stage found in Apes and Man. Cuneolingual gyri (*cul*) well developed. (*Cf.* preceding figure.) *Labeling: cc*, corpus callosum; *cul*, posterior cuneolingual gyrus; *l*, lunate sulcus; *lc*, lateral or posterior calcarine sulcus; *mc*, medial or anterior calcarine sulcus; *oct*, occipitotemporal sulcus; *po*, parieto-occipital sulcus.

mates, had gradually culminated in the visual centers of the human brain, may be imagined to have progressed somewhat as follows:

The first phylogenetical stage in the process of anthropogenesis, just above the level of the Terrestrial Shrews, may be exemplified by the partly arboreal Tree Shrews or Tupaiidae of Southeastern Asia (*Ptilocercus lowii, Tupaia tana, T. minor, Urogale everetti*, etc., *see* Fig. 279, *B, C;* and chap. XIV), and by the Prosim-Hedgehog, Elephant Shrew, Jumping Shrew, *Solenodon, Centetes*, etc. (Fig. 279, *A*).

The early Tarsiers (Tarsioidea, Fig. 279, *E*) and the true Monkeys, which have developed from them (Lower Anthropoidea, Figs. 280, 281, 302, 306) may serve as an illustration of the next, the second, stage. This further trend was apparently also caused by a continued emphasis upon vision as the leading sense, necessitated by a more complete change from a terrestrial to an

arboreal mode of life. In the Monkeys the visual projection center, the striate area of the cerebral cortex, concerned with an immediate utilization of visual impressions, attained its relative maximum of surface expansion.

Anatomically, this evolutionary phase culminated, in the words of G. Elliot Smith, in the development of "a mushroomlike outgrowth," a large occipital operculum (*oo*), with the opercularization of a part of the extrastriate cortex hitherto exposed, and in the formation of a simian sulcus (*l*), found in most of the modern Monkeys, both American Platyrrhines and Old World Catarrhines, especially in the Cercopithecidae (Mangabey, Macaque, Baboon, etc.); the most primitive species, e.g., the Marmosets, are an exception (*see* Figs. 306, 307).

3. Cortical visual centers of the advanced Monkeys and Apes.—The anatomical peculiarities of the cortical visual centers found in the large modern Anthropomorphous Apes were foreshadowed by conditions present in certain Catarrhines of the Old World, for example, the Langur or Langoor of India (*Semnopithecus* or *Presbytis*, Fig. 304), and decidedly so in the larger Platyrrhines of the New World.

In this, the third, phylogenetical stage the striate area exposed on the convex face of the occipital lobe is already noticeably reduced and somewhat displaced backward, to the occipital pole. In the *Ateles* or Spider Monkey, considered to be the most advanced of the Platyrrhines, this transformation is quite striking (*see* Figs. 282, 283). The examination of its brain and a comparison with that of the Macaque (Figs. 280, 281) suggest that this "decline and recession" of the occipital operculum was induced not by an originally lesser expansion of the striate area in comparison with the Lower Catarrhines, but—since, in fact, in the *Ateles*, the Chimpanzee, and the Gorilla that area either is as extensive as in the Macaque or even increases in surface—by a genuine increase and elaboration of the cortex surrounding the striate area. The relative size and the sulcal and gyral elaboration in the *Ateles* indicate that all adjoining regions—the parietal, temporal, and extrastriate occipital—had contributed to this development. The greatest contribution appears to have been from the cortex sunk in the deep simian fossa or pit, found in the Lower Monkeys, such as the Macaque, largely comprising the cytoarchitectural para-peristriate area of G. Elliot Smith, the fields *18–19* of Brodmann, or the visuopsychic area of Campbell.

The incipient augmentation of this cortical locality is indicated, in the Rhesus Macaque, by several small gyri entirely concealed in the simian pit, named by Gratiolet (1854) *plis de passage*, also called *Brückenwindungen*, or "annectent gyri," meaning gyri connecting the parietal and occipital regions (*see also* Zuckerkandl 1906; Holl 1907, 1908; Hulshoff; Anthony 1928, 1943; Economo 1930; Mettler 1935; Connolly 1936, 1950; Kinosita 1942–44).

The cortex forming the annectent gyri and lining the remainder of the simian pit (*l*) evidently served as an "oriment" or "phylogenetical starting point," which, from modest beginnings, through gradual augmentation and expansion—the stages represented by the Mangabey, Spider Monkey, and Gibbon—developed into the next phylogenetical stage found in the large Anthropomorphous Apes (Chimpanzee, Orangutan, Gorilla; *see ag* in Fig. 284, *A*, *B*, *E*; Fig. 286). The prime factor responsible for this fourth phylogenetical stage seems to be a shift in the functional emphasis from what was originally largely a perceptive to an apperceptive or "psychic" utilization of visual and other impressions. Such an "intellectualization," in turn, necessitated a further expansion of the entire cortex between the visual, somesthetic, and auditory centers, resulting in the development of the spacious posterior parietotemporo-occipital "association area" of Flechsig (*see* chap. IV, 2; and Fig. 115, *IX*).

Owing to this expansion of the cortex in a limited space, manifested in a gradual emergence of the annectent gyri upon the free surface of the brain, and an over-all increase of the cortex intervening between the terminal areae of the three principal afferent pathways—the visual, auditory, and somesthetic—the original simian occipital lobe or occipital operculum was rolled back, and the lateral portion of the striate area displaced backward and rolled in to form the lateral or posterior calcarine sulcus of the hominoid and hominid brain (*lc*).

The other consequence of this transformation was an alignment and a more or less complete

fusion of the lateral calcarine with the medial calcarine sulcus (*mc*), the beginning of which is well illustrated in Figure 285 (upper diagram). In this way the phylogenetically younger lateral component became merged with the older medial component. This fusion may be considered a preparation for the final phylogenetical stage, a calcarine fissural complex of the modern human brain, where in some cases such fusion may be complete to a degree where all traces of the original constituents are obliterated. During this evolutionary process, owing to a turning-back and folding-in of the opercular portion of the striate area, the posterior cuneolingual gyrus is formed (*cul*, in Figs. 285, 286).

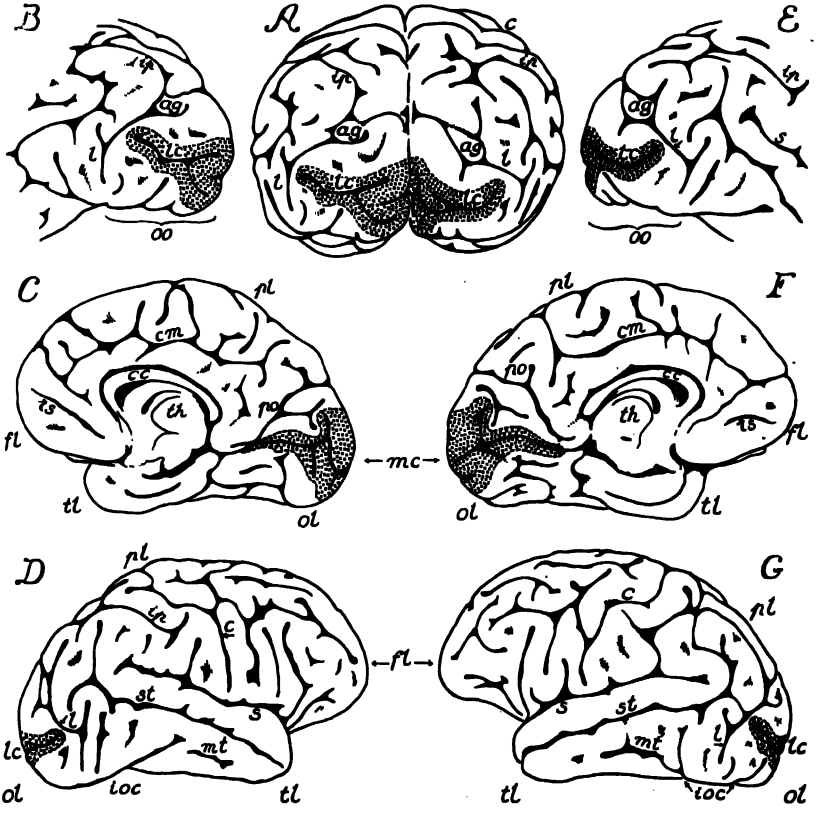

FIG. 284.—External configuration of the cerebral hemispheres of a four-day-old baby Chimpanzee and the extent and location of the visual cortical center, the striate area (*stippled*), in the intact brain. *A*, posterior view of both hemispheres, showing the two occipital lobes in relation to each other and to the rest of the brain; *B*, posterolateral view of left occipital lobe; *C*, medial, *D*, lateral views of right hemisphere; *E*, posterolateral view of right occipital lobe; *F*, medial, *G*, lateral views of left hemisphere. Reproduced at less than natural size. *Cf.* following figure. (For blood supply of Chimpanzee brain *see* Fig. 376.) *Labeling: ag*, annectent gyrus; *c*, central sulcus; *cc*, corpus callosum; *cm*, callosomarginal sulcus; *fl*, frontal lobe; *ip*, intraparietal sulcus; *l*, lunate sulcus; *lc*, lateral calcarine sulcus; *mc*, medial calcarine sulcus; *mt*, middle temporal sulcus; *ol*, occipital lobe; *oo*, occipital operculum; *pl*, parietal lobe; *po*, parieto-occipital sulcus; *rs*, rostral sulcus; *S*, Sylvian fissure; *st*, superior temporal sulcus; *th*, thalamus; *tl*, temporal lobe; *mt*, middle temporal sulcus; *st*, superior temporal sulcus.

4. CORTICAL CENTERS OF VISION IN PREHISTORIC HUMAN RACES.—It must be assumed that the above-outlined trend in the phylogenetical development of the primate cortical visual centers continued in those Hominoids which gradually became transformed into various pithecanthropine and early prehistoric human races, in preparation for the anatomical conditions found in Modern Man.

human races and their immediate precursors: *Australopithecus africanus* (Dart), *Plesianthropus transvaalensis* (Broom), and *Paranthropus robustus* (Broom), and the various races of *Homo primigenius* that followed: *Homo soloensis* or Solo Man, *Pithecanthropus erectus* or Java Ape-Man, and *Sinanthropus pekinensis* or Peking Man (Fig. 287). In these, the details of the surface of the parieto-occipital lobes, especially

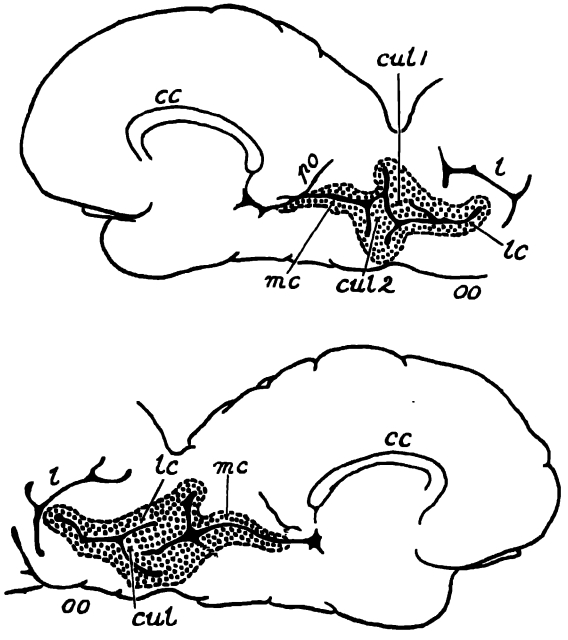

FIG. 285.—Right (*upper diagram*) and left cerebral hemisphere (*lower diagram*) of the same brain of a baby Chimpanzee as that shown in Fig. 284. Both striate areae fully exposed, and occipital opercula (*oo*) turned back to simulate a terminal evolutionary phase found in the human brain, with more or less the entire calcarine fissural complex displaced onto the medial face of the brain's hemisphere (*cf.* Fig. 290). Constituent parts of the calcarine fissural complex: the medial (*mc*) and lateral calcarine sulcus (*lc*) in the human brain usually form a single sulcus when examined superficially. In the Ape they may still be separated by a cuneolingual gyrus (*cul*) into their original constituents, as shown in lower diagram. Or the two sections may actually merge into a continuous furrow, as in the upper diagram, the two vestiges of the posterior cuneolingual gyrus (*cul1*, *cul2*) merely indicating a polar "hinge" around which the occipital flap begins to rotate. *See* similar conditions in the Macaque (Fig. 281), Spider Monkey (Fig. 283), and Man (Figs. 289, 292, 293, 294, 295). *Labeling: cc*, corpus callosum; *l*, lunate or simian sulcus; *oo*, occipital operculum; *po*, parieto-occipital sulcus. Note the considerable length of the calcarine sulcal complex (*mc* and *lc*) and of the striate area (*stippled*), equaling half the length of the hemisphere.

This fifth phylogenetical stage, more or less human, as much as can be judged from available data obtained from the study of endocranial casts, seems to have been attained by the earliest and most primitive known incipient

a lunate sulcus (*l*) and a pronounced occipital operculum with the posterior calcarine sulcus (*lc*), have been described and strongly resemble those of the present Anthropomorphous Apes (*cf. A* in Fig. 284, and upper sketch in Fig. 286,

with the left lower sketch in Fig. 287; *see also* Shellshear 1926; Shellshear & Smith; G. E. Smith 1927; A. Keith; Ariëns Kappers 1935; Ariëns Kappers & Bouman; Weidenreich; Broom & Schepers 1946; *see*, however, Clark, Cooper & Zuckerman, 1936; and Packer 1949).

In the light of these observations it is fairly evident that, just as in the features characterizing their skeletal remains, the ancestors of modern humanity which populated distant parts of the Old World in remote times appear to have been an intermediary between the prehominid precursors, from which they developed, and *Homo sapiens* or Modern Man, into whom they slowly and painfully became transformed. (*Cf.* chap. XV.)

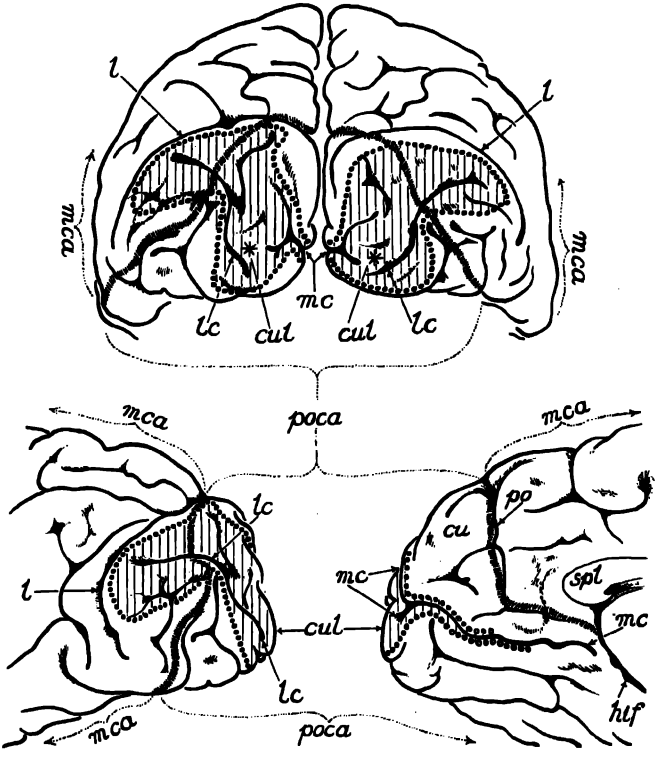

FIG. 286.—Occipital lobes of "Bushman," an adult Gorilla, showing striate areae and their relation to the sulcal and gyral configurations and to the middle and posterior cerebral arteries. *Upper sketch*, back view of both occipital lobes; *left lower sketch*, lateral view of left occipital lobe; *right lower sketch*, medial view of same lobe. Boundaries of striate areae marked by dotted lines, solid where on the surface, circles where concealed within fissures. Striate areae marked by vertical shading. Note slight asymmetry of occipital opercula; oblique position of lateral calcarine sulci (*lc*); considerable extent of opercular striate areae; polar position of cuneolingual gyri (*cul*) separating medial (*mc*) from lateral calcarine sulci (*lc*); shaded line separating arterial territories passing obliquely across occipital opercula, leaving extreme segments of striate areae closest to lunate sulci (*l*) in the territories of the middle cerebral arteries (*mca*), and the larger polar portions, together with portions along medial calcarine sulci in the territories of the posterior cerebral arteries (*poca*). *Labeling: cu*, cuneus; *cul*, cuneolingual gyrus; *hif*, hippocampal fissure; *l*, lunate sulcus; *lc*, lateral calcarine sulcus; *mc*, medial calcarine sulcus; *mca*, territory of middle cerebral artery; *po*, parieto-occipital sulcus; *poca*, territory of posterior cerebral artery; *spl*, splenium of corpus callosum. Poles of occipital lobes marked by asterisks (*). Reproduced below natural size.

5. CORTICAL VISUAL CENTERS OF MODERN MAN.—The anatomical features of parts of the human brain related to sight, like other parts of the brain, and the remainder of Man's bodily organization necessarily and unavoidably resemble those of his prehuman ancestors. Some of these features are almost identical with the simian, whereas others are more or less changed, in many cases being transformed to a degree where only a thorough study of all pertinent centage of the brains of some living human races considered to be primitive: Egyptian Fellahs, Sudanese, Malayans, Negroes, Javanese, Indonesians, Dayaks of Borneo, Bushmen, and particularly characteristic of the aborigines of Australia (G. Elliot Smith; Karplus; Brodmann 1906; Ingalls; Kooy 1921; Ariëns Kappers, Huber & Crosby; Murphy; Shellshear; Connolly 1943, 1950).

Other investigations, however, have dis-

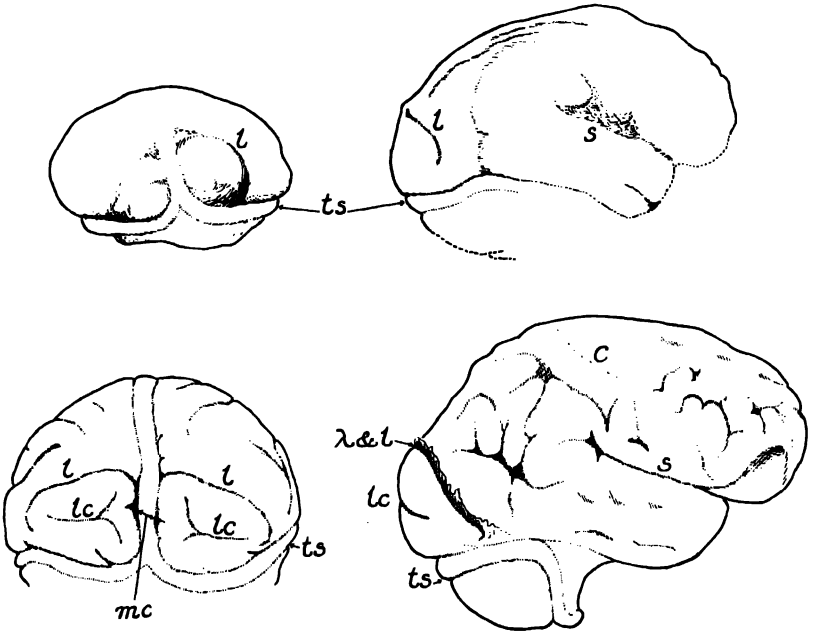

FIG. 287.—Posterior (*left diagrams*) and lateral aspect (*right diagrams*) of endocranial casts of two most primitive known prehistoric human or human-like races: *Pithecanthropus erectus*, or Java Ape-Man, with a cranial capacity of 855 cc. (*upper diagrams*, from G. Elliot Smith 1927), and *Sinanthropus pekinensis*, or Early China Man (*lower diagrams*, from Shellshear & Smith 1934). Note the large occipital opercula and typical pithecoid shape and arrangement of the lunate, lateral, and medial calcarine sulci in both races, approaching those in modern Anthropomorphous Apes (*cf.* Figs. 284, 286). *Labeling: c*, central sulcus; *l*, lunate sulcus; *lc*, lateral or posterior calcarine sulcus; λ & *l*, lambdoid suture and lunate sulcus; *mc*, medial or anterior calcarine sulcus; *S*, Sylvian fissure; *ts*, transverse sinus.

points may reveal the ancient traits and homologies, if they can be found at all.

One remaining feature of primitive "pithecoid" conditions much studied by anatomists is the well-developed, more or less typical, crescent-shaped lunate sulcus (*l*) and the large occipital operculum observed in an important per- closed the presence of a clearly marked, though usually smaller and irregularly shaped, vestige or vestiges of a lunate sulcus in numerous instances in the brains of Chinese, Japanese, and the following Caucasians: Ashkenazic Jews, Germans, Swedes, Poles, English, Russians, and others (Weinberg; Antoni; Goldstern; Kuhlen-

beck 1928; G. Elliot Smith 1929; Economo 1930; Levin 1936; Ngowiang 1936; Chi & Chun Chang 1941; Connolly 1943, 1950).

A lunate sulcus, much less a vestige of it, may therefore not be considered a "sign of race," and even less a "stigma of racial inferiority or degeneracy," since it was found in the brains of such eminent persons as Mendeleyev, the Russian chemist who discovered the "periodic law of elements" (Levin 1936); C. Monakow, a celebrated lifelong investigator of the brain (R. Anthony 1935); and a number of other outstanding individuals.

From the published figures of the brains of some of the most prominent thinkers and artists Helmholtz, Mommsen, Bunsen, and Menzel—the presence of a more or less well-formed lunate sulcus and of a lateral or posterior calcarine sulcus appears either fairly certain or at least probable (Hansemann 1899, 1907). A similar situation may have obtained also in the case of Mallory, a prominent American pathologist (*see* chap. XII, 10).

It is possible, however, that where an unusually well-developed lunate sulcus and an occipital operculum are frequently found and where the striate area extends to a considerable distance beyond the occipital pole and where other "simian features" of configuration of the occipital lobes are consistently met with, as, for example, in the Australian aborigines (Shellshear), these peculiarities cannot be discounted as of no anthropological significance. Unfortunately, because of the lack of systematic large-scale investigations, it is at present impossible to pass any valid judgment on this important and intriguing problem.

A large occipital operculum, marked off from the rest of the hemisphere by a deep, crescent-shaped lunate sulcus, and a striate area extending over the convexity of the occipital lobe much farther than is usually found in the so-called "advanced" races of mankind are, in any case, features strikingly resembling, and for reasons discussed elsewhere in this chapter homologous with, the anatomical conditions in the Infrahuman Primates, especially in the Anthropomorphous Apes.

An illustrative example of pithecoid conditions found in numerous human brains is a specimen depicted in back view in Figure 288. It is of a human male, of Polish nationality, of Roman Catholic denomination, born in 1888 in "Congress Poland," which at that time had been for approximately one hundred years a part of the Russian Empire, of parents who were born and died in the same country—all circumstances showing it to be highly probable that the individual was "racially a pure Pole." A careful examination of the sulcal and gyral configuration and of the cortical structure in both occipital lobes revealed conditions remarkably resembling those typical for the Anthropomorphous Apes (*cf.* Figs. 284, 286).

On the left side a "triradiate" lateral or posterior calcarine sulcus (*lc*), surrounded above and below by posterior, superior, and inferior paracalcarine sulci and separated from the posterior forked end of the medial or anterior calcarine sulcus (*mc*) by a posterior cuneolingual gyrus (*cul*), was found (Fig. 289, lower diagram). A long, deep, semicircular lunate sulcus (*l*), together with a well-developed prelunate sulcus (*prel*), set off a typically simian occipital operculum from the rest of the hemisphere.

The striate area, indicated by stippling, partly lined the medial (*mc*) and the entire lateral calcarine (*lc*) sulci, including the inferior and part of the superior posterior paracalcarine sulci, as well as the terminal segment of the inferior occipital sulcus (*io*). The lunate sulcus (*l*), along its entire extent, remained approximately 3 mm. beyond the posterior boundary of the striate area.

In the right occipital lobe a similar situation was found, except that the lunate sulcus consisted of two components and the striate area did not extend over the pole as far as on the left side (Figs. 288, 289, upper diagram).

In another brain specimen whose race could not be determined but which, because of a high degree of pigmentation, may have been that of an American Negro, a very similar situation, with some differences, was found (Fig. 290). Here, too, the medial calcarine sulcus (*mc*) was found separated from the lateral calcarine sulcus (*lc*) on both sides symmetrically, by a posterior cuneolingual gyrus (*cul*), with a well-developed lunate sulcus (*l*) encircling the back ends of the calcarine sulcal complexes and marking off typical pithecoid occipital opercula. As in the brain of the Pole, here, too, the

striate areae remained a few millimeters behind the lunate sulci. Whereas, however, in the brain of the Pole the left occipital operculum was considerably larger, in the presumably Negro brain both opercula and the exposed parts of the striate areae were approximately equal. (*Cf. also* Figs. 291 95.)

Whether these features of the visual center are in any way to be considered racially characteristic or are merely individual peculiarities is an important problem that can be solved only by thorough, careful work. For this, in the first place, abundant material in a good state of preservation is necessary, permitting conclusions valid from the statistical viewpoint. The other indispensable condition, heretofore rarely met with, is not only the examination of the sulcal and gyral pattern, which alone may be misleading, but, above all, an exact determination of the limits of the striate area. This is a task not offering serious difficulty, since the stria of Gennari in fresh or well-preserved material can be easily seen without the aid of a magnifying glass or at slight magnification.

The sixth and final evolutionary stage of the phylogenesis of the calcarine fissure is possibly represented by those brains of Modern Man—allegedly the majority in the Caucasian races—in which the occipital operculum and the lunate sulcus, the vestigial remnants of simian conditions, have largely or entirely disappeared (Fig. 296). Here, apparently owing to a great expansion of the extrastriate cortical areae, the entire striate area has been pushed onto the medial

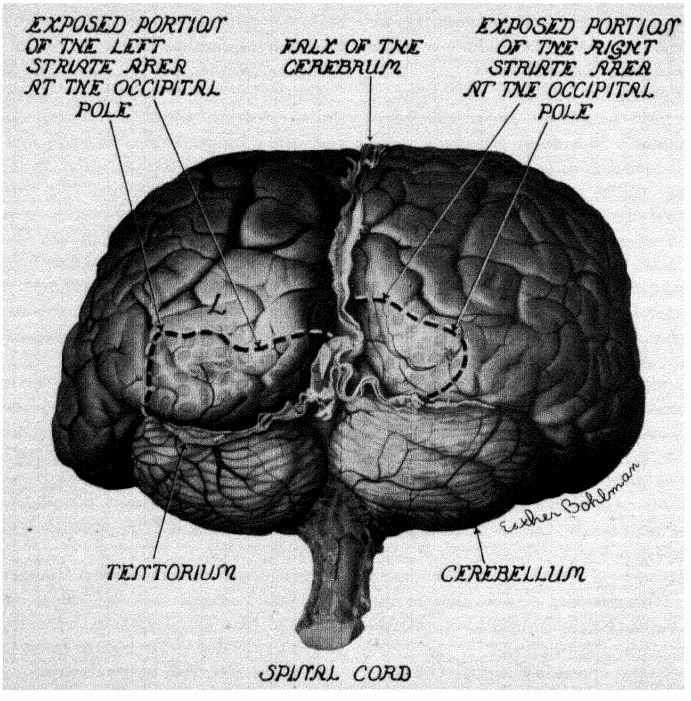

FIG. 288.—Back view of an adult human brain showing well-formed occipital opercula, with extensive exposed portions of striate areae (marked by *circles*), and other so-called simian features characteristic of Apes (*cf.* Figs. 284, 286). Note a lunate sulcus (*L*) on left side, marking off an occipital operculum larger than on the right side, an asymmetry considered normal in the human brain. The specimen from a person of pure Polish extraction (*see* text). *See* following figure and compare with Figs. 290 96. Falx cerebri, tentorium, cerebellum and spinal cord left *in situ*.

surface of the hemisphere and largely rolled in or invaginated into a deep posterior segment of the calcarine fissure. In such cases a pithecoid lunate sulcus and an occipital operculum are absent or, at any rate, are difficult to identify. (*Cf.* Fig. 290.)

But even here the original morphological elements of which the final evolutionary result is composed are usually still more or less recognizable. The short, but deep, sulci hidden within the posterior section of the calcarine fissure, running in front of and behind the posterior cuneolingual gyrus, usually noticeable by superficial dents in the lips of the closed fissure, are

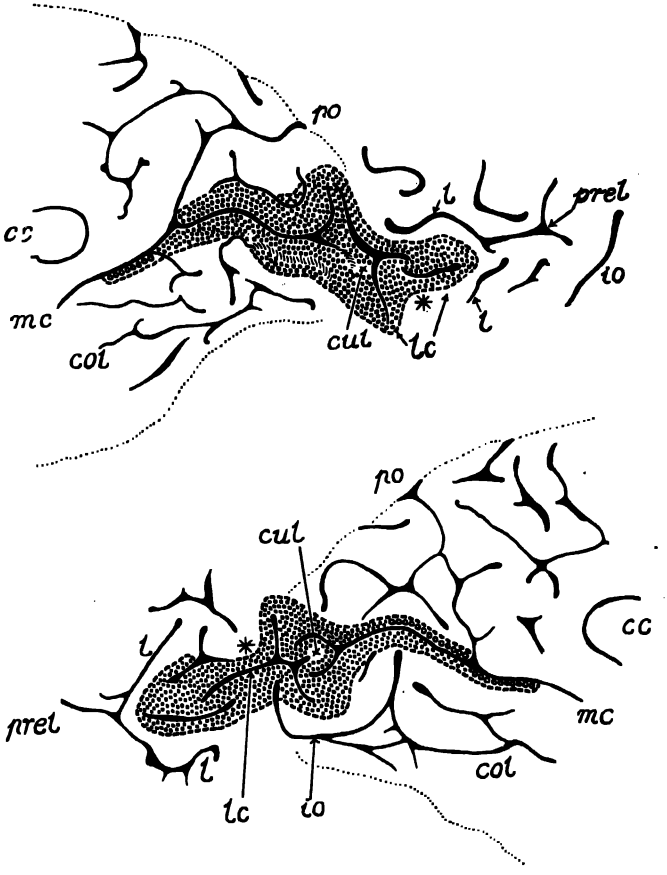

FIG. 289.—Right (*upper diagram*) and left sulcal complex (*lower diagram*) of the calcarine fissures of a person of Polish extraction depicted in the preceding figure. Both occipital opercula are turned backward, in order to align them with the plane of the medial face of the brain's hemisphere. Thus straightened out, the identity of various parts of the sulcal and gyral pattern with the simian becomes apparent (*cf.* Figs. 281, 285). The portions of the striate areae spreading on the exposed surface are indicated by solid dotting, those buried in the anterior calcarine sulci by circles. Occipital poles marked by asterisks (*). Brain outlines indicated by dotted lines. (*Cf.* Figs. 281, 283, 285.) *Labeling: cc*, corpus callosum; *col*, collateral sulcus; *cul*, posterior cuneolingual gyrus; *io*, inferior occipital sulcus; *l*, lunate sulcus; *lc*, lateral calcarine sulcus; *mc*, medial calcarine sulcus; *po*, parieto-occipital sulcus; *prel*, prelunate sulcus.

the vestiges of prongs of the lateral calcarine sulcus and of the ascending and descending rami with which the original medial calcarine fissure of the Monkeys and Apes terminates at its posterior extremity. (*Cf.* Figs. 280–86 with Figs. 289–92.)

6. PROBABLE PHYLOGENETIC FACTORS RESPONSIBLE FOR THE FORMATION OF THE CORTICAL VISUAL CENTERS OF MAN.—The ideas expressed in the preceding subsections concerning the probable course of the phylogenetic development of the cortical visual centers of the advanced human races from the initial conditions found in the infrasimian, prosimian, and lower simian representatives of the Primates are further supported by the following considerations.

In the catarrhine Monkeys, exemplified by the Rhesus Macaque (Figs. 280, 281), the occipital pole, marked with an asterisk (*), divides the striate area into two approximately equal halves, the medial, largely buried in the phylogenetically older medial or anterior calcarine sulcus (*mc*), and the lateral, that spreads over the lateral face of the occipital lobe (*ol*) or occipital operculum (*oo*), which, with the exception of a shallow lateral or posterior calcarine sulcus (*lc*), lies exposed on the lateral face of the brain. These two constituents of the future calcarine fissural complex of the Ape and Man, the older originating on the medial face (*mc*) and the younger on the lateral face (*lc*), still remain separated at the phylogenetic stage represented by the Macaque.

In the brain of the advanced Platyrrhines, such as the *Ateles* or Spider Monkey (Figs. 282, 283), the situation remains roughly similar, with, however, some significant changes. The two calcarine constituents (*mc* and *lc*) are still separated, but the occipital opercular portion of the striate area is partly folded into a deep posterior calcarine sulcus, thus reducing the extent of this area on the free face of the lobe. All these changes have obviously been induced by a considerable expansion of the surrounding extrastriate cortex, manifested in the emergence of the annectent gyri (*ag*), and a general increase in surface and in the sulcal and gyral elaboration of the entire cerebral cortex in the *Ateles* as compared with the Macaque.

In the Anthropomorphous Apes—for example, in the Chimpanzee and the Gorilla (Figs. 284, 285, 286)—slightly more of the opercular striate cortex than in the Spider Monkey is buried within a deep, more or less three-pronged lateral calcarine sulcus (*lc*), the remainder still being exposed along this sulcus. In spite of this, however, the general situation remains the same as in the Macaque, although it more strikingly resembles that found in the Spider Monkey.

In the Chimpanzee additional significant changes are noticeable, indicating a further elaboration of the visual cortical centers. First, the inner extremities of the lateral calcarine sulci (*lc*) facing the occipital poles are forked. On the left side the two prongs encompass the lower prong of the medial calcarine sulcus (*mc*), an arrangement that appears to be a common simian heritage (*cf.* lower diagrams in Figs. 283 and 285). The two calcarine fissural elements (*mc* and *lc*) are still kept apart by a < or rather ≷-shaped intervening fold of the striate cortex (*cul*), precisely as is found in some human brains (Fig. 289, lower diagram; Figs. 291, 292, upper diagrams).

In human brains the same fold (*cul*) is known as the posterior cuneolingual gyrus, and so, by the same token, the fold in the Chimpanzee's brain must be considered a homologue of the same gyrus. In the Spider Monkey the homology with the Chimpanzee is also quite apparent (*cul*, in both diagrams in Fig. 283), even though the anterior extremities of *lc* are not forked and the intervening fold is therefore simpler, somewhat resembling the situation found in the Rhesus Macaque (Fig. 281). All this evidence shows the bridge of the cortex separating the medial (*mc*) from the lateral calcarine sulci (*lc*) in the Macaque to be, in fact, an oriment or primordium of the posterior cuneolingual gyrus of the more advanced Primates, including Man. A similar situation also obtains in the Gorilla (Fig. 286).

In all four otherwise widely separated representatives of the Primates—a catarrhine Macaque, a platyrrhine *Ateles*, the hominoid Chimpanzee and Gorilla, and Man—in the specimens described the essential arrangement of the primitive constituents of the "calcarine fissural complex" (*mc* and *lc*) accordingly remains the same (even though, undoubtedly, in the Ape, and

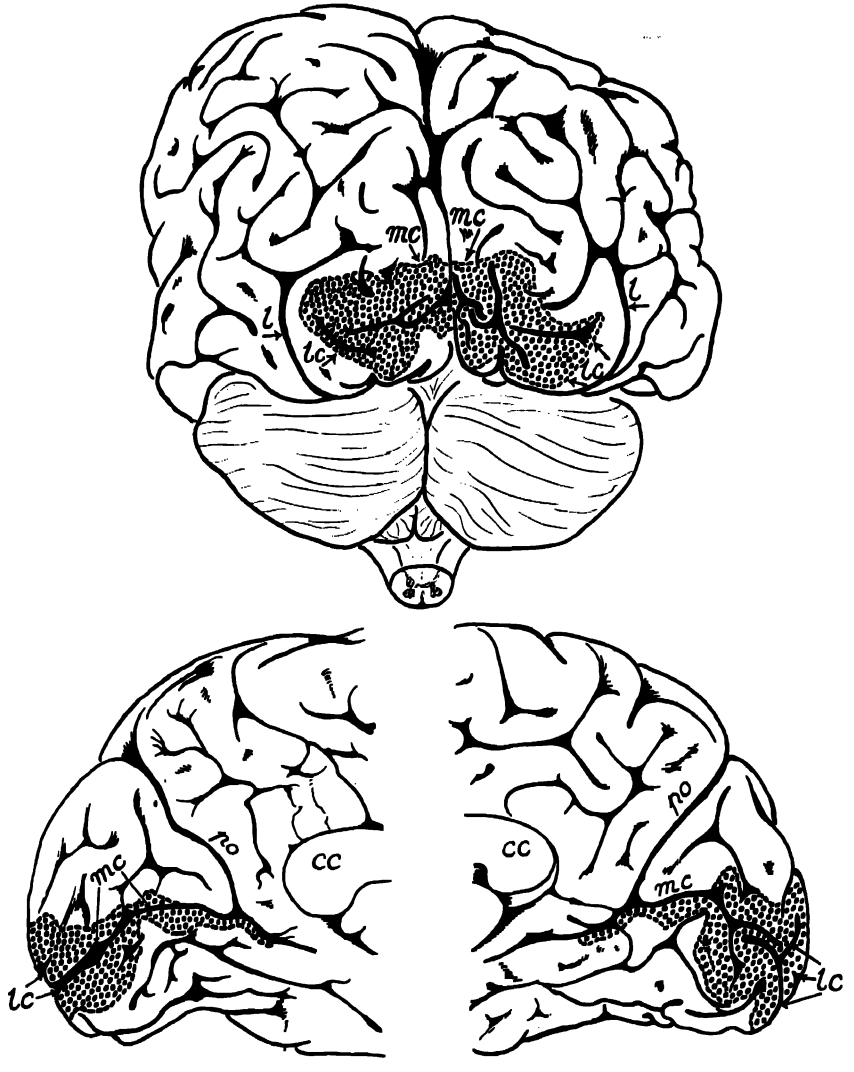

FIG. 290.—Back view (*upper diagram*) and medial aspect (*lower diagram*) of right and left occipital lobes, possibly of an American Negro, with pronounced lunate sulci (*l*) setting off large, symmetrically developed occipital opercula, with sizable parts of striate areæ exposed over the occipital poles. These features markedly resemble those found in Anthropomorphous Apes (Figs. 284, 286) and in prehistoric human races (Fig. 287), in contrast to conditions in some brains of the Caucasian or White Race, where the striate areæ are entirely moved to the medial face of the cerebral hemispheres and where the lunate sulci and occipital opercula are absent (Fig. 296). A symmetrical arrangement of opercula may also be an ancient feature, whereas in the White Race the left occipital operculum is larger (Fig. 288). Striate area indicated by stippling. Specimen somewhat out of shape, owing to careless handling. *Labeling: cc*, corpus callosum; *l*, lunate sulcus; *lc*, lateral calcarine sulcus; *mc*, medial calcarine sulcus; *po*, parieto-occipital sulcus.

even more so in Man, their relationship is obviously increasingly more intimate).

The right calcarine fissure of the same baby Chimpanzee affords an illustration of the next step in the process of calcarine fusion (Fig. 285, upper diagram). In this instance, the cuneolingual gyrus is broken through (*cul1* and *cul2*), and an actual fusion of the medial (*mc*) and the lateral calcarine sulcus (*lc*) into a continuous furrow has taken place (even though the original constituents are still clearly recognizable). the actual pole of the occipital lobe (* in Fig. 281), in an advanced Monkey (*cul*, in Fig. 283) and in an Anthropomorphous Ape (*cul*, in Fig. 285) becomes a cuneolingual fold. This fold, even though it still represents the pole, definitely assumes the shape of a posterior cuneolingual gyrus, identical with the same gyrus in the human brain, where it may or may not be at the pole (Figs. 289, 295).

The posterior cuneolingual gyrus, the original "occipital pole" of the Lower Simians, clearly

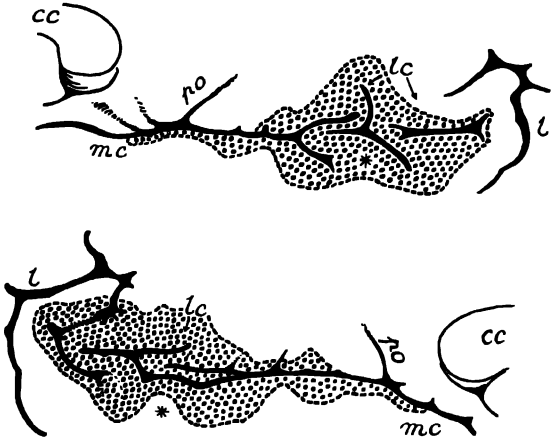

FIG. 291.—Right (*upper diagram*) and left calcarine sulcal complex (*lower diagram*) of the brain shown in Fig. 290, with sulci left *in situ*. Both occipital opercula are presented turned back, in order to bring the lateral calcarine sulci (*lc*) in line with the medial calcarine sulci (*mc*), as normally found in many specimens. In the upper diagram the composition of the calcarine fissure of a series of discontinuous sulci is apparent; in the lower diagram the calcarine appears in this view as a continuous fissure, its makeup of several constituents being revealed in Fig. 292. Exposed portions of striate areae indicated by stippling; portions buried in rostral segments of fissure indicated by circles. Occipital poles marked by asterisks (*). Note large segment of striate cortex along the lateral calcarine sulcus beyond the occipital pole, larger than found in Fig. 289. (*Cf.* following figure.) *Labeling: cc*, corpus callosum; *l*, lunate sulcus; *lc*, lateral calcarine sulcus; *mc*, medial calcarine sulcus; *po*, parieto-occipital sulcus.

In a similar human specimen the fusion of the medial and lateral calcarine components has also advanced to what appears as a single, continuous calcarine fissure when inspected superficially (Fig. 291, lower diagram). The examination of the sulci and gyri concealed in the fissure even in this case shows the original sulcal and gyral elements still present, including an anterior bifurcation of the lateral calcarine sulci and a posterior bifurcation of the medial (*lc* and *mc*, in Fig. 292, lower diagram).

The preceding examples and considerations show that a point which in a Lower Monkey is functions as a "pivot" or "hinge" around which, during the process of anthropogenesis—owing to an overexpansion of the extrastriate regions of the cortex—the occipital operculum rotates and is turned back. In this way the lateral or posterior portion of the striate area is brought in line with the medial or anterior portion. This is the situation found in advanced human brains (Fig. 296). The lateral calcarine sulcus of the Infrahuman Primates becomes the posterior portion of the composite calcarine fissure of advanced humanity, variously called by different investigators three-pronged or shamrock-

shaped *sulcus triradiatus*, external or lateral calcarine sulcus, *sulcus extremus* or *fissura extrema* of Seitz, and the like.

Since, however, the expansion concerns not only the parts of the extrastriate cortex in the simian fossa proper but also those along the upper and lower margins of the occipital operculum, the latter is not only turned back but also rolled or folded in, leaving but a small part of the striate cortex, or none at all, on the exposed face of the occipital lobe around the pole (as, e.g., in Figs. 293, 296).

Thus it comes about that what in most human brains is the occipital pole is the region which in the Monkey still remains on the lateral face of the hemisphere, more or less close to the simian sulcus, and that the original simian occipital pole in many, perhaps most, human brains is displaced medially and anteriorly, marking as a posterior cuneolingual gyrus the original boundary between the medial and the lateral sections of the original simian calcarine fissural complex.

The paramount single factor responsible for the notable mechanical changes in the phylogenesis of the primate cortical centers of vision, instead of merely a uniform surface and volume increase of the striate and extrastriate cortex, appears to be the topographical representation of the retinae in the striate area. A discrete representation of various parts of the retinal surface in distinct parts of the striate area implies a functionally unequal importance of the various segments of this area. The lateral or posterior portion of the striate area in all Primates, from Monkeys through Apes to Man, represents the two homonymous central-foveal and areal halves or hemifoveae and hemiareae, as described in chapter VII, 4 and 5 (*see* Figs. 259, 260).

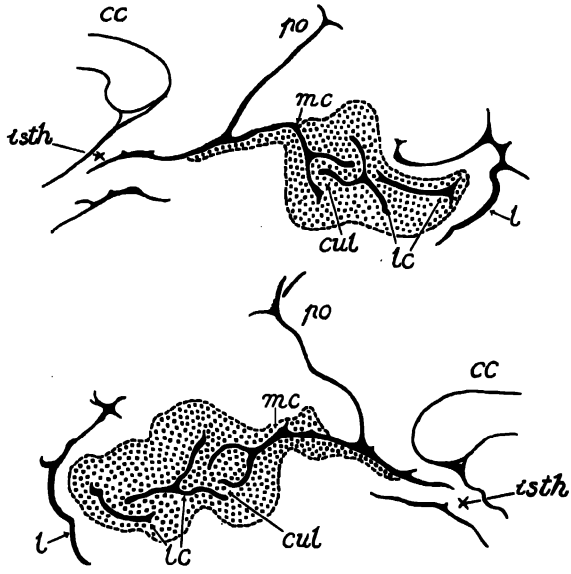

FIG. 292. Right (*upper diagram*) and left calcarine sulcal complex (*lower diagram*) of the same brain specimen shown in Figs. 290 and 291, with fissures opened, in order to demonstrate the original sulcal composition. Note posterior cuneolingual gyrus (*cul*) in both diagrams separating the medial (*mc*) from the lateral calcarine sulcus (*lc*), although this is not apparent in lower diagram of the preceding figure, where the calcarine fissure appears continuous; the composition of the lateral sulci of several distinct sulcal components, one of them a typical triradiate sulcus. *Labeling: cc*, splenium of corpus callosum; *cul*, posterior cuneolingual gyrus; *isth*, isthmus of fornico-hippocampal gyrus; *l*, lunate sulcus; *lc*, lateral calcarine sulci; *mc*, medial calcarine sulcus; *po*, parieto-occipital sulcus.

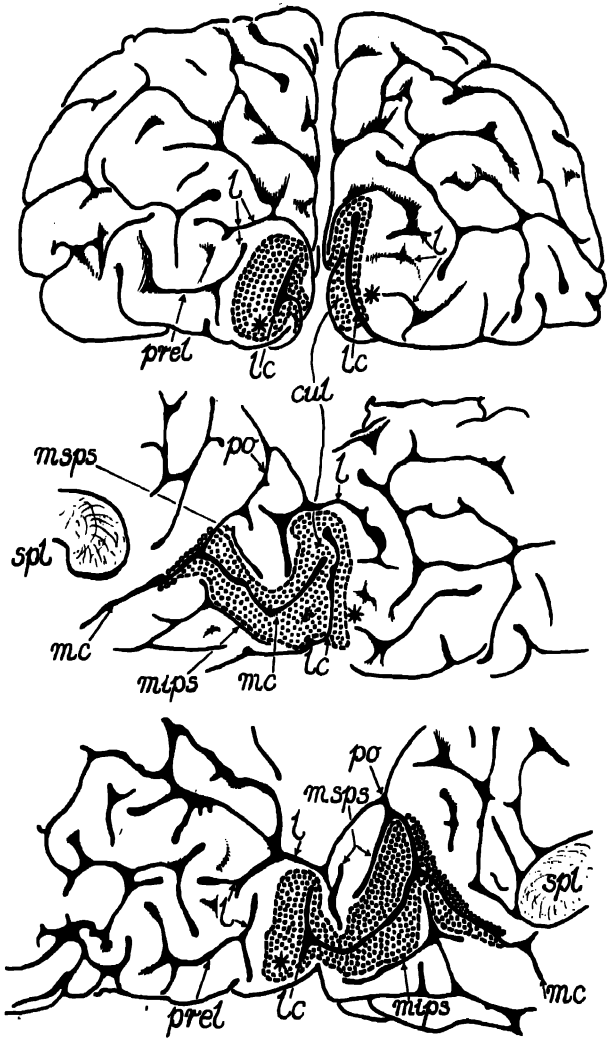

FIG. 293.—Occipital lobes of a human brain of unknown racial origin showing the configuration of the calcarine sulcal complex. *Upper diagram*, posterior view of both occipital lobes; *middle diagram*, right-side calcarine complex; *lower diagram*, left-side calcarine complex. Occipital poles indicated by asterisks (*). Medial calcarine sulcus (*mc*) in right occipital lobe separated from lateral calcarine sulcus (*lc*) by a posterior cuneolingual gyrus (*cul*), in left lobe both sulci merging into a continuous calcarine fissure. Lunate sulcus (*l*) on both sides broken up into several constituents. The striate area is indicated by stippling (where superficial) and by circles (where submerged). The left polar portion of the striate cortex slightly larger than the one at the right occipital pole, both, however, much smaller than those in specimens represented in Figs. 288 and 290. *Labeling: cul*, posterior cuneolingual gyrus; *l*, lunate sulcus; *lc*, lateral calcarine sulcus; *mc*, medial calcarine sulcus; *mips*, medial inferior paracalcarine sulcus; *msps*, medial superior paracalcarine sulcus; *po*, parieto-occipital sulcus; *prel*, prelunate sulcus; *spl*, splenium of corpus callosum.

Since the central foveae and areae, in virtue of their peculiar structural organization and location, are parts of the peripheral photoreceptive membranes—the retinae—most essential for direct, distinct, epicritic, or gnostic vision, it is legitimate to assume that most gnostic retinal impulses are transmitted to the cerebral cortex via the foveal-areal portions of the striate areae. In particular, with the gradual perfection of vision in the course of primate phylogeny, especially its "intellectualization," the foveal-areal portions of the central visual pathways and of the striate areae became the principal avenues and stations for the visual impulses that became the basis of primate intelligence.

In the long process of anthropogenesis or

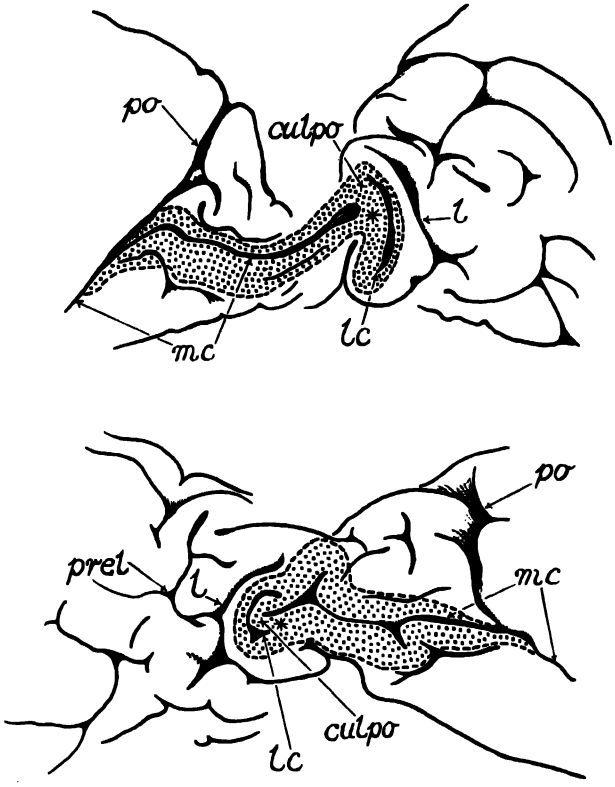

FIG. 294.—Right (*upper diagram*) and left occipital lobe (*lower diagram*) of a human brain of an undetermined race, with both inner and outer faces presented in one plane. Sulci and gyri drawn *in situ* (not opened). Both lobes show a symmetrical and remarkably pithecoid or Chimpansee-like configuration, with a deep, sickle-shaped lunate sulcus (*l*) sharply setting off a typically simian "occipital operculum" from the rest of the hemisphere (*cf.* Fig. 284). Lateral calcarine sulci (*lc*) are semilunar furrows resembling lunate sulci. The fact that they are lined by the striate cortex shows their true nature, that is, to be parts of the calcarine fissural complex. The occipital poles, indicated by asterisks (*), are either on the posterior cuneolingual gyrus (*culpo*) or close to it. The medial calcarine fissures (*mc*) in their cuneal stretch are unusually deep and completely lined by the striate area, except in the precuneal stretch, where they are lined only along their floors. The lateral calcarine sulci (*lc*) are quite shallow. The anterior cuneolingual gyri are small and completely concealed in the medial calcarine sulcus. The striate areae are indicated by stippling. *Labeling: culpo*, posterior cuneolingual gyrus; *l*, lunate or simian sulcus; *lc*, lateral or posterior calcarine sulcus; *mc*, medial or anterior calcarine sulcus; *po*, parieto-occipital fissure; *prel*, prelunate sulcus.

"rise of Man," therefore, not only did the opercular portion of the simian striate area expand fastest and transform a shallow "lateral" or "diagonal" sulcus into an incipient posterior calcarine sulcus of the hominoid and hominid or human brain, but also that portion of the extrastriate or para-peristriate areae that surrounds it expanded most.

On anatomical and physiological grounds it is legitimate to think that the opercular extrastriate cortex, in virtue of its close association with the foveal portion of the striate area, became the principal repository of the "psychic" or gnostic visual "engrams" or traces of past impressions and experiences (*cf.* chap. VII, 7).

In consequence, this cortical territory, which in the Lower Monkeys lies chiefly buried in the simian sulcus, increased most in the advanced Monkeys, in the Apes, and even more in Man, necessitating, in turn, a displacement backward and inward precisely of the exposed areal-foveal portion of the striate area that ultimately formed the posterior, polar segment of the calcarine fissure of the human brain.

In this light the major factor contributing to the full development of the extensive occipito-temporo-parietal association region of Flechsig located between the three centers most important for the human intellect—the visual, auditory, and somesthetic—appears to be the stream of gnostic visual impulses from the central foveae via the posterior calcarine sulcus to the surrounding cortex (*see* chap. IV and Fig. 115, *IX*). It is not astonishing that the posterior calcarine sulcus shows such a diversity of topography and configuration, in view of the tremendous individual variation in the faculty of vision, particularly its "psychic" aspects; and similar reasons may be responsible for the racial peculiarities of this region, still to be studied in detail.

The least active, most inert, and hence, in an evolutionary sense, most conservative or stable part of the primate cortical visual center is the ontogenetically and phylogenetically oldest portion of the striate area in and along the medial calcarine sulcus (*mc*), close to the fornicate-hippocampal *isthmus*, where the extreme monocular nasal periphery of the contralateral retina is represented (*cf.* Figs. 259, 260). This portion and the adjoining part of the para-peristriate area necessarily experience the smallest surface expansion and suffer the least shifting of their position relative to the other parts of the brain in the course of an evolutionary process that has brought about the profound changes described in the preceding.

As an over-all result of the facts and considerations given in the preceding pages, there emerges a realization of the unity of the visual cortical centers in the entire Order of Primates, from the lowliest Monkeys through the various intermediate stages to Man. In that entire order the calcarine fissural complex, its relation to the striate area, and the topographical representation of the retina are laid down according to the same plan.

This forces one to make two important deductions. One concerns the functional factors that, in the final analysis, are responsible for the anatomical identity, or at least the homology, of all principal features of the calcarine-striate complex: these must be adjudged to have been the same from the phylogenetic emergence of the Primate Order until now. The other deduction related to the preceding concerns the systematic or taxonomic classification of all Primates into a single, closely knit group, irrespective of any further subdivisions based upon the other, sometimes less essential, features of the bodily organization of the same group. (*Cf.* chap. XV.)

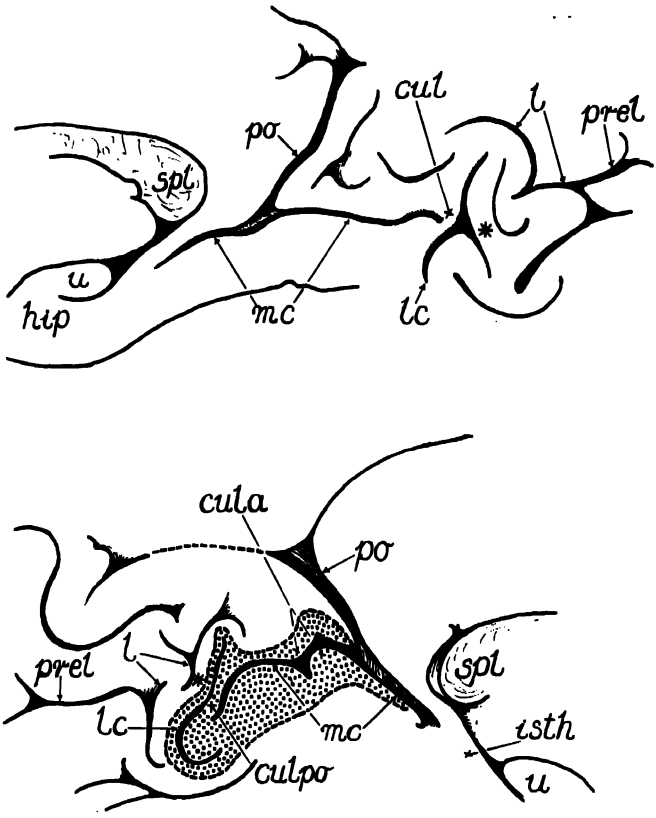

FIG. 295.—Occipital lobes of two different human brains of undetermined racial origin, presented with both inner and outer faces spread in one plane, with sulci drawn *in situ*. *Upper diagram*, right lobe; *lower diagram*, left lobe. In upper diagram the medial calcarine sulcus (*mc*) is a continuous furrow, terminating without forking next to the posterior cuneolingual gyrus (*cul*). The lateral calcarine sulcus (*lc*), of a typical three-pronged shape, a triradiate sulcus, is accompanied caudally by an accessory posterior calcarine sulcus. The entire calcarine sulcal complex is set off posteriorly by a double lunate sulcus (*l*). The cuneus (between *po* and *mc*) has the usual shape of a wedge. In the left hemisphere (*lower diagram*) the middle calcarine sulcus (*mc*) forms two arches, reducing the cuneus to half its usual size. The lateral calcarine sulcus (*lc*), in its semilunar shape and vertical position, simulates a lunate sulcus; the fact that it is lined by striate cortex reveals it to be a posterior component of the calcarine complex. The true lunate sulcus (*l*) is represented by two sulci, the lower one with a long prelunate extension (*prel*). The striate area is indicated by stippling. Anteriorly it extends in the lower calcarine lip almost as far as the fornico-hippocampal isthmus (*isth*). Along most of *mc* the striate cortex extends more over the lower lip, this possibly being related to the presence of anterior cuneolingual gyri, one in each lip (*cula*), making for a shallow fissure in this locality, becoming deep close to *culpo*. In the posterior lip of the posterior calcarine sulcus, the striate cortex in part does not emerge onto the exposed surface. Poles of occipital lobes marked by asterisks (*). *Labeling: cul, culpo*, posterior cuneolingual gyrus; *cula*, anterior cuneolingual gyrus; *hip*, hippocampal gyrus; *isth*, fornico-hippocampal gyrus; *l*, lunate sulcus; *lc*, lateral calcarine sulcus; *mc*, medial calcarine sulcus; *prel*, prelunate sulcus; *po*, parieto-occipital sulcus; *spl*, splenium of corpus callosum; *u*, uncus of hippocampal gyrus.

SEC. 4. LOCATION, EXTENT, AND GENERAL CHARACTERISTICS OF THE STRIATE AREA

1. DEFINITION OF THE CORTICAL CENTERS OF VISION.—The cortical centers of vision are those portions of the superficial gray substance covering the cerebral hemispheres which are directly or indirectly concerned with the visual function. Specifically, in a restricted sense the striate areae of the occipital lobes where fibers of the visual radiations terminate are to be considered the cortical visual centers. In a wider sense all parts of the cerebral cortex which, according to experimental, clinical, and pathological evidence, serve any of the receptive, associative or integrative, and motor functions of vision may likewise be considered to belong to the visual sphere. (*Cf.* chap. VI, 1.)

2. LOCATION AND EXTENT OF THE STRIATE AREA IN THE HUMAN BRAIN.—The portion of the cerebral cortex where the afferent fibers of the visual radiation terminate, named by G. Elliot Smith the "striate area," identical with the "visuosensory area" of Bolton and Campbell, "field *17*" of Brodmann, or "area *OC*" of Economo, is located in the occipital lobe of each cerebral hemisphere (Figs. 298, 300, 301).

This area is distinguished by a pronounced, pale, and relatively wide stripe approximately in the middle of the thickness and parallel to the surface of the cortex. The line is visible to the unaided eye on a surface cut through a fresh or preserved specimen. It is called the outer stripe of Baillarger or, more commonly, the stria of Gennari or Vicq-d'Azyr (*see* Fig. 87, *1*, *10*, in chap. III, 5; and Figs. 226–29).

In the human brain the striate area is located in and around the calcarine fissure, being mostly or entirely confined to the inner, medial face of the occipital lobe (Figs. 278, 288, 290, 293–96, 300, 301).

The location, shape, extent, and boundaries of the striate area vary greatly individually, as illustrated by the accompanying figures. The boundary of the striate area by which it is delimited from the adjoining "parastriate area" of G. Elliot Smith, or "field *18*" of Brodmann, is marked by an abrupt cessation of the stripe of Gennari (in unstained preparations or those stained for myelinated nerve fibers, e.g., by Weigert's method, Fig. 316, right half), or by a cessation of a double inner granular layer in Nissl preparations (Figs. 312, 313).

Its anterior boundary usually begins a short distance in front of the junction of the inner parieto-occipital sulcus (*po*) and the calcarine fissure (*mc*), not far from the splenium of the corpus callosum (*cc* or *spl*, in Figs. 289, 290, 291, 292, 293, 294, 295, 296). At this end, the striate cortex is ordinarily found only in the lower lip of the fissure, the upper lip belonging to the cortex surrounding the striate area, the "paraperistriate areae" of G. Elliot Smith, or "fields *18–19*" of Brodmann (Fig. 278). A striate area completely displaced into the lower lip is a rare occurrence (Ngowyang, Landau, Brodmann, Hoesel). A reverse arrangement, with the striate cortex in the upper lip and with none in the lower lip or with the striate cortex lining both lips more or less symmetrically, is only rarely found.

In the cuneal stretch of the calcarine fissure the striate cortex spreads over both lips, emerging also to a varying extent upon the free medial surface in a zone along both sides of the fissure, usually less along the upper or cuneal than along the lower or lingual lip.

At the tip or pole of the occipital lobe the striate area usually spreads a little over the posterior or posterolateral, convex face of the hemisphere (Fig. 293). In other cases where there is a persistent occipital operculum, the posterolateral exposed portion is considerable, both sides being fairly equal and symmetrical in shape or, on the contrary, of unequal size, with the left one usually the larger (Figs. 288, 290). In still other specimens the striate area falls short of the pole, as discussed in the preceding section (Fig. 296).

Ordinarily, the portion not concealed in the sulci amounts to less than half the total area, with more than half the striate cortex concealed within the sulci of the calcarine complex (Figs. 228, 229, 290, 291). The proportion of the striate cortex concealed in the sulci and that spreading over the inner and outer faces of the occipital operculum, as well as the longitudinal extent and, in particular, the shape, size, and

location of the occipital operculum and opercular striate cortex, vary considerably individually and may also vary according to race, as discussed in the preceding section.

When one area, usually the left, is larger, a more or less pronounced asymmetry results (Fig. 288; *see* G. E. Smith 1907; Brodmann 1918). Such asymmetry is ordinarily, though not regularly, associated with the "skew asymmetry" of the brain and of the cranium and with an unequal division of the venous sinuses at the "torcular of Herophilos," where the superior sagittal sinus proceeds mainly to the right, the straight sinus mainly to the left. The causes of this peculiar arrangement, already found in the prehistoric human races and occasionally also in Monkeys and Apes, are little understood but are apparently complex, being both developmental-mechanical and architectural-functional. (*See* Figs. 282, 287; *see also* G. Elliot Smith 1907; Brodmann 1918; Le Gros Clark 1934.)

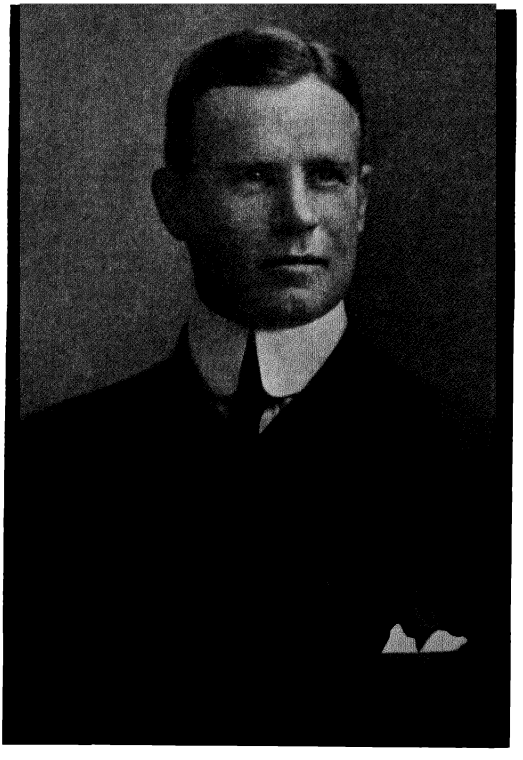

FIG. 297.—Alfred Walter Campbell (1868–1937), neurologist, neuropathologist, and alienist of Sydney, Australia. Pioneer investigator of the minute structure of the cerebral cortex. Author of the classical monograph *Histological Studies on the Localisation of Cerebral Function*, 1905 (from M. J. Australia, January 22, 1938). Courtesy of Professor Sydney Sunderland, of the University of Melbourne, Australia. *See also* Haymaker & Baer, *The Founders of Neurology*, 1953.

The surface of the striate area in an adult human brain, according to Cunningham (1943) (G. Elliot Smith and Le Gros Clark), amounts to about 3,000 sq. mm., varying in different brains and hemispheres from 2,700 to 4,000 sq. mm. According to the investigations of Brod-

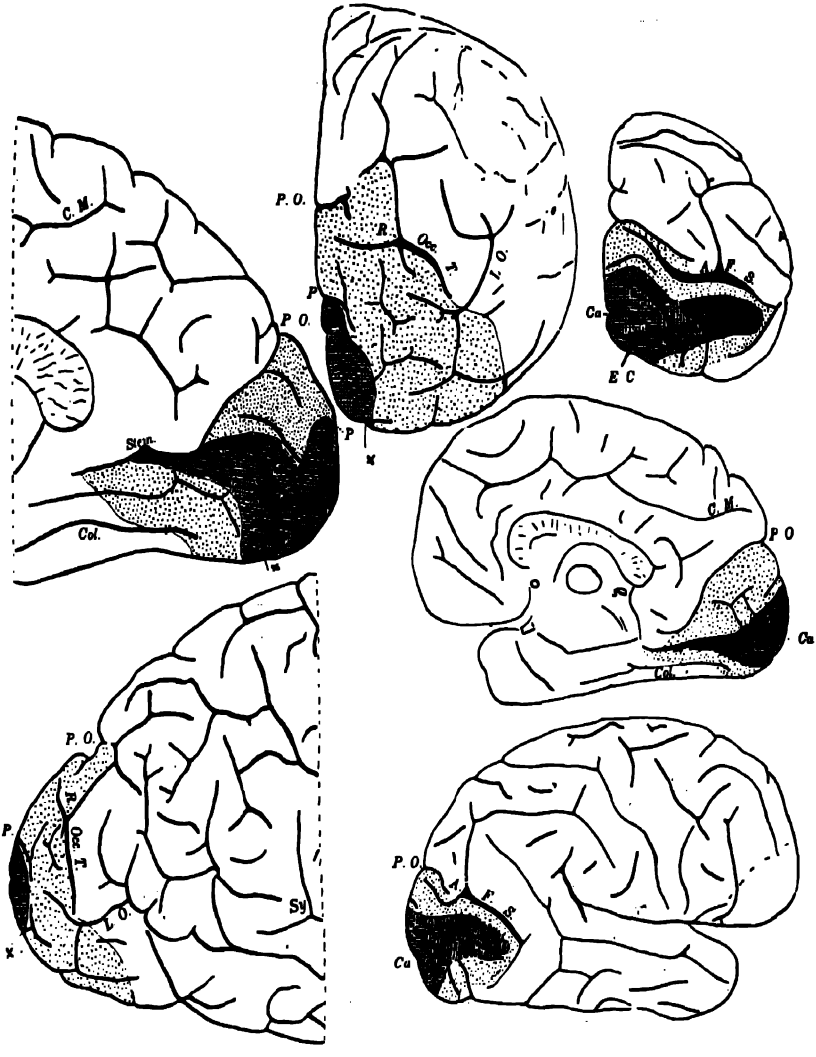

FIG. 208.—"Drawings to illustrate the distribution of the visuo-sensory (cross-hatched) and visuo-psychic (dotted) areas in the human being and orang. The three figures to the right are from the ape, and the wide lateral extension is to be specially noticed; observe, also, that the visuo-sensory area closely follows the fissure marked *E.C.*, the so-called 'external calcarine' fissure (the sulcus intrastriatus lateralis of Elliot Smith) [termed in this book 'lateral calcarine sulcus' (*lc*)] and that the visuo-psychic field is closely related to the 'Affenspalte' (*A. F. S.*). In the human brain the ramus occipitalis transversus (*R. Occ. T.*) seems to form a corresponding visuo-psychic limit. *Ca.* = calcarine fissure. *Stem* is placed above the division distinguished by that name. *Col.* = collateral fissure. *P.O.* = parieto-occipital fissure. *C.M.* = calloso-marginal fissure. *L.O.* = lateral occipital fissure of Eberstaller. *Sy.* = Sylvan fissure. *P.* = superior polar fissure of Bolton. × = inferior polar fissure of same writer." From A. W. Campbell, *Histological Studies on the Localisation of Cerebral Function*, p. 119, 1905. (*Cf.* Figs. 280, 284, 286.)

mann (1911), the size of the striate area varies between 2,950 and 4,400 sq. mm., being, on the average, 3,450 sq. mm. Filimonoff (1932) found the size of the same area to vary from 2,208 to 2,877 sq. mm., the mean extent being 2,613.

Since the area of the retina of a normal adult human eyeball is approximately 350 sq. mm., the ratio of its area to that of the striate area is roughly 1 to 7.

3. LOCATION AND EXTENT OF THE STRIATE AREA IN INFRAHUMAN PRIMATES AND IN OTHER MAMMALS.—In the brain of the Macaque and in other Old World Monkeys, almost the entire occipital lobe or operculum, sharply separated from the rest of the hemisphere by the simian or external occipitoparietal or lunate sulcus (*l*) and by the inferior occipital sulcus, is taken up by the striate area (Figs. 280, 302). Only a narrow zone along these sulci belongs to the adjoining extrastriate cortex. In the large Platyrrhines and in the Anthropomorphous Apes the portion of the striate area exposed on the posterolateral face of the occipital lobe is already noticeably reduced in comparison with most catarrhine Monkeys, even though it is still relatively larger than in Man (Figs. 282 84, 286, 303).

On the inner side of the hemisphere, in the Monkey, the striate area remains concealed in the calcarine fissure, except at the posterior pole along the ascending and descending prongs of the fissure.

In most Infraprimate Mammals the striate area is relatively smaller in extent than in the Simians (Figs. 308, 309). It is an area approximately semilunar in shape, close to or at the occipital pole, extending for some distance along the upper margin of the hemisphere anteriorly and posteriorly and in most species also spreading over the upper, inner, and lower surfaces of the hemisphere. In Mammals with poorly developed sight, such as the African Jumping Shrew (Fig. 279, *A*) and the European Hedgehog (Fig. 309, *B*), the striate area is quite small and is located at the occipital pole or close to it on the convex face of the hemisphere.

During life and in fresh specimens the striate area over the simian occipital lobe is of a peculiar pale yellowish-orange color and also has a characteristic arrangement of the blood vessels, features by which it may readily be distinguished from the surrounding cortex. (*Cf.* chap. X, 7.)

4. THE STRIATE AREA—A SINGLE, HOMOGENEOUS, UNIFORMLY ORGANIZED CORTICAL TERRITORY.—The striate area, both in Man and in the Simians, has a remarkably uniform structure in all its parts. Morphologically, contrary to the statement of some investigators, it is not possible to notice any abrupt or sufficiently pronounced local differences which could be accepted as landmarks or boundaries by means of which the striate area could be further subdivided into smaller component territories or subareae.

This observation is at variance with the opinion of those students who insist that the striate area is made up of a number of subareae (Klempin 1921; Gurewitsch & Bychowski 1923, 1928; Volkmann 1926; Alouf 1929; G. Elliot Smith 1929–30; Beck 1930; Beck & Kleist 1931; Ngowyang 1934). Local variations, found in total thickness or thickness of particular layers of the striate cortex in so extensive an area, are merely expressions of physical factors caused by the surface configuration, if they are not plain artifacts.

The histological uniformity or homogeneity of the striate area, however, does not mean that its finer structural details are precisely the same in all parts. It means only that those changes that do occur do so gradually, almost imperceptibly, without alteration of the basic structural pattern, which remains essentially the same in the entire extent of the striate area. In its structural uniformity the striate area resembles the retina, of which it is a cortical representation. The variation concerns merely the less essential features. What differs is the number and size of the nerve cells and their expansions and, because of this, the total thickness and structural fineness of the cortex. But the kinds or varieties of neurons and their arrangement remain everywhere essentially the same.

The thinnest striate cortex in Man is in the posteriormost portion, contained in the pocket of the lateral or posterior calcarine fissure, close to or at the occipital pole, where the hemifoveae are represented. Conversely, the thickest cortex, approximately twice the thickness of the polar, is at the opposite, anterior, extremity of

the striate area, where the monocular nasal portion of the contralateral retina is represented. In the Monkey the foveal-areal cortex is on the lateral face of the occipital lobe close to the simian sulcus, while the peripheral, extra-areal cortex remains buried in the anterior segment of the calcarine fissure on the medial face of the hemisphere.

The locality of the striate cortex related to the central foveae is also most delicately organized, while the locality representing the far and the extreme retinal periphery is relatively

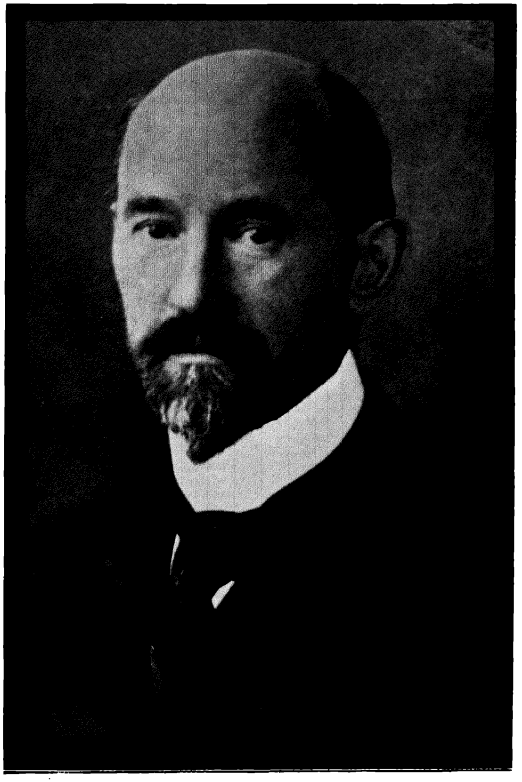

FIG. 299.– Korbinian Brodmann (1868 1918), the neuroanatomist. Together with A. W. Campbell (*see* Fig. 297), founder of modern cytoarchitecture of the cerebral cortex of Man and of other Vertebrates (from J. f. Psychol. u. Neurol., v. 24, p. i, 1919). For biography *see* O. Vogt in the same volume, and Haymaker & Baer, *The Founders of Neurology*, 1953. (*See also* W. Spielmeyer in München. med. Wchnschr., v. 65, p. 1138, 1918; F. Nissl in Ztschr. f. d. ges. Neurol. u. Psychiat. [Orig.], v. 45, p. 329, 1919; L. Schwarz in Schweiz. Arch. f. Neurol. u. Psychiat., v. 4, p. 184, 1919–20.)

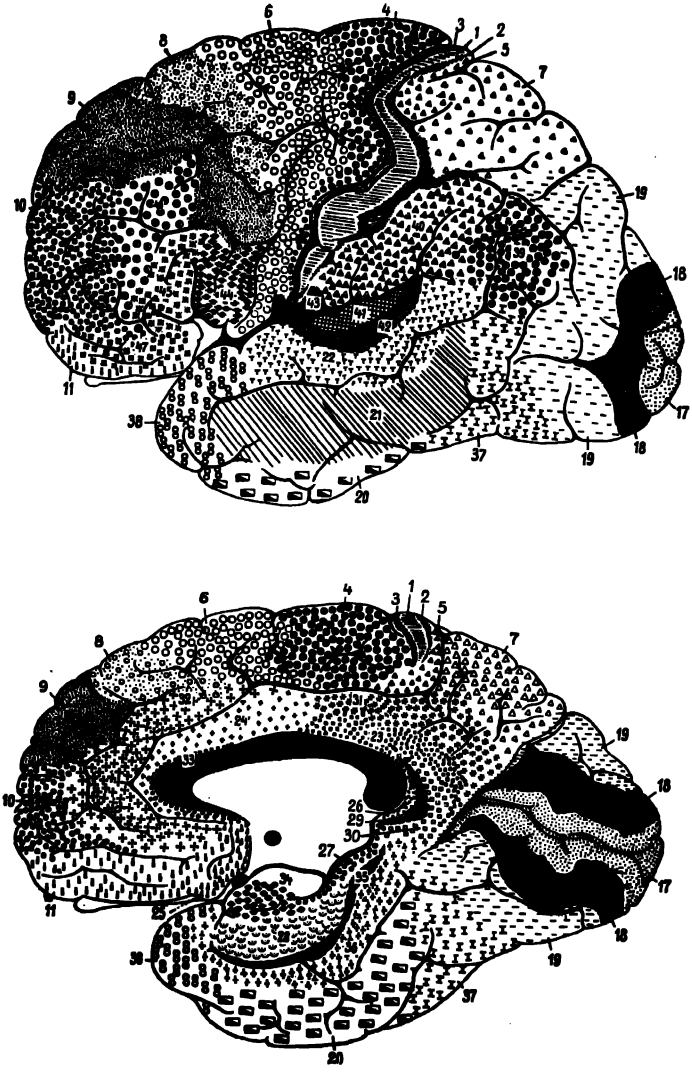

FIG. 300.—Brodmann's cytoarchitectural charts of the human cerebral cortex. *Upper figure*, lateral view of the left hemisphere; *lower figure*, medial view of the right hemisphere. Principal subdivisions: *1, 2, 3*, postcentral areae; *4*, gigantopyramidal precentral area (motor); *6*, frontal agranular area; the *4* and *6* together forming the precentral agranular region; areae *8, 9, 10, 11, 44, 45, 46*, and *47* compose the frontal granular region; areae *17, 18*, and *19* constitute the occipital region, of which the first is the striate area, *18*, the parastriate area, and *19*, the peristriate area of G. Elliot Smith; areae *20, 21, 22, 36, 37, 38, 41*, and *42* constitute the temporal region; areae *23, 24, 25, 31, 32*, and *33* comprise the cingular region; areae *26, 29*, and *30* make up the retrosplenial region; areae *27, 28, 34*, and *35* are the hippocampal region. The insular region (*13, 14, 15, 16*) is not indicated in these diagrams. From K. Brodmann, *Vergleichende Lokalisationslehre der Grosshirnrinde*, 1909. (*Cf.* Figs. 274, 275, 301.)

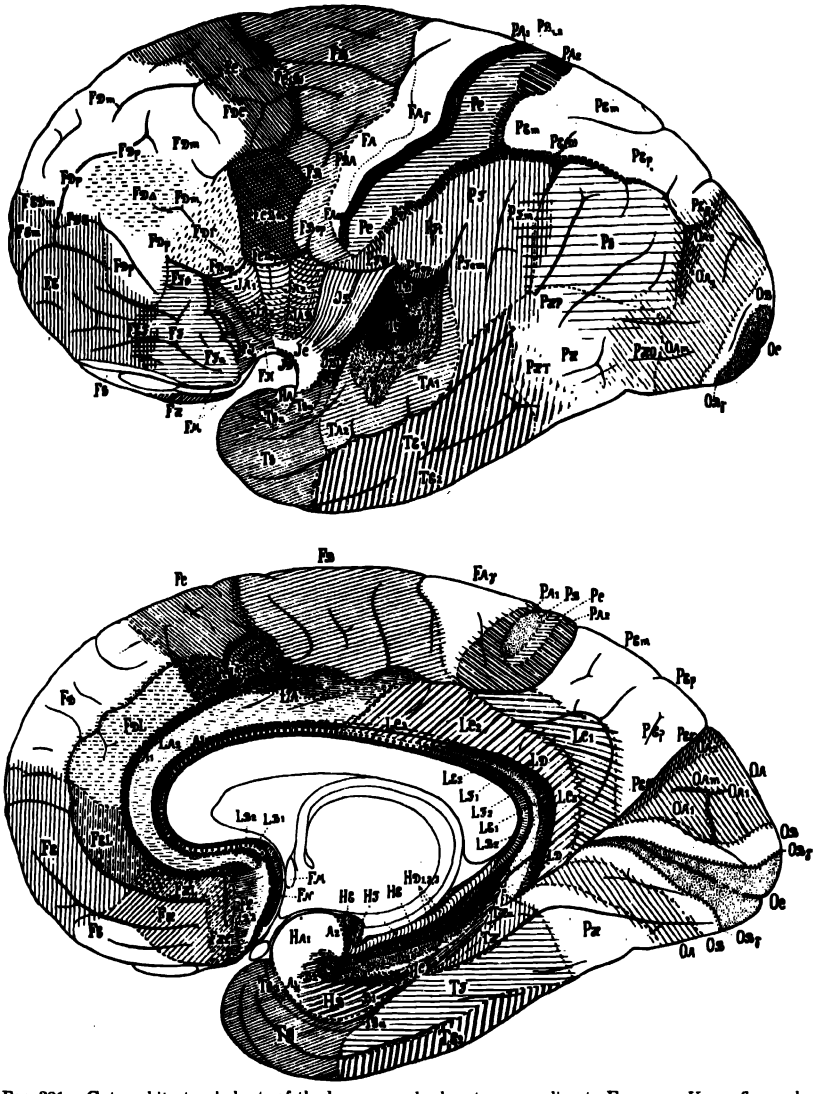

FIG. 301.—Cytoarchitectural charts of the human cerebral cortex, according to Economo. Upper figure shows lateral view of the left hemisphere; the lower figure a medial view of the right hemisphere. The principal receptor areae containing relatively the greatest number of granule cells or the most pronounced parts of the so-called *koniocortex* ("dusty cortex"), are: *Oc*, occipital granular area of Economo, identical with striate area of G. Elliot Smith, or with field *17* of Brodmann; *PA, PB, PC, PD*, make up the anterior parietal region of Economo, or postcentral region (areae *1, 2, 3*) of Brodmann; *TB, TC, TD*, represent the granular supratemporal area of Economo, approximately coinciding with the transverse temporal areae *41* and *42* of Brodmann. From Economo & Koskinas, *Die Cytoarchitektonik der Hirnrinde*, etc., 1925. (*Cf.* Figs. 274 and 275, showing functional localization, and Brodmann's charts in Fig. 300.)

crude. The intermediate zone filling the territory between these two extremes keeps the balance between both. But the differences, as pointed out above, are unessential and gradual. The rather vague boundaries, by means of which several beltlike zones may be distinguished in the retina, are smoothed over in the striate area. Nor do such structural extremes as are found, for example, in the central fovea, on the one hand, and in the zone close to the ora serrata of the retina, on the other hand, have a clear counterpart in the striate area. The reason for this striking difference is rather obvious: in the central fovea, where the cones are most

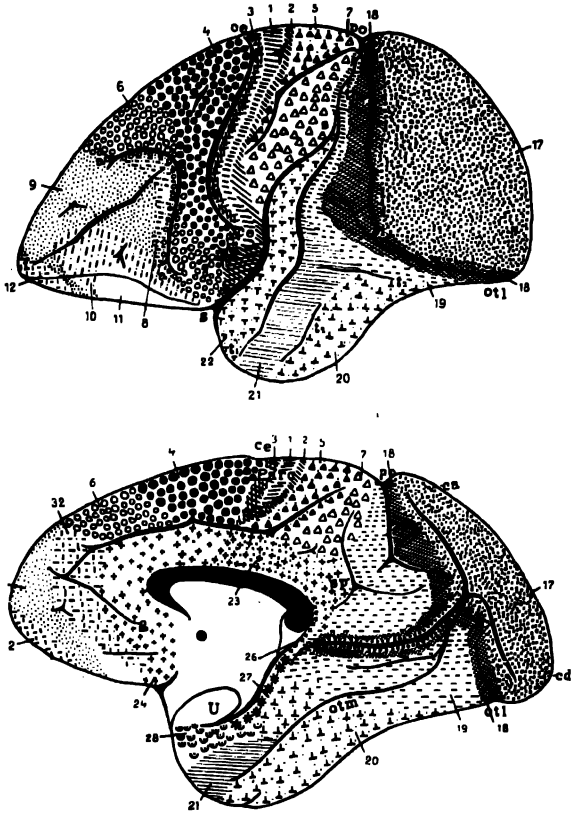

FIG. 302.—Cytoarchitectural charts of the brain of an African Cercopithecus Monkey. Upper figure represents a lateral view of the left hemisphere; the lower figure a medial view of the right hemisphere. The striate area, field *17*, or the cortical visual center (*medium stippling*), covers on the lateral face almost the entire occipital lobe or *o. operculum*, extending not quite to the simian sulcus (*si*) and to the inferior occipital sulcus (*oll*). On the medial face, field *17* spreads over a portion of the occipital lobe along the ascending and descending prongs of the medial calcarine sulcus (*ca*, *cd*), whereas along the main stem of this sulcus it is submerged, indicated by asterisks (*). The numbering of the areae same as in Fig. 300. From K. Brodmann, *Vergleichende Lokalisationslehre der Grosshirnrinde*, 1909. (*Cf.* Figs. 280, 281, and 306.) *Labeling: a*, arcuate sulcus; *ca*, *cal*, calcarine sulcus (medial, *mc* in Fig. 280); *ce*, central sulcus; *f*, frontal pole; *g*, genual sulcus; *oll*, lateral occipitotemporal sulcus; *otm*, medial occipitotemporal sulcus; *Parc*, paracentral lobule; *po*, parieto-occipital sulcus; *si*, simian sulcus; *S*, Sylvian or lateral fissure; *sp*, subparietal sulcus; t_1, t_2, superior and medial temporal sulci; *U*, uncus of hippocampal gyrus.

numerous and concentrated in a relatively small area, the vitreal layers, through which the rays of light would otherwise have to pass, are pushed aside in order to increase the central acuity, whereas in the cortical representation of the fovea, where much more space is available, the transition of the layers from point to point is smoothed over. (*Cf.* chap. V, 10 [5].)

SEC. 5. CELL LAYERS OF THE STRIATE AREA

1. General histological characteristics of the primate striate area.—The striate area of Man, Ape, and Monkey, when examined in appropriately stained microscopic sections, e.g., by Nissl or Weigert methods, is characterized partly by features common to other localities of the cerebral cortex and partly by features found nowhere else. The arrangement of the bodies of nerve cells and of the thicker and thinner myelinated nerve fibers grossly follows the pattern found elsewhere. One general peculiarity is a more or less pronounced stratification parallel to the surface of the cortex. Another is the columnar arrangement of cells, vertical to the surface, less well defined here than in some other localities.

The striate cortex is thin when compared with the other cortical regions and fields—for example, with the precentral motor cortex. In Man its average thickness is from 1,300 to 1,600 microns, or 1.5 mm., more or less; in the Rhesus Macaque it is approximately 1,000 microns, or 1 mm. The thickness varies considerably even on the same level, depending on the plane of cutting and also on the physical factors that mold the sulcal and gyral relief, including the presence or absence of blood vessels and the like. Ordinarily, the thinnest striate cortex is found in the floor of the fissures, the thickest on the summit of the gyri. The thinnest striate cortex apparently is found at the occipital pole, where in Man the central foveae are represented, or in Monkeys close to the simian sulcus.

The striate area is, on the whole, much richer in nerve cells than the remainder of the cerebral cortex. The size of its cells, on the contrary, is much smaller, the intercellular spaces reduced, and the distribution of cells more uniform. The result of this is the dense, relatively homogeneous appearance of this cortical locality, for which reason it has been named by Economo *koniocortex* or "dusty cortex," meaning "granular cortex."

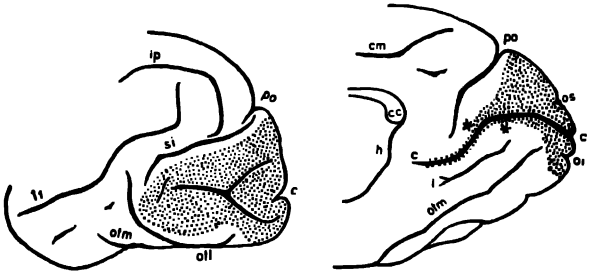

Fig. 304.—Striate area of a Langur or Hanuman Monkey (*Presbytis cephalopterus, Semnopithecus leucoprymnus*) of Ceylon, a catarrhine cercopithecid Old World Monkey. Left diagram represents the lateral view of the left occipital lobe; the right diagram the medial view of the right occipital lobe. The asterisks (*) indicate points in the upper and lower calcarine lip at which the striate cortex emerges from the calcarine fissure (*c*) upon the exposed surface of the lobe. From K. Brodmann, *Vergleichende Lokalisationslehre der Grosshirnrinde*, 1909. (*Cf.* Figs. 282, 283, 284, 285, 286.) *Labeling: c*, calcarine fissure (medial, *mc* in our Figs. 280, 282); *cc*, corpus callosum; *cm*, callosomarginal sulcus; *h*, hippocampal sulcus; *ip*, intraparietal sulcus; *l*, limiting calcarine sulcus; *oi*, inferior branch of lateral calcarine fissure; *otl*, inferior occipital sulcus; *otm*, medial occipitotemporal sulcus; *po*, parieto-occipital sulcus; *si*, simian sulcus; l_1, superior temporal sulcus.

When examined without the aid of a magnifying apparatus and even more so at slight magnification (50×), a vertical section through the striate cortex stained by the Nissl method reveals an unequal distribution of nerve cells. Close scrutiny shows at least eight parallel and alternating layers, five dark ones rich in cells (*2, 3, 4-a, 4-c, 6*) and three of lesser density (*1, 4-b, 5*, left numbers in Fig. 312, also Fig. 314).

In approximately the middle of the thickness there is a conspicuous belt where the cells are relatively few (*4-b*). The upper limit of this rarefied zone roughly coincides with the bound-

ary between the upper and the lower half, the lighter zone itself being approximately one-sixth the thickness of the entire striate cortex. This lighter zone almost coincides with the bulk of the stria or stripe of Gennari or Vicq-d'Azyr visible by the unaided eye as a white line in fresh and fixed specimens and in Weigert-stained preparations as a dark belt (thick fiber belt *G*, in right half of Fig. 316). Another even sharper, but less wide, rarefied cellular zone is close to the lower boundary of the striate cortex (*5*, left half in Figs. 312, 313).

The stripe of Gennari divides the striate cortex roughly into two halves of almost equal thickness (right diagram in Fig. 316). The upper half, closer to the surface, situated above the stripe, is made up preponderantly of small, uniformly distributed cells not greatly different in size. The columnar arrangement, although not pronounced, is noticeable here. The lower or inner, deeper half of the striate cortex below the stripe of Gennari is less homogeneous. It comprises the inner rarefied zone (*5*) between the two denser ones (*4-c*, *6*). The cells here are less uniform in size, and the columnar arrangement somewhat less prominent. The few large cells, the largest in the striate cortex, found in groups and singly at irregular intervals in both rarefied zones (*4-b* and *5*), are conspicuous here.

Externally, the territory of the striate cortex rich in cells (layers *2–6*) is separated from the pial membrane (*p*) by a plexiform layer, where the nerve cells are almost absent (layer *1*). The thickness of this layer equals approximately one-eighth of the belt of the cortex containing cells. The inner boundary of the striate cortex toward the white subcortical matter (*Al*) is fairly sharp. A boundary line where the striate cortex adjoins the surrounding parastriate cortex is well marked along its entire circumference.

2. STRATIFICATION OF NERVE CELLS OR CYTOARCHITECTURE OF THE PRIMATE STRIATE AREA.

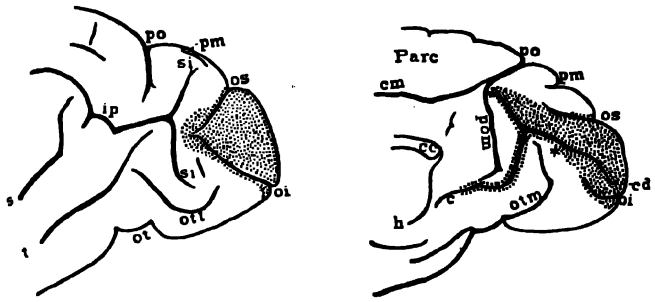

FIG. 305.—Striate area of the platyrrhine South American Woolly Monkey (*Lagothrix lagotricha* or *L. humboldtii*). Left diagram shows the lateral view of the left occipital lobe; right diagram the medial view of the right occipital lobe. Asterisks (*) indicate a portion of the striate area concealed within the anterior segment of the calcarine fissure (*c*). From K. Brodmann, *Vergleichende Lokalisationslehre der Grosshirnrinde*, 1909. (*Cf.* Figs. 282, 284, 286, 303, 304.) *Labeling: c, cd*, calcarine fissure (medial); *cc*, corpus callosum; *cm*, callosomarginal sulcus; *h*, hippocampal sulcus; *ip*, intraparietal sulcus; *oi* and *os*, inferior and superior branch of lateral calcarine sulcus; *ot*, occipito-temporal incisure; *ott*, inferior occipital or lateral occipitotemporal sulcus; *otm*, medial occipitotemporal sulcus; *Parc*, paracentral lobule; *pm*, paramesial sulcus; *po*, parieto-occipital sulcus; *pom*, medial parieto-occipital sulcus; *S*, Sylvian or lateral fissure; *si*, simian sulcus; *t*, temporal sulcus.

—The nerve cells of the striate cortex in Man, Ape, and Monkey, according to a generally accepted view, are arranged in several more or less distinct horizontal layers parallel to the cortical surface. Following Brodmann's suggestion, eight layers may be distinguished—a greater number than in any other locality of the cerebral cortex (left numbers in Fig. 312). In the striate area, however, since it is a part of the *neocortex* or "new cortex" of the great cerebral hemispheres, the characteristic basic six layers are readily identified (right numbers in same figure), the increase being caused by a splitting of the fourth layer into three sublayers

(*4-a*, *4-b*, *4-c*). As in the remainder of the neocortex, the layers or sublayers of the striate cortex, even when clearly recognizable, with the exception of the first layer, are nowhere completely separated from one another by layers or zones devoid of cells, as is the case in the retina and in the laminated lateral geniculate nucleus (*see* chap. V, 2, and chap. VI, 8, 9).

The features by which the particular layers may be identified are the number, size, shape, distribution, density, and other possible characteristics of the constituent nerve cells and fibers. While each of these features may vary from place to place of the areal extent, the transition from one layer to the next is everywhere continuous, the subdivision of the striate cortex into layers being in a sense an artifact. For, in reality, all superimposed layers of the striate cortex, as of the neocortex elsewhere, are structurally intimately tied up, the entire cortex forming, in fact, a single, solid nervous mass.

In spite of this intimate relationship of the several layers of the striate cortex, the undeniable structural differences from stratum to stratum are to be accepted not merely as accidental features useful as landmarks but as a true morphological expression of a locally varying function. Each layer, although a part of the total structure, is to be looked upon as a differentiated cortical mechanism performing its own specific function, the function of the cortex

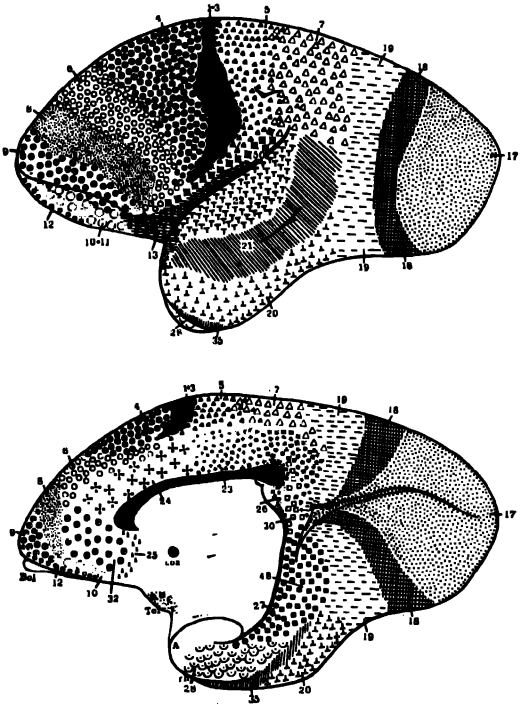

FIG. 306.—Cytoarchitectural charts of the cerebral cortex of a South American Marmoset Monkey (*Hapale jacchus*). Upper figure shows the lateral view of the left hemisphere; lower figure the medial view of the right hemisphere. Striate area, or field *17*, indicated by medium stippling. Numbering same as in Figs. 300 and 302. From K. Brodmann, *Vergleichende Lokalisationslehre der Grosshirnrinde*, 1909. (*See also* following figure.)

being, accordingly, the sum total of the functions of its constituent specific structures.

The layers which in the primate striate cortex may, with fair justification, be distinguished in preparations stained by the Nissl method are as follows.

3. PLEXIFORM LAYER (*1*).—The first layer, identical with the "zonal lamina" of Brodmann, equal in size to the medium-sized cells of the intermediate lamina of the inner granular layer (*4-b*). These larger cells may be present in any part of the plexiform layer, either close to the second layer, immediately underneath the pial membrane, or anywhere in between. They are mostly irregular, multipolar, and sometimes fusiform or spindle-like in shape. Of the smaller nerve cells, some are pyramidal, resembling

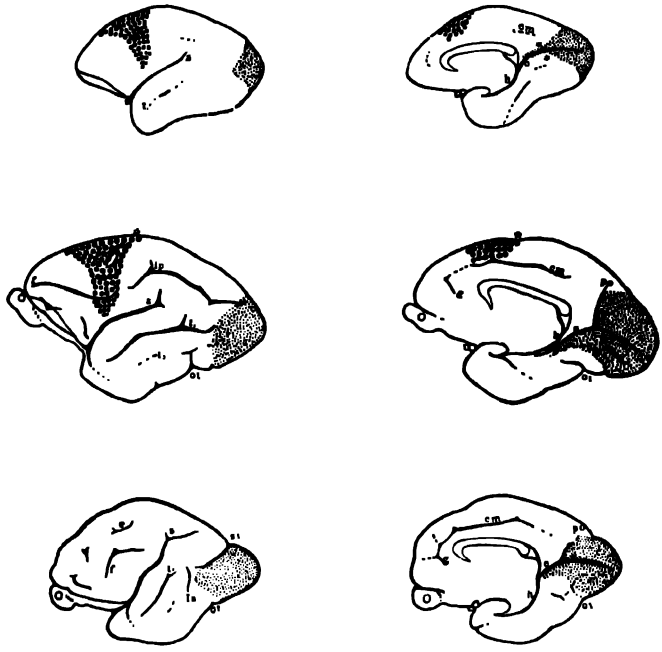

FIG. 307.—Lateral (*left*) and medial (*right*) views of the cerebral hemispheres of three species of Lower Primates, indicating the shape, position, and extent of the motor area (*coarsely stippled*) and of the striate area (*finely stippled*): *upper figures*, South American Marmoset (*Hapale jacchus*); *middle figures*, a Lemur of Madagascar (*Lemur macaco*); *lower figures*, an Indian Loris (*Nycticebus tardigradus*). From K. Brodmann, *Vergleichende Lokalisationslehre der Grosshirnrinde*, 1909.

or "molecular layer" of Economo, in Man comprises approximately one-eighth the total thickness of the striate cortex and less in the Monkey (*1*, in Fig. 314). It is closest to the pial membrane coating the surface of the cortex.

In the plexiform layer there are only a few true nerve cells, mostly of small size. Some cells, however, are considerably larger than the diminutive cells of the second layer (*2*) and are those of the second layer, but the majority are irregularly spherical or triangular. Occasionally, a group of a dozen or so of these small cells is arranged in a row parallel to the general arrangement of the layers. The number of neuroglial elements is likewise small.

Owing to the scarcity of nerve cells, the plexiform layer appears empty, contrasting in this respect with all inner layers taken together

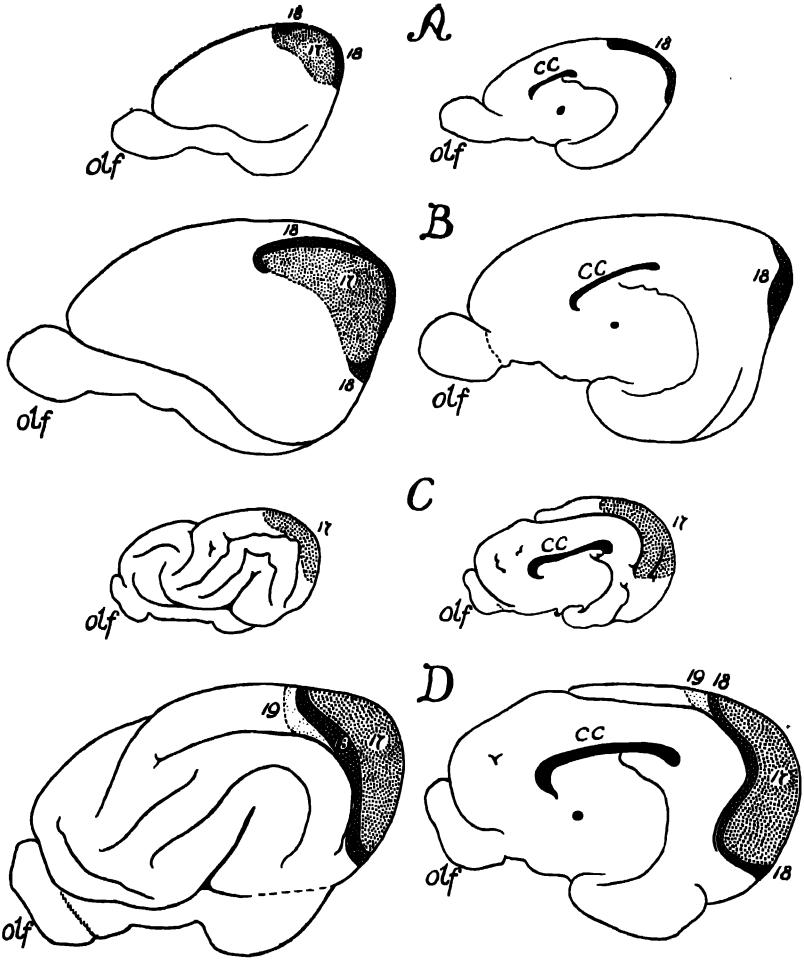

FIG. 308.—The shape, extent, and location of the striate (*17*), parastriate (*18*), and peristriate (*19*) areæ of various representative Mammals. *A*, European Spermophile or Ground Squirrel (*Spermophilus citillus*, *Zieselmaus* in German, *Súslik* in Russian, 1¾× magnification); *B*, Rabbit (*Lepus cuniculus*, 1¾× magnification); *C*, Stone- or Beech-Marten (*Mustela foina*); *D*, Kinkajou (*Cercoleptes* or *Potos caudivolvulus*, 1½× magnification). *Labeling: cc*, corpus callosum; *olf*, olfactory bulb. From K. Brodmann, *Vergleichende Lokalisationslehre der Grosshirnrinde*, 1909. (*See* following figure.)

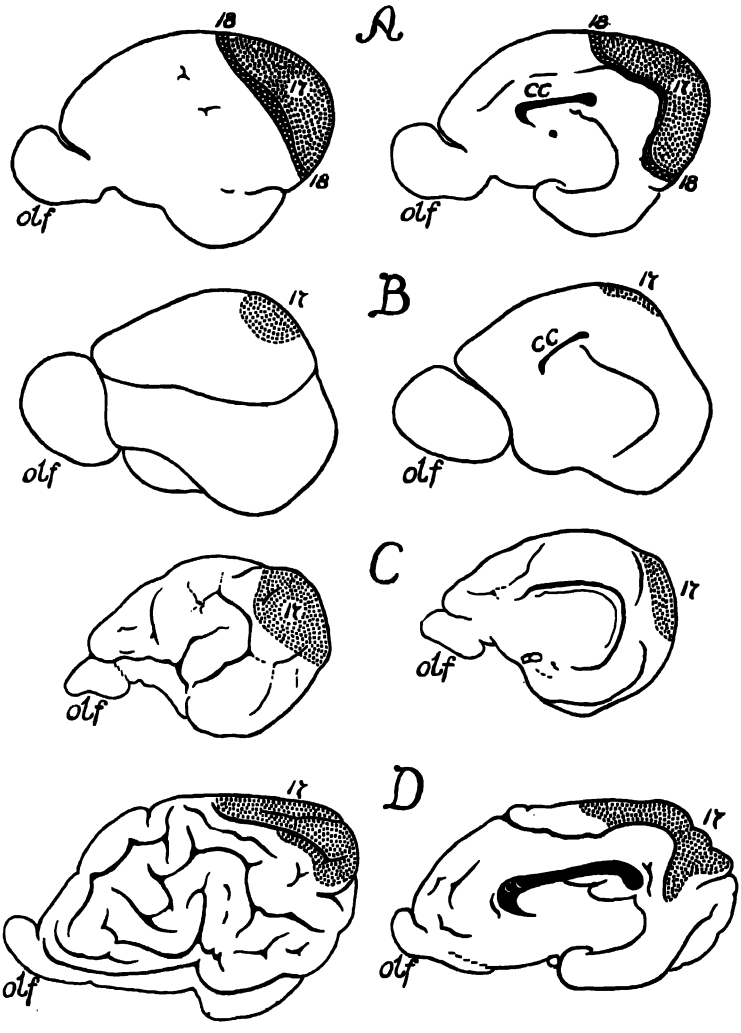

FIG. 309.—The shape, extent, and location of the striate (*17*) and parastriate (*18*) areae of some Mammals. *A*, Flying Fox or Fruit-eating Bat (*Pteropus edwardsii*, 1⅔× magnification); *B*, European Hedgehog (*Erinaceus europaeus*, 2½× magnification); *C*, Kangaroo (*Macropus penicillatus*); *D*, Domestic Goat (*Capra hircus*). From K. Brodmann, *Vergleichende Lokalisationslehre der Grosshirnrinde*, 1909. (*See* preceding figure.) *Labeling: cc*, corpus callosum; *olf*, olfactory bulb.

(*2–6*). In spite of this, the plexiform layer is part of the striate cortex. This fact is best shown by the spreading here of the numerous expansions of nerve cells residing in the subjacent layers, to be described subsequently.

4. OUTER GRANULAR LAYER (*2*).—The second layer, identical with the "external granular lamina" of Brodmann, or "outer granular layer" of Economo, is represented by the uppermost condensation of the cellular territory of the striate cortex next to the plexiform layer (*2*, in Fig. 314).

The cells of the outer granular layer are very small, among the smallest in the striate cortex. They are of a short pyramidal shape, with an apical dendrite directed toward the surface and spreading within the first layer. The thin layer of cytoplasm of the cell body contains a scanty chromophile substance. Occasionally there is found a somewhat larger cell of an irregular spherical or oval shape, which more properly deserves the name "granule cell." The "granular" impression to which the layer owes its name is, however, caused by the small size of most of the cells, their great number, and density of arrangement.

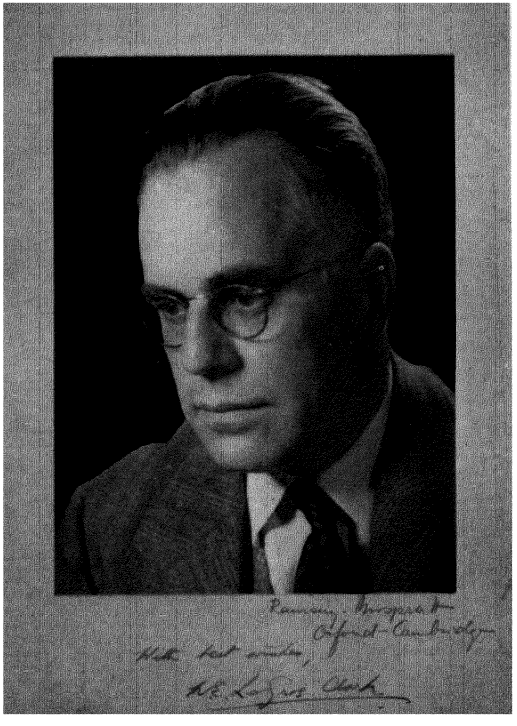

FIG. 310.—Sir Wilfrid Le Gros Clark (1895), professor of anatomy in Oxford, England. An eminent student of the nervous system, in particular of the visual, and of Man's phylogenetical origin. Courtesy Professor Clark.

5. PYRAMIDAL CELL LAYER (*3*).—The third layer, identical with the "pyramidal lamina" of Brodmann or "pyramidal layer" of Economo, is the inner continuation of the second layer and

is approximately five times as thick. Its nerve cells, although similar in shape, are appreciably larger than those of the second layer. Although not so dense, the cells of this layer may, because of their great number, represent, in Man, almost one-fourth or perhaps more of the nerve cells of the entire striate cortex. They gradually increase in size from the vicinity of the second to the subjacent fourth layer. The larger of the

FIG. 311.—Theodor Hermann Meynert (1833-92), professor of psychiatry in Vienna, Austria. One of the foremost pioneers of modern brain research. (*Cf.* Fig. 113, and the appended references on biography.)

elements are mostly of pronounced pyramidal shape, with a fairly long apical dendrite pointing toward the surface of the cortex and a few shorter and thinner basal dendrites spreading in a more or less horizontal direction. Certain of these cells are more or less globular or spherical and multipolar.

The cells in this layer are agglomerated into small clusters, from two or three to six cells, the clusters in turn arranged in indistinct vertical columns. A cell of typical pyramidal shape and of a size equal to that of the largest elements, with pronounced Nissl granules, is rarely found in this layer. These may be considered displaced giant ganglion cells characteristic of the fifth layer (*4-b*).

6. OUTER LAMINA OF THE INNER GRANULAR LAYER (*4-a*).—The fourth layer, identical with the "superficial internal granular lamina" or *4-a* of Brodmann and Economo, like the second layer, appears to be a condensation of the rather uniform, many-celled outer, or supra-Gennarian, half of the striate cortex. It immediately adjoins the subjacent and rather vacant fifth layer of Gennari and Vicq-d'Azyr (*4-b*).

It appears denser in comparison with the third layer (*3*) and even more in comparison with the fifth layer (*4-b*), because of the pres-

ence of small nerve cells of irregular globular shape, the typical "granules." There are also a few cells of somewhat larger pyramidal type, essentially identical with those in the third layer. On occasion, one of the larger cells characteristic of the fifth layer (*4-b*) may also be present, containing well-formed intracellular chromophile granules. The number of the granule-like cells in this lamina, however, is but a fraction of the number of similar cells in the deep inner lamina of the fourth layer (*4-c*).

7. MIDDLE LAMINA OF THE INNER GRANULAR LAYER (*4-b*).—The fifth layer, identical with the "intermediate internal granular lamina" or *4-b* of Brodmann and of Economo and largely with Gennari's or Vicq-d'Azyr's fiber layer, situated approximately midway in the cortex, is characterized by a relatively small number of cells. It separates the outer cortical half, made up of layers *1* to *4-a*, from the inner, represented by layers *4-c* to *6*, both of which are packed with nerve cells. These halves are of almost equal thickness.

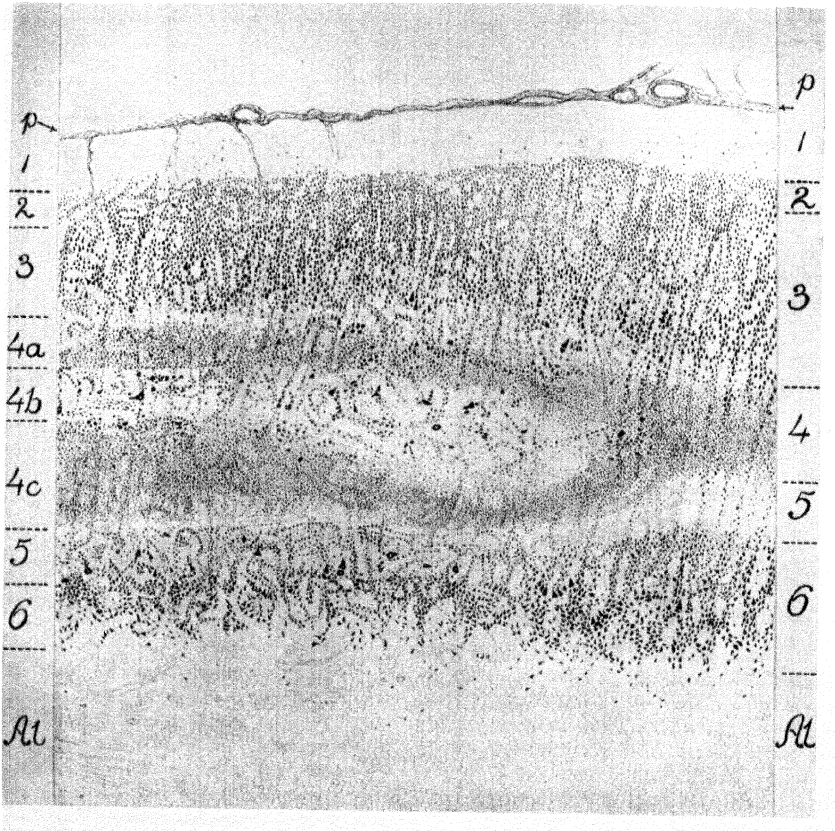

FIG. 312.—Cell arrangement in the marginal portion of human striate cortex stained with Nissl–toluidine blue method (Lenhossék's modification), showing the merging of the three sublayers of the inner granular layer of the striate area (*4-a*, *4-b*, *4-c*) into a single layer *4* in the parastriate area at the right end of the figure. (*Cf.* microphoto in Fig. 313; for stratification *see* Fig. 316.)

The elements found in the *4-b* layer are of several varieties. The bulk is represented by neurons of a size slightly larger than the typical granules of layers *4-a* and *4-c*, usually of spherical, pyriform, elliptical, or ovoidal shape. Other cells, somewhat larger than the cells of the *4-a* layer, always with their long axes horizontal, with an abundant chromophile substance, and expansions spreading in various directions, are conspicuous. The larger of these multipolar ganglions, among the largest nerve cells of the striate cortex, are characteristic of this layer. Their well-developed chromophile granules, separated by intergranular lines or channels, and their robust expansions are indicative of their essentially "motor" nature. These large neurons, possibly identical with the "solitary cells" originally described by Meynert (1872), are found at irregular intervals, usually singly, sometimes in the company of one or more smaller similar cells. These elements, because of their location, may be termed "outer solitary or giant cells" of the striate cortex (*cf.* par. 9, this section). Less frequently, these giant cells are displaced into the adjoining layers *4-a* and *4-c*. Such large and medium cells are more numerous

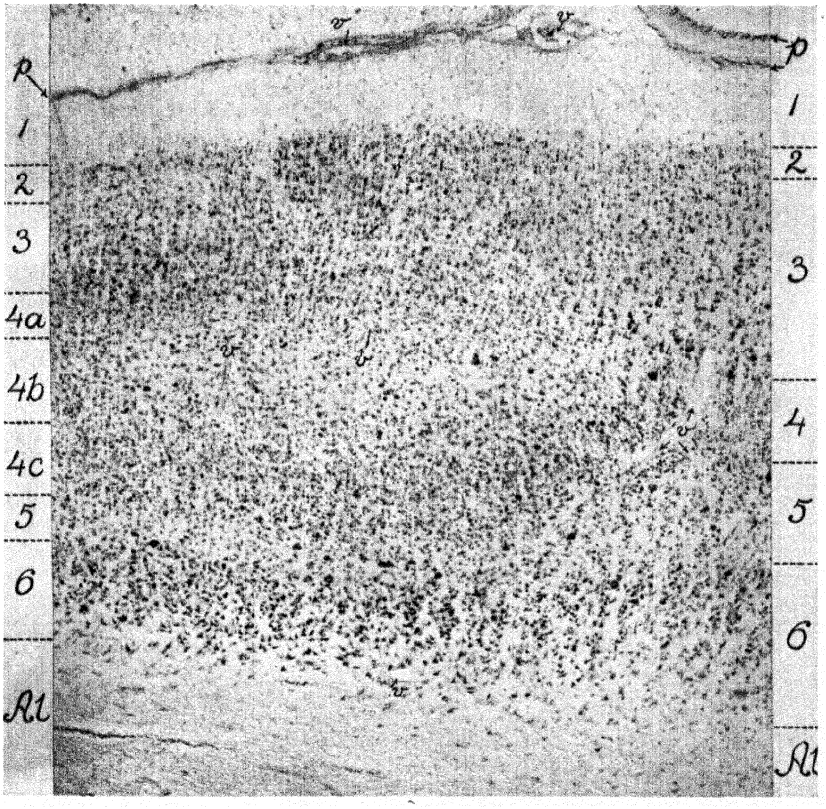

FIG. 313.—Microphotograph of a Nissl-stained section of the human striate area close to its boundary, showing the merging of the three sublayers (*4-a*, *4-b*, *4-c*) of the inner granular layer (left portion of the photo) into a single layer of the parastriate area (*4*, at the right of the photo). *Labeling: Al*, *alba*, or white subcortical fiber substance; *p*, pial membrane or vascular cover of brain; *v*, blood vessels. (For stratification *see* Fig. 316; *cf.* preceding figure.)

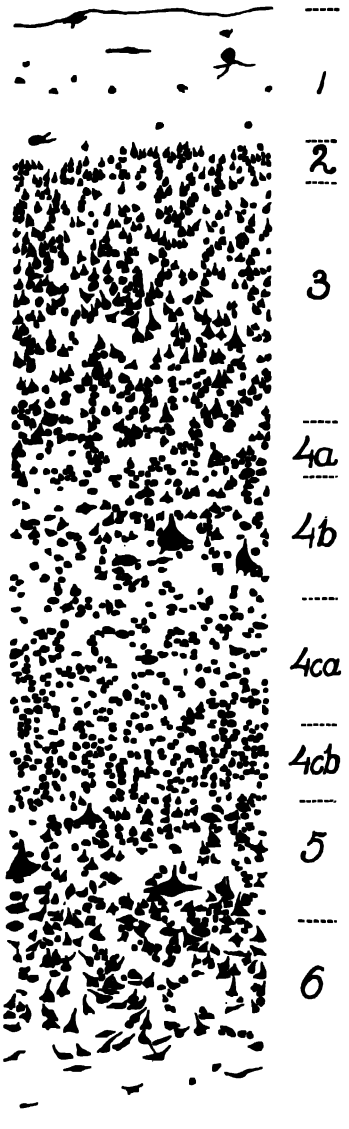

FIG. 314.—Cell layers of the human striate cortex from the lower lip of the calcarine fissure, stained with the Nissl–toluidine blue method. Camera lucida drawing magnified 120×. *Stratification: 1*, plexiform layer; *2*, outer granular layer; *3*, pyramidal cell layer; *4a*, *4b*, *4c*, outer, middle, and inner lamina of the inner nuclear layer; *4ca*, *4cb*, outer and inner zone of *4c*; *5*, ganglion cell layer; *6*, multiform cell layer. (*Cf.* Figs. 312, 313, 316.)

in the Monkey than in Man. Scattered among these varieties are nerve cells of a diminutive size which perhaps belong to the true "granules."

8. INNER OR DEEP LAMINA OF THE INNER GRANULAR LAYER (*4-c*).—The sixth layer, identical with the "deep internal granular lamina" of Brodmann and of Economo, is the richest cell layer in the infra-Gennarian half, comprising approximately from one-fifth to one-sixth the total thickness of the striate cortex.

The bulk of its cells are typical "granules" of small size and of spherical or irregular shape, with scanty cytoplasm and chromophile substance. Because of this, the sixth layer presents a rather homogeneous and somewhat paler appearance than the remainder of the striate cortex. In addition to the granules, there is a considerable number of cells of globular, ovoidal, or irregular shape, approaching in size the medium-sized elements of the fifth layer (*4-b*), containing distinct chromophile granules. Cells somewhat resembling small pyramids, with an apical dendrite pointing toward the surface, are few. A columnar arrangement of the cells is indicated. The greatest condensation of this layer is in a deep zone adjoining the ganglion layer, zone *4-cb*. Here also the distribution of cells is most homogeneous, the larger and somewhat less dense cells being confined to the zone closer to the fifth layer, zone *4-ca* (*see* Fig. 314).

9. GANGLION CELL LAYER (*5*).—The seventh layer, identical with the "ganglion lamina" of Brodmann or "ganglion layer" of Economo, appears as a narrow break between the sixth (*4-c*) and the eighth (*6*) layers. Cells of large and medium size, found singly and in small clusters, are conspicuous in it. In size, shape, and other details they are practically a counterpart of the large "solitary cells" of Meynert in the fifth layer (*4-b*). Because of their location, they may be called "inner solitary or giant cells" of the striate cortex (*see* par. 7, this section).

Some of the small nerve cells scantily filling

this layer are irregularly multipolar in shape, while not a few resemble small pyramids with an ascending apical dendrite. In the Monkey the majority of the large multipolar and pyramidal nerve cells are found not in this but in the eighth layer (layer *6*). Because of this, the ganglion layer here appears more empty of cells and with more precise boundaries than in Man.

10. MULTIFORM CELL LAYER (*6*). The eighth, or innermost, layer of the striate cortex, adjoining the subcortical white matter, identical with the "multiform lamina" of Brodmann or the "layer of fusiform or spindle-shaped cells" of Economo, is a narrow zone filled with cells small in size and irregular in shape. Their visible dendrites are relatively long, some resembling the ascending apical dendrites, others spreading in various directions. Not a few cells are triangular, ovoidal, elliptical, or oblong fusiform, their narrow, horizontally or obliquely placed bodies extending at both ends into long, thin dendrites. In the Monkey this layer is distinguished by the presence of numerous large and medium-sized nerve cells resembling Meynert's "solitary cells." Some of the largest ganglions, which in Man are confined to the seventh layer (*5*), are found in the Monkey in the eighth (*6*).

SEC. 6. FIBER SYSTEMS OF THE STRIATE AREA

1. GENERAL REMARKS ON THE MYELOARCHITECTURE OF THE PRIMATE STRIATE AREA.—The striate area contains numerous axis cylinders enveloped in myelin sheaths of various thicknesses, easily made visible by the appropriate staining technique, e.g., by Weigert's, Kultschitzky's, and other similar methods.

The arrangement or distribution of the myelinated nerve fibers, in this locality as elsewhere in the cerebral cortex, is not uniform, the fibers being assembled in more or less pronounced layers or strata and in bundles. The pattern into which the various fiber layers, bundles, and nettings in the striate cortex are arranged, even though essentially the same as in the remainder of the neocortex or "new cortex," is a peculiar one and characteristic of the striate cortex, not found anywhere else in exactly the same arrangement.

The fiber pattern, like the cell pattern, of the striate area is essentially the same in its entire extent, nowhere exhibiting sufficient differences to warrant further subdivision of this area into secondary fields. The fiber structure of the entire striate area, accordingly, is a uniformly organized field with slight local changes in detail which are accomplished only gradually. In contrast with its uniform fibrous structure, its boundary toward the surrounding parastriate area is quite sharp (Fig. 315). The striking peculiarities of its fibrous structure, in contrast with other areas of the occipital lobe and of the rest of the brain, define the striate area as a special territory of the cortex, with a function of its own.

2. FIBER SYSTEMS OF THE STRIATE CORTEX.—In a preparation cut vertical to the brain surface, the bulk of the myelinated fibers appears confined approximately to the inner or lower half of the striate cortex (Fig. 316, right figure). This territory comprises the conspicuous stripe of Gennari or Vicq-d'Azyr (*G*), whose upper limit is slightly above the level separating the outer from the inner half of the cortex.

In the inner or lower half of the striate cortex, corresponding with the cell layers *4-b* to *6*, most of the well-stained fibers are arranged in vertical bundles, grossly parallel to one another, extending from the subcortical fibrous sub-

stance (*Al*) to the stripe of Gennari, above which a few thin bundles may be seen for a short distance.

Other systems of fibers in the infra-Gennarian half are arranged obliquely, some assuming a horizontal course, cutting the vertical bundles at approximately right angles. When examined at high magnification, the vertical bundles appear to be made up mostly of fine and quite fine fibers, a few only are of medium thickness, with the thicker fibers more frequently close to the subcortical fiber substance. Of the system of oblique and horizontal fibers, some are of medium thickness or even quite thin, while a considerable number of them are quite coarse, the coarsest fibers attaining a caliber ten or more times greater than that of the thin fibers.

In addition to these coarse fibers, there are many thin and very thin ones, crisscrossing in various directions and forming a fine fuzz or meshwork between the vertical bundles. The character of the fibrous plexus changes somewhat, however, from level to level of the infra-Gennarian region. Most dense and containing the most coarse fibers is the plexus closest to the subcortical fibrous substance, corresponding to layers *5* and *6*. Less dense and made up of less coarse fibers is the plexus in layer *4-c*. In the stripe of Gennari or Vicq-d'Azyr, principally corresponding to *4-b* and partly also to *4-c* of the cell layers, there are only a few somewhat coarser fibers, but the fuzz of thin and very thin myelinated fibers is particularly dense. Fine fibers pursue an irregular course here, winding

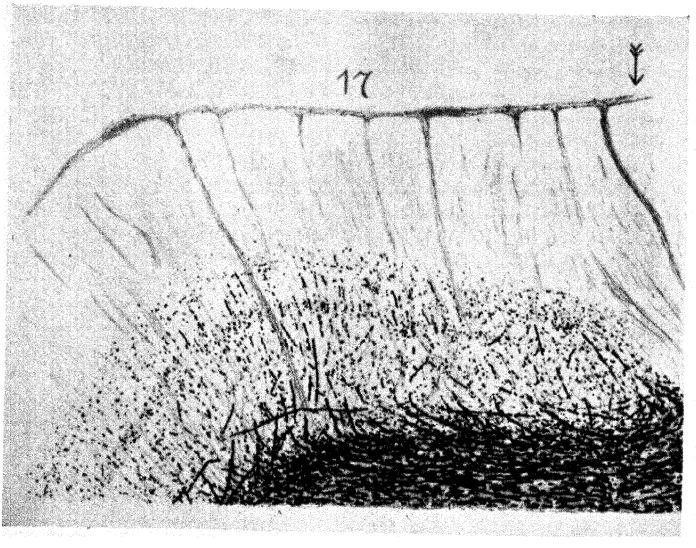

FIG. 315.—Upper lip of the calcarine fissure of Fig. 238 reproduced at higher magnification (about 45×) and turned upside down, to show the termination of the afferent visual fibers or of the visual radiation in the striate area of the Monkey brain. The striate area of G. Elliot Smith, identical with Brodmann's field *17*, contains a characteristic structure which stops abruptly at the point indicated by an arrow. The uppermost and widest of the several layers, placed approximately in the middle of the cortex, corresponds to the stripe of Gennari or Vicq-d'Azyr. The degenerated afferent visual fibers, in this case experimentally interrupted at a distant point in the radiation, are seen as black lines and specks streaming from the underlying subcortical fiber substance into the cortex as far as Gennari's layer. In the ventral layers these fibers observe a slanting course, as found by S. Ramón y Cajal in the human cortex (fibers marked *a* in Figs. 327 and 328). In their greater thickness and oblique course, the fibers of the visual radiation contrast with other fiber categories which remained normal in this experiment. Note also rapid decrease of the layers of the striate cortex before their cessation at the boundary line of that cortex. From S. Polyak, *The Main Afferent Fiber Systems*, etc., Berkeley, 1932.

and twisting in all directions. A horizontal direction prevails, however, although the individual fibers can be followed for but a short distance. The same is also true of the thick infra-Gennarian fibers which can be followed as far as Gennari's stripe.

In the supra-Gennarian half of the striate cortex, abutting on the surface of the cortex, the arrangement of the myelinated fibers is much simpler. Here the vertical bundles are mostly absent except in layer *4-a*, where their broken-off tips may be followed for a short distance into layer *3*. The meshwork of the fine, irregularly arranged fibers also becomes thinner here. In the second cell layer the fibers again increase in number (Kaes & Bechterew's plexus), until, close under the pia, a somewhat denser layer of mostly horizontal fibers of medium and thin

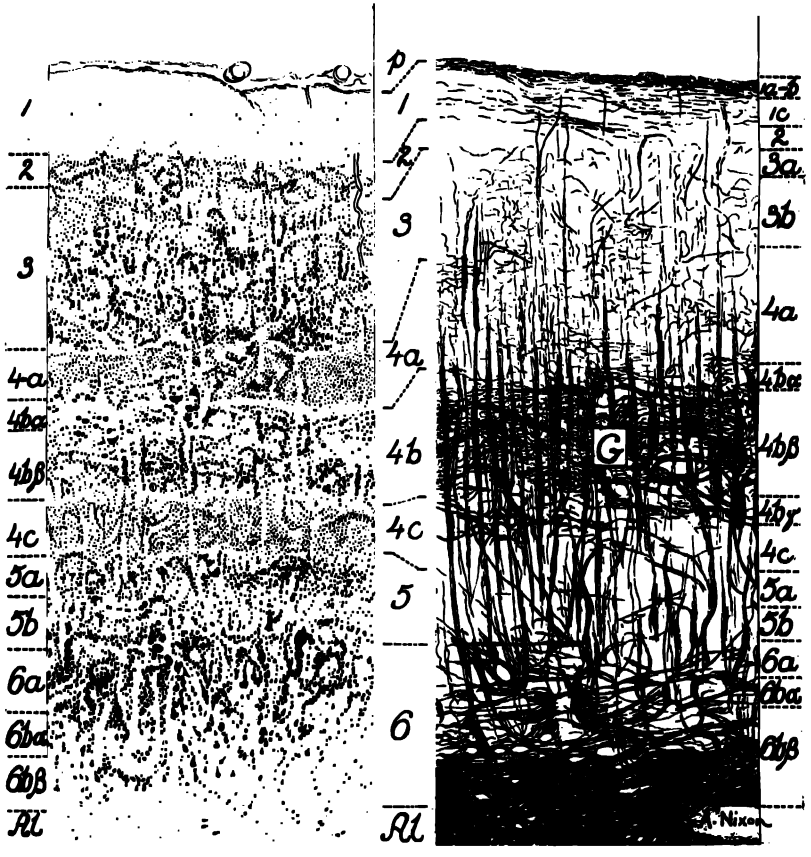

FIG. 316.—Arrangement of the nerve cells and fibers in layers and sublayers parallel to the surface in a vertical section through the human striate area or visual cortical center. SEC. 7. MINUTE STRUCTURE OF THE STRIATE AREA AS REVEALED BY HISTOANALYTIC STAINING

1. Introductory remarks.—The methods of staining the microscopic sections of the striate area, as is also true of other parts of the nervous system, are many, from the most simple, employed routinely, to special procedures. The first are used in daily laboratory practice to show the entire structure; the others, to reveal special constituents of the tissue. Of the first, the most used are the several variations of the hematoxylin and eosin or phloxin method, which stains all tissue constituents fairly equally.

Of the special procedures, the most useful are the Nissl staining of the nerve cells and that of Weigert, which stains the myelinated nerve fibers. Both of these, in comparison with the hematoxylin and eosin stain, show more distinctly the particular tissue components, for example, the varieties, number, and arrangement of the nerve cells or fibers in a particular locality (Figs. 313, 316).

Useful as the methods of Nissl and Weigert are, they bring out only the cruder parts or the "skeleton" of the tissue, while the finer details, such as the relationships of cells and fibers to one another and, in particular, the synapses, remain mostly undisclosed. The methods capable of showing such relationships, especially the synaptical contacts of the terminal twigs of the nerve fibers with the bodies of the nerve cells, are the Golgi method and that of Ehrlich, or to some extent the various modifications of the silver staining by Bielschowsky, S. Cajal, Davenport, and Bodian.

Both the Golgi and the Ehrlich methods, however, have their limitations, in that they put a considerable demand upon the skill, experience, and patience of the investigator. Owing to this, few parts of the nervous system have been thoroughly investigated by these methods—the cortex of the brain, the carrier of the higher or intellectual functions, still remaining almost entirely unexplored.

The first impression one receives while examining a Golgi-stained preparation of the striate cortex of a human or simian specimen is of unbelievable complexity. The nerve cells, with their countless expansions crossing in all directions, intermingling and overlapping in the most varied ways, seem to produce real or apparent interrelationships beyond the power of human intellect and patience to analyze in a single lifetime. It may, indeed, be doubted whether even the well-planned diligence of a team of trained investigators could uncover more than a portion of the synaptical relationships present in the cortex of the human brain.

It is in this light that the following description of the constituent elements of the striate cortex, partly condensed from the work of the preceding investigators, is to be accepted and understood. A vast task remains still to be accomplished by those future investigators interested in penetrating more deeply into the organization of the brain.

In the following, first, the work of Santiago Ramón y Cajal on the minute structure of the human striate area is briefly summarized. In this, for the sake of uniform presentation, the naming of the layers and sublayers was rearranged according to the basic six-layer type introduced by Brodmann and adopted in this book. In addition, O'Leary's paper on the striate area of the Cat, studied by the Golgi method, was considered. To this, finally, we have added our own observations; these are based entirely upon primate material, human and from the Rhesus Monkey, of various ages, including full grown. In this way some general idea may be formed about the types of neurons, their arrangement, and something of their synaptic concatenations. The synaptical relationships and their functional interpretations, in this and in other parts of the cortex, remain a problem for the future.

2. Santiago Ramón y Cajal's investigation of the striate cortex.—In the following is given a brief summary of the studies of the striate cortex made six decades ago by S. Ramón y Cajal (Fig. 317), almost the only investigator paying attention to the types and synaptical relationships of neurons of this and other parts of the cerebral cortex. His work, isolated as it is, shows not only the brilliance of mind and character of this great investigator but also the formidable difficulties encountered in this work, and an astonishing lack of enterprising spirit and reluctance in the subsequent generations to follow his splendid example. (*See* Polyak, *J. Comp. Neurol.*, v. 98, 1953.)

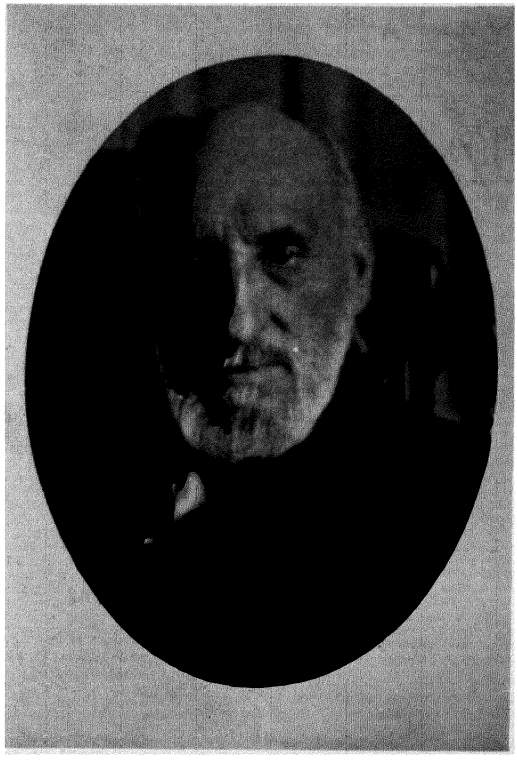

Fig. 317.—Santiago Ramón y Cajal (1852–1934) at the age of seventy-three. Snapshot by the author made during a visit to the Instituto Cajal in Madrid in 1925. (*See also* Figs. 52, 131, and J. Comp. Neurol., v. 98, 1953.)

Plexiform layer.—This layer, thinner in the striate area than in other cortical regions, is made up largely of the expansions of the nerve cells residing in the subjacent layers: the small pyramidal cells of the second layer, the medium-sized pyramids of the third layer, and especially also the apical dendrites of the larger pyramids whose bodies are placed in the infra-Gennarian half of the cortex. There are, in addition, a few star-shaped cells that possess a short axon fiber here, and some whose axon fiber spreads horizontally, parallel to the cortical surface (*E*, *F*, *G*, in Fig. 318).

Outer granular layer.—This layer contains true pyramidal cells of small size and other numerous cells with short axon fibers, one variety with a double dendritic ramification, the other

whose ascending axon fiber divides in a more or less horizontal fashion.

Pyramidal cell layer.—The pyramid-shaped cells which form the third layer in the striate area are smaller than those in the motor cortex. No mention is made by Cajal, however, of the "granules," corresponding to Brodmann's sublayer *4-a*, which apparently have been included by him in the pyramidal layer, even though this is not expressly stated. Possibly the inner granules are the unusually formed neurons found by Cajal either in this layer or in sublayer *4-a:* their long dendrites are oriented vertically, and so are their delicate axonal arborizations, which pass in the form of long, narrow streamers or ribbons, interconnecting narrow vertical segments of several superimposed layers, possibly sublayers of the inner granular layer (*E*, *F*, in Fig. 320).

Inner granular layer.—This layer, as presented by S. Ramón y Cajal, is especially characteristic of the visual cortex. One of its features is the large star-shaped cells whose expansions are oriented sidewise, instead of toward the cortical surface, as in the pyramids. The other characteristic feature is a rich fiber plexus, corresponding to the stripe of Gennari and Vicq-d'Azyr, by which the cells are largely crowded out from this level. (*See* Figs. 327, 328.)

The large star-shaped cells, the outer solitary cells of Meynert, have an ovoidal or triangular body whence originate thick dendrites spreading up and down or horizontally (layer *A* in Fig. 319). They divide in the same layer and spread for long distances. The horizontal dendrites are most numerous and quite long. None of the dendrites spreads as far as the first or plexiform layer, thus easily distinguishing this neuron variety from the true pyramids.

The thick axon fiber originates from the inferior face of the cell body or from a dendrite, passing almost vertically through all subjacent layers down to the subcortical fiber substance. Close to its origin, the principal axon fiber gives

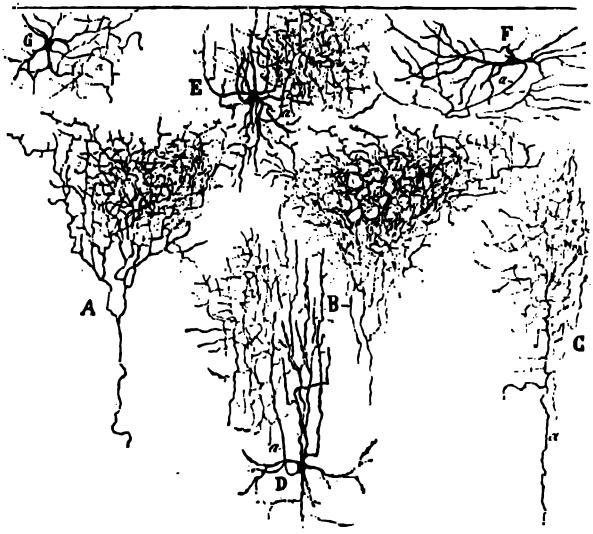

FIG. 318.—Types of axonal ramifications or teledendrons in the first and second layers of the striate cortex in a fifteen-day-old child. *A* and *B*, a dense plexus in the layer of small pyramidal cells; *C*, same, though less dense; *D*, small neuron with an ascending axon fiber, *a*, producing a similar terminal arborization; *E*, spider-shaped asteriform or star-shaped cell with a dense axonal arborization in the first or plexiform layer; *F*, *G*, other small neurons with short and little-ramified axonal expansions. From S. Ramón y Cajal, *Studien über die Hirnrinde des Menschen*, J. A. Barth, Leipsig, 1900–1906.

off recurrent or horizontally running collateral branches spreading in the Gennarian fiber layer of the fourth layer.

Another constituent of the fourth layer is the pyramidal cells, that evidently became displaced from the third layer. Still another element is the star-shaped cells, which are provided with a short axonal fiber ascending into the suprajacent layers (*A*, *B*, *C*, *D*, in Figs. 320 and 322). These cells are irregularly scattered in the fourth layer. They possess an ovoidal or triangular body, whence arise short dendrites, covered with "spines," spreading not far from the body. The axon fiber divides close to the body into numerous branches directed horizontally or downward, coming into contact with the bodies of the large star-shaped cells. Another variety possesses an axon fiber that gives off collaterals in the fourth layer and divides in the second layer into terminal arborization. Cajal also found similar neurons in the Cat (Fig. 323).

Of another type in the inner granular layer, according to Ramón y Cajal, are small star-shaped neurons, now called inner granules (Fig. 321). In his description, however, he mentions only those granules which, in the aggregate, form zone *4-c* of Brodmann, since he did not notice similar granules in zone *4-a* (*cf.* following subsection).

The first granular variety, fairly numerous, resembles the small cells scattered among the large outer solitary cells of Meynert in zone *4-b*. The others are small star-shaped cells, or true "grain," which give zone *4-c* its characteristic appearance. The body is spherical, fusiform, or

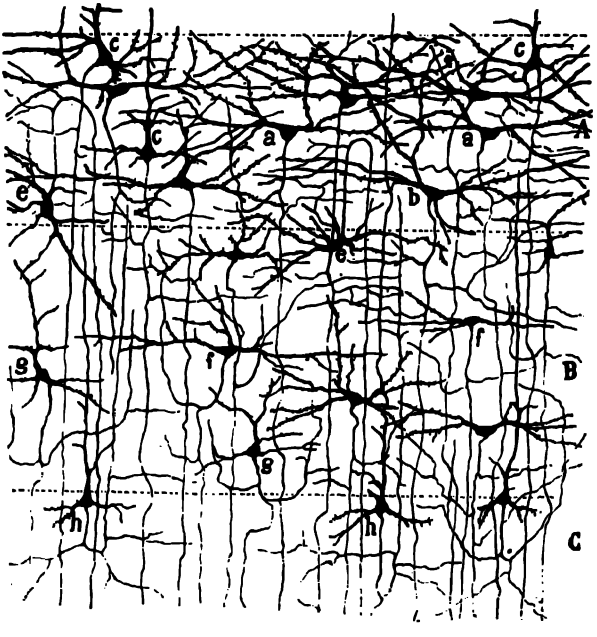

FIG. 319.—Asteriform or star-shaped cells from the calcarine fissure of a twenty-day-old child. *A*, layer of large star-shaped cells, corresponding to Brodmann's sublayer *4-b*; *B*, layer of small star-shaped cells or Brodmann's sublayer *4-c*; *C*, layer of small pyramidal cells with recurrent axons, probably Brodmann's layer *5* (in part); *a*, semilunar cells; *b*, horizontal spindle-shaped cells; *c*, neuron with a thin descending axon fiber; *e*, cells with recurrent axons; *f*, horizontally oriented spindle-shaped cells; *g*, triangular cells with thick recurrent collaterals; *h*, pyramidal cells with recurrent axons situated at the boundary of the sublayer *4-c*. From S. Ramón y Cajal 1900–1906.

star-shaped, usually not more than 10 or 12 microns in diameter. Each of these midget neurons possesses four, five, or more thin dendrites radiating in all directions, dividing repeatedly, and never spreading beyond the zone where they reside. Each granular neuron also gives rise to a very delicate axon fiber, which, by preference, spreads in an ascending direction. Close to its origin the axon fiber pursues a meandering course, and at some distance it splits up into a loose arborization, which, with other such arborizations, forms a dense plexus enveloping the bodies of the large and medium-sized solitary cells of Meynert in zone *4-b* (*d*, in same figure).

The function of the inner granular cells, in Ramón y Cajal's view, would be to intensify the impulses transmitted by way of afferent visual fibers from the laminated lateral geniculate nucleus, and hence from the retina, to the large

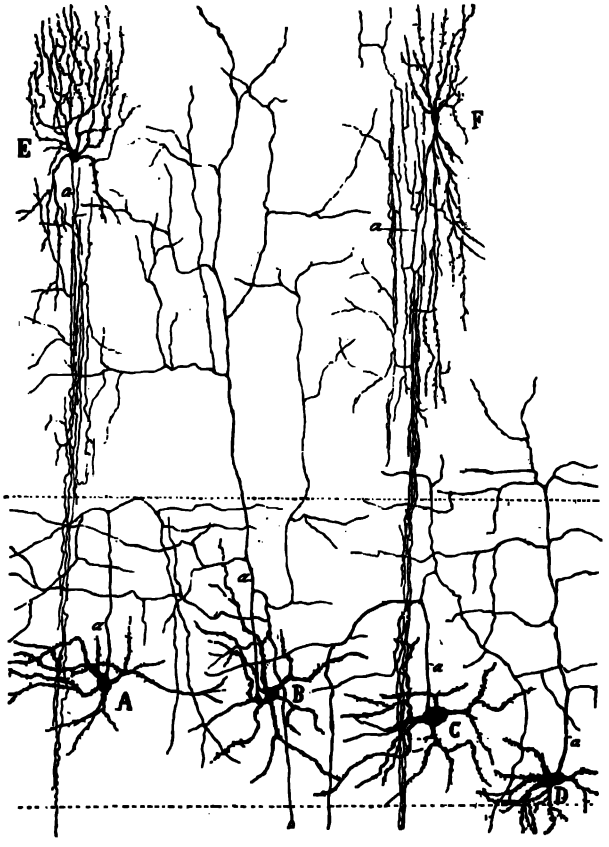

FIG. 320.—Types of neurons from the fourth layer of the visual cortex of a fifteen-day-old child. *A*, cell whose axon spreads in the upper zone of the fourth layer; *B*, cell with an axonal spread in the third and fourth layers; *C*, cell with an axonal spread in the third layer and in the zones *4-b* and *4-c* of the fourth layer; *D*, cell whose ascending axon spreads in the fourth layer and in the adjoining zone of the third; *E*, *F*, small neurons of the layer of the medium pyramids (or possibly of the adjoining sublayer *4-a*?), possessing a double dendritic tuft and a long, narrow axonal expansion, *a*, oriented vertically and interconnecting several superimposed layers (possibly sublayers *4-a*, *4-b*, and *4-c* of the fourth layer). From S. Ramón y Cajal 1900–1906.

outer solitary cells of Meynert, and in this way to the striate cortex. One way would be by a direct termination of the afferent fibers at the solitary cells; the other by an interposition of the granular cells and an interruption at the synapses of their short axons at the same solitary cells.

S. Ramón y Cajal further described other minute neurons in the fourth layer resembling neuroglia. These are provided with numerous and third layers, instead of passing downward into the subcortical white substance; some of the axonal collaterals occasionally descend into the fifth and sixth layers (*h*, in Fig. 319). The second variety is the large star-shaped neurons, with numerous radiating dendrites and an axon fiber splitting up in the third and fourth layers (*f* in same figure; *a* in Fig. 324). The third is small and large pyramidal cells, few in number, with an apical dendrite ascending as far as the

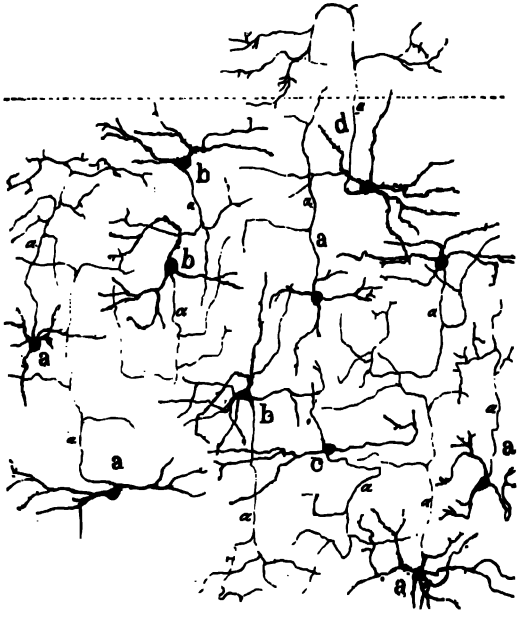

FIG. 321.—"Grains" or granular cells from the sublayer *4-c* of the inner granular layer of Brodmann, with short, variously oriented axonal expansions, as they appear in Golgi-stained preparations of a one-month-old child. *a*, type with a thin ascending axon; *b*, *c*, cells with a descending axon; *d*, a somewhat larger cell with an axonal spread apparently in the sublayer *4-b*; small italic letter *a* indicating axonal expansions. From S. Ramón y Cajal 1900–1906.

short, fine, varicose dendritic expansions and an axonal fiber that terminates with an arborization of very fine and dense branches around the small star-shaped neurons (*E* in Fig. 322).

Finally, there are in the inner granular layer, according to Ramón y Cajal, the following types of neurons present in small numbers (Fig. 325). The first variety (*c*, *e*) are pyramidal or ovoidal cells, with a fine axon fiber arching upward and probably terminating in the second first or plexiform layer and with an axon fiber descending to the subcortical fiber mass (*b* in Fig. 325).

According to our own estimate, the bodies of the last two varieties reside in the upper tier of the fifth layer of the striate cortex as classified in this book, just above the level of the internal solitary or ganglionic cells.

Ganglion cell layer.—This layer is characterized by the presence of giant pyramidal cells

which may be called "inner solitary cells" of Meynert (*see* sec. 5 [7, 9], this chapter). These cells are arranged in a single tier, at some distance from one another (*a*, in layer *B*, in Figs. 325, 326). In Golgi preparations one sees the base of their bodies expand into thick and extremely long dendrites, which spread strictly horizontally to the cortical surface, their length sometimes exceeding that of the apical dendrite as far as the superficial plexiform layer and an axon fiber, which, after descending for a short distance, turns upward, where it splits in the plexus of the fourth layer (Gennari's layer), with one collateral descending to the subcortical white substance (*g*, in Fig. 326).

Other medium pyramids send an apical dendrite as far as the superficial plexiform layer and an axon fiber, which, after descending for a

shaped cells with a short axon fiber ramifying in the same layer.

Multiform cell layer.—The cells of fusiform shape have two dendritic expansions, an ascending and a descending one, and an axon fiber passing down into the subjacent white substance. The others are medium-sized pyramids with a descending axon, and perhaps some other neuron varieties.

ate area and which terminate in that area. These fibers are distinguished by considerable thickness and a slanting course as they enter the striate cortex, where they branch among its cells.

In preparations stained for myelin (Weigert method) one sees in the sublayer *4-c* and in a part of sublayer *4-b* a dense fiber plexus of mostly horizontally arranged fibers. This is

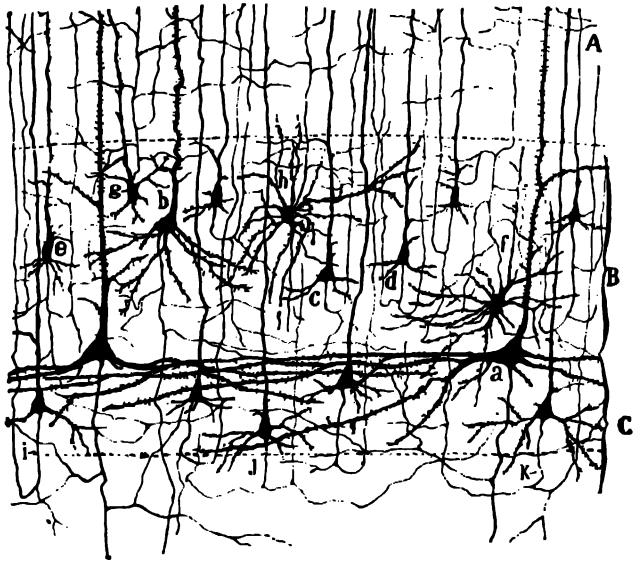

FIG. 325.—Neurons from the fifth and sixth layers of the visual cortex of a fifteen-day-old child. *A*, sublayer *4-c*; *B* and *C*, parts of the fifth and sixth layers; *a*, giant pyramidal cells, the inner solitary cells of Meynert as here classified; *b*, medium-sized pyramidal cell provided with a long descending axon fiber; *c*, small pyramidal cell with a recurrent ascending axon fiber; *d*, pyramidal cell with an axon fiber with two loops; *e*, pyramidal cell with an axonal expansion dividing into several ascending branches; *f*, *g*, *h*, star-shaped cells with axon fibers spreading in *4-c* and in the fifth layer; *i*, *j*, *k*, pyramidal cells with recurrent axon fibers ramifying in the fifth and sixth layers. Fiber systems of the striate area, according to S. Ramón y Cajal.—S. Ramón y Cajal recognized two principal constituent categories of fibers of the striate area. The first is made up of the fibers which, in a general way, may be termed "centrifugal"; these originate from the cells residing in that area, particularly from the large star-shaped and pyramidal neurons, and terminate outside the striate area. The other category, which may be termed "centripetal" fibers, is of those whose origin is outside the striate area. These fibers are distinguished by considerable thickness and a slanting course as they enter the striate cortex, where they branch among its cells.

In preparations stained for myelin (Weigert method) one sees in the sublayer *4-c* and in a part of sublayer *4-b* a dense fiber plexus of mostly horizontally arranged fibers. This is Gennari's or Vicq-d'Azyr's stripe, a whitish line visible without the aid of a magnifier on a surface cut through the striate cortex (Figs. 226–29). In Golgi-stained preparations one may see these fibers as far as their terminal arborizations (Figs. 327, 328).

These fibers, because of their unusual thickness, are quite conspicuous as they pass through the subcortical substance into the cortex. Their course as they pass through the ventral layers as far as the fifth layer (inner solitary

or ganglionic cells) is usually oblique. Here they assume a horizontal course, divide into long, horizontally meandering branches, and remain confined to the same horizontal level. Some of these afferent fibers go as far as the upper limit of sublayer *4-b*, where they also split up and

ferent optic fibers climbs higher than the upper limit of sublayer *4-b:* hence the small and medium pyramids of the second and third layers are not directly related to these fibers. This, however, is not quite certain, since fine collaterals occasionally ascend from these fibers

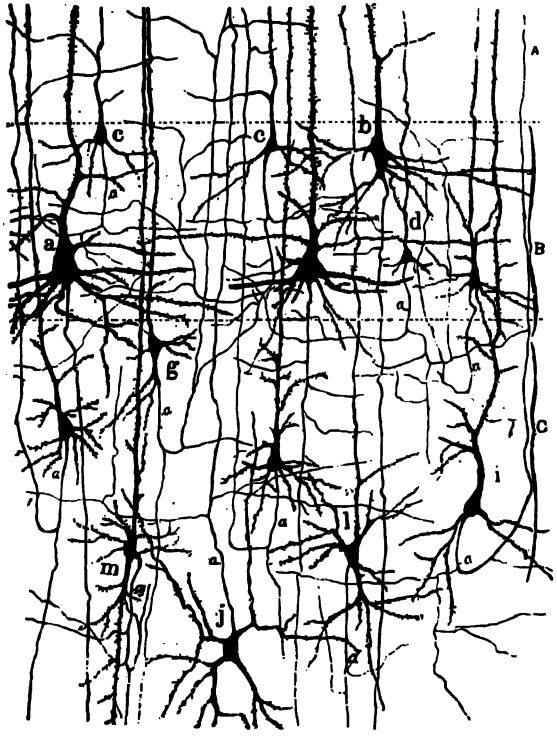

FIG. 326.—Types of neurons of the deep layers of the visual cortex of a twenty-five-day-old Cat stained with the Golgi method. *A*, lower zone of the layer of star-shaped cells (*4-c*); *B*, layer of giant pyramids (*5*); *C*, layer of medium pyramids with a recurrent axon fiber (also part of *5*); *a*, giant pyramids; *b*, medium-sized pyramids with a descending axon fiber; *c*, *d*, pyramids with descending and bifurcating axon fibers ramifying around giant pyramids; *g*, triangular cell with a recurrent axon fiber and descending collaterals; *i*, pyramid-shaped cell with a recurrent ascending axon fiber; *j*, *l*, a star-shaped and a triangular cell of the fusiform or spindle-shaped layer *6*, one provided with an ascending axon fiber, the other with a descending axon fiber; *m*, spindle-shaped cell provided with a descending axon fiber. From S. Ramón y Cajal 1900–1906.

become horizontal. During their passage they usually give off a few collateral branches for the neurons of the fifth and sixth layers.

These coarse afferent fibers give off the thickest branches only after they have entered sublayer *4-b*, where they divide. None of these afand penetrate into the marginal zone of sublayer *4-a* (Fig. 327, *D*).

The afferent fibers produce a thick plexus in the striate cortex of the human fetus in sublayer *4-c* and a similar but much thinner tangle with fewer secondary branches in sublayer *4-b*.

A good representation of this plexus is given in Figure 328. Here layer *B*, corresponding to sublayer *4-c* of the inner granular layer in Figure 314, shows a dense tangle, with nests left vacant in which are lodged the granules and the star-shaped cells with an ascending axon fiber, while layer *A* with looser plexus, corresponding to caliber corresponding rather well with the thick fibers originating from the laminated lateral geniculate nucleus. In this respect they resemble the thick afferent fibers of the sensory-motor and olfactory regions of the cortex, while such fibers are absent in Flechsig's association areas of the brain. Also, clinical and anatomical evi-

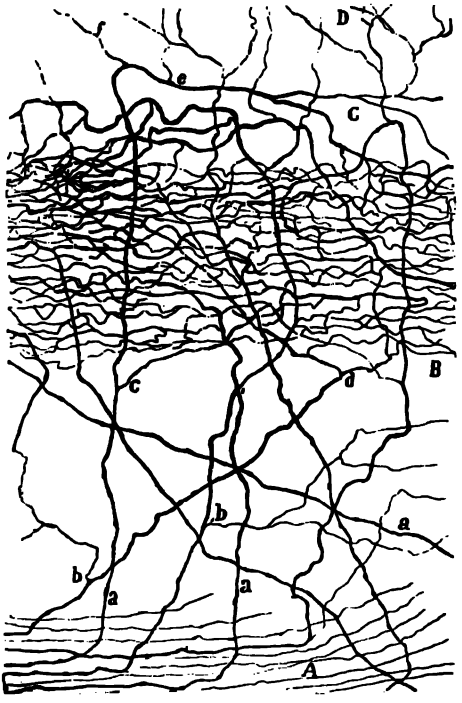

FIG. 327.—Entrance of fibers of the visual radiation into the visual cortex or striate area in a three-day-old child, Golgi stain. Thick axis cylinders arising from the subcortical fibrous substance (*A*) divide and in this way form a plexus-like formation, the stripe of Gennari or Vicq-d'Azyr. *B*, layer of small star-shaped cells or sublayer *4-c* of Brodmann; *C*, afferent fibers turning horizontally in the fourth layer, probably in *4-b*; *D*, layer of medium pyramids, probably identical with sublayer *4-a* or *3* in Nissl-stained preparations; *a*, principal afferent visual fibers; *b*, collateral branches destined for the deeper layers of the striate cortex; *c*, *d*, collateral branches ascending into Gennari's plexus. From S. Ramón y Cajal 1900–1906.

sublayer *4-b*, envelops large star-shaped cells, the outer solitary cells of Meynert.

S. Ramón y Cajal gives the following reasons to support his view of the formation of Gennari's stripe by the terminations of afferent optic nerve fibers arriving by way of the visual radiations. First, these fibers are much thicker than the association and callosal fibers, their dence indicates the termination of Gratiolet's visual radiation in the calcarine cortex.

The contention of S. Ramón y Cajal was subsequently fully substantiated by my experiments on cats and monkeys. These experiments showed the presence of such thick fibers with a slanting course in the infra-Gennarian half of the striate cortex and terminating in Gennari's

or Vicq-d'Azyr's stripe, hence proving that they are those of the visual radiation originating in the laminated lateral geniculate nucleus. (*Cf.* thick, slanting fibers *a* in Fig. 328, with similar fibers in Fig. 315; *see also* Polyak, Berkeley, 1932, and *J. Comp. Neurol.*, v. 44, p. 197, 1927; *see* following subsection and figures.)

There are, however, other categories of fibers, according to S. Ramón y Cajal, in addition to infra-Gennarian layers, especially from the pyramids that possess an arching axon fiber (*b*, in Fig. 328), also the collaterals of axon fibers of the large- and medium-sized star-shaped cells of sublayers *4-b* and *4-c* and the terminal arborizations of the granular and other small cells provided with short axons.

These minute cells, the "grain" of the inner granular layer, representing the bulk of the

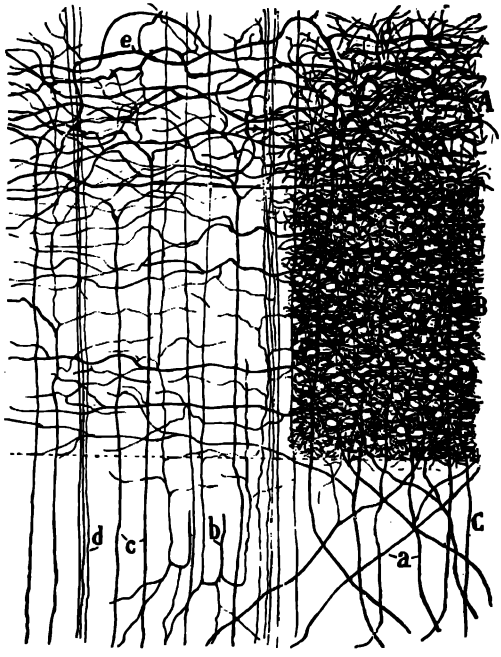

FIG. 328.—Fiber plexus in the stripe of Gennari or Vicq-d'Azyr as found in the striate area or visual cortex of a twenty-day-old child, Golgi stain. *A*, *B*, sublayers *4-b* and *4-c* of the inner granular layer; *C*, fifth layer; *a*, afferent visual fibers; *b*, recurrent axon fiber of a cell of the fifth layer; *c*, ascending axon fibers of pyramidal cells of the sixth layer; *d*, axon bundles of medium and small pyramidal cells (from second and third layers); *e*, loops of afferent visual fibers with collateral branches ascending into sublayer *4-a*. From S. Ramón y Cajal 1900–1906.

those originating in the lateral geniculate nucleus, which contribute to Gennari's stripe. These may possibly be the association fibers originating in the extrastriate parts of the cortex, even though Cajal was not able to identify their cells of origin. Certainly there are fibers originating from the cells residing in the striate cortex itself, for example, from those in the small neurons of sublayers *4-a* and *4-c*, appear to be partly responsible for the myelinated appearance of Gennari's stripe, to which, because of their great numbers and compact arrangement, they contribute a share, in spite of the shortness of their axonal expansions and poor myelinization. In any case, long and well-myelinized fibers are not found in Gennari's

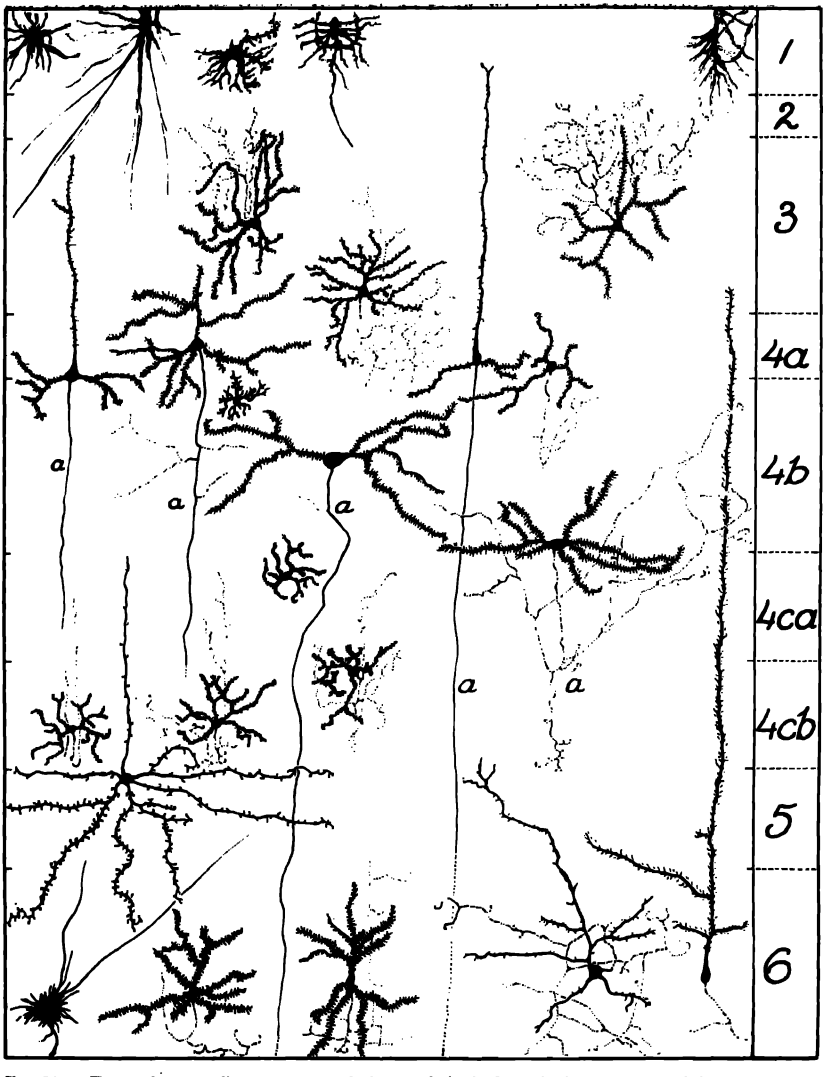

FIG. 329.—Types of nerve cells or neurons and of neuroglial cells from the foveal portion of the striate cortex of an adult Rhesus Macaque stained with silver bichromate or the Golgi method. Note the shape and size of the cell bodies and their location in the layer or sublayer given at the right margin and the character and location of the dendritic and axonal (*a*) expansions, according to which several neuron varieties may be distinguished. *Cf.* similar subsequent figures. stripe, as the absence of such fibers in that stripe in an experiment of Le Gros Clark (1941) and in that described in chapter VII, 7, in this book shows.

The observation that the stripe of Gennari is not entirely missing in the human pathological cases where the visual radiation was destroyed or was absent also tends to corroborate the concept that the terminal arborizations of the afferent visual fibers in that stripe are only one of several contributing factors, albeit they seem the most important. (*See* chap. XII.)

3. COMMENT ON CAJAL'S INVESTIGATION OF THE STRIATE AREA.—In our own attempt to verify and to amplify S. Ramón y Cajal's work, advantage was taken of Leitz's Ultropak oil-immersion objectives, in addition to the less powerful dry optical systems. This advantage is the superior optical resolution which the Ultropak apochromates afford in studying the thick preparations which the Golgi technique requires, compared with the poor resolution which the usual dry objectives give. Covering the slides with cover slips, according to a "dry procedure" described in *The Retina*, was an additional advantage, since this made possible easy use of the oil-immersion systems of the Ultropak design. Following are a few remarks which seem worthy to be added to those of S. Ramón y Cajal recorded under the preceding subsection.

The various types or parts of neurons found in the simian striate area are illustrated in Figures 329–41. Whether or not they represent all types, future study of abundant material of Golgi-stained sections alone may show. Such study may also decide how far the various types described by S. Ramón y Cajal are true neuron varieties constantly found in the primate striate area or to what extent they are merely adaptations of one or another standard type to secondary factors, such as the crowding into available space of a particular layer or sublayer, and so forth.

In examining our illustrations, beginning with the first layer and down to the sixth, no certain nerve cells are found in the first or plexiform layer. This is possibly caused by the scarcity of true neurons in this layer and by the haphazard character of the Golgi method. Contrasting with this are numerous expansions of the several types of neurons spreading in this layer whose body resides in any one of the subjacent layers down to the sixth. These expansions bear the character either of dendrites or of axonal teledendrons. The impression one gains is that this layer is principally or preponderantly made up of such expansions, together with the marginal neuroglia and its fibers, in addition to blood vessels.

The second layer is made up of small, closely packed cells of more or less pyramidal shape, corresponding with those found in the Nissl stain. Unlike the latter, however, the Golgi method shows these cells to vary in their expansions and hence in their functional character. Some of the cells may represent Golgi type *I*, their delicate axon fibers passing down to the subcortical substance, to terminate in other parts of the brain. Such axons, while still close to their body of origin, as a rule emit a few collateral branches which ramify around neighboring cells in the second and possibly the third layers. Some collaterals may traverse considerable distances in the striate cortex before terminating. Exactly where the principal axon fibers terminate remains a problem to be further determined by the various methods, including experiments, e.g., by the study of retrograde cell degeneration after destruction of distant parts of the brain.

Other small neurons of the second layer, also pyramidal in shape, certainly belong to Golgi type *II*. Their delicate axonal expansion spreads not far from the place where the cell body resides. Whether such cells belong to a single variety or represent several varieties, further careful study may determine. The impression one gains is that there may be several such neuron varieties, distinguished by their external features. In one type the body and the dendritic expansions, provided with numerous thorny "spines," resemble the type just described, while their axonal expansion splits into several branches and twigs, spreading in a small area in the first, second, and third layers. In another type found in the second and third layers, characterized by smooth dendrites, almost entirely devoid of any "spines" and oriented rather vertically, the very thin axonal expansions run up and down like streamers arranged in long but narrow

bands, reaching up to the first layer and descending as far as sublayers *4-a* and *4-b*. Remarkable are, finally, the neurons which resemble the granular cells or "grain" which are typical of the fourth layer, especially *4-a* and *4-c*. Their delicate axis cylinder divides into a number of contorted twigs, which, together, form a dense and almost inextricable plexus or tangle, within which the cell body and its dendrites are quasi-suspended, as in a tiny cloud.

The neurons whose bodies reside in the third layer also belong to several types. They, in general, resemble the neurons of the second layer, being, however, larger in body and in their expansions. Some of them, of the shape of small and medium pyramids, possess dendritic expansions abundantly provided with thorny "spines." Their axonal fibers descend in a rather straight course through the subjacent layers down to the subcortical fiber substance. Several collateral branches of the axon are given off to neighboring cells. Other neurons, with their dendritic branches radiating in a more even way and all of about the same length, may be more justly compared with a star. Their axonal expansion, abundantly ramified, spreads in a part of the second, third, and fourth layers.

The neurons of the fourth layer appear more diversified than in the remainder of the striate cortex. They vary much in the shape, size, and distribution of their bodies and in the varieties of their dendritic and axonal expansions. The most conspicuous are the large solitary ganglion cells of Meynert. Their ovoid, horizontally placed body is usually confined to sublayer *4-b*. Their thick dendrites, covered with numerous robust "spines" terminating with spherical nodules, are mostly oriented horizontally or obliquely (Figs. 337, 338). Their axons, few of which we were able to pursue any distance from the body, descend toward the subcortical substance. Whether all these neurons send their axon fibers away from the striate cortex is more than questionable. As shown in Figure 329, the axis cylinder may split up into several branches, which further divide and spread over a considerable area of sublayers *4-b* and *4-c*, terminating around its cells. Still other similar cells, instead of confining their dendrites to a somewhat restricted horizontal zone of sublayer *4-b*, stretch these in an octopus-like fashion in all directions, including sublayers *4-a* and *4-c* (Fig. 331). A further variety of Meynert's solitary ganglion cells possesses a robust apical dendrite which ascends as far as the superficial layer of the cortex, resembling in this way a large motor pyramidal cell (Fig. 330). It may be of considerable physiological interest to compare the dimensions, especially the volume or mass, of the giant solitary cells with those of the diminutive granular cells, as depicted in Figure 337.

The other neuron variety of the fourth layer, conspicuous because of its great numbers, is among the smallest neurons of the entire nervous system. These are the "granular cells" or "grain." These diminutive neurons, confined to sublayers *4-a* and *4-c*, when completely stained with silver nitrate, have a characteristic appearance. Their short dendritic expansions, carrying a moderate number of small thorny "spines," are restricted to a narrow territory around the cell body, where they twist in all directions (Figs. 337, 339). Their delicate axonal expansions, one to each grain, usually descend and soon divide into a few branches, which, after making a turn, spread vertically toward the upper layers. Their axonal side branches, however, are numerous and together form an inextricable feltwork between the cell bodies. Together, these teledendric axonal expansions of the inner granular cells represent a vast mechanism connecting sublayers *4-b* and *4-c* and probably also *4-a*, but especially the granular cells of sublayer *4-c*, with one another. In their aggregation these countless minute grain neurons form a concatenated pad made up of countless short synaptical circuits.

Similar to the typical granular cells, but perhaps a bit larger and with longer dendrites spreading in all directions, provided with only a few spines or none at all, are cells of sublayer *4-ca*. Their delicate axonal expansions spread mostly in the manner of ribbons in a narrow vertical zone, fusing superposed segments of sublayers *4-a*, *4-b*, *4-c*, and *5* into functional units, whose elements are activated simultaneously. Other larger neurons with dendrites radiating in all directions, residing in the transitional zone between *4-b* and *4-c*, interconnect larger segments of these sublayers into functional units. Further investigation is required to identify these neurons with one or another ele-

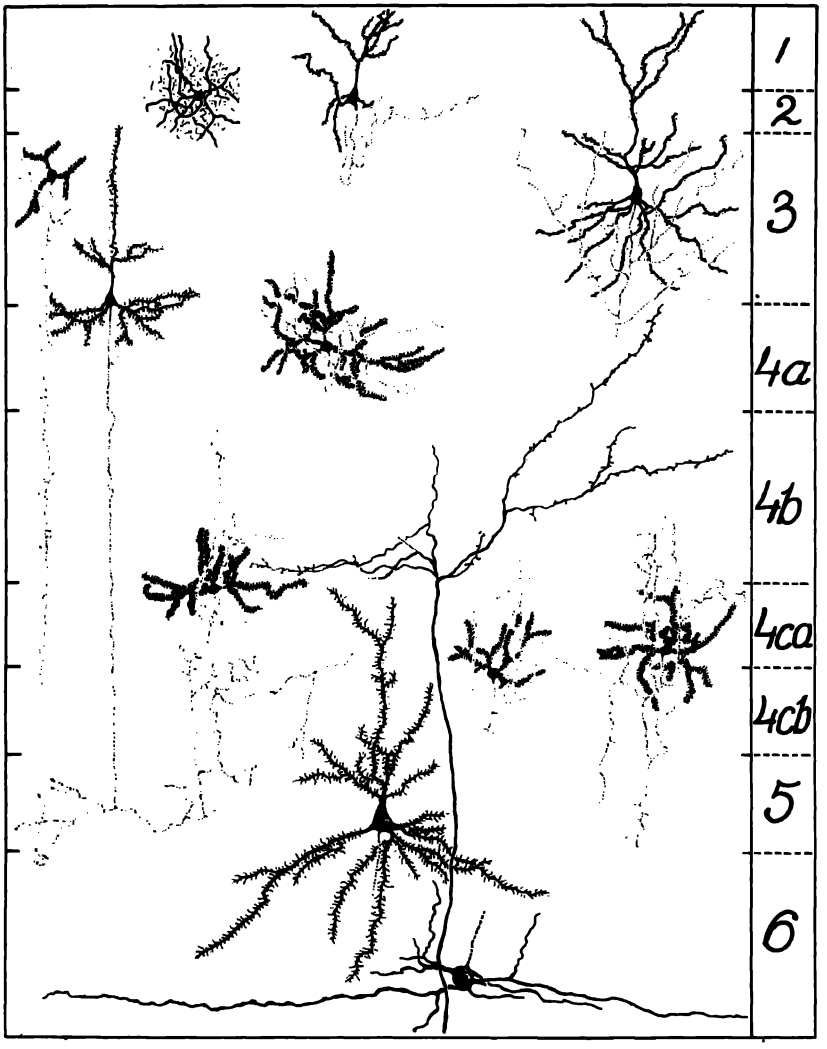

FIG. 333.—Types of nerve cells or neurons from the foveal portion of the striate cortex of an adult Rhesus Macaque stained with silver bichromate or the Golgi method. Layers and sublayers indicated along the right-hand margin. For description *see* text. Approximate magnification 100×.

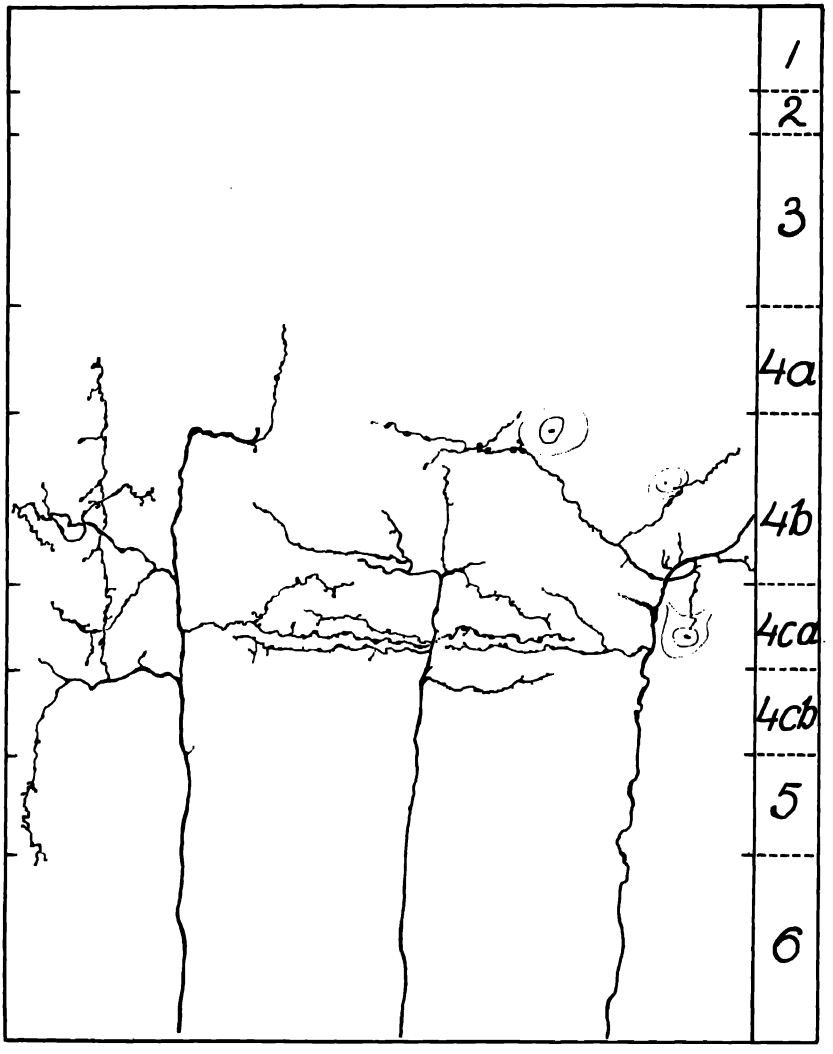

FIG. 334.—Terminal arborizations or teledendrons in the striate cortex of an adult Rhesus Macaque stained with silver bichromate or the Golgi method. Note the course of the visual fibers as they enter the fourth or inner granular layer, the character of the terminal arborizations, their location and spread, and the terminal nodules. Some branches have been omitted in order to make details clearer. Note a few terminal nodules in contact with the surface of the nerve cells given in outline. Freehand drawing at an approximate magnification of 100×.

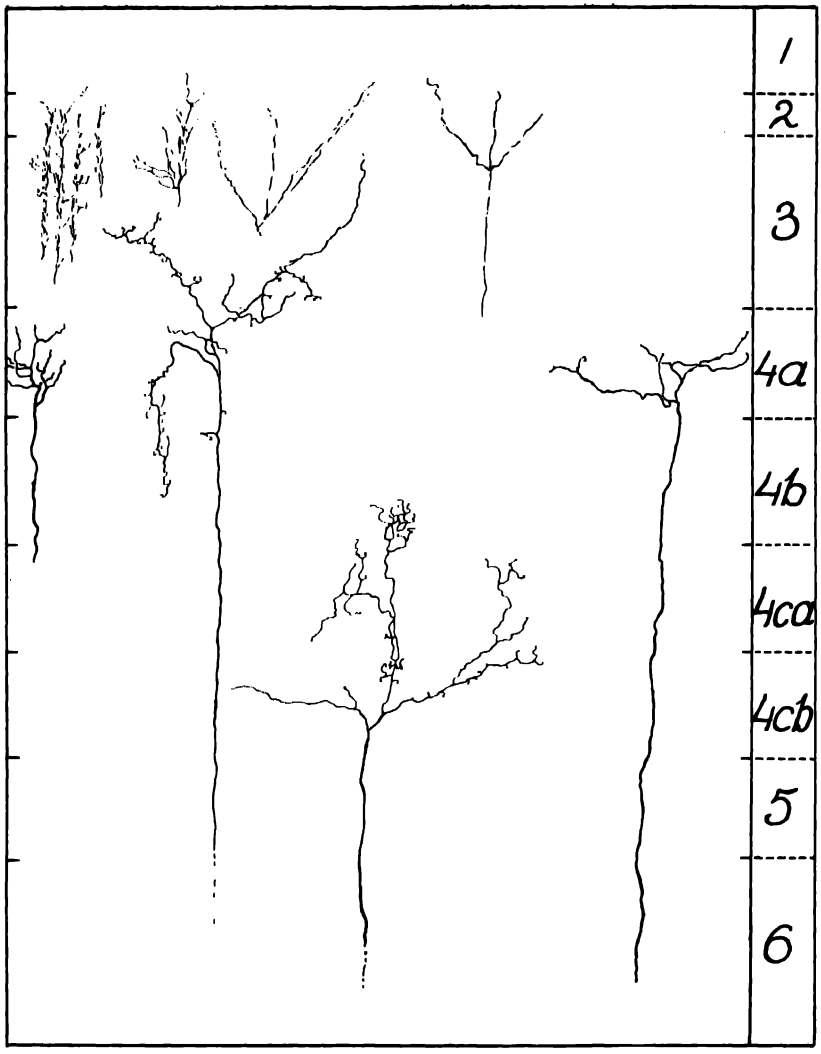

FIG. 335.—Diverse types of the terminal axonal arborizations or teledendrons in the striate cortex of an adult Rhesus Monkey found in preparations stained with silver bichromate or the Golgi method. It is very likely that many more different types will be found when the same cortex is further investigated. Freehand drawing at an approximate magnification of 100×.

ment visible in Nissl-stained preparations or, better yet, in those stained with the Klüver stain (personal communication; *cf. also* Klüver & Barrera 1953, 1954).

The numerous neuron varieties populating ventral layers *5* and *6* of the striate cortex are also conspicuous by their unequal size and distribution. Their particular morphological details and connections are as yet little known. The impression is that many more neurons residing here are oriented laterally, in a horizontal direction, than in the layers above. There are, however, some conspicuous exceptions represented by the small pyramidal cells whose body is located in layer *6* and whose apical dendrite ascends as far as layer *3*. Altogether, the number of the second type of Golgi or association neurons in these two layers may be much larger than heretofore suspected.

Of the afferent fibers entering the striate cortex and terminating here, we may describe only those which, according to their location and spread, may be the axis cylinders of the cells of the laminated lateral geniculate nucleus. Such

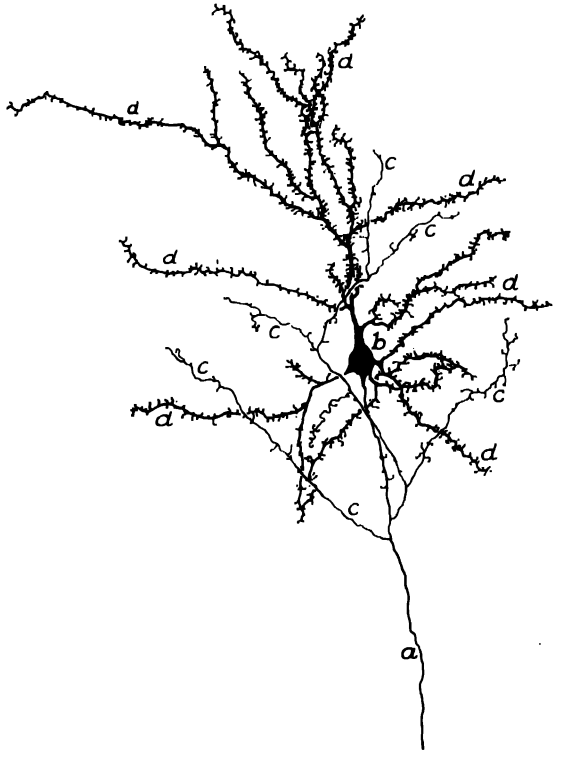

FIG. 336.—Small pyramidal cell of the second layer from the foveal portion of the striate area of an adult Rhesus Macaque stained completely, including all terminal twigs and nodules. Leitz *Ultropak* oil-immersion objective, transillumination, camera lucida drawing, 600× magnification. Rapid Golgi method. Note the pyramid-shaped body (*b*), from which several principal dendritic expansions (*d*) spread in all directions, carrying numerous "spines" or minute terminal thornlike twigs, each terminating with a small spherical nodule; from the lower end of the body a single axonal fiber (*a*) descends to the subcortical fiber mass or "white substance" of the brain; from the axon fiber two or three thin collateral branches (*c*), also carrying a few terminal twigs with spherules, differently shaped than the dendritic "spines," spread within the cortex in the same territory where the dendrites ramify.

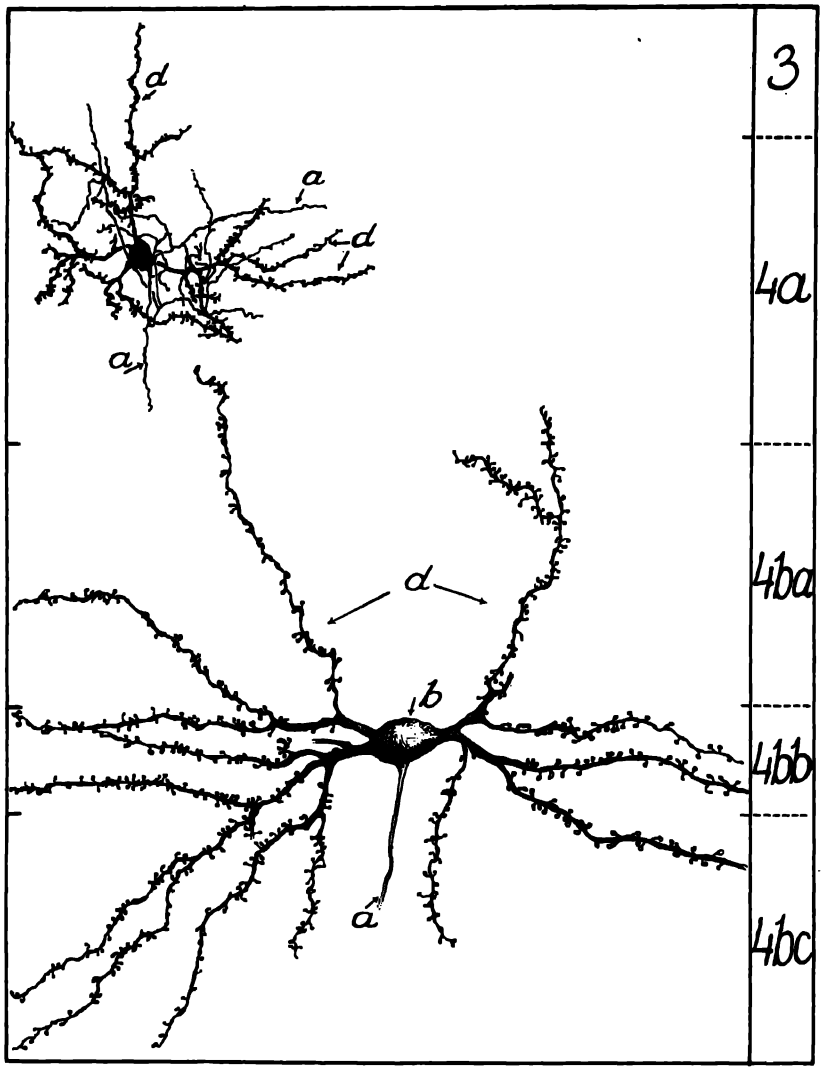

FIG. 337.—Large "solitary cell" of Meynert, with its ovoidal body in sublayer *4-bb* compared with a minute granular cell of the outer lamina of the inner granular layer (*4-a*). Foveal portion of the striate cortex of an adult Rhesus Macaque. Rapid Golgi method, Leitz *Ultropak* oil-immersion objective, transillumination, camera lucida drawing, 600× magnification (*cf.* following figure). Note body (*b*) of the "solitary cell," containing in its volume several times the volume of the body of the granular cell; the long and robust dendrites (*d*) of the solitary cell, covered with numerous minute twigs carrying spherical terminal nodules, spreading preponderantly in a horizontal direction; the smooth and straight axon fiber (*a*) of the same cell, descending from the lower face of the body; different appearance of the same detailed structures in the granular neuron, the most conspicuous being the axon fiber (*a*), which divides into a few delicate and contorted threads spreading within the same territory in which the thicker bramble-like dendrites also spread.

are the teledendric ramifications in sublayer *4-b* of Gennari (*see* Figs. 332–35). These terminations are conspicuous because of their robust build, as pointed out by S. Ramón y Cajal (*cf.* Figs. 327, 328). In the foveal portion of the striate cortex of a baby Rhesus Macaque the horizontal spread of an individual fiber of this type may measure, on the average, from 100 to 150 microns and on occasion as much as 250–300 microns. This, computed for the occipital operculum, where the hemifovea and, in fact, the ipsilateral homonymous halves of both central foveae are represented, would give at least 10,000–15,000 independently stimulable functional units to each vertical foveal half. This, in turn, is in fair agreement with the number of cones populating the foveal territory (*see* chap. V, 9 [5]). The number of the stimulable units in the entire central foveal cortex, comprising parts of both striate areae, would, accordingly, be twice the indicated number. In the same foveal portions of the human striate areae, the number of units would be correspondingly larger, in order to satisfy the greater number of central foveal cones of human foveae.

These afferent fibers, as we said, terminate in the middle sublayer or *4-b* of the inner granular layer. However, they are not arranged in exactly the same way but are staggered, some being closer to sublayer *4-a*, the others closer to *4-c*. Whether this has any functional significance requires further study.

Another question pertains to the variety of the afferent fibers in the striate area. Even disregarding all other terminations, such as those of the numerous fibers originating in parts of the cortex outside the striate area of one and of the other hemisphere and omitting short association fibers arising in the same striate area, which, as Le Gros Clark's and our own experiments indicate, are extremely numerous, it is legitimate to expect more than one variety of termination in each minute territory of the striate area. This, at any rate, is probable, since, in the experiments with retrograde degeneration, all cell laminae of the lateral geniculate nucleus are affected whenever a lesion above a certain minimal size is made in the striate area, provided that the lesion involves the inner granular layer or layers ventral to it (*see* chap. VII, 5).

The synaptical contacts of the terminal twigs and nodules of the afferent geniculate fibers apparently apply to the multitudinous nerve cells and their expansions, which, in the aggregate, form the three sublayers *4-a*, *4-b*, and *4-c* of the inner granular layer. It is very difficult to be certain of this, even in the abundant and successfully stained Golgi sections and with the best available optical systems, such as the Ultropak oil-immersion apochromates. This special problem requires further methodical investigation. The close approach of the branches of the terminal afferent arborizations to the dendritic expansions of the minute grain cells compactly filling sublayer *4-c* may indicate this. The same may also be true of the similar granular cells of sublayer *4-a*. It may also be true with respect to the pyramid-shaped neurons whose bodies lie above the stripe of Gennari and whose horizontal and ventral dendrites also spread in *4-b* or close to it.

The following functional interpretation of the course of retinal impulses in the striate cortex arriving by way of the coarse afferent visual fibers, in view of our incomplete knowledge, must remain tentative (Fig. 342). These impulses, after passing through the laminated lateral geniculate nuclei, are first transmitted to sublayers *4-a* and *4-c* of the striate areae of the occipital lobes of the brain. Here the stimulation is directly transmitted to the countless grain cells, their involvement depending on the place of the stimulated portion of the retina or retinae. In the granular sublayers the excitation is propagated from neuron to neuron. At the boundary of the excited territory the excitation quickly becomes exhausted in the labyrinth of countless minute synapses through which the granular cells are concatenated into a solid pad. Here the granular excitation dies down, since the granular cells act as a functional barrier. However, other and somewhat larger neurons, with somewhat longer and more widely spreading expansions, especially axonal, may continue to propagate a portion of the impulse in a less intensive way into wider parts of the striate area, while still other neurons may transmit another share of the impulse to other cortical areae of the same and of the opposite hemisphere of the brain. A residue of this excitation may remain as a permanent trace, the "memory." Still other and more robust neurons may respond by eliciting various

motor acts that automatically accompany the visual act: the turning of the eyes toward the source of stimulus, the regulation of the size of the pupil and the amount of light entering the eyes, and so forth.

Just how such varied impulses, generated in the retinae and transmitted by way of the afferent visual fibers to the inner granular layer of the striate area, may be multifariously changed and modulated, depending, on the one hand, upon the initiating external physical stimulus and, on the other hand, upon their passage through the synaptical labyrinth of interconnected neurons, differing in many ways in their innate properties and responsiveness, and how fusion of the two ocular images into a single cerebral phenomenon is finally produced are exceedingly complex problems. Our present knowl-

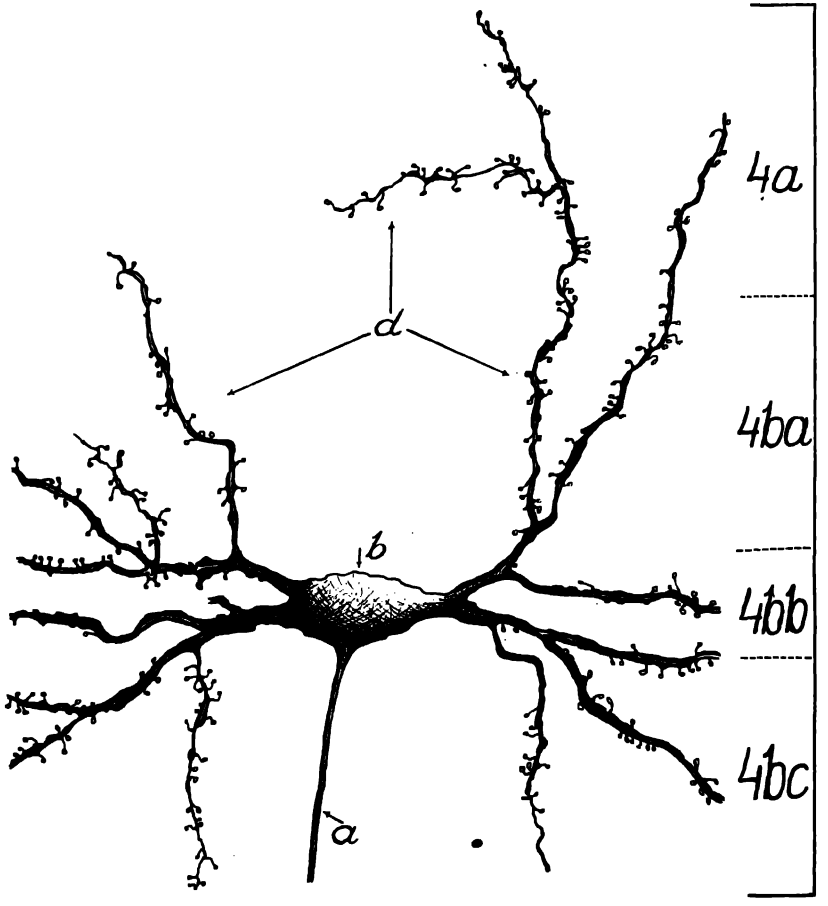

FIG. 338.—Same "solitary ganglion cell" of Meynert as in the preceding figure, approximately 1,200× magnification. Note the absence of "spines," "nodules," and "varicosities" along the initial portions of dendrites (*d*) and in the axon fiber (*a*); varying shape, size, and distribution of the "spines," these structures being interpreted as organelles whose function is the reception of the nervous impulses. (*Cf.* Fig. 341.)

edge, unfortunately, is too meager to make further speculation along this line profitable. The morphological and functional analysis of the striate cortex is thus suggested here as one of the important problems for future research.

In conclusion, mention must be made here of the neuroglia and the blood vessels, both essential constituents of the striate cortex. The neuroglial cells and their expansions are abundantly present in all parts of the striate cortex. In the most superficial stratum the neuroglial bodies and nuclei are arranged in a row, forming the marginal neuroglia. From here expansions pass down into the first layer, where they radiate in various directions. There are some curious expansions which loop back so that they both originate and terminate in the limiting membrane of the brain, just beneath the pial membrane, which, in the aggregate, they form. Other neuroglial fibers pass between the nerve fibers proper, the axis cylinders, and dendrites, thus, together with the numerous minute, ragged neuroglial sheets and excrescences, forming the sustaining and metabolic stroma for the specific nervous structures or parenchyma.

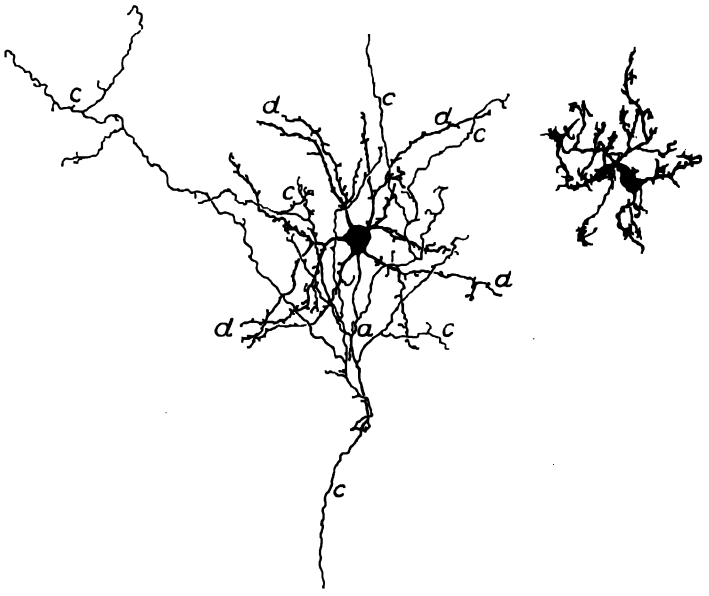

FIG. 339.—Granular cell or "grain" (*left sketch*) and a microglial cell (*right-hand sketch*) stained with silver bichromate or the rapid Golgi method. From the inner sublayer of the inner granular layer (*4-ca*) of the foveal region of the striate cortex of an adult Rhesus Macaque. Leitz *Ultropak* oil-immersion objective, transillumination, camera lucida drawing, 600× magnification. Note that from the spherical body of the granular cell several dendritic expansions (*d*) spread in all directions; they carry numerous "spines" or minute thornlike twigs, except in the initial segments close to the body; each "spine" terminates with a minute spherical nodule; from the lower face of the body a single smooth axon fiber (*a*) descends for a short distance, dividing into several delicate collateral branches (*c*), each carrying a few minute twigs terminating with nodules, different from the dendritic "spines." Note also that the entire teledendric ramification of the axonal fiber is located within the territory of the dendritic processes, or not far from it. The microglial cell also has many minute twigs, which, however, seldom carry terminal nodules but end in sharp points.

Some of these neuroglial fibers pass farther down into the subjacent second and third layers of the cortex. A number of the evidently originally marginal neuroglial cells are detached from the limiting membrane, to which, how-

ever, they are still held by one or more expansions. Still other similar neuroglial cells are entirely separated from the limiting membrane and are, with all their expansions, imbedded in the first layer. These elements, in their morphological appearance, resemble the neuroglial astrocytes elsewhere. Some of them possess rather smooth fibers radiating from the nucleus-containing body, whereas the others have fibers beset with minute ragged fringes, labeling them as the protoplasmic variety of astrocytes. However, the fickleness of the Golgi stain must also be taken into consideration, owing to which some cells may assume the appearance of protoplas-

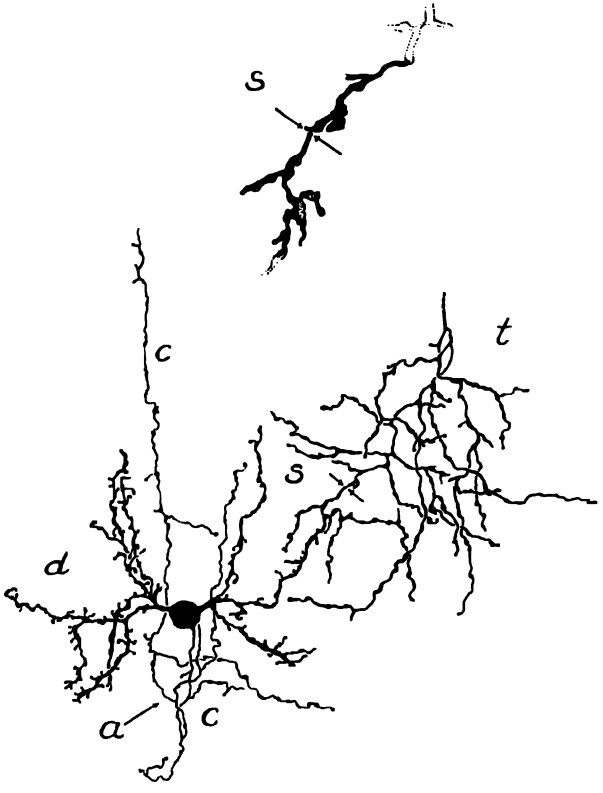

FIG. 340.—Inner granular neuron from the foveal portion of the striate cortex of an adult Rhesus Macaque stained completely, with all its expansions, in addition to a terminal arborization of an afferent fiber. Rapid Golgi stain, Leitz *Ultropak* oil-immersion objective, transillumination, camera lucida drawing, principal magnification 600×, upper sketch 1,400×. Left lower end of the figure shows an inner granular neuron, complete with all its dendrites (*d*) and with a single and thinner axis cylinder (*a*), from which several delicate collaterals branch off. The dendritic expansions are much thicker, carrying numerous short terminal twigs, practically all ending in spherical nodules or terminal thickenings. Along their course the dendrites also show spindle-shaped varicosities of different size. Similar but smaller varicosities and a few spines with terminal nodules are present also in the axon fiber and its collateral branches. The lower right-end part of the figure represents a terminal ramification or teledendron of an axon fiber belonging to another neuron, possibly residing in the laminated lateral geniculate nucleus: an afferent visual fiber of a special variety (*t*). At the point indicated by arrows (*s*), one terminal twig of the teledendron approaches a terminal twig of a dendrite of the granule cell almost close enough to touch it, apparently in a synaptical junction, this being shown at higher magnification in the upper sketch.

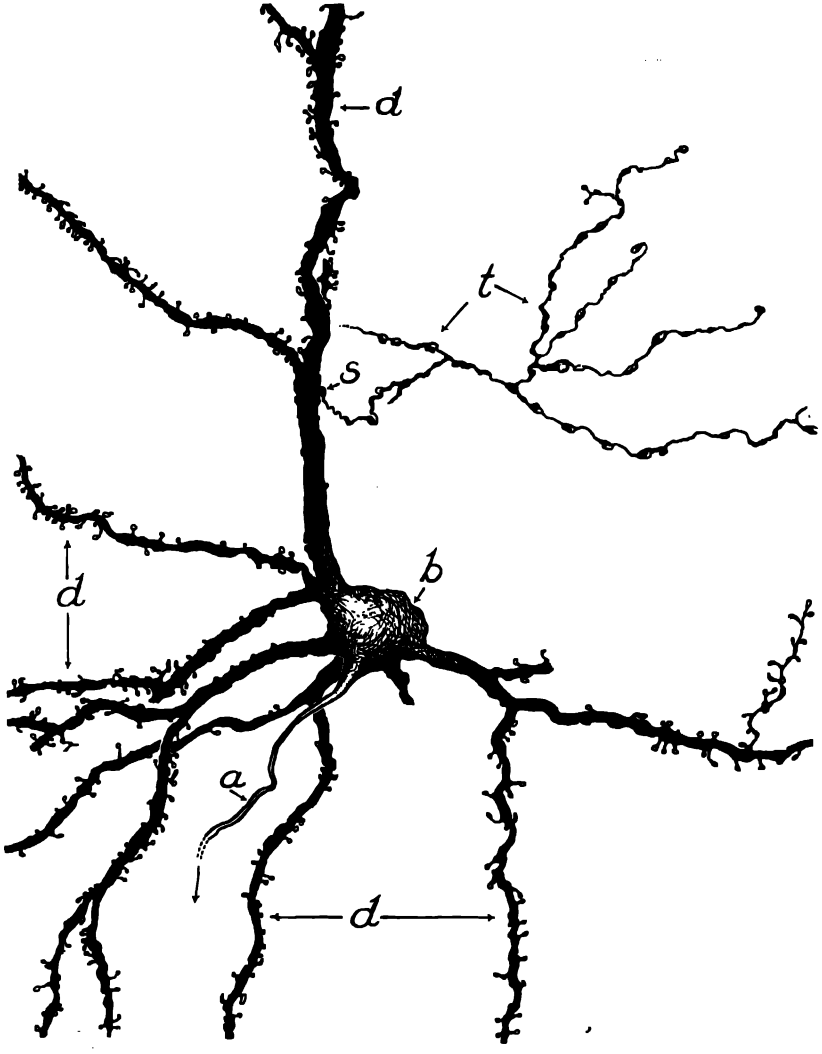

FIG. 341.—Principal parts of a large pyramidal neuron or inner solitary cell of Meynert from the fifth layer of the foveal portion of the striate area of an adult Rhesus Macaque stained with the rapid Golgi method. Leitz *Ultropak* oil-immersion objective, transillumination, camera lucida drawing, magnification *ca.* 850×. Note numerous synaptical buds or nodules attached to the dendrites (*d*), except in the parts proximal to the cell body (*b*), and none present in the single and smooth axon fiber (*a*). The right upper corner of the figure shows a terminal ramification or teledendron (*t*) belonging to a fiber of another neuron residing elsewhere. Its several branches show numerous spindle-shaped varicosities and a few twigs and terminal nodules of a different character. At the point indicated by *s*, by the accident of stain one of these terminal nodules is shown attached to the surface of the stout apical dendrite with which it undergoes a synaptical juncture. The number of the synapses in a large neuron of this variety may be considerable, since the number of the synaptical buds in this particular cell was roughly one thousand, which does not include the synapses with the smooth parts of the dendrites or of the cell body.

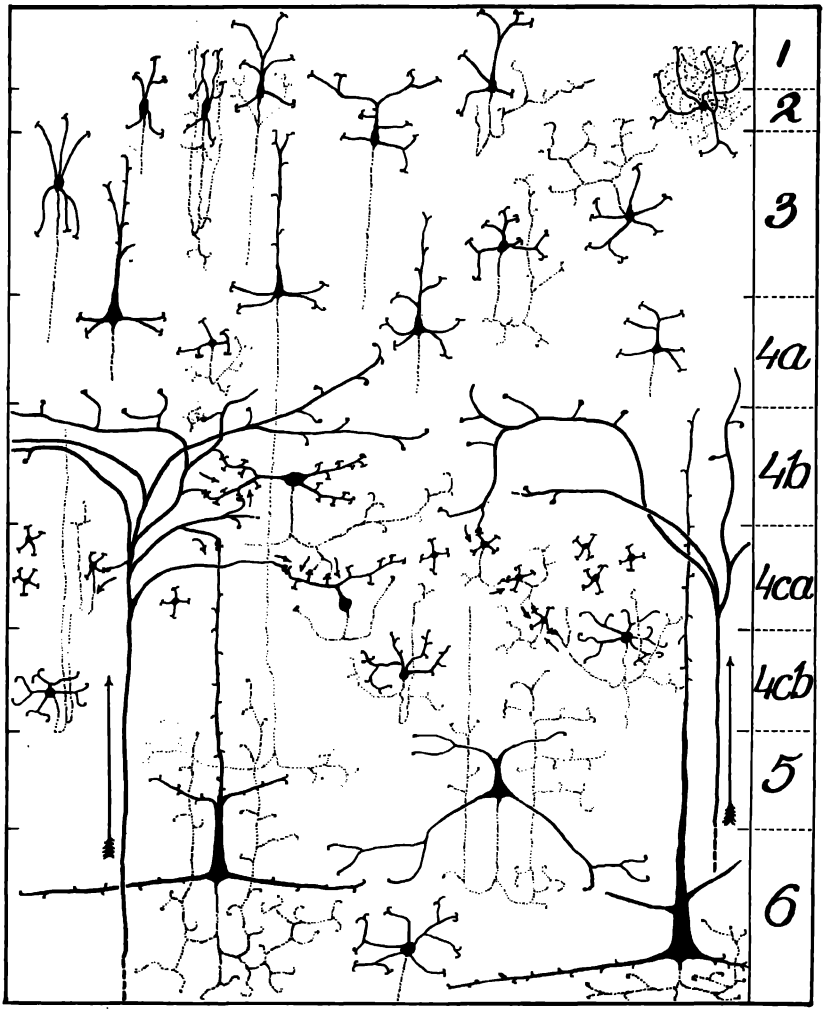

FIG. 342.—Preliminary scheme of the types and synaptical relationships of neurons in the primate striate cortex, based on the study of Golgi-stained preparations. The fibers of the visual radiation, marked with large arrows at the right and left, terminate in the inner granular layer (*4*), principally *4a*, *4b*, and *4c*. Along these fiber terminals arrive impulses from the two retinae of the eyes via the laminated lateral geniculate nuclei. These retinal impulses are transmitted to a variety of neurons, to some directly, to others by means of various intermediary neurons. The most important and most numerous, although smallest, of the striate cortex appear to be the so-called granular cells of sublayer *4ca* and *4cb*, with a few also present in *4a*. These "granular" cells are synaptically directly related to the afore-mentioned terminals. Other neurons of various sizes and shapes also undergo direct synaptical relationship, while still others are related indirectly to the same terminals. In addition, the granular cells are synaptically connected among themselves, as well as with other large and medium-sized neurons, and are likewise related to other terminals of fibers originating in various areas and regions of the same and of the contralateral hemisphere of the brain, including fibers arising in the striate area itself. The composing structures and synaptical concatenations of the striate area appear exceedingly complex, requiring further investigation. Only a few of these are presented in this figure. The spreading of the impulses is indicated by the arrows.

mic astrocytes, the others that of fibrous astrocytes, even though they may be essentially the same.

The same type of neuroglial astrocytes are present in all layers of the striate cortex down to the sixth layer, and also in the subcortical white substance. In the latter they appear frankly as fibrous astrocytes. Of the other types the presence of the mesodermal microglia of Río-Hortega, typical in appearance and provided with characteristic thorny spines, was ascertained with the high-power Ultropak oil-immersion apochromates. The oligodendroglia, probably also present, however, requires further investigation.

Chapter IX

General Theory of the Organization of Nervous Systems and the Visual Function

SEC. 1. INTRODUCTION

1. NERVOUS SUBSTANCE, THE ANATOMICAL SUBSTRATUM OF VISION.—In the response of the vertebrate organism to stimulation by physical light, called "vision" or "sight," two different organs or sets of organs are involved. First are the peripheral organs—the eyes - constructed upon the principles of geometrical optics. Their task is the formation of retinal images. This part of the process of vision is entirely physical, if we disregard the fact that the dioptrical media and most other ocular structures are made up of living tissue (the formation of retinal images does not differ basically from that in the photographic camera). The interpretation of this part of the eye's structure is the object of physiological optics.

The obtrusiveness of the eyes as the organs of sight makes it easy to slight the other and equally important realization that the eyeball is nothing more than an elaborate dioptrical container of the delicate retinal membrane. It is this membrane that must be considered the true photoreceptor (*see* chap. I, 5 [4, 5, 6]).

In the retina and in the nervous structures that make up the remainder of the visual system, processes take place which are subjectively interpreted as vision. In order to understand these processes, it is necessary to know both the basic organization of the nervous system and the composition of the nervous constituents of the visual pathways and centers.

The gross and minute features of the optic nerves, chiasma, and tracts and of the subcortical and cortical visual centers are described in chapters V, VI, VII, and VIII. The nervous constituents making up these parts are the veritable material substratum or carrier of vision, including the higher or psychic functions of sight. An attempt to solve the age-old problem of "psychophysical parallelism" must, accordingly, begin with a general analysis of the nervous structures and their correlation with those functions that are the manifestations of their activity.

2. THE PROBLEM OF THE GENERAL ORGANIZATIONAL PRINCIPLE OF THE NERVOUS TISSUE.—An attempt at a correlation of the various aspects of the faculty of vision with the nervous constituents of the visual system and any other similar attempt concerning audition, the somesthetic sense, motility, and many other functions of the body, regulated or chiefly performed by the nervous system, must be preceded by a discussion of the general principles upon which the nervous system is organized. It is legitimate to assume that these principles are observed in all parts of the nervous system, even though their application may vary in detail.

Everywhere in the nervous system, especially in the brain and spinal cord, a basically similar arrangement is found: numerous nerve cells of different shapes and sizes, connected with, or separated from, one another by a multitude of nerve fibers of varying thickness, all imbedded in a supporting neuroglial stroma and interlaced by blood vessels and connective tissue. The first problem with such composite tissue is to determine the general character of the reciprocal relations of its constituent structures. In an agglomeration of countless structures not greatly varying in size or other observable properties, their reciprocal relationship may be expected to play a decisive role.

3. HISTORICAL REMARK.—The present advanced knowledge of the intrinsic makeup or basic organizational plan of the nervous system

is the result of an effort extending over more than a century and a half. It began with Felix Fontana (1782) and Ehrenberg (1833–36), and it culminated toward the end of the nineteenth and during the beginning of the twentieth centuries in the classical work of Santiago Ramón y Cajal and his contemporaries—Golgi, Gehuchten, Retzius, Koelliker, and others. In this effort the investigation of the retina and of other parts of the visual system played a substantial role (Treviranus, Hannover, Bidder, Corti, Remak, Heinrich Müller, Koelliker, Max Schultze, S. Ramón y Cajal, and others). (*See* chap. I, 6–9, and chap. IV, 2, 3; for the figures to illustrate this chapter *see* chap. V, 3–8; chap. VI, 9; and chap. VIII, 7.)

SEC. 2. THE HYPOTHESIS OF *NEURORETICULUM* OR THE "NERVE NET"

1. The state of neurohistology during the early period of modern microscopy. At the beginning of the modern microscopic era, around the middle of the nineteenth century, knowledge of the origin, development, morphological character, and interrelationships of nerve cells and, in general, even of their identity was slight. This is understandable, since histological technique was then still in its infancy, as only bits of fresh tissue, after being "teased" or dissected with needles, were examined with "dry" objectives.

The preliminary fixation of tissue, first in chromic acid, introduced by Hannover (1840), and then in chromic salts, used by H. Müller (1852), only gradually began to be accepted. But even when thin translucent sections were studied by H. Müller and serial sections cut and stained with carmine by Gerlach (1858), diffusely stained preparations showed but little contrast of finer structural details. The optical equipment of that period also was a handicap before the problems of stage illumination, of oil-immersion systems, and of the construction of apochromatic objectives and compensating eyepieces were solved by Abbé (1872, 1878, 1886).

It is remarkable that under these circumstances the pioneers of modern microscopy were able to make important discoveries, such as the connections of nerve fibers with cell bodies (Corti 1850) and the fact that each nerve cell possesses two kinds of expansions, several short ones and a single long one that becomes a nerve fiber (Deiters 1863).

Efforts to trace the tortuous processes within the "gray substance" and learn the nature of Leydig's "punctate substance" or "neuropil" that fills the space between the cells of the brain and the spinal cord, however, failed. This was much more regrettable, since precisely this substance was suspected of containing peculiar arrangements that could throw light upon the true relationships of the nerve cells and fibers.

It was, perhaps, unavoidable that the idea gradually gained ground that most or all nerve cells were in some way directly connected with one another. In the opinion of Gerlach (1872), for example, the posterior spinal root fibers, after entering the gray substance of the spinal cord, were supposed to divide into a net surrounding the nerve cells and would again assemble at the other end and leave the cord as anterior root fibers. The concept of the "nerve net" became popular for a while and was supported by most of the hard-working authorities of the day, who were diligently hunting for the "anastomoses" in their preparations and happily presenting them in illustrations in their papers.

It is significant that even at that time a few clearer minds dared to oppose the then fashionable theory held by the crowd of numerous lesser lights now forgotten. Meynert (1872), in the same volume of Stricker's *Handbook* in which Gerlach championed his theory of "nerve nets," considered the "separation" of the nerve fibers and their "isolation" as a basic feature of the nervous tissue, while Max Schultze (1871) in the same handbook expressed grave doubts about the general occurrence of anastomoses between the nerve cells.

Ever since then the "nerve-net concept" has

had its sympathizers, some of them championing their cause to the bitter end (thus Held's animosity toward S. Ramón y Cajal). After having seemingly been defeated by the advocates of the "neuron concept," the Proteus of the "nerve net" managed on several occasions to stage a come-back, sometimes almost winning a temporary victory, for example, when Bethe (1903) and Apáthy (1894, 1897, 1907, 1908) proclaimed the neurofibrils to be the "principal nervous substratum."

2. TENETS OF THE NEURORETICULAR HYPOTHESIS.—The essentials of the nerve-net hypothesis, briefly, are as follows:

The constituent elements of the nervous system, the nerve cells and nerve fibers, are more or less interconnected by protoplasmic bridges, forming sets or systems along which the excitations are propagated.

From its phylogenetical beginning in the lowliest multicellular animals and from its earliest ontogenetical inception until its full maturity, the nervous system represents a cellular and fibrous *syncytium*, wherein the "cells" are little more than local condensations or foci distributed in an otherwise more or less continuous and uniform mass.

The nerve fibers, especially of the long peripheral nerves, and the various fiber systems of the brain and spinal cord either are preformed (Hensen) or arise by fusion of the numerous cells that thus form a syncytial chain (Schwann, Balfour, O. Schultze), or else the axis cylinders grow along the pre-existing plasmatic bridges called "plasmodesms" or "neurodesms" (Held 1909).

A similar principle would obtain during the process of regeneration of the nerve fibers (Bethe, Spielmeyer, and others). In no way could the nerve cells be regarded as even remotely genetically, structurally, and functionally independent units, as insisted upon by the sponsors of the "neuron theory."

3. HYPOTHESIS OF NEURENCYTIUM.—The nerve-net hypothesis attained its most extreme form in the concept of a "universal nervous network," or *neurencytium*, espoused by Golgi, Apáthy, and Bethe, but in particular by Held (1927, 1929). According to this concept, all nerve elements of an organism were fused into a "general network" permeating the entire body, merging even with neuroglia and other tissues. The "nerve cells" were merely locally differentiated foci or condensations in this continuum, with no clear boundaries between the cells. The neurofibrils were the only conducting structures, the neuroplasm of the cells and fibers being little more than a living vehicle of the fibrils (Apáthy, Bethe, Péterfi). The neurofibrils were supposed to be the products of special cells and passed indiscriminately from cell to cell, irrespective of the apparent barriers (Apáthy, Nissl, Held). The synaptical boundaries between the territories of the individual nerve cells were nonexistent.

In the final analysis, the universal bodily nerve net was the instrument by means of which the unity of the organism was brought about and was maintained (Held). Theoretically, in the nervous system thus organized—if the term "organized" is applicable to it at all—the excitations or nervous impulses, no matter where they arose, would spread in an unaccountable way in any direction without change in quality or quantity.

The questions concerning the purpose of the countless morphologically differing nerve cells and their various modes of reciprocal interlocking, how the various patterns of the arrangement of nerve cells should be interpreted in terms of concrete physiological manifestations, and how the hypothetical continuity of the nervous system could be made to harmonize with the numerous locally varying functions had never been answered by the champions of neuroreticularism, except in ambiguous generalities.

4. THE NEUROFIBRILS AND NEURORETICULUM.—The hypothesis of the nerve net had been variously modified to suit the particular idea of the individual investigator. After periods of relative oblivion, it had been repeatedly revived, and even today it is being championed with a stubbornness worthy of a better cause.

At present, the crude protoplasmic anastomoses, cocksurely championed by the older school of Gerlach, Tartuferi, Golgi, Dogiel, Carrière, B. Haller, and others, are rarely mentioned. In the modern "neuroreticularist" version the

task of welding countless nerve cells into a "whole" is usually assigned to more subtle structures. These are the "neurofibrils" first noticed by Remak (1843, 1853), Leydig (1857, 1885), Deiters (1866), Koelliker (1867), Ehrlich (1886), Flemming (1893), and Lugaro (1896), but clearly seen only by Max Schultze (1866, 1870, 1871, 1872, 1873), H. Schultze (1879), Kupffer (1883), Apáthy (1892), Dogiel (1893, 1895), Flemming (1895). Bethe (1898), and Simarro (1900).

Precise knowledge of the neurofibrils, however, dates from the publications of Apáthy (1894, 1897, 1907, 1908), Bethe (1903), S. Ramón y Cajal (1903, 1904, 1906), and Bielschowsky (1904, 1927, 1928, 1935). From that time the role of the unifying neuroreticulum was assigned to these subtle, often elusive, threads. The neurofibrils, as the neuron-combating neuroreticularists insisted, continuously pass from one nerve cell to another, regardless of apparent cell boundaries, and are present even outside the nerve cells proper.

Since the protagonists of this concept had exalted the neurofibrils to the role of the only conducting nervous structure, they had, by the same token, relegated the cytoplasm of the nerve cells and axoplasm of the nerve fibers to a secondary role. In this way the genetical and structural individuality and relative functional independence of the nerve cell had been contested or denied outright, and the whole "neuron" concept either trimmed to a point where it could not be recognized (thus by Bielschowsky 1928, p. 119) or condescendingly deposited upon the historical scrap-heap of useless mistakes (by Abderhalden; Klarfeld 1925; P. Schröder 1926; Tiegs 1926, 1927, 1929, 1931; Held 1927, 1929; E. T. Brücke 1929, p. 771; Péterfi 1929; Boeke 1936, 1938, 1940, 1941 42, 1943–45, 1949; Beritoff-Beritashvili; and others).

The uncompromising opposition of reticularists to the "neuron" concept was to some extent motivated by subjective factors. Golgi was against it because, as a sympathizer of the "cerebral equipotentialism" of Flourens and of Goltz, he was against any form of functional cerebral localization (*see* chap. III, 4 and 8). Again, Held's idea of an organism required a material substratum as a carrier of its unifying activity which he believed he had found in his *allgemeines Grundnetz*, or "general elemental reticulum" (Held 1929, pp. 23, 41).

Similar motives of a rather philosophical order may have been responsible for the origin of Bethe's doctrine of "plasticity," for the highly speculative "resonance hypothesis" of P. Weiss, and the like, all difficult to harmonize with any clear structural and functional delimitation within the nervous system. To other opponents, again, the whole "neuron" concept was simply obnoxious. Stöhr, Jr., for example, declared it an outright "invention."

5. Critique of the hypothesis of "neuroreticulum." –A charitable verdict, fully justified upon the evidence given in chapters V, VI, and VIII of this book, concerning the reticularist doctrine is that it served a useful role as a counterpoise to the exaggerations of the advocates of "neuronism." Its stubborn opposition and its sometimes violent critique aroused efforts among its adversaries which, without it, would very likely never have been made.

For the rest, the work and ideological presentation of the reticularists are largely wasted effort. Their critique was mostly negative. The obligation squarely resting upon them to give a lucid, reasoned explanation of how the undeniable fact of numerous locally varying functions in the nervous system could be made to harmonize with their doctrine has been consistently dodged or sidetracked into a realm of semimystical "dynamism."

Their pretense of being in revolt against the "old-fashioned" Schwann-Schleiden-Schultze concept of the "cell" as a structural element of the bodily organization impresses one as meaningless scientific faddism. Their claim to have proved the presence of a "continuous nerve net," a *continuum*, a *Grundnetz*, a *neurencytium*, a special "gray substance," or a "molecular substance of the brain," and what not, as a nervous substratum existing outside and besides the regular nerve cells and their expansions, wherein the latter would be dissolved as individual structures, must be considered meaningless after the evidence given in the preceding chapters.

In particular, the fantastic schemes of Apáthy, Bethe, and especially of Nissl (*see* Péterfi 1929, p. 128) have never been substanti-

ated by positive evidence, while Held's and Boeke's presentation of the peripheral nervous system lends itself to a different interpretation (*see* Nonidez 1936–37). Held's belief, to which he clung to the last (Held 1929, p. 5), viz., that the "gemmules" or "spines" of the dendrites were terminal buttons of the afferent nerve fibers, an argument which he repeatedly used to prove a wholesale merging of the nerve cells and their expansions, was long since revealed by S. Ramón y Cajal (1896, 1909–11, 1934, p. 92) to be an error and is easily refuted by any cursory examination of a good preparation stained with silver bichromate and examined by high-power oil-immersion Ultropak apochromatic objectives (*cf.* Figs. 337, 338, 341).

The continuity of the neurofibrils, supposed by the neuroreticularists to pass directly from one cell to another, has been refuted by a number of modern investigators. Tello (1931) showed the intracellular neurofibrils of the cochlear and vestibular sensory epithelium to be in no direct connection with the neurofibrils of the terminal branches of the cochlear and vestibular nerves. S. Ramón y Cajal (1932, 1934) and, in an especially clear way, Bartelmez & Hoerr (1933) and Bodian (1937 and later) have demonstrated the distinctness of the neurofibrils in the afferent terminals from those in the cytoplasm of the body of the related neuron, being separated from each other by a "synaptical membrane."

That the "neuropil" or Leydig's "punctate substance," a finely granulated mass characteristic of many localities of the gray nervous centers, is not the continuous nonsynaptical network which it had been proclaimed to be by the neuroreticularists and by adherents of the concept of functional equivalence of the brain, but is a tangle of interlacing neuron processes and is therefore to be regarded as a "synaptical field," has been convincingly demonstrated by C. J. Herrick in his numerous studies of the central nervous system of Lower Vertebrates (Herrick 1934). A similar composition of the molecular layer of the cerebral cortex and of other parts of the brain was made certain by my own study of the best Golgi-stained preparations with the help of oil-immersion objectives of the Ultropak type (magnifications used up to 2,000×).

The continuity of the neurofibrils in the somatic motor nerve terminations with the myofibrillar substance by means of the "periterminal reticulum," described by Boeke (1926 and later), has been questioned by S. Ramón y Cajal (1934; *see also* Heidenhain, Wilkinson). The anastomosing of the expansions of nerve cells frequently observed in cultures of living nerve tissue (Levi, Bauer, and others), and in the growing nerves of young animals (Speidel 1932, 1933, 1935) is a process not yet fully analyzed, whereas Hensen's hypothesis of the preexisting connections of nerves with the peripheral organs and Schwann-Balfour-Schultze's syncytial or catenary hypothesis of the polyblastic origin of nerve fibers, as well as Held's hypothesis of the embryonic axons growing within the preformed protoplasmic bridges called "plasmodesms" or "neurodesms," all still defended by the reticularists (*see* Bielschowsky 1928, p. 131; Péterfi 1929, p. 131; Spielmeyer), after the brilliant experiments of Harrison (1908, 1910, 1912, 1924) and of Speidel (1932–35), have nothing positive to show in their favor.

Finally, the nervous system of primitive animals such as the Coelenterates had been shown by Bozler (1927) and by Woollard & Harpman (1939) to be synaptical in character rather than a continuous network, as the reticularists and many other writers under their influence had believed it to be for many decades (for Young's observation of the fusion of giant axons in Squid, *see* following section).

Even in the visceral organs, whose working would naturally require a more diffuse arrangement of the nerves, a supposedly continuous "terminal reticulum" described by Boeke (1926, 1936, etc.) had been revealed by Nonidez (1936–37) as largely nonnervous, of the nature of connective tissue. (*Cf.* also Kuntz 1953, p. 54.)

General histobiological considerations also militate against the "nerve net" as an organizational principle of the nervous system. If no barriers and boundaries separating the individual neuron territories existed, as they necessarily would not in a syncytium, a differentiation of diverse cell types from an original common form would hardly be possible. In an undifferentiated system neither dynamical polarity nor functional specificity of the nerve cells would have been developed. Such a nervous system would be histologically homogeneous, as

are, for example, the striated muscle and the glands, where each of the many nuclei and myofibrils or agglomerations of cells appears to perform the same function.

In such a nervous system all elements would be of the same kind and would be connected with one another in a like way. Such a homogeneously built nervous system would not be capable of a locally differentiated activity, unless assisted by some unaccountable dynamical factors of a nonstructural nature, beyond the power of microscope to reveal and outside the judgment of a microscopist.

If, then, a neuroreticular syncytial nervous system contained some structures differentiated within the syncytium, these, in order to perform complex functions, would have to be endowed with exactly the same properties as those possessed by a multicellular synaptical nervous system. An imaginary nervous system containing "syncytial synaptical connections," proposed by Bocke (1926 and later), is therefore inconceivable, implying, as it does, two mutually exclusive principles—one, the syncytium, synonymous with continuity; and the other, the synapse, meaning contact barriers through which discrete nerve cells are related to one another.

This critical review may fittingly be terminated by the statement that not one single detail described in this book, mostly pertaining to highly differentiated nervous tissue of fully mature organs of Monkeys, Apes, Man, and other animal species, supports the contention of the neuroreticulum hypothesis as a general organizational principle (*see* sec. 4, this chapter).

SEC. 3. THE NEURON THEORY

1. THE ORIGINS OF THE NEURON THEORY.—A concept of a general organizational plan of the nervous system opposite to the idea of neuroreticulum is that of the *neuron*. It may be defined most simply as the "cell theory" of Schleiden, Schwann & Schultze applied to the nervous organs. It maintains that, like most other tissues and organs, the brain, spinal cord, and peripheral parts of the nervous system are made up of more or less independent cellular individuals, the "neurons."

Genetically, the young neurons arise at an early embryonic stage as structurally independent ectodermal cells of rather uniform appearance, the "neuroblasts" of W. His (1887, 1893; portrait, Fig. 343). During subsequent differentiation and adult existence they preserve a fair measure of trophic and functional independence and are to be considered as morphological and dynamical entities.

The idea of independent nerve cells was arrived at toward the end of the nineteenth century, almost two decades after Gerlach (1872) promulgated his concept of nerve nets. Mention was made of Max Schultze (1871) and of T. Meynert (1872), who may be considered as its forerunners, to which also Hughlings Jackson (1869) may be added.

But the actual origin of the idea may be traced directly to the improved neurohistological technique, in particular to the discovery of special histoanalytical methods: Golgi's silver bichromate method (1878; Fig. 344) and Ehrlich's vital methylene blue method (1886). These two stains have contributed more to the advancement of neurology than any other single factor, not excluding even the improvements of microscopical optics by Abbé, mentioned in the preceding section.

It is an odd freak of history, however, that Golgi, whose method became such a mighty tool in the hands of S. Ramón y Cajal and

others, persisted in his loyalty to Gerlach's reticularism. Ehrlich, however, because of the experience he gained with his newly discovered method, was among the first to abandon the concept of nervous continuity.

Soon after, as new observations with the silver bichromate technique began to accumulate, the idea of independent nerve cells gained ground. First promulgated by Kupffer (1872), W. His (1886, 1887), and Forel (1887), it was molded into a theory by Waldeyer (1891, portrait, Fig. 345). After it was splendidly corroborated by R. T. Harrison (1908, 1910, 1912, 1924), who showed by in vitro cultures the sprouting of axis cylinders from the growing embryonic neuroblasts, it became widely accepted.

At last the goal, out of reach of the preceding

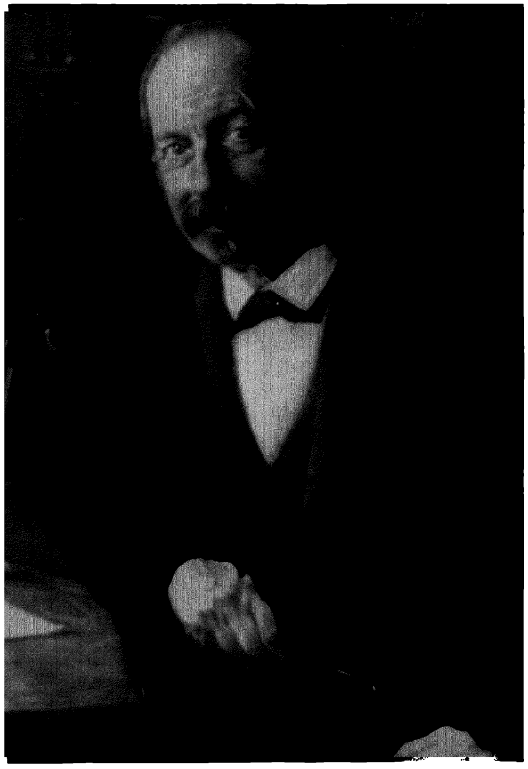

FIG. 343.—Wilhelm His, Sr. (1831–1904), professor of anatomy in Leipzig, Saxony, Germany. Pioneer student of the fetal nervous system. Discoverer of the "neuroblasts" or young, plastic nerve cells which make up the nervous tissue of the brain and of the spinal cord during early stages of embryonic development. The concept of "neuroblasts" as relatively independent structural units or "building stones," in turn, led to the "neuron theory" of Waldeyer (*see* portrait Fig. 345), S. Ramón y Cajal (*see* portrait Figs. 52, 131, 317), Van Gehuchten, and others. According to the neuron theory, the nervous organs are composed of structurally and functionally relatively independent nerve cells, the "neurons," related to one another by contact in multifarious ways, altogether making up the complex nervous tissue. The "neuron theory" is opposed to the "doctrine of *neuroreticulum*," or a continuous nerve net, championed by Gerlach, Apáthy, Bethe, Held, and some modern investigators. From a portrait at the University of Chicago, Department of Anatomy. Biography by Mall, Am. J. Anat., v. 4, p. 139, 1905, and Haymaker & Baer, *The Founders of Neurology*, 1953.

generation, which used older, inadequate "teasing" techniques and nonselective carmine stain, was sighted. The limitless variation in shape and size of the nerve cells and of their various expansions, their arrangement, termination of processes, and the manifold contacts—all details inexplicable on the basis of a neuroreticulum—began to make sense.

The neuron concept made it possible to understand in what way nerve cells, varying little in one or another detail, especially in their expansions and the manner of reciprocal contacts and probably also in biochemical and functional properties, were able to produce countless patterns of histological relationships that must have counterparts in distinct dynamical manifestations.

Altogether, in the opinion of its adherents, the new "neuron theory" gave a far more adequate picture of the intrinsic organization of the

Camillo Golgi

FIG. 344.—Camillo G. Golgi (1844–1926), professor of general pathology at Pavia, Italy. Nobel Prize laureate for the year 1906 (with S. Ramón y Cajal). Discoverer of a staining method for nervous tissue, the silver dichromate stain known as the "Golgi method." The Golgi method shows individual nerve cells together with all their expansions, including the ultimate or terminal twigs, thus permitting the study of the character of each cell type and the exact topographic and functional relationship of each nerve cell with other nerve cells and other tissues (*cf.* corresponding figures in this book). The Golgi method and, to a lesser extent, Ehrlich's vital methylene blue stain, more than any other single histological method, in the hands of S. Ramón y Cajal and many other investigators has helped to unravel the complex structure of the nervous organs and laid the foundation of the modern concept of its organization. From München. med. Wchnschr., v. 54, 1907. *See also* W. Haymaker's *Guide*, 1948; Haymaker & Baer, *The Founders of Neurology*, 1953.

nervous system than the theory of neuroreticulum ever did. (*See*, for additional information, S. Ramón y Cajal 1909–11, v. 1, p. 1, esp. pp. 66, 80, and his articles published 1934 and 1935.)

2. TENETS OF THE NEURON THEORY.—The principal tenets of the "neuron theory" are as follows:

a) Specific nervous parenchyma and nonspecific nervous supporting constituents.—The tissue of the brain and spinal cord consists of nerve cells proper and of their expansions or processes. Together, these represent the nervous parenchyma or the constituent on which the specific function of the brain and spinal cord depends. The nerve cells originate from the ectodermal or outermost layer during the early period of embryonic development. The neuroglial cells and processes are also ectodermal in origin but form a supporting, nonspecific framework within which the nerve cells proper and their expansions are imbedded. The mesodermal blood vessels are a normal constituent of most nervous tissue, contributing to its growth and maintenance.

b) The neuroblasts.—The young multiplying nerve cells of the early stage of an embryo, the neuroblasts, at first appear alike and exhibit a considerable degree of independence from one another. Only by degrees, as they become further differentiated into mature neurons and develop numerous expansions, with which they become interlocked into sets of neurons in adult tissue, do they relinquish part of their original genetical independence. Yet even in the fully grown nervous organs the cellular boundaries of the adult neurons in most cases may easily be determined by an appropriate technique.

c) The neuron body with its expansions forms a physiologic and trophic unit.—Each nerve cell, including all its expansions, is a relatively independent unit, a "neuron" or "neurone," capable of individual existence within the tissue of which it is a part.

The neurons of Higher Vertebrates possess a cell body or perikaryon and processes of two kinds: protoplasmic dendrites, which usually are short, thick, and of which there are several to each cell, and a single long, smooth, and rather uniformly thick axon or axis cylinder (corrupted from "axis of the cylinder") or nerve fiber.

All expansions of a neuron, comprising both dendrites and axon with its terminal ramification or teledendron, grow from the cell body by sprouting during the process of maturation or regeneration: the "outgrowth theory" of Kupffer, W. His, S. Ramón y Cajal, and Speidel. They do not grow within the "plasmodesms" or preformed protoplasmatic bridges or along the *Leitzellen* or "conductor cells" of the German writers, exemplified by neuroglia and Schwann's cells, but follow intercellular spaces (*see* Harrison's experiments with living tissue, and S. Ramón y Cajal's experiments in 1920 on nerve regeneration).

The processes are nutritionally dependent upon the perikaryon containing the nucleus, which is, accordingly, the trophic center of a neuron. Cut off, the processes die or else regenerate by sprouting from the cell body, as is also the case with the axon, irrespective of length.

Each neuron leads an independent existence to a varying degree. Depending on whether a nerve cell suffers reparable or irreparable damage when injured, it shows signs of degeneration, or it may disappear completely, with the adjoining but synaptically unrelated neurons, if not directly affected, remaining normal. The synaptically related neurons, on the contrary, are trophically interdependent, this dependence varying in degree from case to case, being most pronounced in monosynaptically related neurons, exemplified in the lateral geniculate nucleus ("trans-synaptic degeneration").

d) Ramifications of neurons: dendrites, axon, and teledendron.—The more numerous and thicker "dendrites," with their terminal branches and button-like nodules or gemmules, improperly also called "spines," ordinarily remain within the confines of the gray substance, whose constituents, with the "body" or "perikaryon," they principally are. The single and usually longer "axon" or "nerve fiber" leaves the territory of the gray substance and, togetherwith other axons, forms the white substance of the brain and spinal cord or, when leaving the central organs, forms the peripheral nerves. The sagittal strata of the parietotem-

poro-occipital regions of the cerebral hemispheres are an example of the white substance, the peripheral nerves being exemplified by the oculomotor and other cranial nerves. The optic nerves, chiasma, and optic tracts are drawn-out fiber bundles of the brain connecting the retina, a detached portion of the brain.

Whether relatively short and remaining within the gray substance or long and passing over into white substance or peripheral nerves, each axon fiber divides into a terminal arborization made up of a varying number of twigs, usually with spherical or irregularly shaped enlargements, swellings, buttons, or nodules at their ends, together called the "teledendron."

Some axons, usually while still within the gray substance, give off "collateral branches," spreading within the same substance. The teledendrons, both of the short axons belonging to neuron cells residing within the same gray substance and of the long axons whose cells of origin are in another part of the brain, spinal

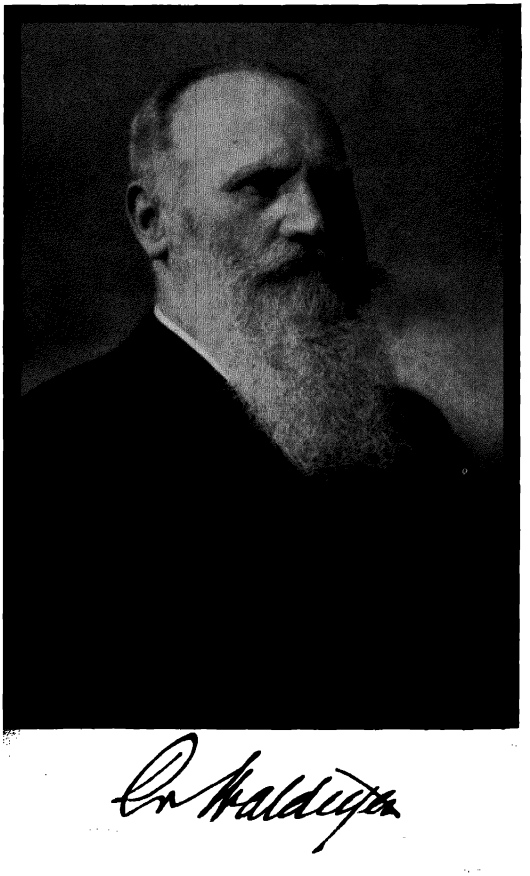

FIG. 345.—Wilhelm Waldeyer (von Waldeyer-Hartz, 1836–1921), professor of anatomy at Strassburg and Berlin. Noted anatomist, creator of the modern concept of "neuron" as a structural and functional unit of the nervous system. From Waldeyer's *Lebenserinnerungen*, 1920.

cord, or a peripheral ganglion, usually terminate within the gray substance whose essential constituent they are. The axonal terminations in the muscles and glands are homologues of the teledendrons.

e) *The functional polarity of the neurons.*—The possession of two kinds of expansions, each usually with sharply defined morphological features, and the peculiar mode of attachment of these two categories of processes to other nerve cells, muscles, glands, and some other structures indicate that these processes also differ functionally. In particular, the dendrites and the surface of the cell body or perikaryon appear to be the only parts of the neuron capable under normal circumstances of receiving extraneous impulses or of being stimulated; these may, therefore, be considered the receptive end, or "ingress," of a neuron. Conversely, the axis cylinder and its terminal arborization or teledendron is the emissive or discharging end, the "egress," of a neuron, along which the excitation or impulse is carried away. The dendrites are somato- or cellulipetal, transmitting impulses toward the cell body, the axonal process being somato- or cellulifugal, carrying the impulses away from the body. In some cases, e.g., craniospinal ganglions, certain retinal bipolars, with the body attached sidewise, a direct transmission from a dendrite to an axon is probable. This is the axipetal conduction arrangement (S. Ramón y Cajal).

There are exceptions to the preceding rule, with an axon terminal attached directly to the initial portion of the other related axon fiber (Bartelmez & Hoerr, Bodian, Young) or to its terminal, such as the arrangement found in horizontal cells (*c*) and centrifugal bipolars (*i*); these require further inquiry.

Considering, however, these apparent exceptions also, the overwhelming evidence supports the view that the neurons of advanced animals are dynamically or functionally polarized, having parts specialized to react to extraneous impulses (dendrites and perikaryon) and other parts capable of inducing reactions in other related structures (axon and its teledendron). This functional polarity, or "one-way propagation of excitation" within each neuron, is another fundamental feature, in addition to the differentiation of neurons into various types or varieties, upon which the structural complexity of the nervous system, especially of the brain, is based.

f) *Synapses.*—The neurons do not merge or continue with one another by means of their processes or anastomatical bridges, as the "neuroreticular hypothesis" insists, but are interrelated through a more or less intimate contact (S. Ramón y Cajal). Usually, the slightly swollen terminal twigs, buds, or nodules of a teledendron of an axis cylinder of one neuron touch one or another dendrite or the surface of the body of a related neuron. The modes of contact vary practically endlessly in the complex nervous system of Higher Vertebrates, the contact in some cases being very slight, the terminal nodule of a teledendron barely touching the surface of a related neuron body or its dendrite, whereas in another extreme the ends of a teledendron firmly clasp or enwrap the body of a related neuron or are otherwise anchored to it.

In all cases, when appropriately studied, the barrier separating the substance of two related neurons can be outlined. In suitable cases the barrier appears as a distinct line, an optical cross-section of the area where the two surfaces are in contact (*see* Bartelmez & Hoerr 1933; Bodian 1937, 1940, 1942). This "synapse," as it was named by Sherrington at the suggestion of Verrall (*see* Fulton 1943, p. 52), has been interpreted by neurophysiologists as a "two-faced membrane," differently organized on both sides of the potential cleavage space or area of contact. How the details of this difference in ultramicroscopic organization of the two faces can ever be examined and defined is one of the remaining great problems.

Figuratively, the working of a synapse may be compared to a valve, under physiological conditions permitting a free flow of the excitation in one direction and hindering it in the opposite direction. It may be assumed that the dendritic or the somatic face of the synapse is of a receptive nature, facilitating the inflow of excitation into the substance of the dendrite or the cell body, while the teledendric face works as an emissive structure.

Since there is physiological evidence that the excitation within the body of a neuron and its processes, the axon and dendrites alike, may spread in any direction, it is necessary to look

upon the synapses as the true cause of a dynamic or functional polarity of neurons by which the unidirectional flow of nervous excitations is determined and regulated.

g) ***The varieties of neurons.*** In the highly differentiated nervous systems of advanced animals, the neurons are found in numerous varieties and types. They vary in many respects: in size and shape of cell body; in number, length, thickness, character of distribution, density, and place of spreading, and in many other subtle details both of dendritic expansions and of axons and axonal ramification or teledendrons; in the number, size, shape, and other features of terminal twigs and nodules; in the character of various cellular inclusions, such as

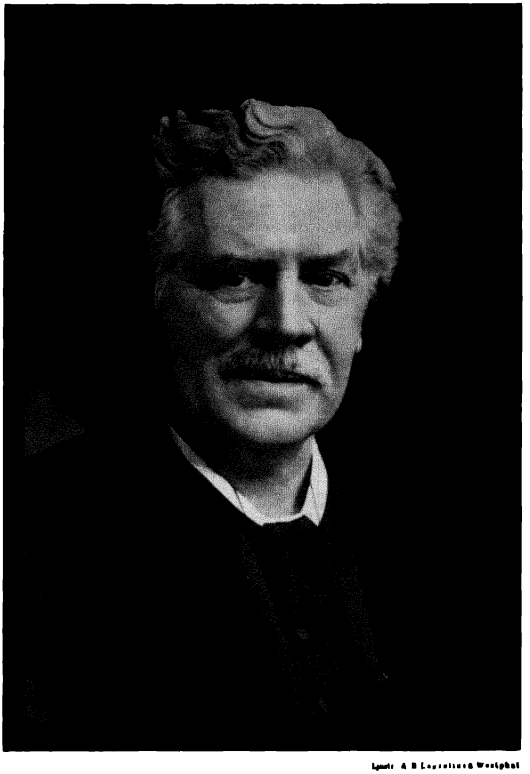

Fig. 346.—Gustaf Magnus Retzius (1842–1919), professor of anatomy at Stockholm, Sweden. Indefatigable investigator of the human and animal body, in particular of the nervous system, and of the sense organs. From Retzius' obituary by V. Ebner, in *Almanach der Akademie der Wissenschaften*, Wien, 1920. Courtesy Oesterreichische Akademie der Wissenschaften, Wien. *See also* Haymaker & Baer, *Founders of Neurology*, 1953.

the nucleus, nucleolus, and diverse granules, particularly of the chromophile substance of Nissl; and in numerous other cytological features demonstrable by various methods of histological staining technique.

In the fully differentiated nervous organs the features characteristic of a certain neuron variety are constant, the number of individuals deviating from the type or including features of two or more varieties being relatively small. This is in remarkable contrast with the uniform appearance of young nerve cells or neuroblasts in the early stages of a nascent embryonic nervous system. It likewise contrasts with the poorly differentiated nervous system of primitive animals close to the bottom of the phylogenetical scale.

In summary, the neuron concept epitomizes the morphological and functional diversity of the advanced nervous system as a climax of a long phylogenetical, and a shorter ontogenetical, process of differentiation from a simple and uniform original condition.

From this a logical deduction may be made that in the early phylogeny and ontogeny the individual nerve cells vary little in their functional capacities, as they vary little in their morphological appearance. As the biological situation of advancing animals becomes increasingly complex, the necessity arises for certain neurons to specialize gradually, to develop their innate potentialities to enable them to perform functions outside the scope of undifferentiated neurons or neurons differentiated in a different direction.

Otherwise expressed, the phylogenetical and ontogenetical differentiation of distinct neuron varieties, with the similar progressive differentiation of other tissues of the animal body, is the essence of progressive animal evolution. In this way new capacities are evolved, by means of which animals are able to utilize more of the physical factors of the world around them in ways which are increasingly favorable in their competitive existence. (*Cf.* chap. XIII, 2, 3.)

h) The physiological or functional specificity of neurons.—Closely related to the morphological differentiation into many varieties is the functional specificity of neurons. In early animal phylogenesis all nerve cells may have been adjusted to respond to a number of extrinsic and intrinsic stimuli, reacting more or less to all of them similarly (*see* chap. XIII, 2). With increasing functional specialization, of which morphological differentiation is but a visible manifestation, each neuron variety became dynamically responsive to a particular kind of stimulus, nervous or nonnervous, whereas the responsiveness to other kinds of stimulus decreased or vanished. In a highly differentiated nervous system a condition has been attained in which some or all specialized neurons have become responsive to one particular stimulation, different in each neuron variety, while at the same time becoming refractory to all other kinds of stimulating factors or reacting inadequately. Here each neuron variety is capable of reacting dynamically and within rather narrow limits of stimulation in its own specific way (*cf.*, e.g., Rushton 1949, 1950).

Similar ideas had been expressed as early as the end of the seventeenth century by Father Mariotte (1668) and again hinted at by Charles Bonnet (1759, 1770) and were subsequently elaborated upon during the early part of the nineteenth century by Charles Bell (1811) and thereafter by Johannes Müller in his concept of the "specificity of nervous energies."

"Functional neuronal specificity" presupposes the ability of each neuron variety to react to a relatively narrow range of extraneous stimuli and to react dynamically to them in its own peculiar way, conditioned by its own innate biochemical constitution. This may manifest itself, for example, in the size or amplitude and in the rate or number of individual impulses registered in a unit of time by a recording instrument in an electrophysiological experiment.

The evidence in support of the functional specificity of neurons is manifold: different physical and chemical constitution of cytoplasm and its inclusions, especially Nissl's chromophile granules; different character of expansions, both dendritic and axonal; dissimilar synaptical contacts and different interneuronal relationships; difference in normal and pathological reactions of different parts of the nervous system or different neurons or sets of neurons. Without the functional specificity of each neuron variety, a complex nervous system is difficult to conceive.

i) Interlocking of neurons, or interneuronal

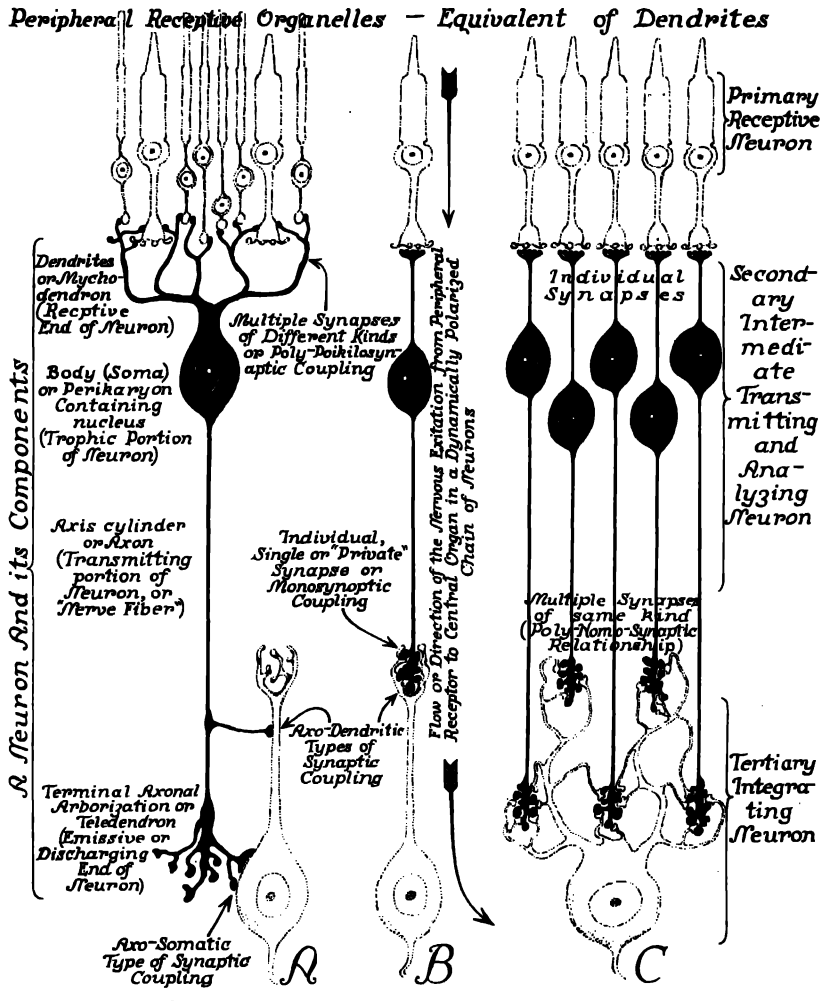

FIG. 347.—Diagram of various neuron types of human and simian retina, showing the essentials of the structural and functional organization of the nervous system. Each complete neuron cell usually has a body, one or several protoplasmic expansions or dendrites, and a single axis cylinder or axon, ending in a terminal ramification or teledendron. Neurons are believed to be polarized functionally or dynamically, each part having a specific function: the dendrites and body a receptive, the axon a transmitting, and the teledendron a discharging role. Each neuron is related by contact or concrescence to another or to several other neurons or to other structures, such as muscles or glands, whose activity it controls. The points of contact of a terminal teledendron of one neuron with the surface of the body or of a dendrite of the related neuron where the influencing takes place is called "synapse" or conjunction. Each neuron variety is capable of reacting in its own specific way, different from the ways of other neuron varieties. The same dynamic specificity also applies to different kinds of synaptical relationships that various neuron types undergo with one another. In this diagram only a few of the many possible relationships are presented: *A*, common pathway for the rod and cone impulses; *B*, individualized or "private" cone synapses; *C*, several private cone synapses converging upon the same ganglion cell. These examples illustrate the possibility of changing in various ways the nervous impulses initiated in the rods and cones (*above*) as they pass through different bipolar varieties (*solid black*) to the ganglion cells (given below in outline).

relationships.—The structural and functional relationships or modes and ways in which countless neurons of various types may be interlocked in different groups or sets is the last, but perhaps the most important, single factor which makes possible the complex organization of the nervous system of advanced animals.

Whereas the factors discussed in the preceding paragraphs concern chiefly, or exclusively, the neurons as individual cellular or histological entities, the interrelationship of the neurons deals directly with the organization of tissue. To make this difference clear, the following comparison may be helpful. Assume that an architect is to design a building, using a single variety of bricks. If he is an admirer of classical styles, he may be able to build a very elaborate structure of Romanesque, Gothic, or Tudor type, using the same kind of bricks but differently arranged. He may very well be able to produce all the intricate decorative patterns of the walls, windows, doors, and chimneys, as required by the particular style, without changing the shape of a single brick. If several kinds of bricks—light red, dark red, blue, and black—are at his disposal, his task is made much easier, and the edifice may be more elaborate. If many more kinds of bricks and, in addition, several varieties of stone, plaster molds, and the like are available, the architect may well succeed in erecting an Alhambra or a Taj Mahal.

An elaborate nervous system, according to this example, would be feasible, even if all neurons were of the same variety. Unquestionably, however, an elaborate and more efficient structure is much more easy to attain if the "building stones," the neurons, vary in many particulars, in shape, size, arrangement, connections, and innate properties.

In practice, obviously, Nature, in creating the nervous system of Higher Vertebrates, considered by some "the most highly organized matter on the globe," has used all available means. The concatenation of the neurons into diverse patterns of cells variously related synaptically to one another is undoubtedly the most important architectural factor.

Differing from all other bodily organs that are more or less uniformly or homogeneously organized in their minute structure, the nervous system represents a huge aggregate of variously synaptically interrelated groups and sets of neurons woven into most intricate tissue patterns. Their synaptical connections indicate that these sets are capable of functioning not only as a part of the total tissue but, under special dynamical conditions, in their own way, more or less independently of other sets of the same tissue.

By disclosing the synaptical relationship of such sets of neurons with one another and with other related neurons of a given system –for example, the visual, auditory, somatomotor, and others –means may be found to understand the spreading of individual or complex excitations passing from the peripheral receptors through the intermediary stations to the cortical centers, or vice versa, their various changes traced therein and the ultimate fate of such excitations estimated.

j) Dynamical states of neurons and their mutual influencing. In the analysis of various factors contributing to the building of a complex nervous system, still another angle needs to be considered: the nature of the excitation elicited in the individual neurons.

According to the reticularist concept, there are no true barriers between the individual nerve cells believed to be interconnected by the protoplasmic anastomoses or neurofibrils. The true substratum along which the nerve impulses spread are supposedly the neurofibrils. Since the neurofibrils are considered by reticularists to be continuous from cell to cell - in fact, Held claimed the continuity and unity of the entire bodily neuroreticulum—it is difficult to see how a nervous excitation arising anywhere within this network could be prevented from spreading anywhere within the system or be modified in any way. According to the neuroreticularist doctrine and like hypotheses, the regulation of the direction, intensity, division, merging, or fusion or any other modification of the currents of excitation within the nervous system remains unexplained.

The hypothesis of neuroreticulum takes into account neither the material nor the dynamical factors responsible for the immense local variation in function demonstrated by modern neurophysiology, especially electrophysiology, and by neuropathology. This adverse judgment must also be passed about any other similar

hypothesis, such as the "resonance hypothesis" of P. Weiss, which pretends to disclaim the need for an elaborate structural relationship in the nervous system as a basis of functional diversity, a claim which is altogether in opposition to observable and measurable facts. Facts observable by the microscope and the innumerable indications from neurophysiological experimenting, clinical observations, and neuropathology overwhelmingly point toward the elaborate anatomical makeup of the nervous system as the principal factor responsible for its functional diversity.

We may put aside, for a while, the basic question of what are the factors which force Metazoans to build their bodies out of the countless minute morphophysiological entities called "cells," instead of letting them grow and prosper as single, huge, syncytial lumps. This apparently is predetermined by as yet unknown factors which initiate, regulate, and terminate the growth and the very life of animals. But, whatever these factors are, they indicate that there is a limit in tridimensional space and in the quantity of matter, as there is in time, beyond which animals cannot go. Hence the growth and perfection of animals must have recourse to the multiplicity and elaborate arrangement of their constituent elements. (*Cf.* chap. XIII, 2, 3.)

The nervous system, as we know it from modern investigations, is obviously an "aggregation," a "composite," or a "collective," made up of countless nerve cells varying almost ad infinitum, artfully put together into a complex whole. In it certain constituents, such as long axis cylinders or "nerve fibers" of the pyramidal tract, of the anterior or posterior spinal roots, and of many other systems, have the task of transmitting discrete nerve excitations from one particular point of the central organ (one or a few nerve cells of the cerebral cortex or of the spinal cord) to a particular restricted locality in the periphery of the body (a few muscle fibers, a small group of glandular cells, for example) or from a small area in the periphery (a small territory of the skin, or a few muscle fibers, or tendon fibers, and the like) to a narrow strip in the posterior gray columns of the spinal cord or to a minute cell nest in the nuclei of the posterior spinal columns, and so forth.

Here, obviously, the nerve fibers, their cells of origin, and their terminal arborizations, both in the periphery and in the central organ, have, to begin with, only one task to perform: to transmit quickly a particular discrete impulse generated in a small group of neurons, or even in a single neuron, to another small neuron nest. The insulation of axis cylinders by myelin sheaths is doubtless a means by which the loss of nervous current to the adjoining structures is minimized. At both ends of the conducting "nerve fibers" the arrangements differ. In the muscles each motor nerve fiber terminates with a group of end-plates attached to several muscle fibers, or a sensory nerve fiber is related to a number of muscle or tendon fibers, remaining entirely unrelated to other fibers of the same muscle. In the spinal cord and in the brain the terminals of the afferent fibers spread around one or several groups of cells of the various nuclei.

Up to this point the connections are adjusted merely to preserve the discreteness or individuality of the incoming nerve impulse and transmit it to the brain. Only in the complex mechanisms of the central organ may further processing of these impulses take place. The preservation of the impulses as discrete dynamical entities, accordingly, is the principal functional task of the nerve conductors. The individuality of dynamical entities remains preserved, however, only as far as the synaptical barriers of neurons. Beyond these, the character of excitation necessarily changes.

One may look upon each individual neuron as a cartridge shell filled with a definite, limited charge. The charges are the same in the same neuron variety and differ in different varieties. Each neuron is capable of developing one particular kind of energy only, which may vary somewhat, little, or not at all in "qualities" and more so in intensity. On the whole, then, there are as many possible elicitable "reactions" or "dynamical states" as there are individual neuron cells in a nervous system, the states in the same neuron variety being roughly potentially the same in quality and different in different neuron varieties.

Where two neurons are connected through a synaptical contact, the excitation of one may be capable of causing an excitation in its related

companion. Because of the synaptical barrier, it is proper to consider the induced disturbance of the dynamical equilibrium in the related neuron as a separate event, even though caused by an excitation from the first neuron. The two excitations—that causing the disturbance and that induced which follows—are not identical, even though they are causally related to each other. Each is determined principally by the innate properties developed during the ontogenetical differentiation based upon the preceding phylogenetical factors.

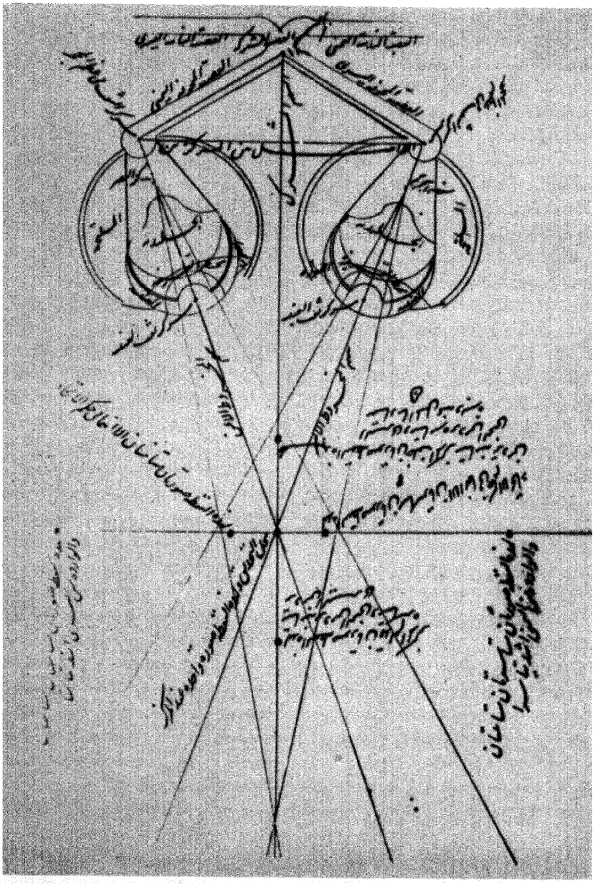

FIG. 348.—**Explanation** of binocular stereoscopic vision, according to Kamāl al-Dīn Abu'l-Ḥasan al-Fārisī, a Persian scholar of optics of the fifteenth century. Photo print of a diagram in an Arabic manuscript written A.D. 1433, entitled *Kitāb al-baṣā'ir fī'ilm al-manāẓir*, or *Book of Reflexions on the Science of Optics*, now in possession of the Ayasofya Library, Istanbul, Turkey. The two eyeballs, connected to the brain through the optic nerves, chiasma, and tracts, converge with their axes, which meet in the common fixation point. The objects situated in front of this point along the common line of vision are depicted on the nasal sides of the two retinae and are therefore ipsilateral and do not overlap: "equilateral or corresponding images." The objects situated behind the common fixation point also produce two images, but these, being on the temporal sides of the two retinae, appear contralateral: "noncorresponding or crossed images." (For further details *see* Figs. 9, 56, 57, 58, 60.)

The direction and the mode of spreading or propagation of the excitations within a complex nervous system depend both on the innate or inherent factors and upon other circumstances, such as the kind or quality, intensity, and temporal duration of the initiating stimulus or excitation, on the condition of the related neurons owing to the preceding stimulation or rest, and the like. The principal factor in this remains the synaptical relationship of the neurons. An excitation from a given neuron may induce a secondary excitation only in that neuron or in those neurons with which it stands in synaptical contact. The other neurons, even those immediately adjoining the activated one, very likely remain entirely at rest, neutral. The elaborateness of the central nervous tissue postulates such a conclusion.

For the reciprocal influencing of the neurons, direct contact in the synapses seems to be a prime requisite. Other contacts, especially those mediated by the insulating myelin and apparently also those established by neuroglia, seem to be of no direct importance. Whether or not there are other relationships of neurons which could be called "distance synapses," there is no certain evidence, even though this remains a possibility that must be further explored. The excitations, then, spread, as far as we know, along the preformed channels represented by the concatenations or sets of neurons.

The initial impression of apparent structural and dynamical chaos reigning in the central nervous organs resolves itself into a firmly knit complexity of the highest order. In it each specialized structural unit performs its own functional role, assigned to it by its position in the synaptical tissue complex. And the function of a particular nervous tissue or locality is the sum total of the particular states of excitations that may be induced or elicited in its constituent neurons.

3. Summary of the neuron theory.—In summary, parts of the visual system, such as the retina, the subcortical visual centers, and the striate area, like the remainder of the nervous system, are composite organs made up of a great number of nerve cells put together according to a certain definite order. These "neurons" are present in numerous well-defined varieties, characterized by their own morphological, biochemical, and functional peculiarities or properties.

The neurons are functionally polarized. Because of this, the excitations normally are propagated from the dendrites or the body to the axon and its terminal ramification, the teledendron.

Each neuron variety possesses its own functional responsiveness or mode of reacting, predetermined partly by its own innate biochemical constitution and partly by its synaptical relationships with other nerve cells or other related structures (receptors, muscles, glands).

All these factors—the results of a long phylogenetical process of differentiation from the originally similar, neuroblast-like nerve cells into structurally and functionally dissimilar types—imply a great deal of structural stability. Even so, the gray nervous masses are not a mere mechanical agglomeration of static elements ruled by purely structural factors but are a living, adaptable, plastic substratum, whose dynamical reactions depend much upon varying extrinsic and intrinsic factors—condition of nutrition, kind and intensity of the external stimuli, the preceding activity, and other more or less fleeting and elusive factors.

This granted, neurodynamics nevertheless is largely governed by anatomical conditions. Whereas dynamical factors influence much of the spreading of the currents of nervous excitations, it is the structures that prescribe along what channels one or another dynamical change, called "nervous current," may or may not be propagated; how it may be subdivided into several secondary currents; or how several discrete currents may fuse into a single stream, as the case may be. If, therefore, no parts of the brain, such as a nucleus, a cortical area, and so forth, may be compared with a machine made up of artfully assembled gadgets, cogs, wheels, gears, or joints always responding in exactly the same way to the same stimulation applied to the same locality, they may respond with a dynamical change now in this way, now in another, only as their intrinsic organization permits.

The complex nervous system of advanced animals is made up of a great number and variety of "neurons" or nerve cells, structurally and

functionally independent in varying degree, each variety attuned to respond in its own peculiar way to a particular external or internal stimulus. The nervous system is a "complex or composite whole," its complex structural make-up being the basis of its functional diversity, its unity being maintained by the synaptical connections of its constituent neurons. The nervous tissue may be compared to a "coat of mail," in which each link, a neuron, although a complete individual, has its own definite place in the whole fabric and may fulfil its functional role only as a part of the whole system.

The relative independence of the neurons, their differentiation into a multiplicity of forms, each reacting in its own way; the unidirectional regulation of the currents of excitation; and the diversity of reciprocal connections of the neurons appear as the prerequisites, principles, and tools of the histophysiological organization of the nervous tissue.

Lastly, the "factor of numbers" should be considered. From what has been said, it is clear that this factor alone could be considered irrelevant. Together with the other factors, however, the "factor of numbers" attains its full importance and makes sense of the increase of the number of nerve cells in the nervous system of the higher animal forms. It is one of the principal means by which its structural complexity is increased and hence its functional diversity and efficiency improved.

A complex nervous system is the result of its intricate structure and diverse biochemical and functional constitution. The numerous morphodynamically varying neurons, interlocked with one another in most varied ways through the synaptical connections that regulate the manifold reciprocal influencing, serve, on the one hand, as a substratum of specific, locally restricted functions and, on the other hand, in the aggregate, bring about and guarantee the unity of the entire nervous system of the individual organism.

4. Modifications of the neuron theory.—It is probable that, as our knowledge increases, the present definition of the neuron theory may have to be modified in many respects. Whether, for example, the neurons, as morphological and functional units, are sharply defined in all parts of the human or animal body or whether in some parts the arrangement approaches a more or less syncytial character needs to be explored further.

Of all parts, the vegetative organs are most likely to show such an arrangement, since their working shows little local variation. However, there is, so far, no positive evidence in favor of such an assumption, and much against it (*see* Kuntz 1953; Fedorow 1935, 1937; Fedorow & Matwejewa 1935; Nonidez 1936–37; Herzog & Günther 1938).

A more "diffuse" nervous system, with the nerve cells retaining their supposedly unpolarized original character, may also more readily be expected in lowly forms than in the highly differentiated classes and orders close to the top of the animal scale. This view was formerly widely accepted under the influence of Apáthy and Bethe (*see* G. H. Parker 1919; Child 1921). Subsequently it has been seriously compromised by Bozler (1927) and by Woollard & Harpman (1939), who found the nervous system of Coelenterates to be synaptical.

The interesting observation made by J. Z. Young (1939) of the fusion of giant axons in the Squid and a similar observation by Glees (1939) of the fused ganglion cells in the selachian spinal cord may more easily be interpreted as an exception of adaptation of the synaptical nervous system to a special function. Both observations, however, require further study.

Other observations, in fact, show the nervous system of the "lower animals," as far as investigated, to be synaptical. In S. Ramón y Cajal's opinion, Insects have the most minutely differentiated nervous system of all animals (*see* Ramón y Cajal 1909, 1915, 1918, 1929–30; Ramón y Cajal & Sánchez 1915; Sánchez y Sánchez 1916, 1919, 1923). In other Invertebrates the nervous system is also synaptical (Sánchez y Sánchez 1909; S. Ramón y Cajal 1916, 1929-30; Droogleever Fortuyn 1920; Hanström 1928).

Even so, while a syncytial nervous system in the lower animals has not been demonstrated, this question must be left open. The work so far done, however, suffices to show the inadmissibility of a wholesale denial of the validity of the "neuron theory" for all nervous tissue, including the central nervous system of Man and of

other Higher Vertebrates, as advanced by many reticularists upon questionable evidence obtained from the entrails of a Leech or an Earthworm (Apáthy), from the nervous system of a Crayfish (Bethe), or from the gut of an *Amphioxus* (Bocke).

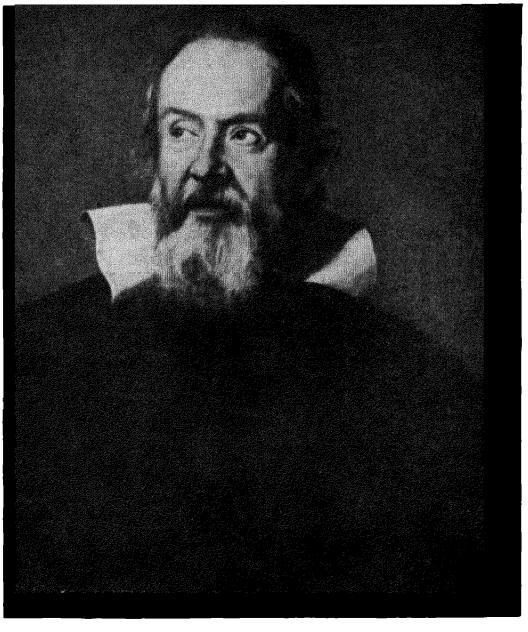

FIG. 349.—Galileo Galilei, the Florentine (1564–1642), the celebrated physicist and astronomer, native of Pisa, Italy, professor of mathematics at Padua and of astronomy at Florence, Italy. Originator of the concept of "force" as an agent of mechanical phenomena and a founder of "mechanics" as a branch of physical science. A forerunner of Newton in celestial mechanics (*see also* Kepler). Constructor of the refracting telescope, which he further improved and first used to study heavenly bodies. Discovered the moon's mountainous surface, the fact that the "Milky Way" is composed of individual stars, the satellites of the planet Jupiter, the rings of the planet Saturn, the seasonal phases of the planet Venus, the sun's spots, and the rotation of the sun around its axis. Investigated by the Inquisition for his adherence to the "heretical" Copernican view of the sun as the center of the solar system and for his opposition to the geocentric concept of Ptolemy. Painting by Subtermans at the Galleria degli Uffizi in Florence, Italy. From P. Capparoni, *Profili bio-bibliografici*, 1928. Courtesy Istituto nazionale medico farmacologico "Serono," Rome, Italy.

SEC. 4. THE MINUTE ORGANIZATION OF THE NERVOUS CENTERS

1. SIMILARITY AND DIFFERENCE BETWEEN THE PERIPHERAL AND CENTRAL NERVOUS SYSTEMS.—The nervous system of advanced animals, such as Vertebrates, is customarily subdivided into two main divisions, peripheral and central.

The peripheral nervous system is made up of numerous, mostly small, accumulations of nerve cells called "ganglions" imbedded in various visceral organs, such as the heart, digestive tract, bladder, and so forth, the most prominent being the prevertebral chain of sympathetic ganglions. These ganglions are interconnected, with one another, with the organs which they supply, and with the brain and spinal cord, by various nerve strands of differing thickness. Other peripheral nerves, cranial and spinal, connect the brain and the spinal cord directly to the muscles, tendons, skin, and the various sense organs.

The central organ is represented by the bulky mass called "brain" or "cerebrum" and the spinal cord. In the peripheral system the conducting nerve fibers, or axons, predominate, whereas the brain and the spinal cord, especially the gray substance of the various nuclei and of the cortex, are largely made up of the bodies or perikarya of nerve cells, their dendritic processes, and the teledendrons or terminal ramifications of the axons.

The difference in intrinsic makeup indicates the difference in function. The peripheral nervous system serves largely to conduct impulses generated in the various internal organs and in the superficial receptors of the skin and of the sense organs to the brain and spinal cord, or from the latter to the peripheral organs of execution, e.g., muscles and glands. The central nervous system, on the contrary, is an organ in which the impulses from the periphery are "integrated" or "processed" into responses appropriate to a particular physiological or biological situation of the individual organism or part of it.

The distinction in the character of the two major subdivisions is only roughly accurate, each serving both conduction and integration to some extent. The numerous sympathetic ganglions of the visceral organs, for example, perform various local tasks by automatically regulating many functions which do not require central control or do so only occasionally and in slight measure. Their activity is largely independent of central control, that is, autonomic. The central organs, especially the brain, receive impulses generated within the body or elicited by the extrasomatic stimuli, out of which arise influences that, directly or indirectly, bring all parts of the organism under a single central authority, thus insuring the life and activity of the organism as a single biological entity.

2. INTRINSIC ORGANIZATION OF THE NERVOUS CENTERS.—Since the basic biological task of the nervous system is to help an individual animal to adjust itself appropriately to its environment, both the conduction and the integration of the nerve impulses are necessary.

In the lowest forms of multicellular animals which possess a differentiated nervous system – the Coelenterates– this system, simple as it is, is nevertheless capable of performing the function of adjustment appropriate to the species. This is noteworthy, since there are no special centers in these primitive animals, their nervous system being made up of a rather uniform plexus of nerve fibers and cells. The cells are here represented by a few varieties only. Their expansions do not merge with one another into a continuous network, as was believed by the neurorecticularists, but are related to one another by true synapses (Bozler 1927; Hanström 1928; Woollard & Harpman 1939). Even in Coelenterates, then, the neurons are neither of a uniform kind nor without an individuality, nor are they put together haphazardly.

On higher levels of the animal scale, with an increased structural and functional complexity, the same basic functions of the nervous system —the conduction and integration of impulses— remain. In fact, the more the functional exigencies of an animal increase, the more complex becomes its nervous system. The most complex arrangement is found in the centers of most advanced animals, irrespective of whether they are Vertebrates, Insects, or Cephalopods. Here the tissue pattern is not only highly differentiated but varies much from place to place. Even

in the same locality, several varieties of neurons intermingle and are synaptically tied to one another in different ways. The only general principle observed in all nervous centers is an arrangement permitting the passage of dynamical changes or influences from neuron to neuron.

The way in which the neurons of a nerve center are able to influence one another or other nonnervous tissues in most cases is by direct contact. An influencing by neurohumors secreted by some nerve cells and by other tissues or by the bioelectrical currents acting at a distance, while possible, requires further investigation (Parker 1930; Scharrer 1940, 1941; R. W. Gerard 1941).

It is obvious that the greatest number of orderly, well-organized contacts may be achieved in a synaptical nervous center where its neurons, especially their perikarya, are assembled in a small space and in compact groups. Such a concentration of nerve cells gives greater possibility of establishing numerous reciprocal relationships with the expenditure of the least quantity of matter. Limited space and therefore shortness of cellular processes by which such contact relationships are established likewise help the economy of time.

In a centralized nervous system, all other factors being equal, a greater number and variety of nervous influences may spread in less time to elicit responses more locally and qualitatively diversified than would be possible in a scattered arrangement, with fewer neurons and fewer neuron varieties and with greater distances between. The greater functional efficiency resulting from the economy of matter, space, and time is clearly the principal advantage in the phylogenetical creation and perfection of the centralized nervous system, especially of the nerve centers. (*See* S. Ramón y Cajal 1909–11, v. 1, pp. 1 ff.; *also* some of his other publications.)

A histological examination of the white substance of the brain and spinal cord shows it to be composed largely or entirely of the conducting nerve fibers or axons. Here no essential modification of the transmitted impulses takes place except such as may be due to a division of the axons into branches. But no change of "quality" or "intensity" and no "transformation" are possible. The gray matter, on the contrary, is organized in such a way as to permit precisely this kind of change in endless variety. Here take place the various subtle processes that may only inadequately be described as "selection," "division," "intensification," "transformation," "inhibition," and the like of the incoming peripheral impulses, and from here the elicited responses are sent back to the periphery. This greater activity of the gray matter is reflected also in its better blood supply, suggesting a higher rate of metabolism compared with the white substance.

The mode of the reciprocal relationships of neurons, according to the neuron theory, is determined by their dynamical polarity. The terminal axonal ramifications of one neuron variety are in contact with the surface of the body of one or several related neurons or are entangled with their dendrites in a definite way, quite specific for each particular neuron variety.

In routinely stained preparations, little may be seen or guessed of the abundance of the true relations of neurons. The gray substance of the cerebral cortex, for example, appears to be composed of a great number of nerve cells varying in shape, size, and distribution, arranged mostly in parallel layers. Between the layers and the individual cells the intercellular substance has a dotted or stippled look, and because of this it was given the name "punctate substance" (Leydig) and *neuropil* or *neuropilem* (W. His). Subsequently, this mysterious substance was revealed, with the help of the histoanalytical methods of Golgi, Ehrlich, Cajal, and others, to be an extremely complicated plexus or tangle, a plexiform substance (Heidenhain 1911) made up of countless, mostly unmyelinated, preterminal and terminal nervous branches and nodules, imbedded within the framework of neuroglial tissue.

The plexiform substance is one of the principal features of the gray matter. In localities where the segregation of cell bodies from the plexiform substance formed by their expansions is complete or almost so, as in the superficial plexiform layer of the cerebral and cerebellar cortex and, above all, in the outer and inner plexiform layers of the retina, these layers are composed practically exclusively of the naked, unmyelinated expansions of neurons. Since the synaptical contacts of the adjoining neurons

take place in these plexiform layers, they have been quite appropriately named "synaptical fields," or layers, by C. J. Herrick (1934).

3. Dynamical factors responsible for the complex organization of nervous centers.—A complex intrinsic organization of nervous centers is an indispensable condition for their functional diversity.

A center made up of a single neuron variety, with neurons whose individuality was largely or entirely suppressed, could do little in modulating a dynamical current "passing" through it. The situation would be improved but little if a dynamical change generated in one neuron were transmitted directly to other neurons, though these belonged to different varieties. In a nerve center thus organized, there would be little variation in dynamical change, called "excitation," spreading from cell to cell. It is more appropriate, therefore, to assume that an excitation when reaching the point of contact does not pass over directly to the related neuron but merely "elicits" or "induces" in the latter a dynamical change that is not entirely identical with the eliciting stimulus.

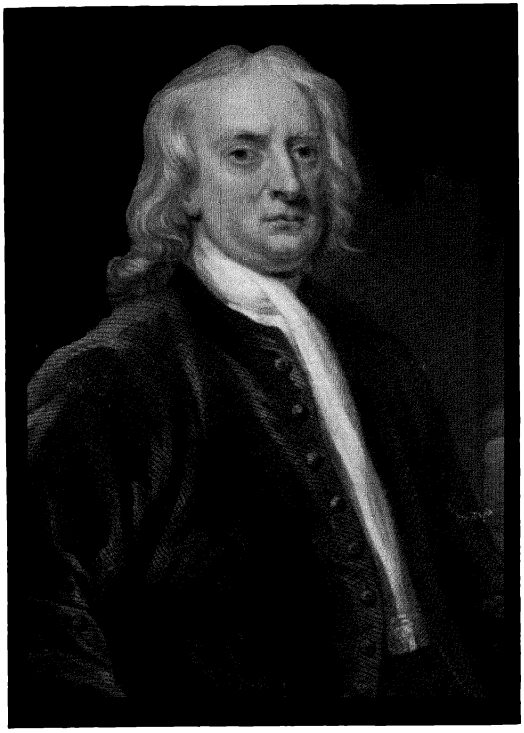

Fig. 350.—Isaac Newton (1642–1727), celebrated English natural philosopher, mathematician, and physicist. Author of the *Principia* (1687) and of the *Opticks* (1704). Originator of the corpuscular or emission theory of light (in contrast with Huygens' wave theory of light *see* Fig. 351). Laid the foundation for the trichromatic theory of color perception (*see* Thomas Young and Helmholtz, Figs. 352, 356). Engraving by E. Scriven, from the original by Vanderbank in possession of the Royal Society of London. Courtesy Professor J. F. Fulton, of Yale University, New Haven, Conn. (*Cf. also* Fig. 76.)

Each elicited dynamical state is necessarily limited to the territory of a particular neuron. There are, at least potentially, as many elicitable dynamical states as there are individual neurons. These states may be similar in neurons of the same variety, and different in different varieties. The similarity of dynamical states of excitation may be compared with the similarity or identity of functional manifestations and is the expression of an innate organization of a particular neuron variety.

The "quality" of a dynamical response, accordingly, is an inherent "specific functional property" of a neuron variety, different from that of all other neuron varieties of a given nervous center.

The quantitative response or "intensity" may largely depend upon the intensity of the initiating stimulus and upon other extraneous factors, such as the duration of the stimulus, the number of related neurons, and so forth.

If the stimulating neuron is related to several neurons belonging to a single variety, as many new individual dynamical states may be released, even though all of them are of the same kind. If the stimulated neurons belong to different varieties, there are as many new states of dynamical change that vary from one another in their "qualities."

Figuratively, a complex nerve center may be compared to an electrical apparatus composed of many minute "closed circuits" related to one another according to the principle of primary and secondary induction coils. As in the secondary coils, so in the related neurons, the current does not derive directly from the primary neuron but is merely "elicited" by it. Likewise, as in the secondary coil, the current further depends in its properties upon such factors as material, thickness of wire, number of turns, distance between the primary and secondary coils, and so forth; so in a system of neurons the secondary, tertiary, and following chains of successively elicited states of excitation depend upon the number and variety of neurons, the way in which these are synaptically related to one another, their functional condition, the kind and intensity of the original stimulus, and probably other factors as yet little appreciated.

A complex nerve center made up of numerous individual neurons belonging to many different varieties related to one another by synapses implies innumerable potential combinations of states of excitation elicited either by external stimuli or by impulses originating within the organism itself. As the excitation spreads in such a center across the synaptical contacts from neuron to neuron, its nature changes with each new neuron variety activated, its path being determined partly by the pre-existing neuron relationships and partly by the various dynamical factors. In this way different sets of neurons are put into action. Translated into the language of neurophysiology, this may be interpreted as "analysis," or the opposite, as "merging," "combination," or "fusion" of excitations, or their "intensification," "facilitation," or "decrease in intensity," which, when complete, is called "blocking," "extinguishing," or "inhibition," and the like.

References: E. Baumgardt 1952; S. J. Holmes 1944; Lenhossék 1895, 1910; Polyak 1941–48; S. Ramón y Cajal 1909–11, 1934, 1935.

SEC. 5. THE STRUCTURE OF THE NEURON SYNAPSES AND THEIR PROBABLE FUNCTION

1. General remarks concerning the factors involved in the working of the synapses.—When the dynamical equilibrium of a neuron is disturbed by an outside stimulus, this "excitation" apparently spreads over all its parts, including its farthest ramifications. The spreading of an excitation within the neuron is a process requiring short, even though measurable, time (*see* Adrian 1935, esp. chap. V). The changed dynamical state is confined to the territory or substance of the stimulated neuron, leaving adjoining, but unrelated, neurons undisturbed. Roughly, such an excitation may be considered a uniform or homogeneous process, specific for the particular neuron variety and intrinsically independent of the possible or actual states of excitation of all other neurons.

The varying size, shape, number, distribution, and chemical composition of the chromophile granules, the different number, thickness,

and arrangement of the dendrites and their "spines," and many other subtle features suggest that the parts of the same neuron are functionally not equivalent. The cytoplasmic core of the perikaryon containing the nucleus, the cortical zone of the perikaryon forming its superficial shell, the axon fiber with its collaterals, and the teledendron, all indicate different dynamical conditions, as already implied by the thesis of "dynamic polarity." Even more subtle local differences at the various points of the active surface of a neuron are indicated by the visible structures and their relationships: e.g., various terminal twigs and buttons in contrast with the main shaft of the same dendrite, and so forth. The neurofibrils again, where present, imply a specific functional differentiation.

The afore-mentioned differences in structural detail indicate dynamic diversity at the various synaptical points. The changes in the dynamical state of a neuron elicited through these points may, therefore, in considerable degree depend upon a particular surface point at which a synaptical contact is established (which in turn means that each particular dynamical state to be transmitted requires its own structural organelles and relationship with other neurons).

The synaptical contacts of the related neurons appear to be quite diversified and yet at the same time very stable. A particular neuron variety is found always to favor a particular mode of synapse with another particular neuron variety, its terminal branches touching it always at the same points, the few exceptions merely emphasizing the strictness of the rule. This evidence indicates, first, that different points of the active surface of a neuron are ultramicroscopically, and hence functionally, differently organized and, second, that homologous surface points in different individuals of the same neuron variety possess the same organization and functional affinities and hence exert the same or a similar influence upon the homologous points of the related neurons.

As an illustration of the foregoing statements, it suffices to call attention to the delicate dendritic filaments of a mop bipolar (*d*) of the primate retina which are always found adhering to the lateral sides of the cone pedicles (*b*), and never to the latter's vitreal faces; whereas a dendritic rosette or bouquet of a midget bipolar (*h*) exhibits precisely the opposite relationship (colored Figs. 177, 178, 179). Mechanical factors alone, quite obviously, would never have been able to enforce such strict structural conformity. The only recourse in explaining such subtle and precise structural differentiation is through an assumption of the working of some as yet wholly unknown forces upon which the phylogenetical evolution and ontogenetical development of all animals ultimately depend.

The surface of a neuron, accordingly, is not uniformly organized or dynamically equivalent. This is true not only of the global difference between the dendrites and the axon but also of the relative functional values of different points of each dendrite, of the surface of a perikaryon, and of a teledendron. The influences which are emitted through the various points of a teledendron or are received through different localities of the same dendrite are, accordingly, not of the same kind but vary in nature. Different dynamical states induced in different varieties of related neurons differ not only because of their varying innate properties but also because the influences through which they are elicited are received through differently organized synapses. This holds whether the source of the influence is different, in the retina, for example, whether it is represented by both the rods and the cones, or whether it is the same, e.g., represented by the cones alone.

2. THE NEURON, A COMPLEX FUNCTIONAL ORGANISM.- The structural features of the nerve cells and their functional properties indicate that each neuron is a complex microcosmic organism possessing differentiated organelles, each specialized to perform a distinct function.

In the particular instance of the retinal cones of Primates, where the synaptical relations are very clear, an accurate analysis of the situation may be made (*see* afore-mentioned colored figures). Anatomically each cone is related to every bipolar variety (*d, e, f, h*) and also to the horizontal cells (*c*). The synapses, all concentrated at the vitreal end or pedicle of the cone, homologous to a teledendron, are quite specific for each variety of related neurons. An examination of the possible spread of a dynamical disturbance elicited in the bacillary part of the

cone cell by the action of physical light and of the possible ways by which the related neurons may be influenced shows the following possibilities.

First, if the disturbance under a given set of conditions, e.g., when the stimulating light is of single wave length, is imagined as a process spreading uniformly over the entire cone cell, to two particular synapses, e.g., to the mop bipolars (*d*), all types of synapses (*c*, *d*, *e*, *f*, *h*) are exposed to the influence of that particular cone process. The selection of a particular synaptical "exit" or "egress" along which the cone process influences one or perhaps two or more related neurons must, then, depend upon the organization of the particular synapse which makes it

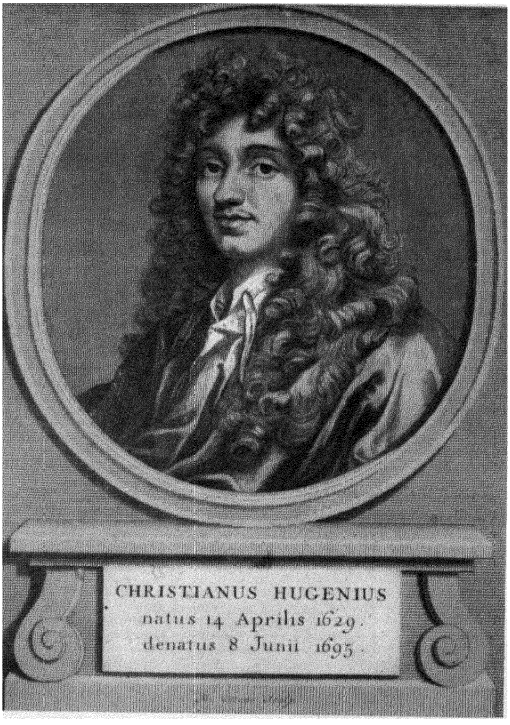

FIG. 351. Christiaan Huygens or Huyghens van Zulichem, of the Netherlands (1629-95), mathematician, physicist, and astronomer. Founder of the "wave theory of light" and discoverer of the basic laws of refraction upon which modern optics is built. Author of the *Treatise on Light* (1678-90). Improved construction of optical instruments, especially the telescope. First described construction of an artificial eye (1654) and declared the crystalline lens responsible for the accommodation of the eye for near vision. Frontispiece engraving by F. Ottens from Huygens' *Opera Varia*, v. 1, 1724.

including all parts of the pedicle and its barbules, it is necessary to postulate that it reaches all synaptical points unchanged. Unless there are within the cone itself certain preformed, discrete intraneuronal structures (so far not found), directing that particular process to only one or "passable" for that particular cone process, while the other synapses remain "closed" or "blocked."

It must further be assumed that the synaptical "permeability" or "impermeability" is also partly conditioned by the innate specific re-

sponsiveness, or lack of it, of the particular bipolar variety to a particular dynamical state of the cone, according to the principle of "functional neuron specificity." When the nature of a cone disturbance caused by the stimulus of a different wave length changes, it again spreads over the entire cone cell, potentially stimulating all synapses, but actually finding a free exit in only one or another differently organized from that synapse which was passable for the first monochromatic cone process. When the stimulus is a combination of several wave lengths acting simultaneously, a process within the cone is a combination of several simple, monochromatic excitations, or a compound process, in any case spreading over the entire cone; in this case most or all synapses may be passable for it, each "taking" from the common source that component to which it is attuned. Seen in this way, the nature of a nervous stimulus (e.g., a cone process), just like the nature of the original physical stimulus (e.g., wave length), is one factor upon which the elicited dynamic state depends, the other being the specific organization of the synapses at the discharging end of the cone cell and the specific responsiveness of the related neuron varieties.

Similar organizational principles are likely to be found in other parts of the nervous system, if due consideration is taken of the special functional requirements of particular local structures.

3. Structure of the synapse.—The precise structure of the minute surfaces through which the neurons are in contact remains unknown. There is, however, sufficient information, direct and circumstantial, to make it possible to form some idea of its organization.

The terminations of neuron expansions, by which they are functionally connected with one another, appear under the microscope in many forms. Usually they are shaped like minute swellings, buds, globules, or nodules at the very ends of the terminal twigs of teledendric ramifications or of dendrites. They vary considerably in size and shape, some being rather large, chunky, irregular varicosities with angular edges; others being minute, dainty, more or less regular, spherical nodules or buds, clearly visible only with the help of high-power Ultropak oil-immersion objectives (giving a total magnification of 1,000×, 1,500×, and more). Still others appear as delicate terminal filaments, with their very ends barely perceptibly swollen. Their numbers also vary much in different neuron varieties or parts of these, some types being sparsely strung along the thicker branches, others hanging in clusters and bunches of various shapes, frequently assembled into bouquets, rosettes, compact or loose baskets, and the like. There is practically no end to the forms which these "synaptical organelles" may assume in the complex nervous system of an advanced animal, and an even greater variation is found in certain species of animals (*see* Bodian's figures). Even so, it is obvious that the synaptical organelles so far described are only a small fraction of the existing ones.

In this exceeding variability there is, however, one stable feature: each particular neuron variety is always distinguished by synaptical organelles specific for this variety. That is, the homologous organelles found in different individuals of a particular animal species, in identical parts of the nervous system, are always of precisely the same size, shape, number, and arrangement. The deviations from this rule seem to be fewer, the higher the phylogenetical status of a species and the higher the functional requirement of a particular organ or part of an organ. In the primate retina, for example, the highest conformity is found in the central area next to the foveal depression; less, away from it, with an increasing irregularity as the distant periphery closer to the ora serrata is examined. Again, the homologous neurons in kindred animal species possess organelles of similar types, even though these are not exactly identical – for example, in Man, Chimpanzee, Macaque, Sparrow, Pike, etc.

The impression gained from extensive study of various animal species suggests an extreme diversity of the synaptical organelles as one of the foremost factors of the functional organization of the nervous system. There is an extensive field open here for future research.

The synaptical organelles, no matter whether they are smaller or larger varicosities, irregular chunks, smooth spherules, or filamentous tendrils of various shapes and sizes, are practically always found in direct contact with the surface

of a related neuron. The area of contact, however, varies much: it may be large in the voluminous varicosities and minute in delicate filaments. Sometimes a large preterminal varicosity, which otherwise may appear as a terminal swelling, sends off a minute twig or nodule which alone touches the surface of a related neuron.

The impression from such instances is that, while a direct contact, no matter how minute, is necessary, the larger preterminal swelling, even though not in direct contact, may nevertheless play a role in the transmission of influences, possibly through the surrounding liquid medium. In any case, in most synapses direct contact is found.

There is no clear evidence of the presence of a special "glue," a kind of undifferentiated intervening "synaptical membrane," a *ciment unitif* or *c. intercalaire*, formerly thought by S. Ramón y Cajal and some other investigators to separate the active surfaces of the two related neurons (on organization of protoplasmic surfaces *see* R. Chambers *et al.* 1950).

The absence of such a living or dead "membranous" sheet and the presence of a direct contact are quite favorable to the transmission of functional influences from neuron to neuron. This harmonizes well with the "neuron theory" and invalidates Boeke's claim, because of the absence of a *ciment unitif*, to dismiss the entire neuron concept or to mix it up into a self-contradictory hypothesis of a "synaptical syncytium."

The observation that an infinitesimal "dead interval" may not always block the passage of influences (Erlanger 1939) and the afore-mentioned participation of larger varicosities in a synaptical contact suggest that in certain instances an intervening space does not necessarily block the synaptical transmission.

In the overwhelming majority of the synaptical arrangements investigated, however, a direct contact of the surfaces of two living substances of the related neurons is found, with no space or extraneous structures intervening. Such points of contact are likewise bare of any neuroglial sheaths, shells, or encasings that otherwise envelop the perikarya and processes of neurons, as described elsewhere (chap. V, 8; chap. VIII, 7). At the points of synaptical contacts all obstacles are done away with, in order to facilitate free influencing of one neuron by another. This is in perfect harmony with complete insulation either by the neuroglial sheaths or by myelin of all other parts of the neurons, such as most of the perikarya and the larger dendrites and axons; without this, the neural energy would become dissipated, annulling the very purpose of an intricate structure of nervous organs.

The synaptical connections and relational arrangements in a complex nervous tissue point to an extremely delicate channeling of the nervous streams and influences, prevented by insulation where their passage would be harmful and permitted and facilitated at the synaptical points where their effect is useful and therefore desirable.

The exact place of contact where the substance of a teledendron of the influencing neuron meets the substance of a body or dendrite of another neuron that is to be influenced has been thought of as a "two-faced" or "interface membrane." Here the two neuron bodies are contiguous, closely pressed to each other, forming in many instances a true adhesion or concrescence. This locality may, in a sense, be considered a single film. The two sides of the film are biochemically and biophysically differently organized and are therefore dynamically polarized.

Something of this dissimilarity of the minute organization of the two sides of the synaptical membrane belonging to two related neurons has been well presented by Bartelmez (1915), Bartelmez & Hoerr (1933), and especially by Bodian (1937, 1939, 1940, 1942; *see also* Maximow & Bloom's *Textbook of Histology*, 3d ed.). Particularly instructive in these presentations are the colossal club endings of vestibular fibers in the fish brain, measuring up to 7 microns in diameter. In each club several distinct neurofibrils may be seen. They are sharply stained, discrete and parallel, nonanastomosing threads, each terminating with a slight swelling which ends abruptly very close to the synaptical surface of the club. The neurofibrils and their swollen terminations remain confined to the territory of their own club, that is, to their own neuron. They do not pass across the "synaptical membrane" over into the substance of the re-

lated neuron, as is claimed by the reticularist school, in spite of the intimacy of contact of the two related neurons. In the body of the related neuron to which the giant club endings adhere, the neurofibrils are much finer, have a different course, and are arranged differently. Clearly, the neurofibrils of the two related neurons represent two different, structurally discontinuous systems. The most superficial layer of the axoplasm of the club also stains somewhat differently, indicating a different chemical composition.

All these details show that, at the point of a synaptical contact, the substances of two related neurons, precisely because of their dissimilarity, may be considered to be in a state of "unstable balance." This condition may easily be upset and transformed into a "state of disequilibrium," resulting in a transmission of influence or "excitation" across the synaptical membrane to the related neuron.

FIG. 352. Thomas Young (1773–1829), founder of modern physiological optics, at the age of forty-nine. In the words of his biographer: "A physician, a linguist, an antiquary, a mathematician, scholar, and philosopher, in their most difficult and abstruse investigations, has added to almost every department of human knowledge that which will be remembered to aftertimes." Student of ocular dioptrics, discoverer of astigmatism of the eye. Made an attempt to explain accommodation of the eye for near and distant vision with the help of the changing form of the crystalline lens. Originator of the earliest consistent theory of color vision, later developed by Helmholtz into the "trichromatic theory of color perception." Discoverer of "interference of light" through which the wave theory of light, proposed by Hooke and Huygens, was advanced (against Newton's "corpuscular" or "emanation" concept). First measured the limits of the fields of view. Frontispiece from Peacock, *Life of Thomas Young*, engraved in copper by G. R. Ward, from a painting by Sir Thomas Lawrence, P.R.A.

4. The nature of the influences transmitted across the synaptical "membrane."

The precise nature of the physical and chemical processes and the identity of substances involved in the transmission of influences or "excitations" across the synaptical membrane still remain little known. According to one hypothesis, the synaptical membrane is semipermeable, permitting negative "ions" to pass over from one side to the other, while preventing similar passage to the positive "ions." Another opinion claims the secretion of a special chemical substance—acetylcholine which would act as a stimulus for the related neuron. Whatever the actual process, it resembles catalytic surface phenomena essential to all life (J. Alexander 1948), which recalls Haeckel's "monera" or first living things proposed long ago, indicative of the "surface" as a basis of life's processes in general.

Speaking figuratively, it seems that there is not so much an actual passage of a material substratum or a direct transmission of nervous excitation as rather an emanation of a certain imponderable "influence" as yet to be precisely defined in terms of microdynamics. In support of this view an example of a relationship may be cited where a bulky neuron is under the influence of a neuron of diminutive size. If in this a principle similar to that valid in physical mechanics obtained, a minute rod cell (*a*) of the retina would hardly be expected to influence a large garland ganglion (*p*) or a parasol ganglion (*m*) through the equally diminutive bipolar cells (*d, e, f*).

Such examples indicate that a trans-synaptic influencing across a chain of neurons is not directly proportional to the initial stimulus and must be determined largely by other factors. One of these factors appears to be the kind and quantity of "latent energy" stored up in the related neuron. This again depends upon the inherent factors specific for each neuron variety. The "influence" passing through a synaptical membrane, then, acts as a suitable "fuse" or "trigger" which merely "releases" this energy, transforming it into a manifest, active process, or, in the language of modern neurophysiology, it "fires" the latent charge of the neuron.

The amount and kind of the response, accordingly, is greatly determined by the responsive capacity of the influenced neuron, in addition to the various qualities of the initiating stimulation. In other words, each neuron is capable of responding only within the limits of its own innate properties or inherent capacities.

Another determining synaptical factor is the size of the contact area. It appears probable that, if all other factors are equal, the volume of the influence ultimately manifested as "intensity" in an elicited response must be greater when the synaptical contact is more extensive. The very restricted contact between a rod spherule and a delicate dendritic filament of a mop bipolar (*a & d* synapse), for example, obviously represents a "bottleneck" offering greater resistance than does a relatively wider contact between a cone pedicle and a dendritic "rosette" or "bouquet" of its related midget bipolar (*b & h* synapse).

But the extent of the actual contact alone, undoubtedly, is not the whole story, as the last-mentioned synapse shows. In this, each "bouquet" represents a group of minute terminal buttons closely packed together and attached to the vitreal face of a cone pedicle. If the scleral expansion of a midget bipolar were a solid disk, as was held by S. Ramón y Cajal, its contact area with the cone pedicle would necessarily be somewhat larger. As it actually is, the tiny spherules making up the "bouquet" are in part separated by minute spaces within which the fluid content of the tissue may freely circulate.

The advantage accruing from this, expressed in terms of microdynamics, may only be guessed. Possibly, the surface of the terminal dendritic spherules not in direct contact with the pedicle also participates in some way in the transmission of synaptical influence. Thus the active surface of the synapse would, in fact, be made greater, provided that the minute gaps between the surfaces of the related neurons were not an obstacle for the passage of trans-neuronal influences, as already discussed. The quality of the influence a midget bipolar receives from the cone via the sides of the spherules of its "bouquet" may likewise in some way differ from the quality of the same influence passing through the minute areas where the spherules are firmly attached to the pedicle.

A further important factor in shaping the quality and quantity of influence transmitted across the synapses is the locality of the con-

tacts. To use the preceding example, the vitreal face of a cone pedicle, obviously, is dynamically not equivalent with its sides. The only plausible interpretation, very clearly expressed in actual structures, is that the influence using the vitreal face of the pedicle as an exit is quite different from the influence emanating from the lateral sides.

Another similar instance is the synapse between the vitreal expansion of a midget bipolar and the basket-shaped dendritic termination of a midget ganglion (*h & s* synapse). This coupling represents dynamically quite a different route from the single-point contact between a teledendric twig of an *e* or *f* bipolar and the main dendritic stem of the same midget ganglion (*e & s* or *f & s* synapses). Similar contrasts among the synaptical arrangements are found everywhere and are the essence of the organization of the nervous system.

In conclusion, the kind and amount of response elicited in a related neuron depend upon several factors: the kind, intensity, duration, order of application, and so forth, of the initiating stimulus; the kind and amount of the latent charge of the influenced neuron; the condition of the influenced neuron, e.g., whether or not it was subjected to a previous stimulation; and last, but not least, the particular synaptical arrangement. (*Cf.* Lenhossék 1895, p. 81; S. Ramón y Cajal 1909–11.)

5. FUNCTIONAL POLARITY OF THE SYNAPSE.—According to Cajal's classical neuron theory, the body or perikaryon and its protoplasmic expansions or dendrites are functionally receptive parts of a neuron; the axis cylinder, with its collateral branches and terminal arborization or teledendron, is the emissive part. A neuron is a dynamically polarized functional unit capable of being influenced at one end and able to transmit its own influence at the other end. A neuron remains inert or refractory to the influences working in the opposite direction.

From physiological experiments it appears that the cause of this functional polarity is not a property of the cytoplasm of a perikaryon or of the substance of dendrites or of an axon but is conditioned by some ultramicroscopic organization of the synapses. It is the points of synaptical juncture that regulate the unidirectional spreading of the dynamical disturbance called "excitation" from the teledendron of the influencing neuron to the dendrites and body of the influenced neuron.

The action of the synapses may be likened to the working of the valves in a system of pipes, permitting the flow in one direction and preventing it in another, the pipes themselves otherwise being passable for the circulating medium in any direction.

According to this view, the polarity of the synapses is the basis of functional neuron polarity and is thus one of the principal factors contributing to the complex organization of the nervous system. It is almost unnecessary to mention that the true causes of the functional polarity of a synapse, which could be expressed in terms of the basic sciences of microphysics, biochemistry, and electrophysiology, remain as yet unknown or are speculative.

An attentive study of the minute relationships of neurons, especially during their period of development, indicates that originally any point of the surface of a young neuron may possess potentialities for influencing both ways, out of which, by a process of "specialization," the final irreversible forms of fully differentiated one-way synapses evolve. The structural-functional differentiation and specialization, in turn, exert a profound influence upon the entire form and function of the neuron. From the young neuroblast cells in the early period of embryonic growth, which all appear similar in size and shape and are endowed with about equal universal potentialities, they produce an infinity of forms and relationships required by an infinity of special functions. The mature neurons of advanced animals, such as the Vertebrates, Insects, and higher Cephalopods, appear in this interpretation as the final product of phylogenetic and ontogenetic differentiation, under the influence of molding forces impossible as yet to define in terms of biochemistry and biophysics.

6. STABILITY OR PLASTICITY OF THE SYNAPSES.—The question of how stable or permanent the synaptical relationships are may be answered only conditionally. The fact that in the highly differentiated tissue of an advanced animal species, such as the primate retina or striate

area, the various neurons are always found synaptically joined in precisely the same way, even though our technique of investigation may vary in detail, suggests practically a firm, permanent condition. The forces or dynamical factors which underlie the functional plasticity of such tissues are of an order beyond the resolving capacity of the ordinary optical apparatus.

The stable neuron relationships of a complex nervous tissue are a final result of the conditions obtaining during embryonic growth. This presupposes a great deal of plasticity. Without freedom of the embryonic neuroblasts to move about, to send expansions in various directions, and to retract them, growth of the gray substance would not be possible. This view is uniformly supported by the histological evidence with fixed and stained tissue and by the observations of the living, growing nerves in tissue cultures and in the animal body furnished by W. His, S. Ramón y Cajal, Harrison, and Speidel.

Whether anything of the original universal plasticity, comparable to the ameboid movement, is preserved in the mature nervous tissue, as had been suggested by Rabl-Rückhardt (1890) and by M. Duval (1895, 1900) and was contemplated by S. Ramón y Cajal is a matter for further research. In the retina of Lower Vertebrates, especially Fishes, the presence of the "photomechanical response," discovered in the pigment epithelium by Boll (1877) and by Kühne (1877) and in the photoreceptor cells by Engelmann (1885), Van Genderen Stort (1887), and Lederer (1908), is a well-established fact (*see* Garten 1907; Arey 1915, 1916, 1919, 1928; Detwiler 1943). It is possible, therefore, that in the mature tissue in certain localities of the nervous system a modicum of the original plastic conditions remains. This question must be left

SEC. 6. THE NEURON RELATIONSHIPS IN GENERAL

1. THE SYNAPTICAL GROUPING OF THE NEURONS.—The relative functional independence and functional specificity and the dynamic polarity of the nerve cells, according to the neuron theory, are essential for the organization of a complex nervous system and its working. These properties enable the neurons to associate in functional sets, synaptically interconnected among themselves and with other sets, in exceedingly varied systems. The study of the group relationships of neurons makes it possible to understand the functional significance of the elaborate structure of the various nervous organs, the functional role of the many neuron varieties, the significance of their varied relationships, the purpose of the agglomeration of nerve cells, and the very sense and purpose of the complex organization of the nerve centers in general.

In the case of a simple nervous system, e.g., of the Coelenterates, and probably in some reflex arcs of the Vertebrates, the pathway along which the nervous excitation is propagated from the peripheral receptors across the centers to the terminal effectors, such as the muscles or glands, can easily be outlined and the function of the whole mechanism understood: an immediate motor adjustment of the individual organism or a part of it to a particular biological situation through central integration (*see* Fig. 223 representing the pupillary reflex arc).

The problem becomes much more difficult in case of a complex peripheral receptor, such as the retina or cochlea, connected with an even more complex central organ, the brain. Here the tracing of an excitation is, for ordinary methods, soon lost in the labyrinth of structures. In order to unravel the functional significance of the structure of these organs, the first step to be made, obviously, is to examine the synaptical relationships of the peripheral receptors, the photoreceptors, or, in the cochlea, the hair cells.

2. SYNAPTICAL RELATIONSHIPS OF A PERIPHERAL PHOTORECEPTOR.—If, from a complex texture of the human or simian retina a cone cell is singled out, it becomes apparent that each cone is synaptically related to all three or four bipolar varieties (*b* & *d* and *e*, *f*, *h* synapses; cf. colored Fig. 179). If we further disregard the possibility that each cone may be related to several of each diffuse bipolar variety, this gives three or four distinct channels into which the excitation from a single cone may be diverted: *b* & *d*, *b* & *e*, *b* & *f*, *b* & *h* relationships.

Since each bipolar variety, according to the concept of the "functional specificity of the neuron," is capable of responding dynamically only in its own specific way, a cone excitation may in this way elicit three or four distinct dynamic reactions on the bipolar level. When, further, the connections of the same bipolars to the ganglion cells are examined, it is found that each midget ganglion is related to every bipolar variety, duplicating their cone relationships: *s* & *d*, *s* & *e*, *s* & *f*, *s* & *h* synapses. Here, then, the effect is reversed; the three or four distinct bipolar channels merge into a single midget

ganglion cell channel (if other relationships are for the moment disregarded).

These are the actual anatomical facts. The puzzling question is: Why should a dynamical process, which on the cone level appears to be single, require on the bipolar level a separation into three or four distinct dynamical states, seemingly for no other purpose than to merge again into a single dynamical state on the ganglion level? This situation seems to make little sense. Neither on logical grounds nor considering a manifest tendency of the organism to economize with matter, space, and time is such useless luxury probable. Obviously, other factors qualifying the apparent situation are involved.

3. FUNCTIONAL SIGNIFICANCE OF THE INTERMEDIARY NEURONS.—Of the probable factors requiring an insertion of a triple or quadruple neuronal link between the cone and the midget ganglion, the first to be considered is the cone excitation. Under the action of light of different wave lengths the elicited cone reaction may vary. It is necessary to postulate this, irrespective of whether the assumption is made of several distinct photosensitive substances or of a single one; in the latter case the various cone excitations may be regarded as shadings of a single photochemical process. (The view of the identical responsiveness of the cones is based upon a conviction that all cones in any one particular restricted retinal area are of the same variety and possess identical function; *see* chap. V, 3 [3], 9 [5].)

Since the excitations of the cone are not transmitted directly to the brain, it is obvious that in a raw, unprocessed state they are not fit to evoke subjective color sensations according to different wave lengths of stimulating light. For this, co-operation of the bipolars is evidently necessary. It stands to reason that the interpolation of several varieties of bipolars between the cone and the midget ganglion imparts to the excitation certain attributes not possessed by the original cone process or processes. The "passage" through the bipolars must, in some way, make the cone process different. This transformation cannot possibly consist in a mere increase of intensity, since this could be as well achieved by an increase in the number of a single bipolar variety. The specific attributes added to the cone excitations as they "pass" through the bipolar links of the chain of retinal neurons may be described as "qualities."

According to the concept of "functional neuron specificity," no cone excitation, in fact, is directly transmitted to the bipolars. What takes place is an eliciting or evoking of as many various excitations as there are varieties of bipolars. These bipolar states, even though in their quality, intensity, and duration they are causally strictly commensurate with the particular cone processes, are nevertheless distinct dynamical events dependent upon their inherent properties. Each bipolar, while reacting to a particular cone excitation, is capable of doing so only in the particular way prescribed by the limits of its own innate property. Each bipolar process, even though elicited by the cone, is an individual dynamical event. Briefly, each bipolar variety most closely specifically attuned to a particular dynamical state of the cone may respond to that particular stimulus either alone or with a minimum response of the other associated bipolar varieties.

The bipolar excitation, when "transmitted" to its related midget ganglion, passes to the brain as a disturbance of a particular kind. The brain messages originating in a single cone vary, then, according to which of its related bipolars was activated. If it was only one, the message has the character of that particular bipolar. In case of a combination of several or all bipolars, the message is a result of the activation of all bipolars.

Dynamical states elicited in the related midget ganglion vary among themselves and are distinct also from the cone processes by which they have been originated. Even when all bipolars have been simultaneously activated, the compound excitation in the related midget ganglion cell is a dynamical process different from the initiating cone process.

4. MODIFICATION OF THE NERVOUS ACTIVITY BY THE INTERMEDIARY NEURONAL LINKS.—The preceding example shows how an excitation deriving from a common source (cone) elicits one or several distinct dynamical states in the intermediate link (bipolars), which, in turn, elicit an

excitatory reaction in the final common pathway (midget ganglion).

Within the ganglion link, again, each state is a distinct dynamical event commensurate in quality or specificity, intensity, and duration with the particular bipolar excitation which initiated it, being either simple or compound, depending on whether it derived singly from *d*, *e*, *f*, *h*, or any combination of these. Altogether, theoretically, a midget ganglion is capable of responding in either six or ten different modes (depending on whether three or four bipolar varieties are accepted), viz.: *d*, *e*, *h*, *de*, *dh*, *eh*, or *d*, *e*, *f*, *h*, *de*, *df*, *dh*, *ef*, *eh*, *fh*.

Here, then, several discrete dynamical processes may follow at different times along the same axon channel to the brain, either as simple or as compound excitations, a particular excita-

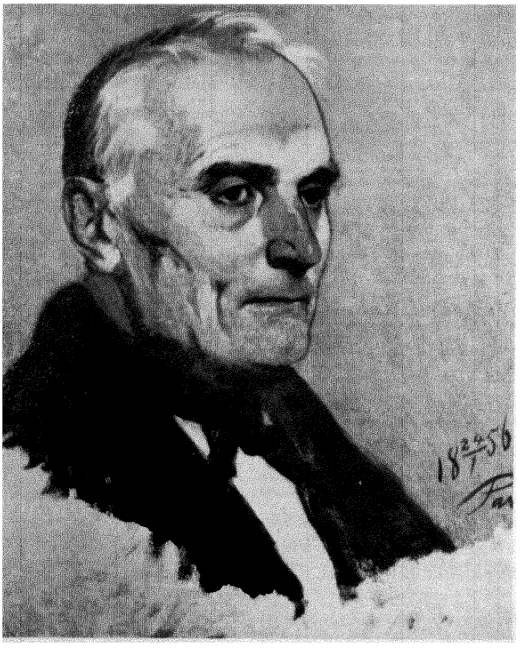

FIG. 354.—Johannes Evangelista Purkinje, or Yan E. Purkyně (1787–1869). Professor of physiology and pathology at Breslau (now Wrocław), then Prussian Silesia, and at Prague, Bohemia. One of the foremost microscopists and physiologists of his time. The year 1832, when he acquired a new large microscope of Plössl, may be considered the beginning of the era of modern microscopy. Discovered the nerve cells of the brain and of the cerebellum, the latter known as "Purkinje cells," and correctly interpreted them (1837). He first described the principal expansion of the nerve cells, the "axis of the cylinder," now called "axis cylinder" or nerve fiber, and its medullary or myelin sheath (1839). Described "Purkinje's fibers," constituents of the conducting His-Tawara's bundle, or cardionector of the heart. Pioneer investigator in the physiology of vision. Discovered "Purkinje's figure" or shadows of the retinal blood vessels, a subjective phenomenon observable entoptically and first correctly interpreted by H. Müller (1854) (*see* Fig. 46). Determined the size of the field of view and the area of distinct central vision. Described the character of peripheral vision, poor in space and color perception but highly sensitive for movements. Discovered so-called "Purkinje-Sanson mirror images" of the eye, one reflected by the anterior surface of the cornea, two by the surfaces of the lens. Described "Purkinje's afterimage" and "Purkinje's phenomenon," the latter consisting of maximum brightness shifting in dark-adapted eye toward the short-wave end of the visible spectrum, out of which grew the modern concept of a duplex organization of the visual apparatus, photopic and scotopic. Sketch from a portrait painting by Jaroslav Čermák, 1856, published in O. V. Hykeš, *Přírodovědecké Pracé J. E. P.*, Praha, 1928. For biography *see* Heidenhain in *Allgemeine Deutsche Biographie;* Purkinje's *Sebrane Spisy* (Collected Papers), Prague, 1928; Haymaker & Baer, *The Founders of Neurology*, 1953.

tion at a particular time. (Concretely, this may be accomplished by "frequency modulation," as suggested by Kohlrausch 1931, p. 1491.) In each case a dynamical change in the midget ganglion and in its axonal fiber terminating in the brain is somewhat different, even though merely a shading of basically the same process. A midget ganglion serves, accordingly, as a common pathway for excitations which, on the bipolar level, use different channels.

For reasons to be discussed later, the midget ganglions must be regarded as the most important neurons on the ganglion level both for color vision and for visual acuity.

The form or quality of excitation elicited in a midget ganglion as a result of an initial cone stimulation is a very different dynamical event from what it would be if there were no bipolars of different kinds acting as mediators. This excitation is modified, perhaps amplified, by additional or increased attributes or "qualities" and thus becomes more diverse in comparison with the original crude cone excitation. Possibly the differences in various shadings of the cone process initiated by light of many different wave lengths become more distinct through the action of bipolars, emphasized, differentiated, contrasting with one another more readily, than the slight nuances of a cone process alone would be. The photogenic messages carried to the brain thereby become more specific, more precise, and more diverse—in every way richer dynamical material to be utilized by the brain.

5. THE NEURONS AS FACTORS IN THE PHYLOGENETICAL PERFECTION OF NERVOUS CENTERS. —From the preceding interpretation of certain neuron combinations an important fact becomes manifest: whenever one or more links are interpolated in a chain of neurons, the structural complexity of the chain increases, and so does its dynamical diversity. Each additional neuron variety means an added functional capacity of that set of neurons. Extended to the whole nervous system, this principle explains a tendency to create additional forms of neurons whenever a new functional demand appears. A functionally more diversified nervous tissue requires not only more neurons but also a greater variety of neuronal forms. (A similar idea had been expressed by Lenhossék 1895, p. 81, and by M. Heidenhain 1911, pp. 826, 927; *see also* Hering 1898 and Nissl 1898 on "functional neuron specificity.")

Considered from another point of view, the tendency of the nervous system, especially of the brain, to increase in bulk, manifested in the entire animal realm from early phylogenetical stages on toward more advanced forms, becomes understandable. Everywhere the nervous centers show not only a progressive differentiation of morphological details but also an augmentation of the number of cellular units or neurons. This urge is obvious, even though it works contrary to another tendency, that to economize in substance, space, and time. The cause is the narrow limits imposed by "functional neuron specificity."

The more specialized a nerve cell, the better it can perform its own specific task; conversely, the same cell is less able to substitute for other functions outside its own range. A more highly organized nerve center, precisely because it is made up of specialized neurons, requires many more of them to satisfy its need for greater functional diversity. A more elaborate organization of nervous tissue, composed of numerous functional units, where each additional nerve cell, each newly differentiated neuron, and each new synaptical relationship mean an increased combining ability, is the only way to make its function more varied and thus to satisfy the more varied conditions of advanced animal life. (*Cf.* S. Ramón y Cajal 1909–11, v. 1, p. 12.)

SEC. 7. THE ELEMENTAL NEURONAL ASSOCIATIONS AND THEIR PROBABLE FUNCTION

1. GENERAL REMARKS.—In the entire nervous system there are probably only a few neurons, if any, which are synaptically connected with only one neuron. Such associations would add little to dynamical influencing and would be senseless, since they would defeat the pur-

pose—integration—for which the nervous system appears to have been created.

In almost all cases which have been well investigated, each neuron is in contact with several other neurons and sometimes with many. A good example is the large motor nerve cells of the anterior gray columns of the spinal cord. Here one finds attached to their perikarya and dendrites numerous terminal nodules of teledendrons of many efferent neurons of a higher order located in the brain stem and cerebral cortex, as well as nodules of afferent posterior spinal root fibers and of integrating neurons of the spinal cord itself. (*Cf.* S. Ramón y Cajal 1909, Figs. 18 and 112; and especially D. Bodian 1937, 1940, 1942.)

The spinal motor cells, accordingly, collect nervous impulses of several kinds into one common channel. In this common outlet, termed "final common path" by Sherrington (1906), they meet several kinds of "excitations," varying in many respects. The resulting impulse is finally delivered by way of the anterior spinal roots to the peripheral organs of execution, such as the muscles and glands.

In an afferent system, such as the visual, the same principle of neuron coupling is found, even though applied in precisely the reverse order: one, two, or a few, of the peripheral receptors of the retina, for example, may represent a "common origin" or "common source" of the impulse. Here begins a synaptical concatenation of many increasingly complex neuronal links, which finally terminates in the cerebral cortex. The organization of such a system indicates that its function in the peripheral segment is chiefly analytical. That is, it splits an originally common peripheral excitation into a number of partial excitations. These, represented in the retina and in the intermediate segment by the lateral geniculate nucleus, are recombined and delivered to the "final integrator," the cerebral cortex, for further and final processing.

The preceding examples illustrate two principal functions of the synaptical relationships: one, which in a general way may be considered "combination," "fusion," or "merging," and the other, which may be considered "subdivision," "splitting," or "analysis" of nervous currents of excitation.

The organization of the advanced nervous centers goes beyond this, however. It may link together two or more sets of neurons into a compound mechanism. Neurons variously intimately related with one or more types of other neurons, serving now in one role, now in another, depending on the variation of dynamical conditions, illustrate such a mechanism (colored Fig. 179).

In the primate retina, for example, the cones are related to three or four distinct varieties of bipolars (*b* & *d*, *b* & *e*, *b* & *f*, *b* & *h* relationships) and to the horizontal cells (*b* & *c* relationship). The rods are also related to the same bipolars, with the exception of the midget bipolar (*a* & *d*, *a* & *e*, *a* & *f* relationships). Each bipolar variety, in turn, is related to each variety of ganglion cells, although in a somewhat different way. All bipolar varieties are used by the excitations arising both in the cones and in the rods, except the midget bipolar (*h*), which serves only the cones.

From this anatomical arrangement it is legitimate to conclude that both cone and rod excitations eventually pass to the brain by way of identical ganglion cells. However, since the neuron chain transmitting cone excitations is differently organized from that transmitting rod impulses, the effect in the central nervous organ must be different in each case.

The preceding example, incidentally, illustrates the economy of space and substance by which the same neurons are used to accomplish different purposes. It also shows how the central result in a complex system of neurons depends both on the kind of initial stimulation and on the synaptical pattern.

In the following are given a few samples of neuron relationships, with their tentative functional interpretation. Undoubtedly, many more such relationships will be found in different parts of the nervous organs.

2. Analytical neuron mechanism.—A classical example of a nervous structure by means of which an originally single excitatory state is, as it were, divided into several different forms of excitation is the relationship between cones (*b*) and bipolars (*d*, *e*, *f*, *h*).

Each cone in the human and simian retina is synaptically related to the bipolar cells belonging to two, three, or four distinct varieties, as

described in chapter V, 4, 11. (The number depends on whether *e* and *f* types are considered as one or two varieties; in the rodless area of the central fovea, *e*, *f*, and *h* varieties alone seem to be present; *cf.* colored Fig. 177.) The photochemical process elicited in the cone by the action of physical light probably varies according to the wave length of the stimulus. Even so, since each cone in the central area is equally

FIG. 355.—Johannes Peter Müller (1801–58), professor of anatomy and physiology at Bonn and Berlin, Prussia. One of the foremost biologists and physiologists of his time. Originator of the concept of "specific energy of nerves" and of the "theory of identical points" of two eyes in single binocular vision. An assiduous student of visual phenomena and of vision in general. (For biography *see* B. Chance 1944; U. Ebbecke 1951.)

responsive to all wave lengths, a cone must be looked upon as a common source of excitation for all bipolar varieties. From this common source each bipolar variety "takes" only that share of excitation to which it is specifically responsive by virtue of its innate "functional specificity" and its particular synaptical contact with the cone pedicle, as previously discussed (*see* secs. 3, 5, 6, this chapter, and par. 6, this section).

The states of excitation elicited in several bipolar varieties must, accordingly, differ in their intrinsic properties or qualities. The eliciting of these secondary excitations may take place either at different times in each bipolar variety or simultaneously in combinations of two or more varieties at a time, or in all, depending upon the character of cone excitation, the condition of bipolars, and probably other factors.

In this or a similar way a single or global

original dynamical disturbance may be subdivided or analyzed by the cone-bipolar mechanism into several component excitations, to be further used by other groups of neurons. The relationship of the horizontal cells with the cones, not being in the path along which the excitations pass to the brain, may rather be labeled as a "diversion" used for a local purpose (*see* sec. 8 [5], this chapter).

3. COMMON PATHWAY MECHANISM. An example of a neuronal relationship serving a purpose precisely opposite to analysis is that of the rods (*a*) and cones (*b*) and the mop variety of bipolar (*d*); (*see* left sketch in Fig. 347). Throughout the primate retina the mop bipolar is related both to the cone pedicles and to rod spherules, each bipolar cell having synapses with a group of both photoreceptors (the minute central area of the fovea, where neither rods nor mop bipolars have been found, is an exception; *see* colored Fig. 177). The mop bipolar, accordingly, serves as a common passage for the excitations originating both in the rods and in the cones. It is therefore appropriate to call it the "common path," as the motor cell of the spinal cord is also called, for the same reason. It is a matter for further consideration how the working of this common pathway should be interpreted in detail.

First, the two different excitations originating in the rods and cones may elicit in the mop bipolar a dynamical change equivalent to a genuine "fusion" or a compound excitation embodying features of both ("spatial fusion"); the other and more likely possibility is that certain excitations arising under special conditions of stimulation both in the rods and in the cones are identical or nearly so, eliciting an identical response in the mop bipolar attuned to them. This may occur either simultaneously or at different times; in the latter case the mop bipolar serves only one kind of photoreceptor.

Such an interpretation would be in accord with the concept of "functional neuron specificity." It may, further, be interpreted in favor of an "identity" of subjective visual experiences caused by certain cone excitations and by those having origin in the rods, e.g., sensation of "white" or "gray."

The synaptical relationships of other diffuse bipolars (*e*, *f*) are similar, even though slightly different, and may be interpreted in a similar way, as slight shadings of the same process. This contrasts with the midget bipolar (*h*), which is related to the cones alone and hence is functionally much more specialized.

4. THE MECHANISM OF SUMMATION.—A combination of neurons by means of which impulses of the same or different kinds may be added and the resulting excitation concentrated or intensified is exemplified in the primate retina by the rod and mop bipolar synapses alone, or together with those of the cones (right and left sketches in Fig. 177, and left sketch in Fig. 347). Here each mop bipolar (*d*) is in contact with a compact group of rods (*a*) and cones (*b*), the groups being larger in the extra-areal periphery. It is legitimate to assume that if more rods are activated, the intensity of excitation elicited in the related bipolar becomes greater, the maximum being attained when the entire related rod group is stimulated: "spatial summation." Such a rod group may be stimulated either simultaneously by the application of a beam of light to the entire group: a "simultaneous spatial summation"; or the individual rods of the group may be stimulated in succession: a "successive spatial summation." In both instances all rods discharge upon the same mop bipolar, in the first in a "volley," in the second as "single shots." What difference in physiological effect this may make and how the phenomenon of summation could be reconciled with the refractory phase or period or state of unexcitability caused in the bipolar cell after its activation remain matters for further consideration. The same principle applies also to the cones, either alone (middle sketch) or in combination with the rods (lateral sketches, Fig. 177).

This anatomical summative mechanism contrasts with the "physiological or temporal summation," as, for example, when the same rods discharge upon the same bipolar cell but do so at different times in short succession. In the instance of different rods related to the same bipolar discharging in succession, the spatial and temporal summations really are combined, an added advantage from the latter being the bringing into play of fresh rods, whose charge, accumulated during a period of rest, is unexpended.

In this situation, while the first few activated rods alone may be unable, with their weak, subliminal impulses, to cause the discharge of a bipolar, they may "sensitize" it or "condition" it, in the sense of a decrease of its threshold, and thus "facilitate" its response to the influences originating in other related rods. In the same way a bipolar response, already taking place but of low intensity, may be intensified by the discharges from the additional related rods.

In the system of cones the retinal periphery may be cited as an example of a familiar mechanism of summation where several cones are synaptically connected to a simple polysynaptic type of midget bipolar (right sketch, Fig. 177).

The principle of anatomical spatial summation may be applied on a larger scale, in successive tiers or links of a neuron chain making up a system. In the initial portion of the vertebrate visual system, not only does each bipolar of the diffuse varieties (*d*, *e*, *f*) assemble into a common path influences arising from a group of rods and cones, or from the cones alone, but again on the ganglion level each cell unites influences from several—in the extra-areal periphery of the retina from hundreds of bipolars into larger functional units. The size of these units varies, the smallest being that belonging to the midget ganglions (*s*) of the central area, the largest to the diffuse ganglion varieties (*m*, *n*, *o*, *p*, *r*) of the extra-areal periphery (Figs. 178, 179). Possibly such units may also vary among themselves in density, depending on the number of bipolars related to a given ganglion variety per surface area of the retina.

The probable effect of the "summative synaptical organization" is the increased intensity of influences passing through it.

5. THE MECHANISM OF AVALANCHE. A mechanism opposite to summation described by S. Ramón y Cajal (1909 11, v. 1, p. 137) in the afferent systems, under the label "avalanche of conduction," consists of terminations of each individual axon fiber around a group of nerve cells. An example of this is the teledendrons of optic nerve fibers in the lateral geniculate nucleus (*see* Fig. 220). As interpreted by Cajal, the functional effect of this arrangement is in the increase in intensity of stimulation as each successive link in a system made up of an increasing number of neurons is activated. Similar arrangements had been described by Tello (1904) (*see* Fig. 216) and by O'Leary (1940). The terminations of the afferent visual fibers in the striate cortex are a good example of a mechanism of avalanche. More information on this subject is necessary (*see* chap. VIII, 7).

6. THE MECHANISMS OF FACILITATION OR INHIBITION. A structural arrangement whose function seems to be an interference with the synapses between other neurons is exemplified by the horizontal cells of the retina (*c*) and by the centrifugal bipolars (*i*) (*see* colored Fig. 179).

The synapses between the compact, short dendrites of the horizontal cells and the cone pedicles are obviously contacts through which the former are influenced by the latter. Termination of the axonal ramifications of the horizontals around the vitreal ends of a distant group of cones and rods that undoubtedly are emissive organelles of the photoreceptors, on the other hand, seems contrary to "functional polarity." The cone pedicles and rod spherules, according to the neuron theory, should be refractory to the influences arriving from other neurons. Yet the undoubted anatomical relationship mentioned demands an acceptance of some kind of influencing, most likely of the photoreceptor-bipolar relationship.

It is possible that through the action of horizontal cells the normal passage of rod and cone influences over to the bipolars is in some way interfered with, e.g., by a suppression of one or the other "quality" or by a change in intensity in the sense of an increased threshold, which, at its maximum, may amount to complete "inhibition" or "blocking." This effect may be attained, e.g., by the secretion of a chemical substance or by a counterionization, which, depending upon its concentration or composition, would work in the sense of a "selection," a "delay," or a "decrease in intensity," or even as a total "inhibition."

Another possibility is the blocking or inhibiting of the rods in daylight vision through the cone influences disseminated via the horizontal neurons, making the bipolars refractory to the rod stimuli. The opposite situation would probably not arise in scotopic conditions, owing to

the high threshold of cones. There is yet another possibility to be considered: inhibition of regeneration of the visual purple in daylight conditions under the cone influence, and a similar inhibition of the substances in the cones not stimulated by light.

The centrifugal bipolar cells (*i*, in same figures) require a somewhat different interpretation. Their axon-like fibers teminate around the pedicles of a small group of cones located in the same territory of the retina. These alone, accordingly, are influenced either by excitations arising from a somewhat larger area via the ordinary centripetal bipolars (*d*, *e*, *f*, *h*) synapsing with dendrite-like expansions of *i*-bipolars, or possibly by the central influences arriving along the exogenous fibers (*l*). The physiological effect of this arrangement may be a lowering of the threshold or "facilitation" of the passage of influences from the related cones over to the bipolars, or vice versa.

7. THE TOPOGRAPHICAL RELATIONS OF THE NEURONS. Whereas the mechanisms dealt with

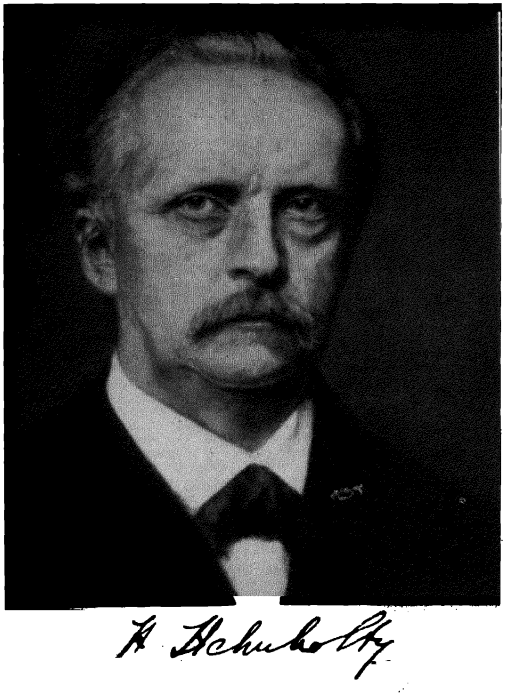

FIG. 356. Hermann Ludwig Ferdinand Helmholtz (1821–94), professor of physiology at Königsberg (now Kaliningrad), of anatomy and physiology at Bonn, of physiology at Heidelberg, and of physics at Berlin. Director of the Physico-technical Institute at Charlottenburg, Germany. One of the most encyclopedic and fertile minds in the field of science. Discovered the ophthalmoscope or "eye mirror," an instrument on which modern ophthalmology is built (Fig. 102). Developed, from Thomas Young's suggestion, the "trichromatic theory," still the most successful interpretation of color vision. Originator of the "resonance theory of hearing," again the most plausible explanation of the basic process underlying the auditory function. Classical investigator of physiological optics and of physics in general. Author of the *Treatise on Physiological Optics* and *On the Sensation of Tone as a Physiological Basis for the Theory of Music*. Portrait by F. von Lenbach, from Oswald's "Klassiker der exakten Wissenschaften," Nos. 1, 79, 80, 124. For biography *see* McKendrick 1899; Königsberger 1902 3; E. W. Melson 1938; Haymaker & Baer 1953; W. Schwagmeyer 1952. (*See also* Fig. 101.)

in the preceding paragraphs are concerned either with preservation or with change or modification of the qualities of excitations or with preservation or change of their intensity in the sense of an increase or decrease or inhibition of excitations, another widespread organizational principle obtains in the nervous organs whose obvious purpose is the preservation or maintenance of orderly topographical relations. Nowhere is this so clearly expressed as in the visual system, as may be expected in a mechanism serving an exquisitely spatial sense like sight. Here but a few salient facts may be recorded from a more extensive presentation given in chapters V, VI, VII, and VIII.

A very orderly arrangement, probably the most geometrical in the organism, is found in the bacillary layer of the retina (*see* Figs. 151 60). A similar orderly topography is maintained to the same or a lesser degree, link by link, along the entire chain of neurons in the visual system, including the striate area of the cortex. The functional significance of this is fairly evident: the preservation of topographical relations of synapses in the striate area nearly corresponding to those present in the photoreceptive bacillary layer of the eye. Whatever its detailed physiological motivation, the necessity of preserving such strict topography must be compelling.

A similar arrangement of neurons and their synapses is found in many other pathways and fiber systems: in the posterior gray columns of the spinal cord; in the inferior, and less so in the superior, olives; in the superior colliculi of the midbrain; in the fiber systems leading to and from the cerebral and cerebellar cortex, including the thalamic connections; and elsewhere.

Interpreted in a very general way, the principle of the topographical relations of the neurons indicates an inability of the nervous system –a mechanism made up of isolated conductors to establish numerous contacts between its many divisions in any other way except upon factual initial and terminal contacts of its conducting structures, the nerve fibers. This automatically relegates to secondary importance in comparison with the principal factor –the preformed nervous structures– all other organizational factors, particularly the purely dynamical ones, that could bring parts of the nervous system into mutual relationship. Further, especially, embryological investigation is required to interpret the topography in the nervous system in terms of the basic functions.

SEC. 8. THE FUNCTIONAL GROUPING OF NEURONS IN THE RETINA

1. INTRODUCTORY REMARK.—In the preceding sections an attempt has been made to illustrate by means of a few samples the principal types of associations of neurons so far found in the nervous system and to indicate their probable function. It now remains to be seen whether the present knowledge of the minute structure of the visual system presented in chapters V, VI, and VIII allows us to determine into what physiological groups its constituent neurons are associated and what functions these groups or systems are most likely to perform in the complex process of vision. It is, however, necessary to admit that only a beginning can be made, the solution of this problem remaining the task of future research.

We may logically begin, first, with the photoreceptors of the retina and follow the paths along which the various excitations generated in the photoreceptors are transmitted to the brain. Thereafter, an attempt may be made to determine which of the particular numerous visual functions and phenomena may best be correlated with one or another of the several sets of neurons. This attempt, because of our fragmentary information, must necessarily remain unfinished until the neurons composing the entire visual system are completely revealed.

2. THE SYSTEMS OF RETINAL NEURONS.—The neurons making up the nervous parenchyma of the retinal membrane may be roughly subdivided into two systems (*see* colored Figs. 177,

178, 179). One is the *receptor-conductor system*, represented by the rods (*a*) and cones (*b*), centripetal bipolars (*d, e, f, h*), and ganglion cells (*m, n, o, p, s*); its principal function is response to physical light stimulation and the transmission to the brain of excitations thus generated. The other is the *integrator system*, composed of the horizontal cells (*c*) and probably also of the various amacrine cells (*k, l*), including the centrifugal bipolars (*i*); its main role is to interconnect neurons of the first division and, by a mutual dynamical adjustment, to make a functional organ of the retina. Both divisions are synaptically intimately interconnected, indicating their continuous functional interdependence.

The receptor-conductor system may be further subdivided on the basis of photoreceptors into a *rod system* and a *cone system*. From the last-mentioned, a *pure or private cone system* may be separated out by elimination of those elements that are common to both categories of photoreceptors.

3. THE ROD SYSTEM OF NEURONS. — This system may be singled out of the complex retinal tissue pattern by following the synapses, beginning with the rods and along the subsequent links to where the excitations are passed to the brain.

The rods are related to all diffuse varieties of centripetal bipolars (*a* & *d, e, f* relationships), and through these to all ganglion cell varieties (*d, e, f* & *m, n, o, p, r, s* relationships). The midget bipolars (*h*) and, of course, the cones (*b*) are the only two units of the conductor division of neurons which are excluded from the rod system. Also, not all brush (*e*) and flat-top (*f*) bipolars, but only some, are a part of the rod system, the mop bipolar (*d*) apparently being the principal link on the bipolar level. Of the integrator group of neurons, the horizontal cells (*c*) have only emissive synapses with the rods, while the various amacrines (*k, l*) and the centrifugal bipolar (*i*) are related to the rod system only by similar efferent or emissive synapses of the diffuse centripetal bipolars.

The arrangement of the receptor and conductor units in the rod system is topical or spatial, with a fair preservation of topographical relations present in the bacillary rod layer. However, because of the relatively large dendritic expansions of diffuse bipolars, their reciprocal overlapping, the synapsing of each bipolar with a group of rods, and the synapsing of each of the diffuse ganglion varieties with many of the diffuse bipolars, the physiological units of the rod system are larger, its "grain" less fine, than in the cone system.

The course of currents of excitation generated in the rods, as reconstructed from their synaptical relationships, is, first, to the diffuse bipolars and from these to all ganglion cell varieties and, via the latter's axons, to the brain. The midget bipolars and the horizontal cells (and hence the cones) remain unaffected. The "local signatures" in the rod system are relatively crude and are not sharply separated from one another. The physiological units, because of a decrease in the number of rod cells synapsing with each bipolar from the central point toward the periphery of a given area, must be expected to show a functional gradient from the zone of the lowest threshold toward the zone where the threshold is highest. The area or zone of the lowest rod threshold will likely depend also on other than purely synaptical factors.

Since all rods are synaptically related to the mop bipolars and only some to the brush and flat-top bipolars, the first may be considered as most nearly the true rod bipolars, the latter two varieties as the auxiliary rod bipolars. It is also possible that the rod excitations may vary to some extent in quality, depending upon the bipolar variety used and on the retinal locality. However, the less complex synaptical relations of the rods and bipolars are indicative of a more uniform or simpler character of the rod excitations passed on to the brain by comparison with the composite nature of the cone excitations.

The third link in the neuron chain making up the rod system of the retina is represented by all ganglion cell varieties. The midget ganglions, because of their relatively slight synaptical connection with the diffuse bipolars, may play a somewhat subordinate role in the transmission of rod excitations. Conversely, the principal role in this task falls upon diffuse ganglions. These, owing to a great number of bipolars synapsing with each ganglion cell, increasing to several hundred and possibly to a few thousand in the extra-areal periphery, may be looked upon as huge collectors or summators of the rod currents

of excitations manifested in an increased intensity. A possibility must also be considered of some additional shading in the quality of rod excitations, depending upon the ganglion variety by which they are transmitted and on the retinal locality.

The functional relation of the rod system to the cone system, judging from their synapses, is passive. That is, the cones are able to influence the dynamical status of the rods, while the reverse cannot take place because of the absence of appropriate synaptical connections.

A rod system may be most nearly realized under physiological conditions of stimulation during scotopic or night vision, when the intensity of stimulus falls below the cone threshold, while the responsiveness of rods attains its full value, in part possibly by the decrease or cessation of inhibitory influences emanating from the scotopic cones.

4. The cone system of neurons.—The cones are related to all varieties of centripetal bipolars (*b* & *d*, *e*, *f*, *h* relationships) and, through these, to all ganglion cell varieties (*d*, *e*, *f*, *h* & *m*, *n*, *o*, *p*, *r*, *s* relationships), all belonging to the receptor-conductor division. In the small rodless area of the central fovea the mop bipolar (*d*) seems to be absent, however (Figs. 177, 178, 179).

The principal link on the bipolar level is the midget bipolar (*h*); on the ganglion level it is the

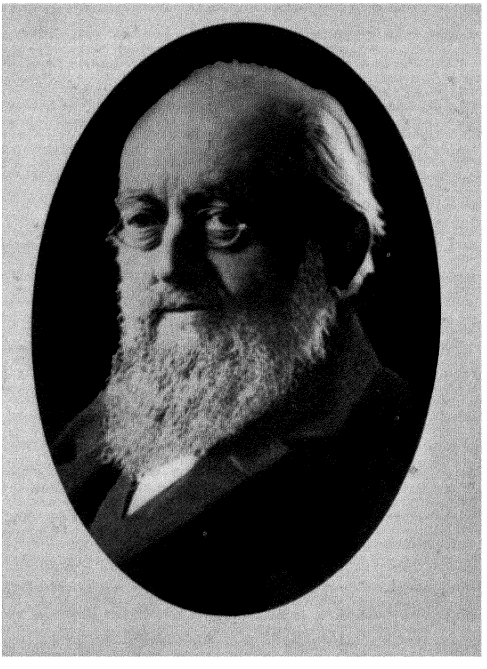

Fig. 357.—Ewald H. Hering (1834–1918), professor of physiology at Prague, Bohemia, and at Leipzig, Saxony, Germany. Notable physiologist and psychologist. A lifelong student of visual functions. Author of the "theory of opponent colors," rivaling the "trichromatic theory" of Young & Helmholtz as an explanation of color perception. Originator of the concept of "cyclopean eye." From München. med. Wchnschr., v. 81, 1934.

midget ganglion (*s*). This mechanism may conveniently be called the *complete cone system*, in contrast to a more restricted monosynaptical system of cone neurons subsequently described. The integrator neurons are more intimately connected with the cone systems, the horizontal cells (*c*) synapsing with the cones both by the receptive dendrites and by the emissive teledendrons, the centrifugal bipolar (*i*) by its teledendron only, and the various amacrines (*k*, *l*) through the emissive synapses of the centripetal bipolars and probably also by direct synapses of an uncertain category with the bodies of ganglion cells.

The arrangement of receptor and conductor units in the complete cone system is topical or spatial, more so than in the rod system. As in the latter and for similar reasons, its physiological units are somewhat larger than the single cones, since each diffuse bipolar is related to a few cones, and so forth. However, with a great reduction in thickness of the cones, with a much reduced spread of both dendritic and teledendric expansions of the bipolars, and with a wholesale decrease in the foveal ganglion cells in both body size and dendritic expansions, together with the great increase of central cones, bipolars, and ganglions, the "grain" of the functional units of the complete cone system in the visual axis is, on the whole, much finer than that of the rod system.

There is still another factor that makes the cone a refined instrument serving maximal visual acuity: a strictly individual synaptical relationship between the cones, the midget bipolars, and the midget ganglions in the central area and fovea (*b* & *h* & *s* relationships). Here each functional unit of the cone system consists of a single cone, a small group of bipolars, including a single midget bipolar, and a small group of ganglion cells, including a single midget ganglion (*b* & *d*, *e*, *f*, *h* & *m*, *n*, *o*, *p*, *r*, *s* relationships).

It is, however, possible and probable that under certain conditions the *b-h-s* chain of neurons alone may be active. This makes it possible to isolate a receptor-conductor mechanism of superior performance: a *pure, monosynaptical* or *individual cone system* of the central area and fovea. In this system all diffuse neuron varieties, both on the bipolar and on the ganglion levels, are eliminated. This leaves to the disposal of each individual cone a "monosynaptical" or "private" channel along which to send messages to the brain.

In the rodless area the size of the functional units in this private receptor-conductor system is determined by the diameter of individual cones; outside it, in the central area, by the interval separating the adjoining cones (outside the central area, owing to the replacement of monosynaptic by polysynaptic forms of midget bipolars, this system is very much roughened).

Each functional unit in the monosynaptical foveal cone system, if imagined free from any direct synaptical relations with the adjoining units of the same system, may under certain physiological conditions be capable of independent functioning. This contrasts both with the complete cone system, made up of all bipolars and ganglions, and with the rod system, where, because of diffuse synapses, an excitation originating in a single photoreceptor or a small group of photoreceptors is never strictly limited to a single conductor unit or entirely separated from the adjoining units, the more so, since in the rod system individual synapses are absent.

Because of the restricted size of its functional units and their isolation from one another, the monosynaptical cone system may be considered the chief instrument responsible for the highest degree of acuity corresponding to the center of the field of view.

The estimated course of the currents of excitations may vary according to which particular synaptical relations are considered. In the "complete cone system" of the central area of the retina an impulse generated in a cone may influence either one, two, or all bipolar varieties (in the rodless area, minus *d* bipolar, which here seems to be absent). The bipolars, in turn, elicit or may elicit dynamical changes in any one, in several, or in all related ganglion varieties. How to visualize such processes and what their physiological significance may be have been discussed in the preceding sections of this chapter and require further investigation.

The structural elements of a "complete cone system" and its functional units resemble those in the "rod system" except for the addition of the cones and midget bipolars. The "local signatures" are likely to be also about the same, ex-

cept in the central fovea, where the cones predominate and are gradually reduced in thickness, principally in the central rodless area. Also, because of the overlapping of expansions, there must be some functional gradient from a central high responsiveness toward the periphery of a functional unit. There are, however, differences: a "complete cone system" is also related to the horizontal cells through which it may actively elicit dynamical responses both in the cones and in rods of the area surrounding the stimulated cone. The cones may likewise be influenced via the centrifugal bipolars either from other parts of the retina or from the brain.

The course of the excitations within the "monosynaptical cone system," owing to its simple synaptical composition, is easy to estimate. A cone disturbance elicits a response in its midget bipolar, which in turn influences its midget ganglion. In this connection the first may be considered a "private cone bipolar," the second a "private cone ganglion." There is no division or analysis or fusion of the transmitted influences, except as may be caused by an intrinsic dynamical modulation within the system itself in response to the variation of stimulus. The only qualification which this statement requires may concern the influences given to, and received from, the horizontal cells and those arriving via the centrifugal bipolars.

From the structural simplicity of the "monosynaptical cone system," however, it would not be warranted to conclude that its function is simple in terms of subjective sensations, already hinted at. Also, since the two receptor-conductor systems, that of the rods and that of the cones, are actually welded into a *common or duplex rod and cone system* in the entire retina except in the rodless area, it is possible that under certain conditions of stimulation the entire receptor-conductor mechanism functions as a unit, in which the same diffuse bipolars serve as a common channel for both rod and cone influences (as it could, for example, during the transitional period from photopic to scotopic vision, and vice versa). In different conditions, when the stimulation is below the cone threshold, the rod system alone would remain in action (thus probably in scotopic or night vision). Conversely, when there is an increase in intensity of stimulation above the cone threshold which may automatically inhibit the rods (hypothetically through the horizontal cells), the cone system would act alone (such a condition is probably realized during photopic, or daylight, vision). In either case the same bipolars and ganglions participate, with the single exception of the midget bipolars, which, under scotopic conditions, remain inactive (as presumably do the cones). (The possible identity of influences mediated by the diffuse bipolars, especially the mop variety, irrespective of whether originating from rods or from cones, e.g., of "gray" or "white" sensations, has been mentioned earlier.)

The third link of the "complete cone system" of the retina is represented by all ganglion varieties, precisely as in the "rod system." In spite of this similarity, the responses elicited therein, taking the cue from the synaptical relations which in the two systems are partly different, may not be identical or may be only partly so. In the "rod system" the stress of activity is upon the mop bipolar and the diffuse ganglions; in the "complete cone system" upon the midget bipolar and the midget ganglion.

There are several factors which should be considered here. First, in the "rod system," since the midget bipolar (*h*) is absent and no cone influences arrive through the diffuse bipolars (*d*, *e*, *f*), not only the responses of the diffuse ganglions (*m*, *n*, *o*, *p*, *r*) but also those of the midget ganglion (*s*) may differ from the responses elicited in the same ganglions when the cone influences are included. Second, within the "complete cone system" itself there may be further shadings of the responses on the ganglion level, each bipolar variety, or a combination of varieties, being capable of eliciting its own particular kind of response in each ganglion variety within the frame of its own particular functional specificity.

In this connection several points seem worthy of further attention. The shrub ganglion (*n*), for example, seems to be a suitable "collector," "summator," "accumulator," or "intensifier" of influences from a group of midget bipolars (right sketch, Fig. 347; also colored figures in chap. V). In this capacity the *n* ganglion is a polysynaptic counterpart of the monosynaptic midget ganglion. Undoubtedly also the re-

sponses of two such varieties as the parasol (m) and garland (p) ganglions, although related to the same bipolars, because of the great difference in their synaptical contacts, generate responses differing from each other in quality and intensity, as they differ from other ganglion varieties. The number of "qualities" of the ganglion messages from the retina to the brain must, therefore, be no less than the number of morphologically distinguishable ganglion cell varieties and probably exceeds it considerably. In this count the finer modulations of each ganglion response, as well as the intensities, have not been taken into consideration.

The midget ganglions, these most interesting of all retinal ganglion cells, pose a special problem. They are the principal conductors of the cone influences to the brain. In what way are they capable of transmitting the great variety of dynamical modulations necessary for perception of the hundreds of hues subjectively appreciated? It is a problem similar to that raised by the cone response to chromatic stimulation.

The great dynamic flexibility of the midget ganglions may be considered especially in the condition when the "monosynaptical cone system" alone works, when all influences from the diffuse bipolars and the diffuse ganglion cells are eliminated.

The actual synaptical relationships of the

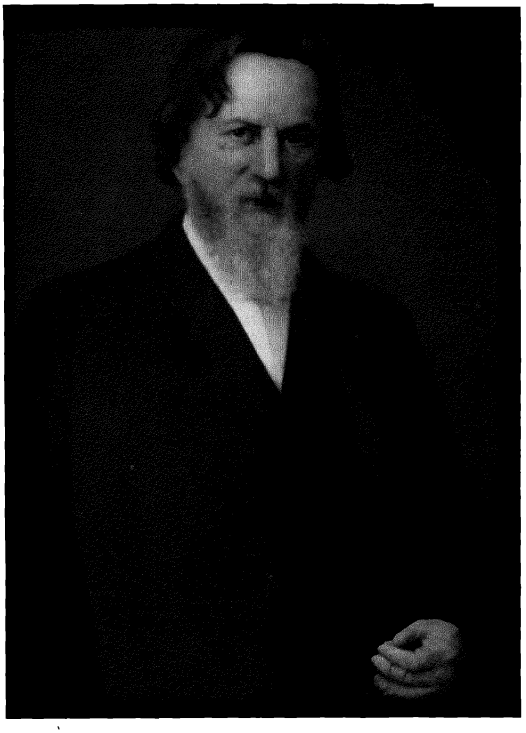

FIG. 358. Frans Cornelius Donders (1818–89), professor of physiology and ophthalmology at Utrecht, the Netherlands, at the age of seventy. Together with Helmholtz (*see* Figs. 101, 356), a founder of modern physiological optics, investigator of the accommodation and refraction of the eye. Portrait by Bramine Hubrecht, Donders' wife, painted 1888, now at Rijksmuseum in Amsterdam, Netherlands. Courtesy Rijksmuseum (Mr. A. M. Muntendam). (For biography *see* H. W. Williams 1889.)

rodless central area, however, indicate that under ordinary daylight conditions all bipolars present (that is, probably without the mop bipolar) and all ganglions may participate, even though, because of their great numerical preponderance, the midget ganglions several times outnumber all diffuse varieties of this locality. Hence the midget ganglions are by far the most important factors in axial vision or visual acuity in general, as this function is usually defined. But whether acting independently or as a part of a neuronal team, the midget ganglions must be capable of a wide range of detailed qualitative grading of responses, in order to satisfy the functional demands of detailed spatial vision and, at the same time, to serve as a substratum of color vision in the region of the visual axis.

5. THE RETINAL INTEGRATORS.—This system of neurons, as far as revealed, is made up of the horizontal cells (*c*), centrifugal bipolars (*i*), some or all amacrine cells (*k*, *l*), and probably other structures. Judging from their synaptical relations, their role is to interconnect various points of the retina and to regulate the working of the receptor-conductor system.

The connections of the horizontal cells and of the centrifugal bipolars have been described in chapter V, 6, and in section 7, paragraph 6, in this chapter. A few more points may be added. The horizontal cells evidently represent a system of intraretinal associations through which each small area of the photoreceptor layer is functionally tied up with its immediate surroundings. In this way, like a coat of mail, the rods and cones of the entire retina are firmly knit into a functional whole. In particular, whenever a cone or a group of cones is stimulated, it automatically influences both rods and cones in the region surrounding it. The rods, however, since they have no synapses with the dendrites of the horizontal cells, are unable to do so. How to interpret this horizontal influencing by the cones in terms of subjective sensations is discussed in the passages referred to above. There, too, the probable function of the centrifugal bipolars was also mentioned.

The amacrine cells (*k*, *l*) still remain an unsolved enigma. Their great numbers are indicative of their importance in retinal responses. It will probably prove correct to consider their function in general as an intraretinal association, by means of which the neurons bordering on the inner plexiform layer, especially the ganglion cells, are in some way influenced. Their expansions, directly in contact with the bodies of ganglion cells, indicate this. But much more factual information is necessary before an attempt may be made at assigning to the amacrines any one of the known functions of vision.

The same is also true of the efferent or exogenous fibers (*l*) of the retina.

6. REVIEW OF THE RETINAL STRUCTURES AND THEIR PROBABLE DYNAMICS. It may be useful to recapitulate briefly the neuron varieties of the vertebrate retina and their synaptical relations. From this, an attempt may be made to construct the probable course of excitations within the retinal tissue before the finished messages are sent to the brain. (*Cf.* colored Figs. 177, 178, 179.)

The initial photochemical reaction to visible physical light takes place in the bacillary layer (2), most probably in the outer segments of the rods (*a*) and cones (*b*), as first evidenced by Heinrich Müller (*see* chap. I, 7 [5]). From here the two categories of excitation pass to the inner rod and cone segments and their bodies and along their respective inner fibers to their vitreal terminations, the rod spherules and cone pedicles.

The rod excitations, in turn, elicit responses in the diffuse centripetal bipolars (*d*, *e*, *f*), always in groups not sharply separated from the inactive bipolars. These again influence any or all varieties of the ganglion cells (*m*, *n*, *o*, *p*, *r*, *s*). The localizing value of the rod messages to the brain, not so detailed as those of the cones, is nevertheless essential, especially because of the high summative effect of the rod system. Just how much the rod influences are propagated laterally is not known, since the amacrine associational system in the inner plexiform layer is still imperfectly known.

The cone influences pass over, actually or potentially, to all bipolar varieties (*d*, *e*, *f*, *h*) and also to the horizontal cells (*c*). The bipolars, in turn, activate all ganglion varieties (*m*, *n*, *o*, *p*, *r*, *s*), whence the messages are further dispatched to the brain. Both the qualities and the localizing value, the latter being much higher

than in the rod system, vary according to which of the intermediate neurons are activated.

The most restricted in space and hence having the greatest localizing value are the messages that pass through the monosynaptical or through any bipolars over to diffuse ganglion of the same area (*b* & *d*, *e*, *f*, *h* & *m*, *n*, *o*, *p*, *r*) have considerably smaller localizing value. Of least value as a localizing factor are those cone influences that pass through the polysynaptic midget bipolars (*h-h*) and other bipolar varie-

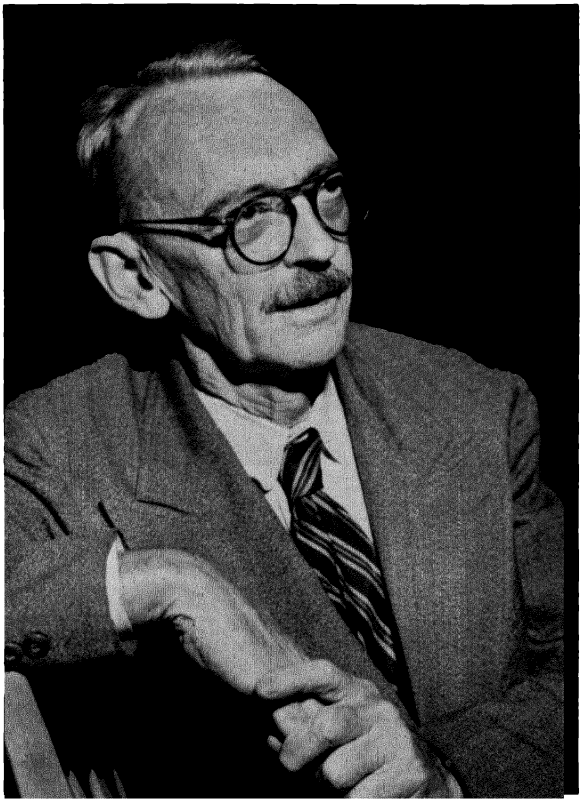

FIG. 359. Karl Spencer Lashley (1890), research professor of neuropsychology at Harvard University and director of Yerkes Laboratories of Primate Biology, Orange Park, Florida. One of the foremost experimental psychologists of modern times. A lifelong student of the visual functions and mechanisms of the visual behavior of animals. Courtesy Dr. Lashley, 1955.

"private" chain of neurons in the central area, especially in the fovea (*b* & *h* & *s*). Only a little less localized are the influences that use both the midget and the diffuse bipolars and the midget ganglions, also in the central area and fovea (*b* & *d*, *e*, *f* & *s*). Influences passing ties with a wide dendritic spread (*d*, *e*, *f*) to the large-sized diffuse bipolars and polysynaptic midget ganglions of the extra-areal periphery (*m*, *n*, *o*, *p*, *r*, *s-s*).

The cone influences that use any one particular bipolar variety as a channel must also vary

in their dynamical qualities and hence are likely to be material for different psychophysiological correlates. But even those influences restricted to the monosynaptical chain of neurons (*b* & *h* & *s*) must be capable of a great range of shadings, for the reasons discussed in the preceding subsection. The most compelling reason to make such a conclusion is the fact that there is not a sufficient number either of neuron varieties or of synapses in the central area to account for the wealth of subjective color sensations in the region of the visual axis.

The cones, unlike the rods, are able to influence both the rods and the cones in the surrounding area through the horizontal cells (*c*) and are in turn influenced by other factors, possibly cerebral or from the surrounding retinal regions, through the centrifugal bipolars (*i*), exogenous or efferent fibers (*t*), and perhaps also by the amacrine cells (*k*, *l*).

From the mere description of its structure and the possible avenues it offers for the spreading of excitations generated in the photoreceptors, the retina is obviously not a simple peripheral receiver of stimuli but a true analyzer and integrator of a high order within which the photic excitations are processed, sorted, and rearranged, before they are dispatched to the brain for further elaboration and use. The accumulation of several million nerve cells belonging to a dozen neuron varieties representing more than fifty distinct kinds of synapses in the immediate proximity of the photoreceptor layers thus becomes understandable. It is an expression of the need for a prompt and speedy processing of the rod and cone excitations before they are passed on to the brain.

Phylogenetically a part of the brain, in the fully developed state the retina performs some functions otherwise reserved to the central organ (*see* chap. XIII, 2, 3). The complex processes of analysis, sorting, and integration, as the steps following the initial photochemical process in the sequence of events underlying the phenomenon of vision, cannot be performed satisfactorily, except by occurring immediately after, and in essentials duplicating, the initial photoreceptive process in the rods and cones.

7. Concluding remarks.—In this chapter, first, the various opinions expressed by preceding investigators concerning the basic organization of the nervous system were examined. Next, an attempt was made to test these opinions with the help of our own observations. The concept of the "neuron" as a genetic, morphologic, and functional unit was found to fit the facts and to satisfy the requirements, whereas the doctrine of "neuroreticularism" or "nerve net," in all its modifications, was found wanting.

In further sections we have tried to interpret functionally the structures found in the vertebrate retina and in this way to test the neuron concept or to modify it. Our aim was, first, to understand the structure and significance of the synapse as a basic feature of the organization of the nervous system. Our second aim was to interpret in terms of the basic functions the synaptical grouping of the neurons making up the retina.

The next logical step should be a similar investigation and interpretation of the remainder of the visual system, in particular of the laminated lateral geniculate nucleus and the striate area. In this way, perhaps, the synaptical channels along which the impulses travel from the photoreceptors through the intermediate stations to the cortical centers of the brain could be traced. Such investigation, if successful, not only would give a hint about the devious channels along which the retinal impulses enter the cortex, and their fate therein, but would possibly provide a firmer foundation for our interpretation of the retinal structures themselves.

In chapter VI, 9, a few details of the finer structures of the laminated lateral geniculate nucleus were described. These show various terminal arborizations of axis cylinders arriving from outside. Some, because of their thick caliber and mode and place of spreading, are most likely of retinal origin. The others possibly belong to the neurons residing in the brain.

Since the ganglion cells of the retina represent several distinct varieties, as our study of Golgi-stained preparations shows, and since in other experiments with small lesions located in various parts of the retina the Marchi method of staining showed myelinated fibers entering all laminae of the nucleus in the corresponding segment, it is probable that all ganglion cells of the retina send their fibers into each lamina.

Hence it is probable that each minute territory of the retina is connected with its own particular minute segment of the nucleus by a multiple or composite cable made up of as many varieties of optic nerve fibers as there are varieties of retinal ganglion cells.

The exact number of component fiber varieties remains unknown. It stands to reason that they may be simpler. This we have expressed, hypothetically, in Figure 361, by triple cables leading from each point of the central area and fovea (*b*, *c*), by double cables from the binocular periphery (*a*), and by simple cables from the monocular crescentic portions of the retinae (*x*, *y*).

This further leads to the problem of types of

FIG. 360.—Dr. Ragnar Arthur Granit (1900), director of Medicinska Nobelinstitutet, Neurofysiologiska Avdelningen, Karolinska Institutet, in Stockholm, Sweden. the individual conducting fiber units vary in different portions of the optic nerve. In the foveal and areal bundles they may be more complex; in the extra-areal periphery and even more so in the extreme monocular crescent, terminal arborizations of the optic nerve fibers in the laminated nucleus. It may be expected that the fibers that mediate a fine epicritic sense such as central acuity, belonging to small ganglions of the central fovea and area, would be

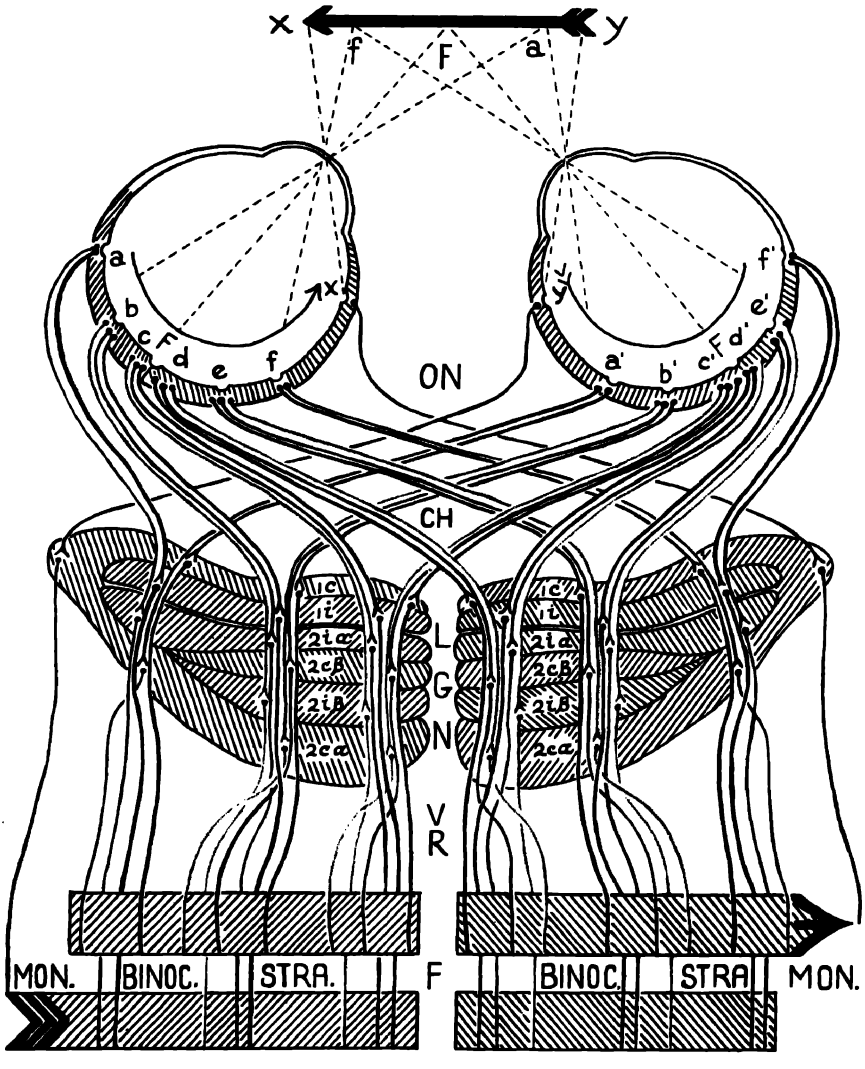

FIG. 361—Components of the primate visual system. Both eyes are focused on the centre *F* of an object *x-y*. The inverted retinal images partly coincide (*a-f, a'-f'*), and in part do not (*x-f, y-a'*). From each point of the images arise fiber bundles (*ON*) which, after partial decussation in chiasma (*CH*), enter laminated later. genic. nuclei (*LGN*). From here fibers of visual radiations (*VR*) continue to the right and left striate area where a single but two-fold cortical visual image is formed. *Note:* the point-to-point transmission of images along the entire visual system, the more complex components in and around foveae (*a, b, c, d, e, f*; *a', b', c', d', e', f'*) transmitting binocular portions (*BINOC-STRA*), the simpler temporal components (*x, y*) transmitting monocular portions of the images (*MON*). (*See* for further details text, and Figs. 401, 439.)

thin and within restricted terminals, whereas those of the large ganglions of the far periphery and of the monocular crescent, instrumental in crude peripheral vision, would be more robust and with wider terminal arborizations. Furthermore, it is likely that the terminal arborizations also vary in the same territory both in spread and in other features, according to the cell variety, the smallest being those of the midget ganglions and the larger belonging to the various diffuse ganglions, for example, those of the *m* and *n* varieties.

Is there a segregation of the optic terminals in different geniculate laminae, according to their origin in different ganglion varieties? This problem requires an unequivocal answer, necessary for the understanding of the intrinsic makeup and working of the visual apparatus. Unfortunately, only a few known observations give some hint as to what the answer may be. Such is the segregation of particular types of cells in distinct laminae. The two ventral laminae, for example, are composed of much more voluminous cells than those that fill the two or four dorsal laminae. It is, then, probable that the terminal arborizations of the giant retinal ganglion cells also spread principally, if perhaps not exclusively, in the two ventral magnocellular layers. But this may not mean that all larger ganglion cells send their axons only to the two ventral layers. The varying size of all ganglion varieties, each variety being present in all regions of the retina, makes this doubtful. The principal difference found is in the dimensions of the ganglions, those in the fovea and next to it being the most reduced in size, those in the far periphery the largest. Hence it is probable that several fiber categories, belonging to different varieties of retinal ganglion cells, terminate side by side in every part of the laminated lateral geniculate nucleus. This is most probable for the small-celled laminae, whereas the large-celled ventral laminae are more likely to contain only the more robust terminal arborization.

The preceding arrangements, still largely hypothetical, indicate a complex synaptical structure of the laminated lateral geniculate nucleus. The complexity of this internode further increases with the additional presence of the so-called "association" cells interspersed among the larger principal cells, as described in chapter VI, 9.

Are there in the lateral geniculate nucleus terminations of fibers arising from other parts of the brain, possibly from the cerebral cortex, as assumed by Brouwer and his co-workers? On the basis of our own examinations of Golgi-stained preparations, the presence of such fibers cannot be denied, even though this requires further study. Certain widespread teledendric arborizations, arriving from outside the nucleus, each fiber spreading over a large segment, most likely belong to this category, as pointed out in chapter VI, 9.

Concerning the visual radiations, the known observations also indicate a composite structure of these fiber systems. The experiments recorded in chapter VII, 7, showed each minute fiber bundle, or segment of the radiation, to be made up of several categories of fibers. First is the arrangement, caused by the semidecussation of optic nerves in the chiasma (*CII*, Fig. 361). Owing to this, fibers from each point of the binocular portions of the homonymous halves of both retinae meet in the same segment of the ipsilateral geniculate nucleus, although they terminate in different laminae, as described in the preceding chapters.

There is good reason to think, however, that each minute fiber bundle is not homogeneous but is made up of several categories of fibers. The evidence in support of this is found in the experiments described in the preceding pages, which showed minute zones of retrograde cell degeneration passing through all cellular laminae of the nucleus. This is the case whether the visual radiation is interrupted anywhere along its course or the striate area is damaged, provided that the ventral, infra-Gennarian layers are also involved. Since it is reasonable to consider different laminae of each homonymous laminar set of the nucleus, the right and the left, to be made up of distinct varieties of the principal nerve cells, each lamina of each set giving rise to its own category of fibers, each bundle of the visual radiation may then be expected to contain all fiber categories. The same postulation must be made for the terminal arborizations in the striate cortex.

The last and most difficult problem arises in tracing the further course and the final fate of the several distinct categories of impulses arriving in the striate cortex by way of the several categories of fibers of the visual radiation. Here, again, the first question is the identity and behavior of the ipsilateral and contralateral homonymous fibers in the striate cortex. The next is the problem of the varieties of neurons therein and their synaptical relationships. The final problem concerns the connections of the striate area within itself, with the para-peristriate areae of the same and the contralateral side, and with other parts of the brain, cortical and subcortical. These problems, as far as our knowledge permitted, have been discussed in the various sections of the preceding chapters, especially in chapter VIII, 7. There it was also shown how important and how vast this problem is—a great challenge to future research.

Chapter X

The Blood Supply of the Vertebrate Visual System

SEC. 1. GENERAL REMARKS ON THE BLOOD SUPPLY OF THE EYE AND OF THE VISUAL PATHWAYS AND CENTERS

1. INTRODUCTION.—The normal function of the central and peripheral nervous organs, like that of any other living part of the body, depends upon several factors. The foremost is the kind, number, arrangement, and synaptical connections of its specific constituents—the nerve cells or neurons—and of the processes by means of which they are connected with one another and with other tissues of the body (*see* chap. I, 8 and 9; chap. V, 3–7; chap. VI, 8, 9, 10; chap. VIII, 5 and 7; and especially chap. IX). Another and almost equally essential factor is the blood supply. The smooth functioning of the intricately organized specific nervous parenchyma depends on the way the arteries that carry the nutritive fluid called "blood" are distributed to the various parts of the brain, the spinal cord, and the nerves.

The factors indispensable for a harmonious discharge of the normal functions are the place and the mode of distribution of the principal arterial stems and of the numerous secondary, tertiary, and other branches; the presence or absence of the anastomotical connections of the larger arterial stems; the character of the capillary network in a particular locality; and the proper vasomotor and other regulation of the amount of blood passing during a given unit of time through a given part of a nervous organ, depending upon its greater or lesser activity.

Of hardly less importance are the arrangements for free return of the venous blood through the veins of the brain and the venous sinuses of the cranium to the heart, at all times permitting replacement of used blood by fresh. Again such general factors as maintenance of normal blood pressure in the circulatory system; normal constitution of the blood by proper functioning of the blood-forming, respiratory, endocrine, digestive, and excretory organs; normal condition of the blood vessels themselves; sufficient intake of nourishing food, including vitamins, salts, and water; avoidance of overworking the circulatory system; and avoidance of acute or chronic poisoning either by infection, by abuse of drugs, or by food poisons—all are necessary for preservation of the favorable conditions required. Any alteration of these factors may temporarily or permanently impair the function and the very life of the specific parenchyma of the nervous organs: the nerve cells proper, their expansions, and synaptical contacts.

It is reasonable to think that the general factors and agencies, when at fault, are more likely to cause diffuse or widespread pathological changes, the variation of the effect depending upon local factors and the innate histological and biochemical properties of the nervous tissue. The pathological processes confined to any one blood vessel, on the contrary, will most likely be of limited scope in space but more profound in degree, affecting only the part of the brain supplied by that particular vessel. The degree of the effect in the latter case may depend upon the degree of interference with normal circulation.

The most profound changes are caused by an occlusion or clogging of the larger blood vessels, especially the arteries, as exemplified by an embolism or thrombosis. In such an event the part of the brain or sense organ supplied by the obstructed vessel may undergo complete degeneration of its nervous parenchyma, with resulting permanent and irreparable loss of the particular function. The same effect may result from a prolonged vasospasm and probably also by a prolonged hemostasis.

The nervous system in general and the visual system in particular are exceedingly complex assemblies of agglomerations or systems of nerve cells, each agglomeration with its own entirely specific function (*see* preceding chapter). A serious localized impairment of any constituent of the visual system therefore impairs or abolishes its function. This function is irrevocably damaged and can at best be only inadequately compensated for by other parts of the nervous tissue.

Since the blood vessels alone provide the visual system with nutritive material and hence supply the food upon which the life of the elaborate neuronal organization of that system depends, an acquaintance with the organization of its blood supply and of vascular diseases in ophthalmic pathology, in neuropathology, and in general pathology is of paramount importance.

The role the vascular factor plays in vision is most dramatically illustrated in numerous types of visual field disturbances, and equally so in various forms of impairment of the higher or psychic functions of vision, in transient blindness, and in many other similar phenomena. From the study of the arrangement of the blood vessels supplying various parts of the visual system alone, the great importance of its vascular supply becomes quite apparent.

The several subdivisions of the visual system, the infranuclear, nuclear, and supranuclear, including the cortical centers, form a chain stretching the whole length of the base of the cranium (*see* chap. VI, 1; and chap. VII, 8). This chain begins with the two eyeballs and terminates with the two striate areae of the occipital lobes. Owing to the great length of the visual system, all principal subdivisions of the cerebral arterial tree participate in its supply. This fact again has an important bearing upon pathology, since each part of the system may be affected in its own way by a disease arising from a peculiar local character of the vascular supply.

In the following paragraphs a general outline of the sources of cerebral blood supply is first given. In the detailed description that follows, only the blood vessels directly related to the visual pathways and centers are presented, their source, course, distribution, connections with one another (if any); their topographical relation to the sulci, gyri, cytoarchitectural areae and regions; and their relation to the localizable functions of the cerebral cortex. Special attention is paid to the blood supply of each of the several parts that make up the visual system. The pathophysiological significance of some of the vessels is also discussed, this subject being treated in some detail in Part III of this book.

It is perhaps not amiss to call attention to our present limited knowledge of the blood vessels and of the circulation in general, which is exceeded only by our ignorance of the intrinsic organization of the nervous system itself. The paramount importance which the vascular system assumes in the normal maintenance of the nervous organs and in their pathology makes additional work on the understanding of the vascular system one of the foremost tasks of modern research.

2. SOURCES AND GENERAL CHARACTER OF THE CEREBRAL BLOOD SUPPLY. - The brain, with the extra- and intracerebral parts of the visual system, is supplied by two pairs of arteries (Fig. 362): the internal carotids (*ica*) and the vertebral arteries (*va*).

At the base of the brain these four large blood vessels are connected by anastomoses or links, which, together, form the "arterial circle" of Willis (*acoa, acea, ica, mcea, pocoa, pocea, basa* in Figs. 366, 367, 368). From this circle emerge three pairs of arteries, one artery of each pair supplying a part of one cerebral hemisphere on its own side—the anterior (*acea*), the middle (*mcea*), and the posterior cerebral arteries (*pocea*). Each of these six arteries divides into several medium-sized branches, which, in turn, by repeated division, produce a great number of smaller preterminal and terminal arteries and arterioles (Figs. 369, 370).

The arteries spread over the surface of all parts of the brain, some exposed and others concealed in the sulci and fissures. In some regions, e.g., over the base of the brain and over the medial face of the frontal lobes close to the "knee" of the callosal body, the main stems remain on the surface (Fig. 369); over most of the inner face and over the entire outer or convex

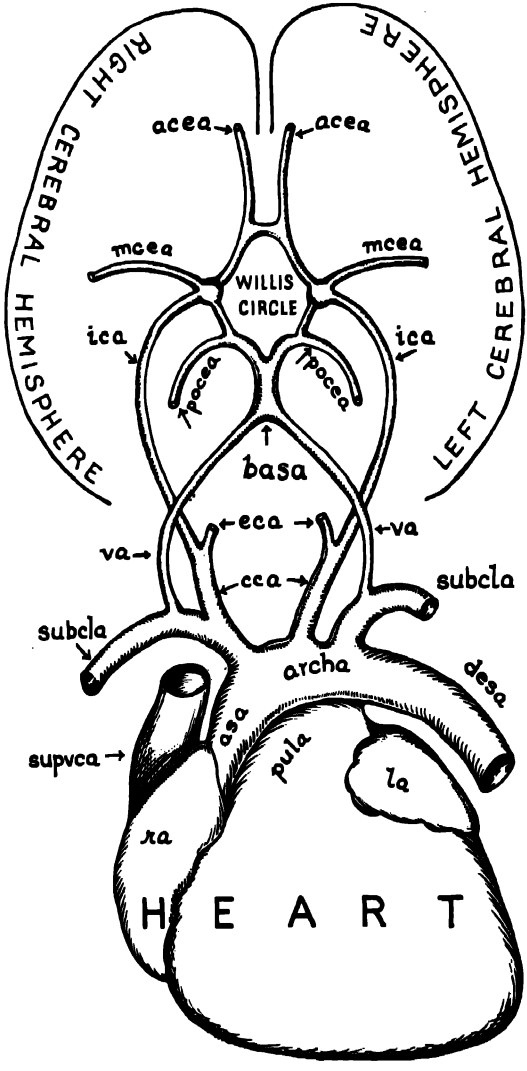

FIG. 362.—Sources of blood supply of the head and brain. The diagram represents the heart in a frontal view, together with the principal vessels arising from it—the superior vena cava, aorta, and pulmonary artery. From the aortal arch arise arterial stems whose branches, the two vertebral and the two carotid arteries, form the arterial circle of Willis. From this circle emerge three pairs of arteries, the right and the left anterior, middle, and posterior cerebral arteries, which are distributed to the corresponding parts of the two hemispheres of the brain. *Labeling: acea*, anterior cerebral artery; *archa*, arch of aorta; *asa*, ascending portion of aorta; *cca*, common carotid arteries; *desa*, descending portion of aorta; *eca*, external carotid arteries; *ica*, internal carotid arteries; *la*, left auricle of heart; *mcea*, middle cerebral artery; *pocea*, posterior cerebral artery; *pula*, pulmonary artery; *ra*, right auricle of heart; *subcla*, subclavian artery; *supvca*, superior vena cava; *va*, vertebral artery.

face of the hemisphere, however, the arterial trunks, by preference, use the furrows that separate the convolutions from one another.

The principal arterial stems pursue the same direction which they assumed during the early fetal development (Fig. 370). This direction, roughly, radiates from Willis' "arterial circle" at the brain's base as a focal point toward the margins and poles of the hemisphere (*cf.* Fig. 375). Hence, while remaining buried as much as possible within the sulci, some arteries in places make bold short cuts across the free convexities of the gyri, only to dip again into the next convenient sulci, within which they continue in the same direction. Still other arteries may sweep across the sulci in the manner of bridges, while yet others, which remain buried during most of their course, may emerge for awhile on the surface in the form of longer or shorter loops.

The arteries, particularly the smaller ones, give off secondary, tertiary, and other branches. By further subdivision into minute twigs, the preterminal and terminal arterioles eventually dissolve into a capillary network that pervades all tissue.

All blood vessels, the arteries as well as the veins of the brain, irrespective of size, while on the surface of the brain, are imbedded within, or are enveloped by, the tissue of the two soft tunics or leptomeninges—the pia mater and the arachnoid membrane. The pia mater especially, whose delicate tissue coats the surface of the brain, filling all furrows, slits, and clefts, serves as a vehicle along which the blood vessels reach their place of destination, the substance of the brain. Most arteries penetrating into the brain's substance are small; in a few places larger arteries may be found pursuing a longer or shorter course.

The ultimate and smallest subdivisions of the arteries—the capillaries or hairlike vessels—may be seen only with the microscope (Fig. 364). They form a continuous network of varying density and pattern, especially rich in the gray matter, such as the cortex of the brain, and the various nuclei. The capillary network permeates all parts of the cerebral tissue, its meshes enveloping minute islands containing nerve cells and their expansions or, depending on the locality, only the nerve fibers and the supporting neuroglial tissue.

Through the capillary network, in the living organism fresh blood is carried along the arteries by the action of the heart and is brought into the closest contact with the living parenchyma of the brain, the nerve cells, and their processes. In this way the essential or specific structures of the brain are provided with the various nutrient constituents contained in the blood and are relieved of the used material, which is carried away by the veins.

Beyond the zone of capillaries, the vessels begin again to merge into larger stems of the venous system (blue in Fig. 364). These venules, by further uniting with their kind, produce larger veins, which reach the venous sinuses of the cranium in a more direct course over the cerebral surface and empty into the large veins of the neck, which eventually empty into the right half of the heart.

SEC. 2. THE BLOOD VESSELS OF THE EYE AND OF THE OPTIC NERVE

1. SOURCES OF THE BLOOD SUPPLY OF THE ORBITAL CONTENTS, INCLUDING THE OPTIC NERVE.—The various structures which fill the orbital cavity or the eye socket, including the eyeball, are supplied with blood principally through the ophthalmic artery (*opha; see also* sec. 3 [2], this chapter). This artery arises from the intracranial portion of the internal carotid artery (*ica*) and passes into the eye socket through the bony optic foramen closely attached to the optic nerve (Figs. 369, 370, 371).

The anterior continuation of the ophthalmic artery, the nasofrontal artery, emerges from the eye socket at the inner or nasal corner or canthus of the eye, where it is continuous with the dorsal-nasal and angular arteries, branches of the facial or external maxillary artery, which in turn originate in the external carotid artery (Fig. 362, *eca*). In this way an arterial circle is completed, its source being in the common carotid artery (*cca*). Other lesser sources supplying the orbital contents are the middle meningeal and the (internal) maxillary arteries.

The venous blood from the orbit and the eye empties principally through the superior and inferior ophthalmic veins by way of the superior orbital fissure, mostly into the cavernous sinus at the cranial floor, which in turn discharges through the superior petrosal sinus and the palatine vein and some other smaller outlets into the internal jugular vein. The anterior continuation of the superior ophthalmic vein, the nasofrontal vein, connecting with the anterior facial vein (in turn discharging into the common facial vein and through that into the internal jugular vein), completes the venous circle. (For details of illustrations not given in this book consult textbooks and atlases of anatomy and also the following monographs: Kronfeld, McHugh & Polyak, *The Human Eye in Anatomical Transparencies;* and Polyak, McHugh & Judd, *The Human Ear in Anatomical Transparencies.*)

2. THE BLOOD SUPPLY OF THE OPTIC NERVE AND EYEBALL. The eyeball and the optic nerve receive their blood supply from a number of small branches of the ophthalmic artery (Figs. 365, 371, *opha; see also* Figs. 369, 370): anterior (*anter. cil. art., acila*) and posterior (short and long) ciliary arteries (*mpcila, lpcila*), and by the central retinal artery (*cra.*).

The ciliary arteries, with the episcleral branches, supply the two outer tunics, the sclera and the uvea (Fig. 365). Of the three constituents of the uvea (chorioid, ciliary body, iris), the chorioid membrane is principally a vascular tunic made up of a dense network of blood vessels imbedded in a connective tissue stroma and of chromatophore cells filled with a dark pigment (Fig. 127). The locality where it is best developed corresponds to the central area and fovea (*A*, Fig. 129). The smallest and most numerous vessels of the chorioid are on its inner side facing the photoreceptor layer of the retina, the choriocapillary layer. The anterior transparent portion of the tough outer tunic, the cornea, and the crystalline lens normally do not contain blood vessels but receive nutritive fluids indirectly, principally from the aqueous and vitreous humors.

The intracranial portion of the optic nerve is supplied by the ophthalmic and anterior cerebral arteries (Fig. 371). The intraorbital portion is supplied by the branches of the ophthalmic artery above, chiefly by the external branches, and to a small extent by the central retinal artery, including a recurrent or postcentral artery.

The venous blood from the two outer tunics—the sclera and the uvea—is carried away principally by the four to six vortex veins,

also by small veins on the surface of the sclera—the episcleral veins—and by the superficial veins of the optic nerve (Fig. 365). The retinal venous blood is returned by way of the central retinal vein. All this venous blood is finally emptied chiefly into the ophthalmic veins, the superior and inferior, and through these principally into the cavernous sinus in the sellar region of the cranial cavity and further into the superior petrosal sinus and internal jugular vein. (*See also* sec. 3 [2], this chapter.)

3. THE BLOOD SUPPLY OF THE RETINA.—The blood supply of the retinal membrane in Man and other Primates and to a greater or lesser degree also in other Mammals is double (Figs. 363, 365), directly from the central artery and indirectly from the ciliary arteries via the choroid membrane.

In many Infraprimate Mammals the principal, and perhaps the only, supplier is the ciliary-choroidal system. In the Inframammalian Vertebrates the retina receives its supply both from the choroid and, osmotically, via the vitreal fluid from special vascular organs protruding from the head of the optic nerve into the vitreal cavity, the "vascular cone" of Lizards, the *pecten* or "comb" of Birds, and other similar organs (*cf.* Figs. 172 76).

The central retinal artery (*cra*), a branch of the ophthalmic artery (*opha*), accompanied by the central retinal vein (*crv*), enters the eyeball by way of the optic nerve (*see* sec. 3 [2], this chapter, and Figs. 148, 363). The bundle of these "central retinal blood vessels" penetrates into the optic nerve, in the adult and in the fetus from the third month on, in the center of the inferior aspect of the nerve or, at most, slightly nasal, at a distance individually varying from 6 to 15 mm., usually 10–11 mm., or from $\frac{1}{4}$ to almost $\frac{1}{2}$ inch, behind the eyeball (Figs. 201, *B;* 202). In the younger fetus the point of entry is in the middle of the lower nasal quadrant. Within the optic nerve the central blood vessels, surrounded by a moderate quantity of connective tissue, fill the so-called vascular channel, preserving a central location throughout their course as far as the papilla of the nerve (Fig. 185).

After passing through the cribriform lamina of the sclera, at the "head" or disk of the optic nerve, the central retinal vessels emerge at the inner vitreal face, whence, divided into branches, they spread over the expanse of the retinal membrane. They may be examined in the living person by means of an ophthalmoscope, or "eye mirror" (Figs. 148, 149, 165–70, 363).

During their passage through the initial portion of the optic nerve, the central retinal vessels, more the artery than the vein, are connected through the capillary and precapillary anastomoses with the ciliary system of the choroid and scleral tunics, which system here forms the arterial circle of Zinn, Haller, and Leber surrounding the cribriform lamina of the optic nerve (Fig. 365). This connection, however, has been disputed by some (Beauvieux & Ristitch 1924) and reaffirmed by others (E. Wolff 1948). Beyond this point, the two vascular systems of the eye—the retinal and the ciliary-choroidal—are normally separated. (*See* later in this subsection for Rucker and coworkers' experiments with monkeys.)

Both the central retinal artery and the vein, usually while passing through the cribriform lamina, divide, the vein a little sooner than the artery, into two principal branches, an upper and a lower papillary artery and vein. While still at the papilla, the four stems divide again dichotomically into a number of branches radiating in all directions. According to H. Magnus (1873), five pairs of larger, and two of smaller, arteries and veins may be distinguished (Fig. 363). These are: an upper and a lower temporal (*st, it*) and an upper and a lower nasal artery and vein (*sn, in*), oriented according to the four quadrants, and a single and somewhat smaller median artery and vein (*mn*) spreading in the middle zone on the nasal side.

Distinct from these five pairs of larger vessels are two minute pairs that partially supply the central area and fovea, or "macula": a superior and an inferior macular artery and vein. Ordinarily, however, this favored structure, both in Man and in other Higher Primates, is supplied by several smaller vessels branching from the larger stems and converging from all sides upon the foveal excavation (Figs. 148, 149, 165–69).

Occasionally the macular artery may arise from the arterial circle of Zinn, Haller, and Leber surrounding the initial portion of the optic

nerve and formed, according to Leber, by the posterior ciliary arteries, whereas the macular vein may take its origin similarly from the chorioidal veins.

In two specimens of the Philippine Tarsier examined ophthalmoscopically, two distinct macular arteries of fair size and a single macular vein, upon which the supply of the central area and fovea in this species principally depends, were found in each eye (Fig. 149).

The division and distribution of the central retinal blood vessels shows much individual variation in detail (Gauss 1930; Bucciante 1933; Jensen 1936; Rucker 1946). Of the larger vessels, the temporal are thicker than the nasal. Also the temporal vessels pursue an arching course, circling above and below the central area and fovea, toward which smaller branches extend. In about one-fourth the cases there are no distinct macular arteries, and the entire foveal region is supplied by the twigs from the upper and lower temporal arteries.

In the central area, only small blood vessels are present. From these a few minute twigs normally slip over the brim, indicated by a circular or elliptical light reflex, into the foveal excavation (Fig. 363). Here they produce a fine capillary network, somewhat denser than in the extrafoveal periphery. In the deepest part of the foveal pit, where all vitreal layers including *6* and zone *5-c* are absent, in the foveal floor or foveola—and here alone—all blood vessels, including capillaries, are absent (*cf.* Fig. 364).

The extent of the avascular or vessel-free foveal area was much studied, especially by observing entoptically or subjectively the "vessel tree" or "figure" first described by Purkinje (portrait Fig. 354). Its diameter and shape vary individually from 0.13 to 0.75 mm., measuring, on the average, from 0.4 to 0.5 mm. across. According to the observation of Leber (1880), the diameter of the avascular center in one of his own eyes was 0.42 mm. on the retina, or 1°35′56″ of arc in his field of view (*see also* O. Becker 1881; Gescher 1925; Weale, quoted by Dartnall & Thomson 1949). The avascular area, accordingly, is practically coextensive with the central territory of the fovea, the so-called "outer" or "external" fovea, where cones alone are present, and is much smaller than the entire foveal excavation. (*See* chap. V, 9.)

The developmental factors which cause the archlike arrangement of the circumareal vessels in the temporal portion of the human and other primate retinae, including those of the pronouncedly nocturnal *Aotes* and *Tarsius* (*see* Fig. 149 and chap. XIV, 12), just like those responsible for a similar arrangement of the optic nerve fibers, remain unknown, precisely as do similar factors that form the foveal excavation. Whatever they are, the elimination of the vitreal layers *5-c* to *9* of the retina that contain blood vessels obviously serves to reduce a dioptrical impediment placed in front of the receptor layer *2*, thus increasing the resolving power and perhaps also the color perception of the retina in the line of direct vision (*cf.* chap. V, 10 [7]).

From the principal arterial branches, smaller twigs separate and, by further subdivision, produce a capillary network permeating the tissue of the vitreal layers throughout the entire expanse of the retinal membrane, excepting the very center of the foveal excavation—its floor, the central avascular area already mentioned. The vessels which compose the system of the central retinal artery and vein are imbedded in the retinal tissue as far as the inner limiting membrane. They supply the retina in its entire extent, from the optic papilla to the ora serrata. In Man, Monkey, and Ape and in some other Mammals there are, as a rule, no precapillary anastomotic connections between the individual larger and smaller arteries (Fig. 364). Nor are there any connections between the territories of the central retinal and the ciliary-chorioidal systems of the eyeball, except in the region of the optic papilla, where there is some connection with the scleral and chorioidal vessels of the ciliary system, as mentioned before (*see* later, this section).

The central retinal artery, accordingly, as a whole, and again each of its individual branches, including the precapillaries, fairly represent true "terminal arteries" or "end-arteries" as defined by Cohnheim (1872). The advantage of this arrangement, in the opinion of some, e.g., Magnus, is the relative independence of the retinal circulation, which keeps that all-important organ out of reach of the noxious influences arising from the pathology of the outer walls of the eyeball. The unavoidable disadvantage is

the impossibility of establishing collateral circulation with the neighboring ciliary-chorioidal system in case the central artery or one of its branches is directly affected by a pathological process, such as thrombosis, embolism, atheroma, and the like. The branches of the central retinal vein are similarly arranged, except that they are united by anastomoses along the serrated margin.

Not the entire thickness of the retina, however, but only approximately the inner or vitreal three-fifths, in Man and his primate relatives, are supplied by the central retinal artery, or precisely all layers beginning with the inner zone of the outer plexiform layer, *5-c*, and inward as far as the inner limiting membrane, *10* (*cf.* Figs. 127, 128, with Fig. 365). The layers external to zone *5-c*—layer *1* to zone *5-b* inclusive—which practically correspond with the photoreceptors, do not contain any blood vessels. They are indirectly supplied with nutritive substances. In this, the major share is contributed by the vascular network of the chorioidal membrane and thus by the ciliary arterial system, particularly its innermost tier, the choriocapillary layer.

It appears probable that the nourishment of the entire bacillary layer, *2*, and also of the outer nuclear layer, *4*, is entirely chorioidal in most of the retinal expanse. This seems, in part, to be also true of the outer zone of the outer plexiform layer, *5-a*, especially where that zone is thick, as is the case in most of the central area (Henle's "outer fiber layer"). Zone *5-b*, however, may possibly receive its supply through the outermost loops of the capillary network of the central retinal system.

In the avascular center of the central foveal excavation, in the foveola, where there are no blood vessels of any kind, zone *5-a* or Henle's outer fiber layer, which here immediately borders on the vitreous—being separated from it only by the thin inner limiting membrane—and possibly also the outer nuclear layer may depend nutritionally, to some extent or entirely, upon the vitreous and thus indirectly upon the central retinal system. The indirect nutritional supply of the outer retinal layers and, in general, the exchange of metabolic substances are obviously of an osmotic nature, both in the avascular center and in the vascular extrafoveal periphery.

The intimate functional relationship between the chorioid membrane and the photoreceptor layer is attested by the exceptional thickness of the chorioid in the territory of the central area, particularly of the central fovea. And it is precisely this locality where the bacillary and other layers, made up of the rod and cone cells, are much thicker and where the nutritional requirement is undoubtedly much greater than in the extrafoveal regions (Man, Ape, Monkey, Tarsier, Golden Eagle). By contrast, it is exactly here that, owing to the absence of inner layers *5-c* to *9*, the vessels of the central retinal origin are also absent (Figs. 129, 161).

A double retinal blood supply, ciliary-chorioidal and central-retinal, is a feature characteristic of all Primates (Man, Ape, Monkey, Tarsier). However, it appears that in the Simians the two systems are not so completely separated as in Man, as the following observation indicates. In Man pressure on the eyeball, by which the central blood vessels in the cribriform lamina are strangulated, produces in a short time an ischemic edema of the retina, resulting in blindness. In the Macaque Monkey this type of visual loss could not be induced experimentally, according to unpublished experiments of Dr. C. W. Rucker, of the Mayo Clinic, Rochester, Minnesota, and his co-workers, indicating an incomplete separation of the ciliary and the central arterial systems.

In other Vertebrates either the ciliary-chorioidal or the central-retinal supply prevails more or less, in extreme types one to the almost complete exclusion of the other. In such a retina the vessels are either absent in the entire thickness of its tissue, the supply depending upon osmosis of the nutrient substances from the vitreous and chorioid; or in another extreme—rare to be sure—the entire thickness of the retina between the outer and the inner limiting membranes is permeated by the vessels belonging to the central system. (*Cf.* Kolmer & Lauber 1936.)

A blood supply of the retina similar to that of Man has been found in all Primates so far investigated, including the nocturnal *Aotes trivirga-*

tus and *Tarsius philippinensis* or *T. carbonarius* (*see* Figs. 149, 166–69, and chap. XIV, 12). In all of them the central vessels emerge on the vitreal face of the optic papilla, spreading in a typical way in all directions, in the temporal portion describing arches above and below the central area and fovea. Such an arrangement has been studied ophthalmoscopically and is easy to see in well-made specimens (Fig. 162). In Lemurs, judging from the plates published by G. L. Johnson (1901) and from his description, there is no true fovea; but the arrangement of vessels indicates an incipient avascularity of the locality homologous with the central area of Higher Primates, the vessels here being fewer and more delicate (so in *Lemur coronatus* and *Galago monteiri*). A similar incipient central avascular area is also present in the Philippine Tree Shrew (*Urogale everetti*), where it may be seen ophthalmoscopically. This seems to be of some interest, in view of the modern opinion, according to which the Tupaiidae, a suborder of Insectivora, are considered by some the phylogenetical precursors of the Primate Order (*see* chap. XIV, 10).

In most other Mammals and in the Inframammalian Vertebrates the source, distribution, and abundance of the blood supply of the retina vary extraordinarily. In the Carnivora, Pinnipedia, Squirrels, and some other Mammals the retina is well supplied with vessels, their source, however, being in part or entirely the chorioid-ciliary system. Also, in some, only the layer of the nerve fibers is permeated by the capillaries; in others, in addition, the ganglion cell layer; in still others the inner plexiform layer also (so in the Alpine Marmot). In the Horse, Tapir, Elephant, *Hyrax*, Insectivorous Bats, some Rodents, Edentates, and Marsupials the blood supply is restricted to the optic papilla or to the adjoining territory, while in the Rhinoceros, *Hystrix*, *Dasypus*, *Echidna*, and *Proechidna*, there are no blood vessels whatever in the retina. By contrast, in the Old World Dormice *Myoxus* and *Eliomys* and similarly in the Raccoon and Opossum, a dense capillary network has been found underneath the outer limiting membrane within the outer nuclear layer, whereas the choriocapillary layer is absent, according to Kolmer. Of all the other Inframammalian Vertebrates, the Eel Family or Anguilidae alone shows complete vascularization.

Other Vertebrates have either a completely or almost completely avascular retina. In these, as in the Higher Vertebrates, the outer retinal layers depend nutritionally upon the chorioid-ciliary system of blood vessels, while the inner layers receive their nutrient fluid by way of osmosis from special vascular structures, such as the pecten or comb of the Birds and the "cone" of Lizards, derivatives of the hyaloid artery protruding from the optic disk into the vitreous.

A remarkable and well-developed vascular system, entirely different from that of any other Vertebrate, is present in the Anuran Amphibians (Frogs, Tree Frogs, Toads). It consists of a "central vein," whose branches, imbedded within the hyaloid membrane of the vitreous, spread over the inner face of the retina. Morphologically and functionally this system closely simulates the system of the central retinal artery of the Higher Vertebrates. No less unique an arrangement was found by Kolmer in the Flying Foxes (*Macrochiroptera*): conical loops of chorioid vessels invading the retinal substance almost as far as the inner limiting membrane.

The Ruminants possess a rich and complex central retinal system, remarkable because of the presence of a long, horizontally placed central area supplied by serially arranged twigs arising from larger horizontal vessels (Fig. 170). (*See* Leber, Johnson, Franz, Kolmer, Kolmer & Lauber, Rochon-Duvigneaud, Rochon-Duvigneaud & Rode, Walls, and others, for additional information.)

The blood vessels of the retina, or "vascular retinal tree" of Purkinje, may be seen "entoptically," that is, introspectively, by looking toward a moderately bright surface in lateral illumination. Subjectively the vessels appear as grayish shadows, the principal upper and lower temporal arteries and veins arching above and below the foveal excavation or "fixation point," toward which smaller twigs spread without reaching it. When the source of light is moved, the "retinal vascular tree" executes a parallactic movement in the opposite direction, a

phenomenon used by H. Müller to prove the photoreceptor function of the layer of rods and cones (*see* chap. I, 7 [5]). In hemianopia, only that portion of the vascular tree is seen entoptically which corresponds to the functional portion of the fields of view (self-observation).

SEC. 3. THE ARTERIAL CIRCLE OF WILLIS AND THE ORIGIN OF THE CEREBRAL ARTERIES

1. THE BASE OF THE BRAIN AND ITS ARTERIES.—The description of the cerebral arteries may conveniently begin with the base of the brain and the "arterial circle" of Willis, where the arteries of the neck meet and whence originate the principal arterial stems of the brain and many smaller vessels for the basal parts of the brain.

When the basal aspect of the brain is examined, the following parts and their topographical relationships are seen (Fig. 366): the two frontal lobes (*frl*) anteriorly, with the olfactory bulbs (*olfb*) and tracts (*olftr*) attached to them; the two temporal lobes (*tl*), flanking a deep central pit on both sides, the interpeduncular fossa of Tarini, the latter limited posteriorly by a prominent central protuberance, the pons or "bridge" of Varoli (*po*), the more slender posterior extension of which is the oblong medulla (*om*) and spinal cord (*sc*). The pons, oblong medulla, and spinal cord are flanked laterally by the large hemispheres of the cerebellum or little brain (*cbl*).

Along the margins of the cord and medulla, between the latter and the pons, from the sides of the pons, and from the central pit, spinal and cranial nerves emerge, some as rows of delicate rootlets, others as more or less formidable trunks (*II*, *III*, *IV*, *V*, *VI*, *VII*, *VIII*, *otr*, etc.). In our figures, for the sake of clarity, most

of these nerves were omitted (consult textbooks and atlases of anatomy and neuroanatomy).

In front of the pons, in the interpeduncular fossa, parts of the visual system lie exposed: the two optic nerves (*II*), joined in the chiasma (*ch*) and continuing as optic tracts (*otr*), and the two oculomotor nerves (*III*). Along the sides of the pons lie the much thinner trochlear nerves (*IV*), whereas the medium-thick abducent nerves (*VI*) originate from behind the posterior margin of the pons where that part is separated from the medulla by a deep transverse dent. The central structure in the interpeduncular pit just behind the optic chiasma is the infundibulum (*inf*), a funnel-shaped extension of the tuber cinereum or "gray hillock" of the hypothalamus, with the two round mammillary bodies behind. The pituitary gland or hypophysis, normally attached to the infundibulum, lodged in the depression of the "Turkish saddle" of the sphenoidal bone, is missing in the usual specimens.

In an intact specimen the interpeduncular fossa is bridged by a thin, smooth, translucent membrane—the arachnoid tunic—a continuation of the arachnoid meningeal cover of the brain. Through it, all nerves and blood vessels of this locality must pass on their way to and from the brain. Each nerve and vessel is here attached, though somewhat loosely, to the arachnoid, which is continuous with the epineurium of the nerves and the adventitial sheath of the blood vessels. Numerous threads and trabeculeS, partly forming bundles and sheets, pass into the fossa, in particular along its anterior, lateral, and posterior sides, to whose floor, formed by the inferior surface of the hypothalamus, they are firmly attached.

The nerves and the blood vessels, skirting the sides of the fossa, including the chiasma with the optic nerves and infundibulum, are all firmly imbedded in the arachnoid web and are thus securely held in place. The central space of the fossa is traversed by a few thin interconnected trabecules only. The described cavity, closed by a superficial arachnoid sheet, is the interpeduncular cistern. In the living, this cistern is filled with the cerebrospinal fluid and is continuous on all sides with the subarachnoid space of the brain.

The two internal carotid trunks (*ica*) emerge from their channels in the petrous temporal bones along the sides of the body of the sphenoidal bone—all parts that form the base of the skull. In the usual presentations of the basal aspect of the brain, these arteries appear to be lodged exactly in the two lateral crotches formed by the optic nerves and tracts (Figs. 366, 367). At a closer examination, however, this perspectival location is revealed to be an illusion, the actual distance between the carotid trunks and the chiasma in an anatomical specimen being not less than 6–8 mm. (Fig. 367). In the living, the distance may be somewhat less, owing to the turgor of the filled vessels, and probably varies depending on the conditions of circulation, as well as individually. A few minute blood vessels of the character of arterioles appear to arise from the carotid trunk before its further division and, imbedded in the lateral arachnoid partition of the fossa, pass to the tuber cinereum and infundibulum.

The topographical arrangement of the arteries at the base of the brain stem and in and around the interpeduncular fossa is as follows (same figures; *cf.* Fig. 362). The two *vertebral arteries* (*va*) course along the sides of the oblong medulla (*om*), gradually turning to its ventral side. Here the two vessels merge, to build a thick common stem, the *basilar artery* (*basa*). The point of juncture is almost at the upper limit of the medulla, although it may be a few millimeters below, or slightly above, the inferior margin of the pons. Before joining, each vertebral artery gives off a small branch—the *anterior spinal artery* (*asa*)—and one or more similar twigs that skirt the medulla as they pass to its lateral and dorsal sides and to the cerebellum—the *posterior spinal artery* (*posa*). One of these, a somewhat thicker blood vessel arising either from the vertebral or from the basilar artery, is the *inferior posterior cerebellar artery* (*ipocba*).

The trunk of the basilar artery (*basa*) is lodged in a shallow, central, longitudinal groove on the inferior face of the pons. From it a number of thicker and thinner arteries originate: medium-sized *inferior anterior* and *inferior posterior cerebellar arteries* (*iacba*, *ipocba*), one on each side; several minute branches that either enter the pontobulbar cleft or skirt it in order to reach the more dorsally situated parts, while

others, branching off along the basilar trunk, the *pontine arteries* (*poa*), spread over the face of the pons or soon enter its substance.

In 60 per cent of the specimens, the auditory artery (*auda*) arises, according to Stopford (1916), from the inferior anterior cerebellar artery, and in the remaining 40 per cent, directly from the basilar artery, or, according to Lelli (1939), always from the inferior anterior cerebellar artery. According to our own observations, both situations may be present on different sides of the same specimen. Minute twigs of the auditory artery supply the common stem of the eighth cranial nerve, whereas the others enter the substance of the pons along the posterior margin.

Other similar small arteries are given off from the basilar stem for the remainder of the pons, including the anterior margin. Two of the thicker ones, unequal on both sides, arising from the intermediate basilar segment, spread partly over the pons in the direction of the crura or "limbs" of the brain, skirting the roots of the trigeminal nerve (*V*), and, if strong enough, may continue over the inferior face of the cerebellum—the *rostral inferior cerebellar arteries* (*ricba*).

Altogether, there are about a dozen arteries, mostly thin, arising directly from the basilar stem between the junction of the vertebral arteries at the caudal end of the trunk and its rostral end, where the two superior cerebellar arteries separate.

The two strong *superior cerebellar arteries* (*sucba*), a right and a left, arise close to the upper extremity of the basilar trunk at the anterior boundary of the pons (Fig. 368). They sweep in front and along the sides of that structure in an ascending course toward the dorsal face of the cerebellum and the midbrain. Initially they are, on the one hand, close to the oculomotor nerves (*III*), which they touch directly, and, on the other hand, to the trochlear nerves (*IV*), from which, however, they are separated by the tough superficial arachnoid laminae that stretch over from the pons to the adjoining temporal lobes (*un*, uncus). Along their further course upward on the lateral and dorsal sides of the midbrain, the artery and the trochlear nerve lie close together.

2. The arterial circle of Willis.—Two or 3 mm. rostrally from the origin of the superior cerebellar arteries, the basilar trunk finally divides into two thick *posterior cerebral arteries* (*pocea*), a right and a left, both located in the interpeduncular fossa. One, usually on the left side, is thicker (right side in Fig. 368). The posterior cerebrals are the principal subdivisions into which the basilar artery continues. Initially they deviate, respectively, toward the right and left pockets of the interpeduncular fossa, crossing the trunks of the oculomotor nerves in front and on the medial sides. They may give off a very fine twig or two to these nerves as they pass over them. Part of their more numerous branches, mostly thin and a few thick ones, sweep around the foot of the peduncle, the majority disappearing in the posterior perforated substance (*pps*), thus entering the midbrain and betweenbrain.

A thicker branch, one on each side, the *posterior chorioid artery* (*pocha*), supplies in part the chorioid plexus of the third cerebral ventricle (*see* Fig. 368; also Fig. 372), others supplying the nucleus of the oculomotor nerve.

Rostrally, each posterior cerebral artery gives off a medium or even a fairly thick vessel, the *posterior communicating artery* (*pocoa*), in this way linking up with the *internal carotid arteries* (*ica*).

Since the two *anterior cerebral arteries* (*acea*) that arise from the internal carotids are connected with each other either by one or by more distinct links, the *anterior communicating artery* or arteries (*acoa*), or by direct merging, the "arterial circle" of Willis is thus completed.

Occasionally, the posterior cerebral artery takes origin from the carotid of its own side, in which case it is connected with the basilar artery through a thin posterior communicating artery. This is, according to Duret, a more frequent occurrence on the right side (shown on left side in Fig. 368).

There are, altogether, seven arterial links that make up the circle of Willis: one anterior communicating (single or double), two anterior cerebrals, two posterior communicating, and two posterior cerebrals. If both internal carotids are included, the number of links increases to nine; if the basilar trunk is also added, there are

ten constituents. The composition of the circle varies greatly in individual specimens.

The obvious function of the circle is to serve as a "general cerebral anastomosis" which equalizes the distribution of blood and blood pressure in all parts of the brain (Duret 1874) – that is, to permit the flow of blood in any direction, e.g., from the right to the left side or vice versa or from the anterior to the posterior parts or in any other combination, as the particular situation demands. Such a situation may arise when any one or two of the four principal arteries, the internal carotids or the vertebral arteries, alone or in combination, are obstructed, while the other two still function. (*See also* McDonald & Potter 1951.) A typical arterial circle is considered to be an arrangement characteristic of Man and of the majority of the Higher Primates, especially of the Anthropomorphous Apes, according to Grünbaum and Sherrington (1902).

3. Parts of the visual system supplied by the arterial circle. The "arterial circle" of Willis and the adjoining arteries participating in it are topographically and functionally closely related to the infranuclear and nuclear divisions of the visual system (Figs. 366, 367, 368, 371). Topographically, the circle surrounds the terminal portions of the optic nerves joined by the chiasma and the initial portions of the tracts, the nerves slipping underneath the circle; the tracts, above. Concerning the functional relationship, each link of the circle or an artery contributing to it takes care of supplying one particular portion or segment of the visual pathways, besides other adjoining structures.

The *ophthalmic artery* (*opha*) arises from the anteromedial aspect of the stem of the internal carotid artery (*ica*) just before its division into anterior and middle cerebrals (Fig. 371). It accompanies the optic nerve, wrapped with it in the dural sheath, through the bony optic foramen or canal, on the lower side, into the orbit. It supplies most of the contents of the orbit, including the eyeball, with blood (*see* preceding section). The artery, as it arises from underneath along the lateral side of the nerve and passes over it to the medial side, gives off a branch, the *central retinal artery* (*cra*), which in Man is the exclusive, and in other Primates the principal, source of blood supply for approximately the vitreal half of the retina (*see* sec. 2 [3], this chapter).

The intracranial and canalicular portions of the optic nerve are supplied partly by the twigs of the anterior cerebral and the ophthalmic arteries and partly by the central retinal artery (through its recurrent or postcentral branches as far as the optic foramen and through its deeper axial twig or twigs running along the central retinal artery and vein).

The layer of photoreceptors (*3*), the outer nuclei (*4*), and the outer and middle zones of the outer plexiform layer (*5-a*, *5-b*) of the retina receive their nutrition via the innermost, choriocapillary, layer of the chorioid membrane, which is in turn supplied by the posterior ciliary arteries (short and long), which are branches of the ophthalmic artery (*see* preceding section).

The arterial supply of the optic chiasma is principally from the two anterior cerebral arteries (Figs. 368, 371). The most medial of the twigs, arising close to the mid-sagittal cerebral cleft, spread over the anterior and superior aspects of the middle, bridgelike portion and also over the terminal lamina of the diencephalon; several other branches arising from the more lateral points along the stems of the anterior cerebrals, closer to their carotid origin, spread over the lateral parts of the chiasma along its angles. A few delicate twigs of the anterior communicating arteries, spreading over the tuber cinereum, may possibly also contribute to the chiasmal supply along its posterior and inferior aspects. Whether other sources—the internal carotids, middle cerebrals, anterior chorioidals, and anterior communicating arteries—regularly participate in the supply of the chiasma, as believed by some (Abbie 1938), or do so only occasionally requires further investigation. The same is also true of the alleged anastomotical arterial network of the pia mater that lines the region of the chiasma.

The initial portions of the optic tracts receive their arterial twigs from the *anterior cerebral arteries*, the first to arise after the separation of the latter from the middle cerebrals (Fig. 368). The middle portions of the tracts are supplied by the twigs from the *posterior com-*

municating artery, which also supplies the *genu* or "knee" and the adjoining portion of the posterior limb of the internal capsule and the anterior third of the thalamus, except its anterior nucleus, which is supplied by the posterior cerebral, according to Abbie.

The principal source of supply of the middle and posterior portions of the optic tract, however, is the *anterior chorioid artery* (*acha*, Fig. 371; *see also* sec. 4 [2], this chapter). This vessel arises from the posterior aspect of the internal carotid artery at about the level of its division into the anterior and middle cerebral arteries, or sometimes from the stem of the middle cerebral artery. (Abbie [1938] considers such a middle cerebral origin very rare and as responsible for Duret's concept of a "lenticulo-optic artery.") The anterior chorioid is the first vessel to emerge along the middle cerebral stem, lateral to the posterior communicating artery. It crosses the anterior perforate substance in a posterior direction, coming to lie on the ventral face of the optic tract, between it and the uncus of the hippocampal gyrus (*unc*). Along its course in this locality it gives off several thin branches, some passing laterally, others medially, along the optic tract. One twig may penetrate the tract at its inferior aspect; still other numerous, very fine branchlets spread over the pial sheath, which covers the inferior surface of the tract and the adjoining portion of the hippocampal gyrus (uncus).

At the point where the anterior chorioid artery reaches the lateral geniculate nucleus, it enters the inferior chorioid plexus (*chpl*) of the inferior horn of the lateral ventricle, whose most oral portion it supplies. Before this, however, it gives off two or more small perforating branches for the lateral geniculate nucleus, one penetrating at the medial (*hilum*), the other at the lateral, contour of its posterior aspect.

Other very fine twigs spread in the pial sheath lining the free, inferior face of the lateral geniculate nucleus. Some of the deep twigs supply the lateral geniculate nucleus, the tail of the caudate nucleus, the roof of the inferior horn of the lateral ventricle, approximately the posterior two-thirds of the posterior limb and the whole of the infra- and retrolenticular portions of the internal capsule, and the adjoining portions of the thalamus and globus pallidus, according to Abbie (1937)—this part of the capsule containing the auditory and visual radiations. Other branches spread over the lateral aspect of the cerebral peduncle adjacent to the optic tract.

In summary, the lateral geniculate nucleus is supplied by the anterior chorioid artery (*acha*) and also in part by the lateral chorioid artery (*laaha*), a branch of the posterior cerebral artery (*see* sec. 5 [2], this chapter; and also L. Chacko 1952).

4. THE ANTERIOR CEREBRAL ARTERY.—This important vessel (*acea*) is the lesser of the two strong branches into which the trunk of the internal carotid artery (*ica*) subdivides (Figs. 368, 371). Its initial portion sweeps above the optic nerve and beneath the base of the frontal lobe toward the mid-sagittal cleft, which separates the two cerebral hemispheres. Along its arching course it gives off numerous small branches in the following order: most posteriorly, to the initial portion of the ipsilateral optic tract (*otr*) and the lateral aspect of the chiasma (*ch*), and also some branchlets to the proximal segment of the optic nerve (*on*), as well as branches that penetrate into the brain's base through the anterior perforate substance (*aps*); twigs arising closer to the mid-line, to the middle segment of the chiasma. Beyond this, there are no other known parts of the visual system to which this artery is related.

As soon as the mid-sagittal cleft is approached, the two anterior cerebral arteries are linked by one or more short, bridgelike anastomoses, the *anterior communicating artery* or *arteries* (*acoa*). Sometimes only a single anterior cerebral artery is found beyond the point of coalescence, which is reminiscent of conditions found regularly in the lower Mammals: an anterior azygos or unpaired cerebral artery (Critchley). On rare occasions the anterior communicating link is absent, the condition then resembling that normally found in the Lower Vertebrates.

The first branch of the anterior cerebral is the *medial striate artery* of Abbie (1937), formerly known as "Heubner's artery" (Aitken) and the "recurrent branch" (Shellshear). It is a medium-thick vessel originating from the anterior cerebral trunk opposite, or slightly peripheral

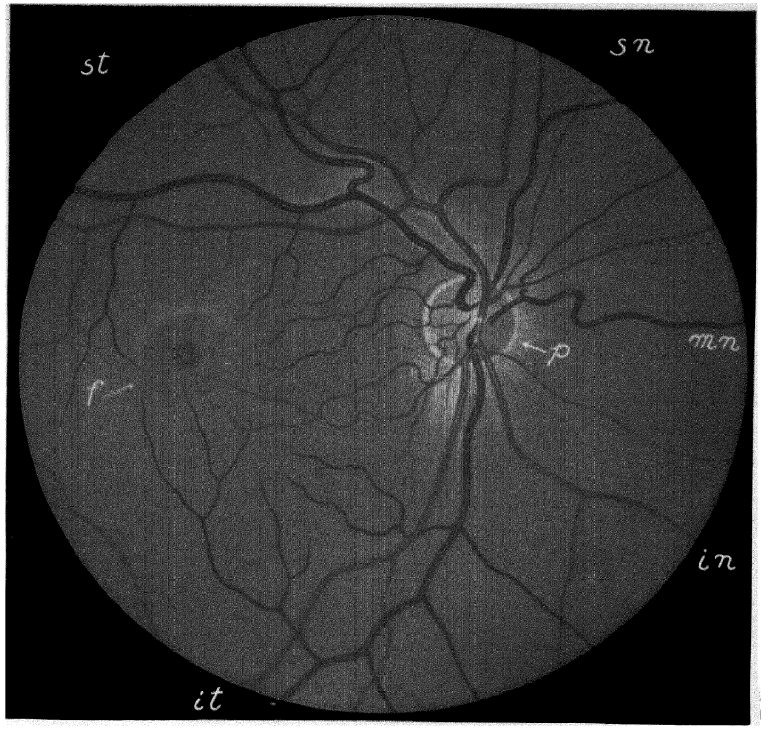

FIG. 363—Fundus or interior of a normal human eye as seen through an ophthalmoscope. Optic papilla (*p*) appears as a round disk, with a whitish, funnel-like physiological excavation in its center. Papilla is encircled by two rings, a white scleral one, and another grayish chorioidal ring on the outside, the latter more pronounced on temporal side (left). Nasal half of the papilla orange-red, left half pink. Central retinal blood vessels: arteries vermilion red, veins carmine red. After first dividing beyond the cribriform lamina, the vessels further subdivide into principal branches: the superior and inferior temporal (*st*, *it*), the superior, inferior, and a middle nasal (*sn*, *in*, *mn*), and the small arteries and veins for the central area and fovea (" macular vessels," unlabeled). Bundles of optic nerve fibers appear as whitish streaks radiating from the papilla, especially along the larger vessels (indication of perifoveal arching). Central foveal excavation (*f*) indicated by a faint grayish oval-shaped reflex (" Schirmer's phenomenon ") about the size of papilla and two papillar diameters temporal from it. Fovea (*f*) encloses in its center a small, circular, dark-red area corresponding to the fundus or floor of the fovea, its deepest point, foveola, marked by a dot-like whitish foveolar reflex in the very center. Blood vessels on the nasal side (right) arranged radially, on the temporal side (left) arching above and below the fovea toward which many small twigs spread, with few terminals just slipping into it over its edge (*compare* Figs. 148, 149, 165, 365). Chorioidal vessels in this specimen remain invisible because of the retinal pigment (*compare* also Figs. 166 to 170). Approximate magnification 8x. (From Th. Axenfeld, *Lehrbuch der Augenheilkunde* 1910, with legend in part re-interpreted.)

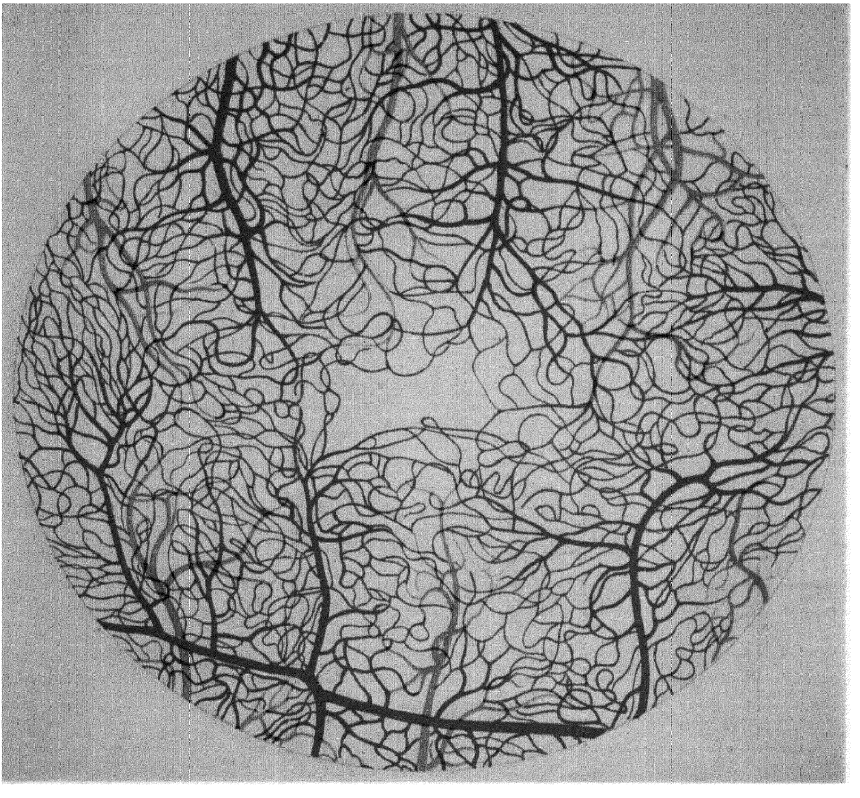

FIG. 364—Blood vessels of human central fovea of the retina, painted from an injection preparation of Heinrich Müller, pioneer investigator of the eye (portrait Fig. 46). The injection, including all capillaries, appears to be complete. Arteries (red), dividing into arterioles and finally into capillaries, are re-assembled into veins (blue) that carry the used-up blood away. In the very center of the foveal excavation all vessels, also capillaries, are absent: the central avascular or vessel-free area, roughly corresponding with the foveal floor (*see* Figs. 129, 161). Dimensions of the vessel-free area, according to original description, 0.31 x 0.41 mm. Position of the arteries relative to the veins is vitrealad. (From O. Becker, Graefe's *Archiv für Opthalmologie* vol. 27 [1], plates *I-II*, y. 1881).

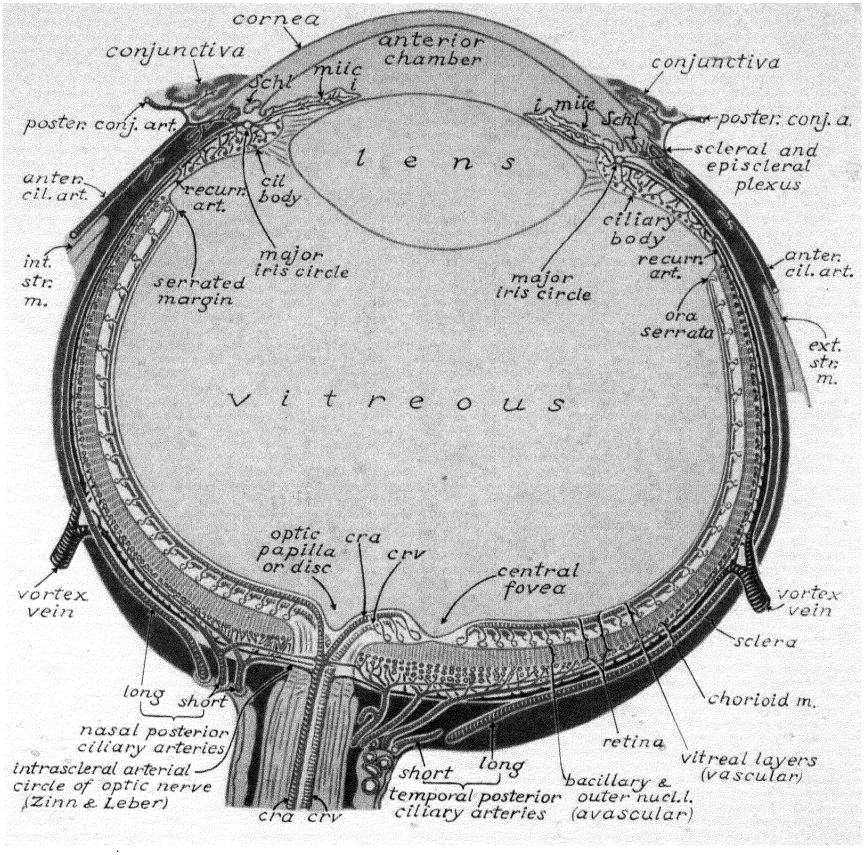

FIG. 365—Blood supply of the human eyeball schematically presented in a horizontal section, 5½x magnified. Retina and chorioid proportionally several times thicker than normal in order to show the arrangement of blood vessels; other structures including sclera, lens, and ciliary body drawn to scale. Partly adapted from Leber 1903 and others (*compare* Figs. 125, 363, 371). Central retinal system in orange (artery) and in light blue (vein), ciliary and conjunctival arteries in red, vortex and chorioidal veins in dark blue. *Note:* the presence of a communication between the central retinal and ciliary systems at the optic disk, and a complete separation of the two systems in the remainder of the eye; the presence of the vessels in the vitreal layers except in the foveal center, their absence in scleral layers (bacillary and outer nuclear layers) of the retina; increased thickness of the choriocapillary layer in the central area, especially fovea (small red circles); complete avascularity of the lens and cornea; rich blood supply of the ciliary body; anastomotical connections between ciliary and conjunctival vessels in the region of ciliary body. *Abbreviations: anter. cil. art.* anterior ciliary artery; *cra* central retinal artery; *crv* central retinal vein; *i* iris; *ext. str. m.* external straight muscle; *int. str. m.* internal straight muscle; *miic* minor arterial iris circle; *poster. conj. art.* posterior conjunctival artery; *recurr. art.* recurrent branch of long posterior ciliary artery; *Schl* Schlemm's canal.

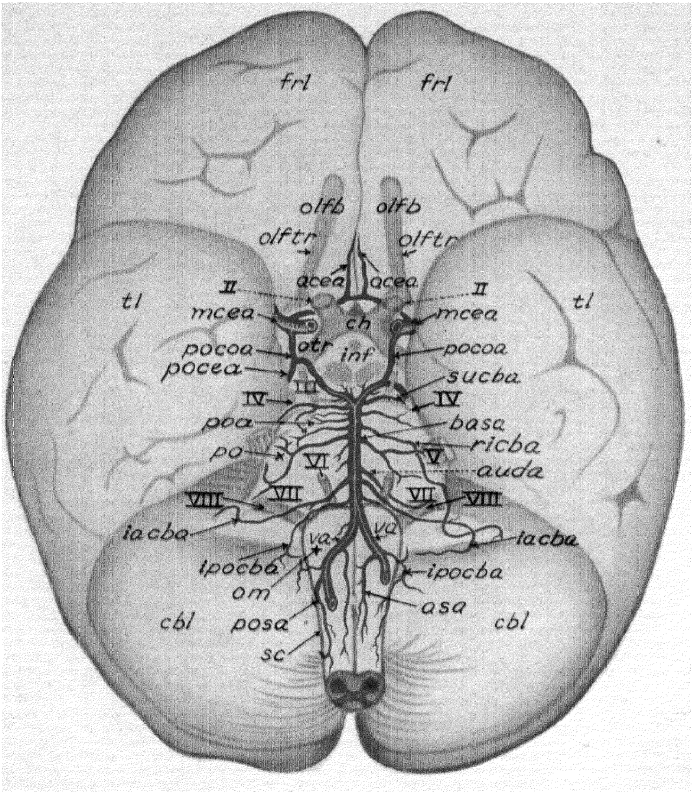

FIG. 366—**Basal** view of the human brain showing the sources of the arterial blood supply, and the arrangement of the principal vessels including the arterial circle of Willis. *Abbreviations: acea* anterior cerebral artery ; *asa* anterior spinal artery ; *auda* auditory artery ; *basa* basilar artery ; *cbl* cerebellum ; *ch* chiasma of optic nerves ; *frl* frontal lobe ; *iacba* inferior anterior cerebellar artery ; *inf* infundibulum of hypothalamus ; *ipocba* inferior posterior cerebellar artery ; *mcea* middle cerebral artery ; *olfb* olfactory bulb ; *olftr* olfactory tract ; *om* oblong medulla ; *otr* optic tract ; *po* pons or " bridge " ; *poa* pontine arteries ; *pocea* posterior cerebral artery ; *pocoa* posterior communicating artery ; *posa* posterior spinal artery ; *richa* rostral inferior cerebellar artery ; *sc* spinal cord ; *sucba* superior cerebellar artery ; *tl* temporal lobe ; *va* vertebral artery ; *II* optic nerve ; *III* oculomotor nerve ; *IV* trochlear nerve ; *V* trigeminal nerve ; *VI* abducent nerve ; *VII* facial nerve ; *VIII* auditory nerve.

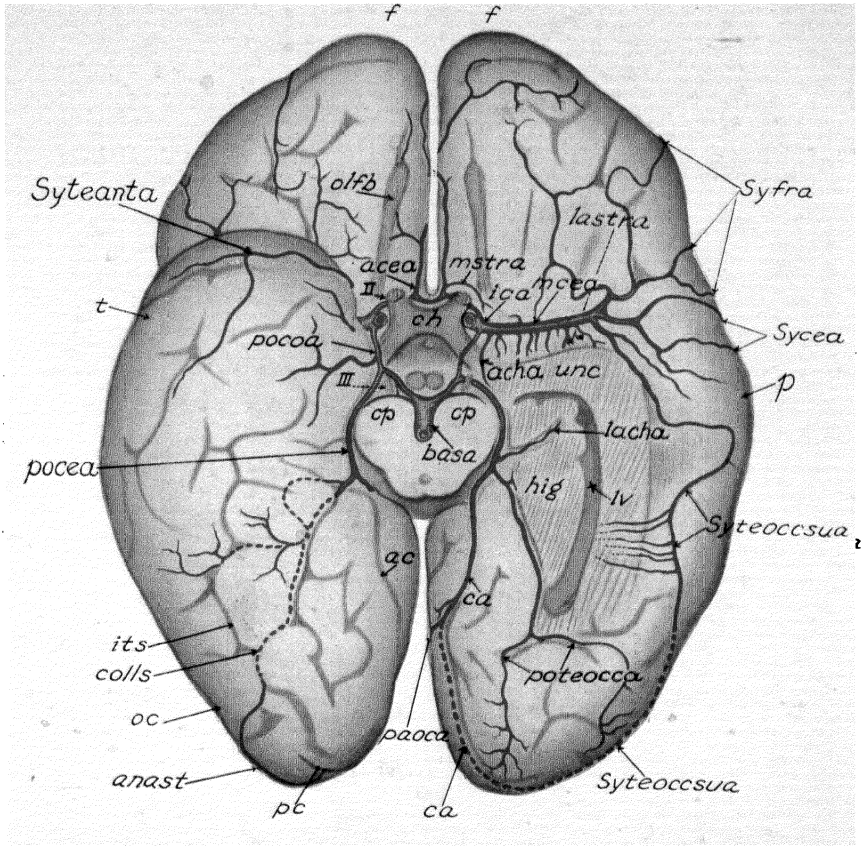

FIG. 367—Basal view of the human brain with ventral portion of the left temporal and occipital lobes removed in order to show the origin, course, distribution, and anastomosing of the deep arteries of the Sylvian pit. *Abbreviations:* *ac* anterior or medial calcarine sulcus; *acea* anterior cerebral artery; *anast* anastomotic connection between superior temporo-occipital Sylvian artery (*Syteoccsua*) and calcarine artery (*ca*) (*compare* Figs. 371, 374); *basa* basilar artery; *ca* calcarine artery; *ch* chiasma of optic nerves; *cp* cerebral peduncle; *acha* anterior chorioid artery; *colls* collateral sulcus; *f* frontal lobe; *hig* hippocampal gyrus; *ica* internal carotid artery; *lacha* lateral chorioid artery; *its* inferior temporal sulcus; *lastra* lateral striate arteries; *lv* lateral ventricle; *mcea* middle cerebral artery; *mstra* middle striate artery; *oc* occipital lobe; *olfb* olfactory bulb; *p* parietal lobe; *paoca* parieto-occipital artery; *pc* posterior or lateral calcarine sulcus and posterior parietal artery; *pocea* posterior cerebral artery; *poteocca* posterior temporo-occipital artery; *Sycea* central Sylvian arteries; *Syfra* frontal Sylvian arteries; *Syteoccsua* superior temporo-occipital Sylvian arteries; *Syteanta* anterior temporal Sylvian arteries; *t* temporal lobe; *unc* uncus or "spur" of hippocampal gyrus; *II* optic nerve; *III* oculomotor nerve. Note anastomotic connection: broken line in right lower portion of the figure, between superior temporo-occipital Sylvian artery (*Syteoccsua*) and calcarine artery (*ca*), and *compare* with Figs. 369, 370, 374.

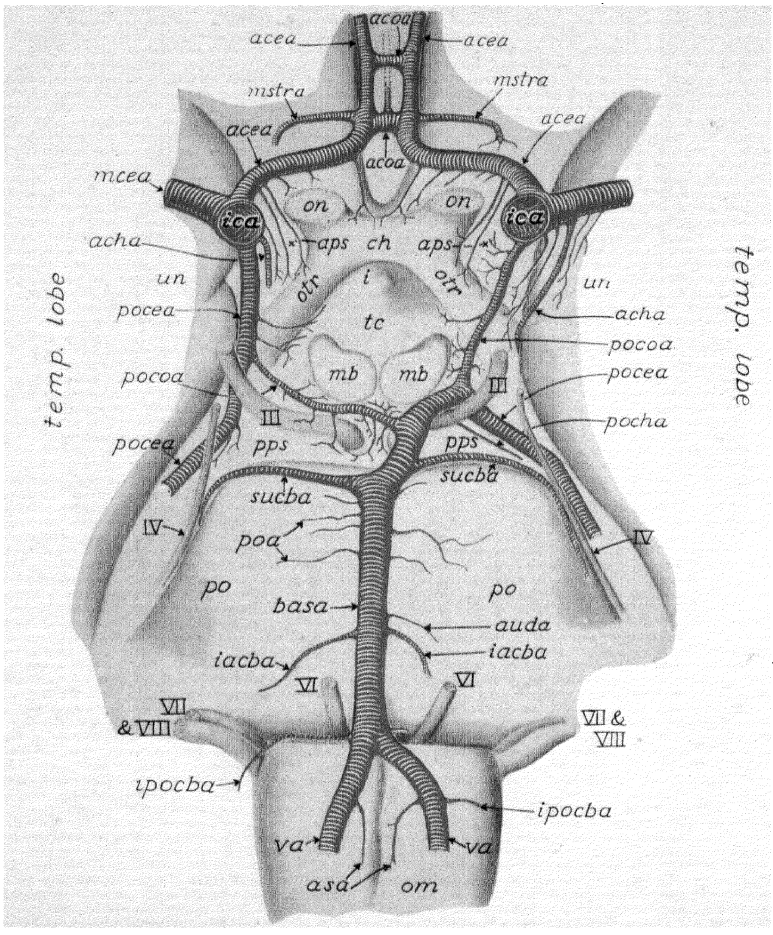

FIG. 368—Arterial circle of Willis of the human brain, and its topographical relations. Approximately 2x magnified, and slightly schematized. Special features in this specimen are a double anterior communicating artery, and on the right side (left in figure), the origin of the posterior cerebral artery (*pocea*) from the internal carotid (*ica*) instead of from the basilar (*basa*), with posterior communicating (*pocoa*) on that side much reduced in thickness and arising from the basilar. *Abbreviations:* *acea* anterior cerebral artery; *acha* anterior chorioid artery; *acoa* anterior communicating artery; *aps* anterior perforate spot or substance; *asa* anterior spinal artery; *auda* auditory artery; *ch* chiasma of optic nerves; *i* infundibulum or "funnel" of hypothalamus; *iacba* inferior anterior cerebellar artery; *ipocba* inferior posterior cerebellar artery; *mb* mammillary body; *mstra* middle striate artery of Abbie, "Heubner's artery" of Aitken, or "recurrent branch of anter. cerebr. artery" of Shellshear; *om* oblong medulla; *on* optic nerve (cut); *otr* optic tract; *po* pons or "bridge"; *poa* pontine arteries; *pocea* posterior cerebral artery; *pocha* posterior chorioid artery; *pocoa* posterior communicating artery; *pps* posterior perforate spot or substance; *sucba* superior cerebellar artery; *un* uncus of hippocampal gyrus; *va* vertebral artery; *III* oculomotor nerve; *IV* trochlear nerve; *VI* abducent nerve; *VII* facial nerve; *VIII* acoustico-vestibular nerve.

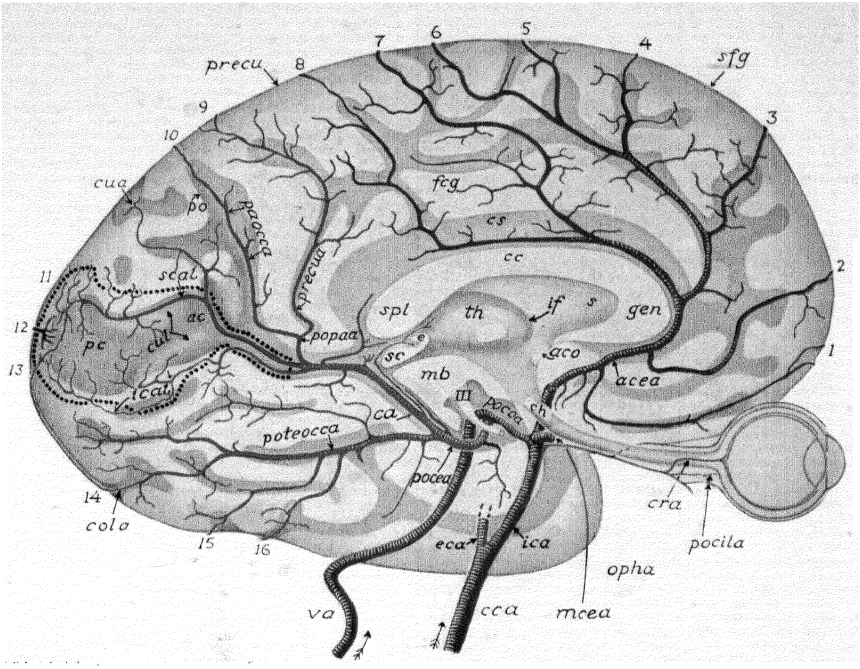

FIG. 369—Arteries of the human brain. Medial aspect of the left cerebral hemisphere with its principal sulci and fissures partly opened to show the concealed portions of vessels. The common carotid (*cca*) and vertebral (*va*) arteries, sources of blood supply of the cranium and brain, given in heliotrope color, are connected by the ipsilateral posterior communicating artery (*pocoa*), in this way forming the arterial circle (*see* Figs. 366, 367, 368, 371). From this circle arise the principal arteries which supply the hemisphere: anterior cerebral (*acea*, light blue), middle cerebral (*mcea*, green) and posterior cerebral (*pocea*, vermilion red). Of the middle cerebral only the initial portion is seen, its continuation and ramification is shown on the lateral face of the same hemisphere in Fig. 370. *Note:* even distribution and straight course of the principal branches of anterior cerebral, preserving their original fetal arrangement (*see* Fig. 375); calcarine sulcus (*ac* and *pc*) supplied by a superior (*scal*) and inferior calcarine artery (*ical*), not greatly differing in size, their separation following a horizontal line; the region supplied by both almost coincides with the striate area marked by a dotted line; posteriorly both calcarine arteries are linked by anastomosis, to which a long branch of the posterior temporo-occipital artery (*poteocca*, *12*) also contributes; additional supply is from extreme terminals of the superior temporo-occipital Sylvian artery (*Syteoccsua*, *13*), a subsidiary of the middle cerebral (*see* Figs. 370, 371, 372, 374). *Abbreviations:* *ac* anterior or medial calcarine sulcus; *acea* anterior cerebral artery; *aco* anterior commissure; *cc* corpus callosum; *cca* common carotid artery; *ch* chiasma of optic nerves; *cola* collateral artery; *cra* central retinal artery; *cs* callosal or epicallosal sulcus; *cua* cuneal artery; *cul* cuneo-lingual gyri; *e* epiphysis or pineal body; *eca* external carotid artery; *fcg* fornicate or cingular gyrus; *gen* genu or "knee" of callosal body; *ica* internal carotid artery; *ical* inferior calcarine artery; *if* interventricular foramen of Monro; *mb* midbrain; *mcea* middle cerebral artery; *opha* ophthalmic artery; *paocca* parieto-occipital artery; *pc* posterior or lateral calcarine sulcus; *po* parieto-occipital sulcus; *pocea* posterior cerebral artery; *popaa* posterior parietal artery; *poteocca* posterior temporo-occipital artery; *precu* precuneus; *precua* precuneal artery; *s* pellucid septum; *sc* superior colliculus of midbrain; *scal* superior calcarine artery; *sfg* superior frontal gyrus; *spl* splenium of callosal body; *th* thalamus; *va* vertebral artery; *III* oculomotor nerve. Small Arabic numerals mark arteries which can be followed in Fig. 370.

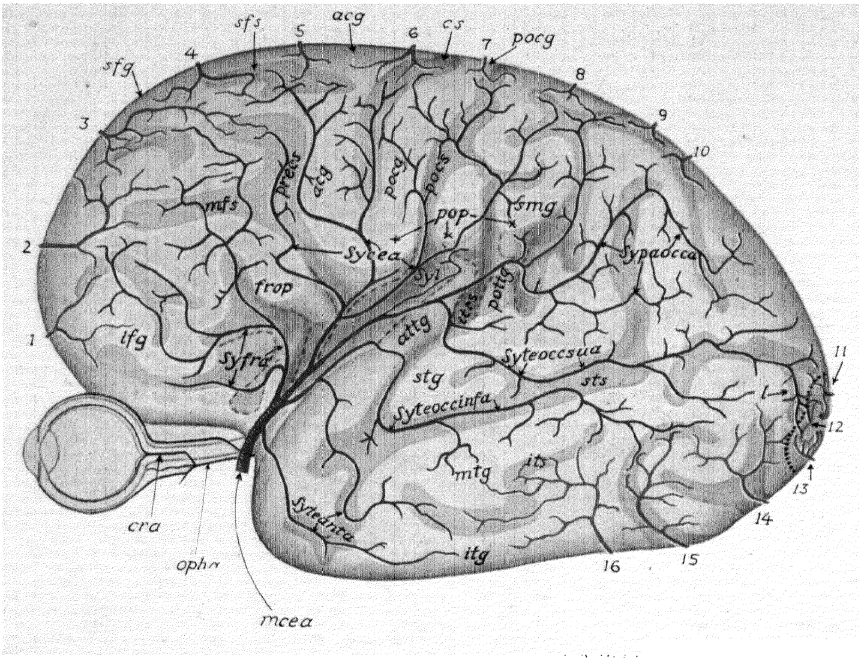

FIG. 370—Arteries of the human brain. Lateral aspect of the left cerebral hemisphere with the principal sulci and fissures represented partly opened to show portions of vessels concealed in the fissures. Middle cerebral artery (*mcea*, green), of which in the preceding figure only the initial stump is seen, spreading over most of the lateral face of the hemisphere, leaving to the anterior cerebral (*1-8*, light blue) and posterior cerebral (*9-11, 13-16*, vermilion) only a marginal zone. The number, division, topographical relations to the limiting sulci and gyri, and the course of principal branches of the middle cerebral artery are revealed by pulling apart the operculums of the frontal and parietal lobes from the temporal lobe, in this way exposing a deep and spacious pocket of the lateral fissure of Sylvius (*Syl*). Of special interest are posterior branches of the middle cerebral, whose deep twigs supply the visual radiation along a part of its course (*see* Figs. 367, 371). The longest of these, the superior temporo-occipital Sylvian artery (*Syteoccsua*), stretches as far as the occipital pole (*12*) where in this individual specimen, together with superior calcarine (*11*), inferior calcarine (*13*), and a branch of posterior temporo-occipital artery (*14*), it shares in supplying the posterior extremity of the striate area (marked by a dotted line). *Abbreviations: acg* anterior central gyrus; *attg* anterior transverse temporal gyrus of Heschl; *cra* central retinal artery; *frop* frontal operculum; *ifg* inferior frontal gyrus; *itrs* intertransverse temporal sulcus; *its* inferior temporal sulcus; *l* lunate sulcus; *mcea* middle cerebral artery; *mfs* middle frontal sulcus; *mtg* middle temporal gyrus; *opha* ophthalmic artery; *pocg* posterior central gyrus; *pocs* postcentral sulcus; *pottg* posterior transverse temporal gyrus of Heschl; *precs* precentral sulcus; *sfg* superior frontal gyrus; *smg* supramarginal gyrus; *stg* superior temporal gyrus; *sts* superior temporal sulcus; *Sycea* central Sylvian artery; *Syfra* frontal Sylvian artery; *Syl* Sylvian fossa or lateral cerebral fissure; *Sypaocca* parieto-occipital Sylvian artery; *Syteanta* anterior temporal Sylvian arteries; *Syteoccinfa* inferior temporo-occipital Sylvian artery; *Syteoccsua* superior temporo-occipital Sylvian artery. Small Arabic numerals mark terminals of arteries originating on the medial face of the hemisphere shown in the preceding figure.

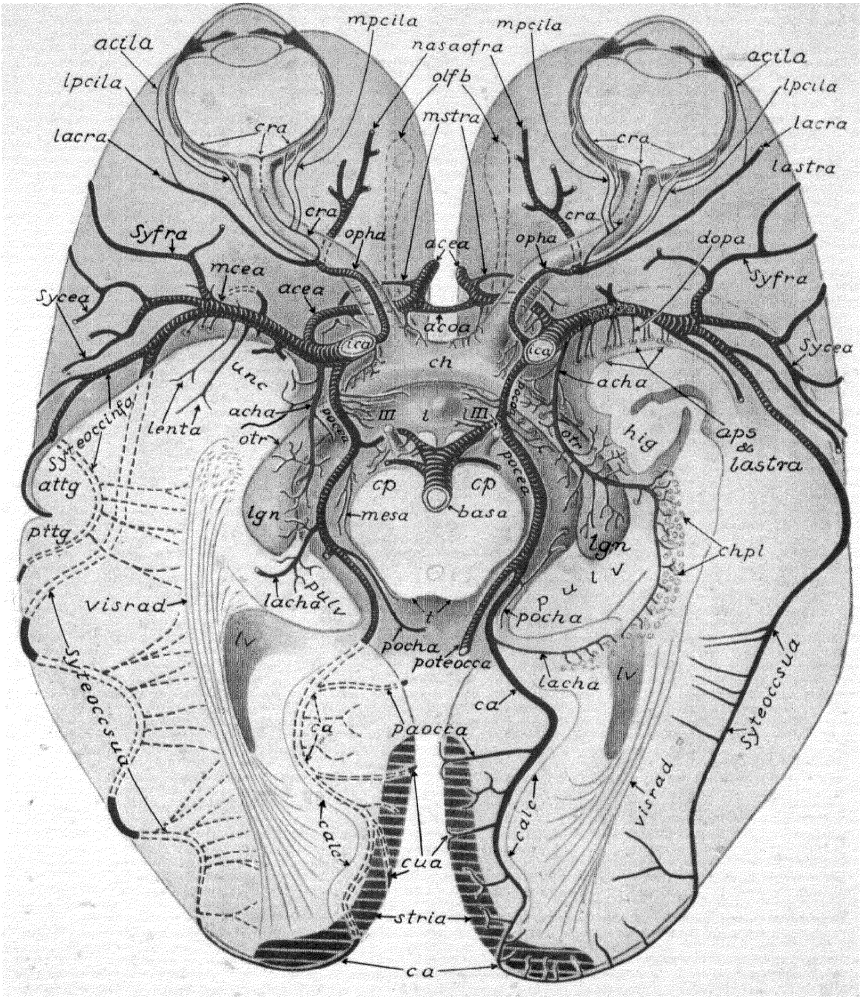

FIG. 371—Arterial blood supply of the human visual system presented in an ideal horizontal plane close to the base of the brain. Centrally located arterial circle of Willis made up of the anterior communicating (*acoa*), anterior cerebral (*acea*), posterior communicating (*pocoa*), and posterior cerebral (*pocea*) arteries interconnects the basilar (*basa*), and the two internal carotid arteries (*ica*). From it three pairs of arteries arise: anterior (*acea*), middle (*mcea*), and posterior cerebrals (*pocea*), spreading their branches over the brain and its dependencies, the optic tracts, chiasma, nerves, and eyeballs. *Note:* the supply of the retinae by central retinal arteries (*cra*), of the remainder of the eyeballs by the ciliary arteries (*acila*, *lpcila*, *mpcila*) arising from the ophthalmic artery (*opha*); multiple supply of the chiasma (*ch*), optic tracts (*otr*), lateral geniculate nuclei (*lgn*), visual radiations (*visrad*), and striate areae (*stria*). *For abbreviations see text.*

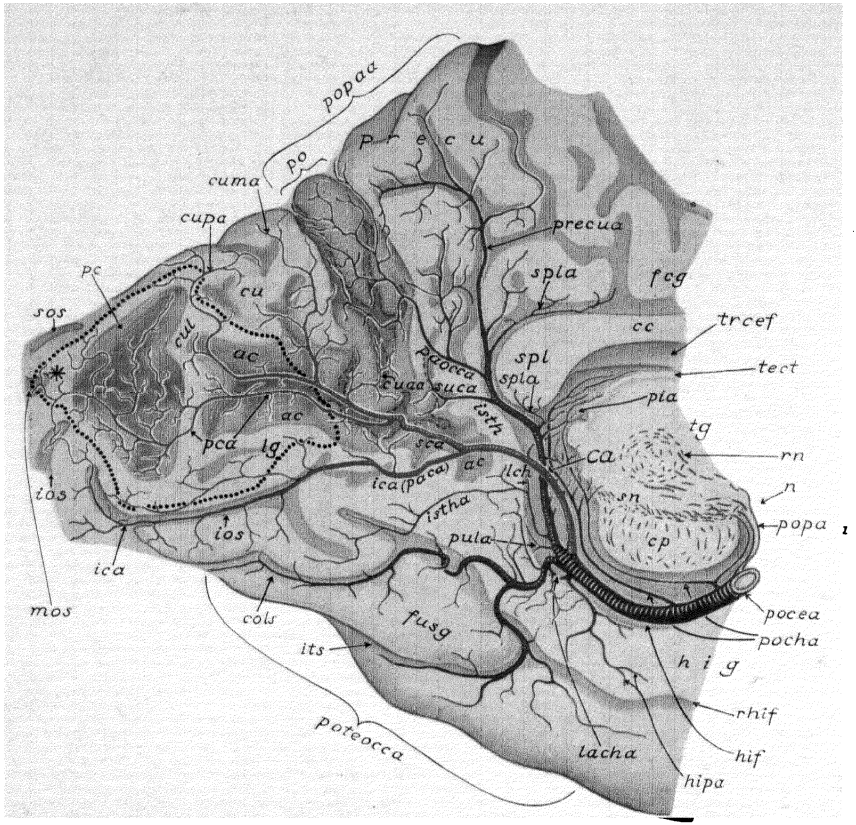

FIG. 372—Posterior cerebral artery. Medial aspect of left occipital lobe with sulci partly opened. Approximately natural size. The trunk of the posterior cerebral artery (*pocea*, heliotrope color) alongside of hippocampal fissure, between the hippocampal gyrus (*hig*) and cerebral peduncle (*cp*), divides in this particular specimen into three principal branches: calcarine artery (*ca*, vermilion red), posterior parietal artery (*popaa*, green), and posterior temporo-occipital artery (*potaocca*, light blue). Calcarine artery in turn produces two main divisions, a superior calcarine (*sca*), and an inferior (*ica*) or paracalcarine artery (*paca*). *Abbreviations: ac* anterior or medial calcarine sulcus; *ca* calcarine artery; *cc* corpus callosum; *cols* collateral sulcus; *cp* cerebral peduncle; *cu* cuneus; *cuaa* anterior cuneal artery; *cul* cuneo-lingual gyrus; *cuma* middle cuneal artery; *cupa* posterior cuneal artery; *fcg* fornicate-cingular gyrus; *fsg* fusiform gyrus; *hif* hippocampal fissure; *hig* hippocampal gyrus; *hipa* hippocampal artery; *ica* (*paca*) inferior calcarine or paracalcarine artery; *ios* inferior occipital sulcus; *isth* isthmus of fornicate and hippocampal gyri; *istha* isthmal artery; *its* inferior temporal sulcus; *lacha*, *lch* lateral chorioid arteries; *lg* lingual gyrus; *mos* middle occipital sulcus; *paca* (*ica*) paracalcarine artery; *paocca* parieto-occipital artery; *pc* posterior calcarine sulcus; *pca* principal calcarine artery; *pia* pial arteries; *po* parieto-occipital sulcus or fissure; *pocea* posterior cerebral artery; *pocha* posterior chorioid arteries; *popa* posterior perforate arteries; *popaa* posterior parietal artery; *potaocca* posterior temporo-occipital artery; *precu* precuneus; *precua* precuneal artery; *pula* artery for pulvinar of thalamus; *rhif* rhinal fissure; *rn* red nucleus; *sca* superior calcarine artery; *sn* substantia nigra of midbrain; *sos* superior occipital sulcus; *spl* splenium of corpus callosum; *spla* splenial artery; *suca* supracalcarine artery; *tect* midbrain tectum; *tg* midbrain tegmentum; *trcef* transverse cerebral fissure; * occipital pole.

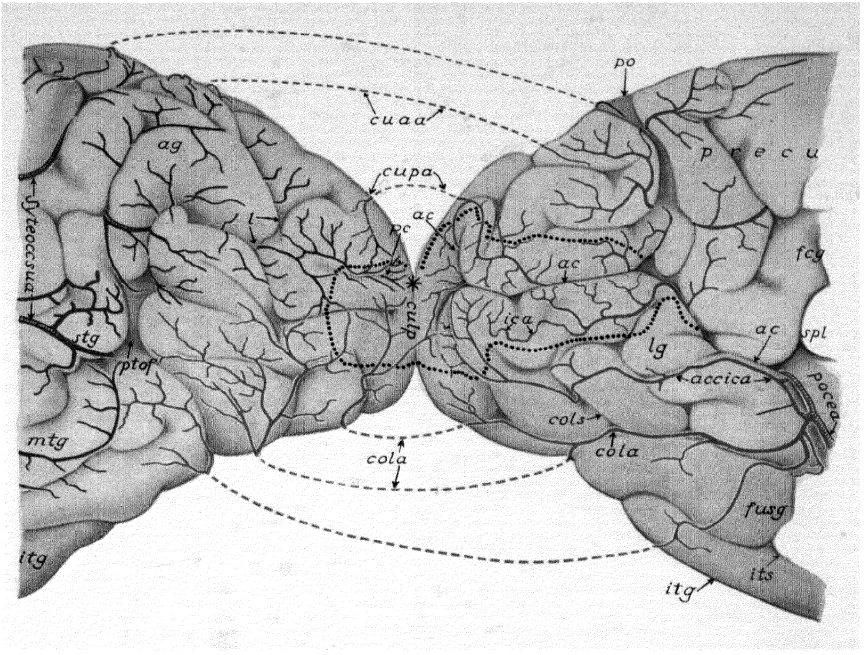

FIG. 373—Arteries of the left occipital lobe with sulci, gyri, and blood vessels left in their natural position. Right half of the figure shows the medial face, left half the lateral face of the same lobe. Middle cerebral artery green, posterior cerebral red. Approximately natural size. To be compared with the following figure. Boundary of the striate area marked by a dotted line. Shallow posterior or lateral calcarine sulcus (*pc*) separated from the anterior or medial c.s. (*ac*) by a posterior cuneo-lingual gyrus (*culp*). The latter, representing occipital pole marked by an asterisk (*), is used in this figure as a " hinge " on which the lateral face of the hemisphere was rotated to align it with the medial face (*compare* chap. VIII, secs. 2, 3, and Figs. 280 to 290). Only a few arteries may be followed in this figure for any considerable length along their course, their origin and relations, remaining mostly undisclosed, are revealed in the following figure. Some branches of the posterior cerebral turn above, the others below, the margins of the hemisphere to reach its lateral face, their identity being preserved by broken lines. Arterial anastomoses are merely indicated. *Abbreviations :* *ac* anterior or medial calcarine sulcus ; *accica* accessory inferior calcarine artery ; *ag* angular gyrus ; *cola* collateral artery ; *cols* collateral sulcus ; *cuaa* anterior cuneal artery ; *culp* posterior cuneo-lingual gyrus ; *cupa* posterior cuneal artery ; *fcg* fornicate-cingular gyrus ; *fusg* fusiform gyrus ; *ica* inferior calcarine artery ; *itg* inferior temporal gyrus ; *its* inferior temporal sulcus ; *l* lunate sulcus ; *lg* lingual gyrus ; *mtg* middle temporal gyrus ; *pc* posterior or lateral calcarine sulcus ; *po* parieto-occipital sulcus or fissure ; *pocea* posterior cerebral artery ; *precu* precuneus ; *ptof* parieto-temporo-occipital fossa or pit ; *spl* splenium of corpus callosum ; *stg* superior temporal gyrus ; *Syteoccsua* superior temporo-occipital Sylvian artery ; * occipital pole.

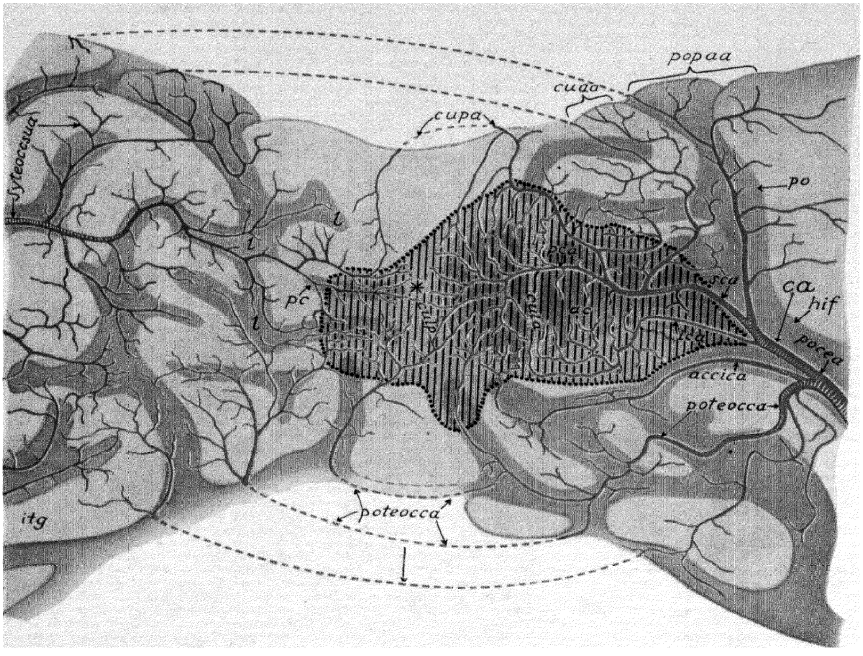

FIG. 374—Left occipital lobe of the same specimen shown in the preceding figure, with sulci and fissures partly opened in order to show arteries along their entire course. Right half of the figure represents the medial face, left half the lateral face, of the lobe. Occipital pole (*) used as a " hinge " on which the two sides were rotated in order to bring them into the same plane. Middle cerebral artery green, posterior cerebral artery red. Striate area vertically shaded. Approximately natural size. *Note :* spacious anterior calcarine sulcus (*ac*) opened wide reveals a low vertically oriented anterior cuneo-lingual gyrus (*cula*) ; distribution of arteries remarkably complex, showing calcarine arteries (*sca*, *ica*) to originate together as a common stem (*ca*) from the posterior parietal artery (*popaa*) ; superior calcarine (*sca*), much the stronger, gives origin to anterior (*cuaa*) and posterior (*cupa*) cuneal arteries ; remaining vessel spreads fanwise as a principal or axial calcarine artery (*pca*) in the posterior half of the anterior calcarine sulcus (*ac*) ; upper lip of the calcarine sulcus supplied by numerous branches from both cuneal arteries, lower lip chiefly by inferior calcarine artery (*ica*), accessory inferior calcarine artery (*accica*), and by the terminals of posterior temporo-occipital artery (*poteocca*) pursuing a devious course below the inferior margin of the lobe ; last-mentioned vessels also supply inferior half of the posterior segment of the striate area located on the lateral side of the lobe, resembling a simian " occipital operculum " (*see* this and Fig. 376) ; superior half of the opercular segment supplied by the terminal branches of a long superior temporo-occipital Sylvian artery (*Syteoccsua*), belonging to the middle cerebral system (*compare* Figs. 370, 373). To a multiple supply of the striate area in this case no less than seven arteries contribute, the two major systems (middle and posterior cerebral), meeting at the occipital pole (*). Several anastomotical connections unite various arterial territories. *Abbreviations :* *ac* anterior calcarine sulcus ; *accica* accessory inferior calcarine artery ; *cuaa* anterior cuneal artery ; *cula* anterior cuneo-lingual gyrus ; *culp* posterior cuneo-lingual gyrus ; *cupa* posterior cuneal artery ; *hif* hippocampal fissure ; *ica* inferior calcarine artery ; *itg* inferior temporal gyrus ; *l* lunate sulcus ; *pc* posterior calcarine sulcus ; *pca* principal or axial calcarine artery ; *po* parieto-occipital sulcus or fissure ; *pocea* posterior cerebral artery ; *popaa* posterior parietal artery ; *poteocca* posterior temporo-occipital artery ; *sca* superior calcarine artery ; *Syteoccsua* superior temporo-occipital Sylvian artery ; * occipital pole.

to, the point of origin of the anterior communicating artery (*mstr* in Figs. 367, 368, 371). It turns laterally, and, after crossing the olfactory trigone, it buries itself in the anterior perforate substance, supplying the anterior portions of the basal nuclei and the anterior limb of the internal capsule.

The further course of the anterior cerebral (*acea*, blue in Fig. 369) lies on the inner face of the frontal lobe, where it closely skirts the genu or "knee" of the callosal body (*gen*). From it, about half-a-dozen fairly thick, long branches are given off (*1–8*), which, partly buried in the sulci and partly by short cuts across the gyri, attain the upper margin of the cerebral hemisphere, beyond which they spread over a more or less narrow zone on the lateral face (*1–8* in Fig. 370).

Altogether, the entire medial and the innermost portion of the orbital surfaces and a narrow zone along the upper margin of the frontal lobe on the convex side are supplied by branches of the anterior cerebral artery, as are also the adjoining portions of the parietal lobe: the paracentral lobule, a portion of the precuneus (*precu*), and a corresponding zone on the lateral face of the hemisphere (*cf.* Figs. 182, 271). These branches have been labeled by Critchley (1930), from the lower surface of the brain upward, as follows: prefrontal (Foix's orbital), frontopolar, anterior internal frontal, middle internal frontal, posterior internal frontal, paracentral, superior parietal, and precuneal arteries. According to the classification of Kleiss (1944 45), four groups of the anterior cerebral branches are to be distinguished: an orbital, a precallosal, a supracallosal, and the pericallosal ramus or group.

References: See bibliography at the end of this chapter.

SEC. 4. THE MIDDLE CEREBRAL ARTERY AND ITS SUBSIDIARIES

1. GENERAL REMARKS.—The middle cerebral artery (*mcea*) is the largest of the three arteries supplying each cerebral hemisphere (green in Figs. 369, 370). It is the thicker of the two principal vessels into which the internal carotid artery (*ica*) subdivides (Figs. 368, 371). The territory supplied by it is likewise more extensive than that of either the anterior or the posterior cerebrals, comprising most of the lateral face of the hemisphere, including the lateral fissure or Sylvian fossa, the most roomy pocket of the cerebral depressions or infoldings (sulci and gyri). (*See* Moutier 1908 on various types or modes of ramification of the middle cerebral artery.)

Of the extensive arborizations of the middle cerebral artery, only a few branches are directly related to the visual system. Some of these, however, are of prime importance and are here described in detail, those of lesser interest are presented in the following only for the sake of completeness.

2. SHORT SUBCORTICAL BRANCHES.—First to arise either from the internal carotid or more rarely from its continuation, the middle cerebral artery, after the separation of the anterior cerebral (*acea*) and the posterior communicating (*poco*a) arteries, is the anterior chorioid artery (*acha*, Figs. 368, 371). Its origin and relationships are described in paragraph 3, in the preceding section. The anterior chorioid is the principal vessel that supplies the optic tract and, conjointly with the lateral chorioid artery (*lacha*, a branch of the posterior cerebral; *see* sec. 5 [2], this chapter), the lateral geniculate nucleus.

Next laterad to it, a series of small arteries arises from the middle cerebral stem; they immediately penetrate into the base of the brain along a line marking the juncture of the frontal and temporal lobes. This locality is the narrow lateral portion of the anterior perforate spot or substance (*aps*), so named because of a number of minute holes left after the afore-mentioned arteries have been torn out (*cf.* Fig. 181). This group of vessels was named *lateral striate arteries* (*lastra*) by Abbie (1937). They enter the substance of the brain, where, according to Abbie, they supply the larger portion of the striate body, including the lentiform nucleus (globus pallidus, putamen), caudate nucleus, and the entire internal capsule.

One of these vessels of medium size, the *deep optic artery* (*dopa*), in its backward course passes through the substance of the putamen to

the infra- and retrolenticular parts of the internal capsule, where it supplies the initial portions of the visual and auditory radiations, according to Abbie (1937). From the actual dissections made by the author there may be, instead, one or two such deep optic arteries. These originate from the middle cerebral stem, 2 mm. apart, plunging at once into the cerebral substance. The course of these deep optic arteries ascends almost vertically, one artery behind the other, the more proximal being the more posterior. Both deep optic arteries enter the substance of the putamen, where they divide repeatedly. Some of their terminal twigs proceed farther up and may reach the subcortical fiber mass above the putamen. Possibly the more posterior artery may participate in supplying the initial portions both of the visual and of the auditory radiations, a point requiring further study. Both deep optic arteries are undoubtedly related to the putamen and possibly also to the external capsule and the claustrum. Because of this, the term *lenticular* or *lenticulocapsular arteries* would be justified (*lenta*, left side in Fig. 371).

3. LONG CORTICAL BRANCHES. The stem of the middle cerebral artery (*mcea*, green in Fig. 370), beyond the lateral striate arteries, passes into the roomy pocket of the lateral fissure of the hemisphere, the Sylvian fossa or pit (*Syl*, Fig. 370). When the margins of this sunken region are pulled apart, about half-a-dozen thick branches, into which the middle cerebral artery subdivides, become visible. Their arrangement over the floor of the Sylvian pit may be compared with the handle of a fan oriented obliquely from the base of the frontal lobe toward the center of the parietal lobe, conforming with the position of the Sylvian pocket. From this locality branches radiate in various directions: anteriorly and dorsoanteriorly toward the frontal lobe, dorsally and posterodorsally toward the parietal lobe, with the central region in between; posteriorly across the back portions of the parietal and temporal regions toward the occipital lobe; and ventrally toward the temporal lobe. Briefly, the arrangement of the middle cerebral branches repeats in a more complicated way a similar, but simpler, radiating arrangement present in the human fetus (Fig. 375) and a somewhat more complex arrangement found in an adult Rhesus Macaque.

In the Sylvian fossa the arteries pursue their course, on the whole, without much regard for the numerous gyri and sulci found here (Fig. 370). As egress from this locality, some use sulci that communicate with the fossa, e.g., at the frontal and parietal opercula (*frop*, *pop*): the postcentral (*pocs*) and intraparietal sulci and a sulcus by which the anterior and posterior transverse temporal gyri of Heschl (*attg*, *pottg*) are separated—the intertransverse temporal sulcus (*itrs*). In contrast with this, other arteries boldly climb out of the Sylvian fossa over the convexities of gyri that form its margins, e.g., those that supply the region around the central sulcus (*cs*) and others that spread over the anterior segment of the temporal lobe.

Altogether, about half-a-dozen Sylvian arteries may be distinguished in the Sylvian fossa: the *frontal Sylvian artery* or *arteries* (*Syfra*), supplying part of the orbital surface, the frontal operculum or inferior frontal gyrus, the inferior frontal sulcus, the middle frontal gyrus, and a part of the superior frontal sulcus; the *central Sylvian artery* or *arteries* (*Sycea*), spreading about four of its branches over the posterior part of the frontal operculum (*frop*), the middle frontal gyrus, and the back part of the superior frontal sulcus (*sfs*), as well as over most of the central sulcus (*cs*) and both the pre- and postcentral gyri (*acg*, *pocg*), except approximately the upper third adjoining the upper margin of the hemisphere, and the adjoining portion of the parietal lobe (*pop*, *smg*); the *parieto-occipital Sylvian artery* (*Sypaocca*), spreading over the posterior portion of the parietal and over the adjoining part of the occipital lobes; the *superior temporo-occipital Sylvian artery* (*Syteoccsua*), supplying the posterior half of the superior temporal gyrus (*stg*) and sulcus (*sts*), its ultimate terminals reaching as far back as the occipital pole (*see also* Figs. 373, 374); the *inferior temporo-occipital Sylvian artery* (*Syteoccinfa*), chiefly supplying the upper portion of the middle temporal gyrus (*mtg*) and the adjoining superior temporal gyrus (*stg*); and the *anterior temporal Sylvian arteries* (*Syteanta*), spreading over the anterior fourth of the temporal lobe, including its anterior pole.

Most of these arteries are in no way directly related to the visual pathways and centers. They supply extensive regions and areae of the cerebral cortex concerned with motor, somesthetic, and auditory functions, besides others as yet inadequately understood. Exceptions are foci of the frontal, temporal, and occipital lobes regulating the movements of the eyes, pupils, and accommodation of vision, and the cortical regions of the posterior extremities of the two hemispheres subserving psychic and associated functions of vision (*see* chap. VIII, 1 [4], and Figs. 274, 275).

The first of the Sylvian arteries related to the visual system is the *inferior temporo-occipital artery* (*Syteoccinfa*, Fig. 370). This vessel, after crossing the superior temporal gyrus, slips into the first temporal sulcus, where it assumes a posterior course. Here it gives off a number of branches which supply the cortical and subcortical substance of the temporal lobe. Some of these branches, especially those given off at the level of the lateral geniculate nucleus, very likely contribute to the blood supply of the initial portion of the visual and auditory radiations (*cf.* Fig. 371).

The superior temporo-occipital Sylvian artery is of great importance to both the normal and the pathological functions of vision (*Syteoccsua* in Fig. 370). It is an important source of blood supply both for the visual radiation and for the striate cortex. This artery is easily the longest of the middle cerebral branches. It separates from the parieto-occipital Sylvian artery (*Sypaocca*) within the Sylvian pit at about the level of the anterior transverse temporal gyrus of Heschl (*attg*). After crossing the superior temporal gyrus (*stg*), it plunges into the superior temporal sulcus (*sts*), within which, halfway between its floor and the surface, it courses toward the occipital lobe. In this locality, where it is topographically closest to the subcortical fiber substance, it gives off a succession of small branches which perforate the cortex of the sulcal floor and enter the sagittal fiber layers of the hemisphere containing the visual radiation and the occipital system of fibers for associated eye movements, besides various other not yet identified tracts and systems (Figs. 226–33, 235, 236). The clogging of this artery, e.g., in the superior temporal sulcus or posteriorly, may cause a part of the visual radiation, as well as other fiber systems, to degenerate (this is well illustrated by case MUNSON, described in chap. XII, 6).

In its further course backward, the superior temporo-occipital Sylvian artery divides into several branches spreading over the middle part of the convexity of the occipital lobe (Fig. 370). The most posterior terminals of this artery extend as far back as the occipital pole (*12*), where they meet the terminals of the calcarine artery (*11*, *13*), especially its principal branch (*sca*, *scal*, or *pca* in Figs. 369, 372, 374; *see also* Figs. 367, 371). In this way an arterial contact is established between the territories of the middle and the posterior cerebral arteries.

The meeting line between the two arterial territories varies individually. It may coincide fairly well with the posterior limit of the striate area (thus in Fig. 372). In other cases a smaller or a wider strip of the striate cortex may be entirely supplied by the middle cerebral artery (thus in Figs. 369, 370, 373, 374), whereas by far the larger portion of this cortex remains supplied by the posterior cerebral artery. (For the pathophysiological significance of the foregoing relationship *see* secs. 6 and 8, this chapter, and chap. XI, 8 and 9.)

A double blood supply of the most posterior portion of the striate area is shown especially clearly in the Infrahuman Primates, the Monkeys and Apes, where it seems to be the rule (Figs. 286, 376; *cf.* sec. 7, this chapter).

SEC. 5. THE POSTERIOR CEREBRAL ARTERY AND ITS SUBSIDIARIES

1. THE ORIGIN AND TOPOGRAPHY OF THE INITIAL PORTION OF THE POSTERIOR CEREBRAL ARTERY.—The posterior cerebral artery (*pocea*) originates from the basilar artery (*basa*), one for each hemisphere, at the frontal end of the pons or "bridge" of the brain (Figs. 366, 367, 371). Occasionally the posterior cerebral takes origin from the internal carotid artery on its own side, in which case the much thinner posterior communicating artery of that side connects it with

the basilar trunk (thus in Fig. 368, left side).

From approximately the point where it gives off the posterior communicating artery (*pocoa*), the posterior cerebral artery turns back around the pons, skirting the foot of the cerebral peduncle from underneath (*cp* in Figs. 367, 371, 372). Here, in the cleft between the pons and the arms of the cerebellum and the inner face of the temporal and occipital lobes (hippocampal gyrus, *hig*, and uncus, *unc*), it gives off several small branches, the *posterior perforate arteries* (*popa*), which supply the substantia nigra (*sn*), red nucleus (*rn*), and a part of the tegmentum (*tg*) of the midbrain.

Next, a series of small branches arises, closely attached to the inferior and lateral faces of the cerebral peduncle, which they in part supply, the larger and longer branches ascending as far as the optic tectum—the *mesencephalic branches* (*mesa*, Fig. 371, left).

2. The choroid and hippocampal arteries.—One or two slightly thicker arteries, arising from the stem of the posterior cerebral artery, turn upward, closely attached to the cerebral peduncle—the *posterior choroid arteries* (*pocha*, in Figs. 371, 372). These ascend along the sides of the midbrain to its roof (*tect*, *t*, also *sc* and *e*, in Fig. 369) and enter the meningeal fold filling the transverse cerebral fissure (*trcef*, in Fig. 372), a spacious cleft separating the midbrain and betweenbrain from the splenium (*spl*) of the corpus callosum (*cc*) of the telencephalon. Along their course they give off twigs for the midbrain, the medial geniculate nucleus, the dorsomedial nucleus of the thalamus, the region of the posterior commissure, and the choroid tela of the third ventricle.

Just before the stem of the posterior cerebral artery divides into its principal branches (*see* below), it gives off from its posterior face a fair-sized twig, the *lateral choroid artery* (*lacha*), which, after slipping into the hippocampal cleft, supplies a segment of the choroid plexus of the inferior horn of the lateral cerebral ventricle next behind that supplied by the anterior choroid artery (*see* Figs. 367, 371, 372, and sec. 4 [2], this chapter). Minute twigs of the lateral choroid also participate in the supply of the pial plexus, which covers the exposed posteroinferior face of the lateral geniculate nucleus. (*Cf. also* L. Chacko 1952.)

Another small branch of the posterior cerebral artery spreads over the surface of a portion of the hippocampal gyrus (*hig*), following the cleft for a short distance and extending on the medial inferior side as far as the rhinal fissure (*rhif*)—the *hippocampal artery* (*hipa*, in Fig. 372). Still other small arterial twigs, about half a dozen of them, enter the posterior aspect of the pulvinar of the thalamus.

3. The subdivisions of the posterior cerebral artery.—As soon as the posterior cerebral artery enters the hippocampal fissure (*hif*), still some distance from the isthmal portion of the fornicate-cingular gyrus (*isth*) that separates the hippocampal fissure from the rostral extremity of the anterior or medial calcarine sulcus (*ac*), its trunk branches into two or three principal subdivisions, depending on individual variation: two, if the calcarine (*ca*) and the posterior parietal (*popaa*) arteries have a common stem (Fig. 369); three if the posterior temporo-occipital (*poteocca*), the calcarine (*ca*), and the posterior parietal (*popaa*) arteries originate separately, in which case all three are of about the same thickness (Fig. 372). Occasionally one or two thicker vessels that supply the inner face of the temporal lobe may originate independently—the *medial temporal artery*.

4. The posterior temporo-occipital artery (*poteocca*).—This artery is the most inferior of the principal branches of the posterior cerebral artery (Fig. 369; blue in Fig. 372). Its course is directed posteriorly and downward. At first, it gives off a few small twigs for the near-by segment of the hippocampal gyrus below the isthmus and for the choroid plexus of the lateral ventricle—the *lateral choroid artery* (*lacha*). Its principal trunk soon divides into several larger branches, mostly concealed in the rhinal fissure and in the collateral and inferior temporal sulci.

The artery supplies an extensive region on the lower face of the temporal and occipital lobes as far as the occipital pole and beyond (*see also* Fig. 370). Its most posterior terminal branches pass below the inferior margin of the

occipital lobe and, after bridging over the occipital pole, slip into the pocket of the posterior calcarine fissure, here undergoing direct anastomotical connections with the terminal arterioles of the principal calcarine artery (*pca* in Fig. 374; *also* Fig. 373). These anastomotical arterial links may measure, according to our own observations, about $\frac{1}{5}$ mm. in diameter (*see* following section).

According to Beauvieux & Ristich-Goelmino (1926), the terminal twigs of the posterior temporo-occipital artery always extend to the occipital pole, where, within the pial membrane, they connect with the calcarine artery by direct anastomoses up to 0.5 mm. thick. Within the cerebral substance there are, however, fewer connections of this size.

5. THE POSTERIOR PARIETAL ARTERY (*popaa*). —This vessel is the intermediate subdivision of the posterior cerebral artery (green in Fig. 372), unless it arises from a stem common both to it and to the calcarine artery (*ca* in Figs. 369, 374). If it arises independently, it plunges at first deep into the hippocampal fissure (*hif*), where it gives off several branches. Most of these are thin, with one somewhat thicker artery, all of them supplying the posterior aspect of the pulvinar (*pula*) and medial geniculate nucleus.

Another smaller branch, the *isthmal artery* (*istha*), emerges upon the hippocampal gyrus close to the isthmus and spreads over it and over a part of the isthmus and over the anterior portion of the lingual gyrus below the anterior or medial calcarine sulcus (*ac*).

Other branches arising in the hippocampal fissure are the lateral choroid artery (*lch*), a twig for a segment of the chorioid plexus of the lateral ventricle in the rear of the pulvinar (*cf. also lacha*, Fig. 371); several delicate *pial* branchlets (*pia*) for the meningeal fold filling the transverse cerebral fissure beneath the callosal splenium; and a medium-sized *splenial artery* (*spla*).

6. THE SUPRACALCARINE AND PRECUNEAL ARTERIES.—The principal stem of the posterior parietal artery (*popaa*) eventually emerges upon the retrosplenial segment of the fornicate-cingular gyrus (*fcg*), where it divides into a number of branches which spread over the medial face of the parieto-occipital lobes (Figs. 369, 372): the *supracalcarine artery* (*suca*), supplying the upper lip of the rostral portion of the anterior calcarine sulcus (*ac*); the much larger *precuneal artery* (*precua*), supplying most of the precuneus (*precu*); and the equally sizable *parieto-occipital artery* (*paocca*), which supplies most of the deep and spacious parieto-occipital sulcus or fissure (*po*). The posterior parietal arteries may vary considerably individually; on occasion a single stem is present, buried in the parieto-occipital sulcus, from which branches arise to spread over the precuneal region (Fig. 369).

The origin, arrangement, course, and termination of all the above-described arteries, large and small, vary much individually. Especially is this the case when the calcarine and the posterior parietal arteries arise from a common stem, the smaller twigs for the mid- and betweenbrain then taking their origin from that stem (Fig. 369).

References: *See* the bibliography at the end of this chapter.

SEC. 6. THE CALCARINE ARTERY

1. ORIGIN AND DISTRIBUTION.—The *calcarine artery* (*ca*) either represents one of the three principal subdivisions of the posterior cerebral artery arising independently within the hippocampal fissure (red in Fig. 372) or forms a stem in that fissure common both to it and to the posterior parietal artery (*ca* in Figs. 369, 374). In both cases its initial portion lies within the hippocampal fissure (*hif*), imbedded between the cerebral peduncle (*cp*) medially and the isthmus (*isth*) of the fornicate-cingular (*fcg*) and hippocampal (*hig*) gyri laterally. Within this fissure it gives off a few smaller twigs for the lateral face of the midbrain (lemniscal trigone and lateral mesencephalic sulcus) and a somewhat thicker branch which penetrates into the posterior aspect of the medial geniculate nucleus.

After emerging from the hippocampal fissure, the calcarine artery or its common stem crosses the isthmus and enters the anterior or medial calcarine sulcus (*ac, cf.* chap. VIII, 2 [1], and *mc* in Fig. 273). Here it gives off a few twigs, one of them thicker than the others, which turns anteriorly toward the splenium of the callosal body (*spl*), which it supplies (Fig. 369).

The principal calcarine stem divides into two or three branches, two in case the calcarine artery originates independently from the posterior cerebral artery in the hippocampal fissure (Fig. 372); three if it has a common origin with the posterior parietal artery, in which case the latter separates from it in the anterior calcarine sulcus or close to it (Figs. 369, 374). In any case, in its further course the calcarine artery proper is represented by two principal branches, usually of more or less unequal thickness, the upper being the thicker.

2. THE INFERIOR CALCARINE ARTERY (*ica*, ALSO *ical*).—This is the lower branch of the calcarine artery (*ca*). After a shorter or longer course within the anterior or medial calcarine sulcus (*ac*), it emerges over the lower lip of that sulcus, with which it runs more or less parallel in the occipital direction. Along part of its course it may be superficially imbedded either in the medial inferior paracalcarine sulcus (*mips*, Fig. 273) or in the inferior occipital sulcus (*ios; see* Fig. 372). Because of its location and character, this artery may also be called *paracalcarine artery* (*paca* in Fig. 372).

On occasion, as in the last-mentioned figure, it may extend backward as far as the inferior (*ios*) and the middle (*mos*) occipital sulci at the very tip of the occipital lobe in the rear of the posterior or lateral calcarine sulcus (*pc*). In other cases it barely touches the occipital pole or may fall considerably short of it (Fig. 374).

From it a number of small, deep branches are given off that enter into the anterior calcarine sulcus (*ac*), some supplying both lips and the fundus, the others supplying, in part or entirely, only the lower lip of that sulcus as far as the fundus.

If the inferior calcarine or paracalcarine artery is almost equal in thickness to the superior or principal calcarine artery (*sca, pca*), it supplies the inferior calcarine lip along its entire longitudinal extent as far as the occipital extremity of the posterior calcarine sulcus (Fig. 372). If, on the contrary, this artery is poorly developed or is situated mostly outside the calcarine sulcus, the posterior portion of the anterior or medial calcarine sulcus (*ac*), the cuneolingual gyrus (*cula*), including its anterior slope, and the pocket of the posterior or lateral calcarine sulcus behind the posterior cuneolingual gyrus (*culp* in Fig. 374) remain outside its territory. In this case these and other adjoining parts of the occipital cortex on both the medial and the lateral faces of the occipital lobe are supplied in part by the superior or principal calcarine artery alone (*sca* or *pca* or *scal*) or, in addition, by the terminal branches of the posterior temporo-occipital artery (*potcocca*), slipping underneath the inferior margin of the cerebral hemisphere, and in part by other vessels, especially the posterior cuneal (*cupa*) and the superior temporo-occipital Sylvian artery (*Sytcoccsua; see* Fig. 374)

3. THE SUPERIOR OR PRINCIPAL CALCARINE ARTERY (*sca*, ALSO *scal*).—This vessel is the upper and usually the thicker division of the calcarine artery. If it is much stronger than the inferior calcarine, most of the calcarine sulcus is supplied by it (Fig. 372). In this case, because of its course, location, and character, it may be considered the *principal* or *axial calcarine artery* (*pca*).

Close to the anterior end of the anterior or medial calcarine sulcus (*ac*) the principal calcarine artery dips into that sulcus and courses along its floor posteriorly. Its location is deep in the fundus, where it can be followed more or less as far as the posterior extremity of the posterior calcarine sulcus (*pc*). It gives off a succession of branches, supplying the upper or cuneal calcarine lip, including the adjoining portion of the cuneus.

One, two, or three fairly thick twigs—the *anterior, middle,* and *posterior cuneal arteries* (*cua, cuaa, cuma, cupa*), attached to the upper lip, emerge onto the medial surface of the cuneus. Here they spread as far as the upper margin of the hemisphere and beyond and also supply the posterior slope of the parieto-occipital sulcus (*po*). One or more cuneal arteries may

arise from the posterior parietal artery instead of from the calcarine.

What is left of the trunk of the principal calcarine artery, now much reduced in thickness, emerges onto the exposed cuneolingual gyrus (*cul*), if such is present, and crosses this gyrus or meanders between the anterior and posterior cuneolingual gyri, if both are present and are submerged, and finally dips behind into the spacious pocket of the posterior or lateral calcarine sulcus (*pc*). Here the principal trunk continues more or less horizontally in the occipital direction, skirting along the deepest points of the floor of the pocket and again climbing up along the posterior wall of the pocket (Fig. 372). Its superficial terminal twigs emerge onto the surface of the very pole of the occipital lobe (indicated by *), spreading over it around the superior, middle, and inferior occipital sulci (*sos*, *mos*, *ios*), if such can be identified. In other cases the principal calcarine artery, as already mentioned, does not extend beyond the posterior cuneolingual gyrus, as described by Beauvieux & Ristich-Goelmino (1926). (*See* Fig. 374.)

Close to the posterior end of the principal calcarine artery, several terminal twigs arise in a successive series from the principal trunk in the posterior lateral calcarine sulcus (*pc*). In the specimen depicted in Figure 372, four twigs are given off above the main stem, and three below. The thicker and longer upper twigs supply the upper and much larger half; the thinner and shorter lower twigs supply the lower, smaller half of the posterior calcarine pocket behind the cuneolingual gyrus (*cul*), their terminals emerging somewhat upon the convex cortex around the pocket.

The twigs are arranged with their stems fairly vertical to the principal calcarine stem, being roughly parallel to one another. Each twig, with its system of arterioles, supplies a small strip of the striate cortex, the adjoining twigs supplying contiguous strips. An overlapping of the adjoining territories seems not to occur, nor is there usually found any mixing of the strips above with those below the principal trunk running horizontally. There are exceptions, however, where a single twig splits into minute terminals, some of which pass above, the others below, the horizontal line indicated by the principal calcarine trunk.

Not all twigs of the principal calcarine artery at the occipital pole are terminal. Some, as a careful examination of specimens reveals, continue into branches which finally merge with the arteries whose principal spread is over the posteroinferior, posterolateral, or posterosuperior faces of the occipital lobe. Such are the posterior temporo-occipital artery (*poteocca*), a subsidiary of the posterior cerebral (*pocea*), and the superior temporo-occipital Sylvian artery (*Syteoccsua*), which belongs to the middle cerebral artery (*see* Figs. 369, 373, 374), and on occasion there may be other connections. Through these direct anastomotical bridges the system of the calcarine artery proper communicates with the adjoining arterial systems whose origins are at a greater or lesser distance from its own. Thus the long terminals of the posterior cuneal artery (*cupa*), on both the inner and the outer face of the occipital lobe, may descend as far as the calcarine sulcus and may approach, and also partly anastomose with, the circumpolar terminals of the principal calcarine artery. The latter artery (*pca*), in turn, may also be anastomotically linked with its mate, the inferior calcarine artery (*ica*), such linkage likewise taking place at the occipital pole (*).

The anastomosing vessels through which the linking of the calcarine artery is established are small, not exceeding $\frac{1}{4}$ mm. in diameter, or 200 microns, in a preserved specimen. They bear the character of preterminal arterioles. It is reasonable to assume that under physiological conditions these anastomotical bridges are wider, filled as they are with blood under steady pressure. Such anastomoses may help preserve nearly normal conditions of circulation in the cortex at the occipital pole whenever the intra-arterial pressure, owing to local pathological factors, decreases within the territory of one or another of the several arteries thus connected. However, because of their small size, these anastomoses may not be able to play the role of a vicarious passage to supply the whole, or even a major portion, of the cortical territory normally supplied by the obstructed vessel, or may do so only inadequately (except when small arterial twigs are affected). For example, in the case of the clogging of either the posterior cere-

bral artery or the calcarine artery alone, most of the striate area, together with the adjoining cortex lining the medial face of the cerebral hemisphere in its posterior portion, may degenerate, with the striate cortex around the occipital pole alone remaining spared.

The multiple arterial supply of the occipital pole, by which the foveal portion of the striate cortex is placed in a favored situation, is very well illustrated by one of our cases (chap. XII, MANTENO case No. 368). Here, owing to an arteriosclerotic occlusion of the common stem of the posterior temporo-occipital and calcarine arteries, almost the entire striate and nonstriate cortex of the calcarine sulcus, as well as almost all the cortex of the interior face of the temporo-occipital lobes, had wasted away, whereas the striate cortex at the very occipital pole, lining the most caudal portion of the calcarine sulcus, remained perfectly normal (Fig. 428). In this case not only the calcarine artery that normally supplies most of the striate area but also the posterior temporo-occipital artery that might have supplied it vicariously were completely eliminated, the supply being preserved entirely by the terminals of the most occipital branch of the middle cerebral artery (*Syteoccsua*). (*See* sec. 8, this chapter, for further details.)

The distribution pattern of the calcarine artery exhibits considerable variation in detail in different brain specimens, and it also varies in each cerebral hemisphere. The two principal calcarine branches, the superior and inferior, may, for example, be almost equal in thickness, of the same length, pursuing a symmetrically similar course, and having a like territorial distribution. In the specimen depicted in Figure 372, the superior calcarine artery (*sca*), though completely concealed within the calcarine sulcus, closely follows the upper lip not far from the surface, sending twigs both into the sulcus and onto the cuneal surface. The inferior calcarine artery (*ica*), in like manner, follows the lower calcarine lip, but on the exposed medial surface, sending a series of branches into the sulcus for the supply of its lower lip. The line of separation or the "divide" between the two territories closely follows the deepest line or floor along the calcarine sulcus.

Again, the inferior lip of the calcarine sulcus may be supplied by two distinct arteries, one arising from the principal calcarine stem within the fissure taking care of most of that lip, whereas the posterior segment of the same lip is supplied by the terminals of one, two, or more long vessels originating independently from the posterior cerebral artery within the hippocampal fissure (Fig. 374). In still other cases the principal calcarine artery, while fairly well developed and supplying the entire posterior calcarine sulcus, may leave a considerable portion of the striate area to be supplied by a circuitous route: the superior Sylvian temporo-occipital artery (*Syteoccsua*), the accessory inferior calcarine artery (*accica*,) and one or two terminal branches of the posterior temporo-occipital artery (*poteocca*). Finally, the terminal branches of the posterior cuneal artery may join with these vessels in supplying the caudalmost portion of the striate area.

These are but a few types observed in a limited number of specimens studied, upon which the present description is based. The impression gained is of an almost unlimited variation of the interlinking of the arteries by which the occipital lobe and pole are supplied, almost every brain and hemisphere differing from all other brains or hemispheres in some details.

On the basis of the preceding observations it is justifiable to conclude that a multiple linking of the arteries precisely at the occipital pole, where the central fovea and hence axial vision are localized, makes that locality arterially well supplied and functionally exceptionally well protected. That this may be the essential anatomical factor responsible for a most fortunate phenomenon frequently observed in the pathology of the cerebral visual mechanism—the "central sparing" or preservation of the foveal-macular parts of the fields of view in an incomplete homonymous hemianopia—is obvious.

Such an interpretation has been made on theoretical grounds and from clinical experience by R. Förster (1890) and was further substantiated by G. Holmes & Lister (1916), Igersheimer (1918), G. Holmes (1919), Monbrun (1919), Beauvieux & Ristich-Goelmino (1926), and Purves-Stewart (1945) in the study of the blood supply of the occipital lobe.

It is the conviction of the author that the phenomenon of the "sparing" of central portions

of the fields of view in homonymous hemianopia is caused entirely by a peculiar organization of the central visual apparatus and by the multiple blood supply of the visual radiation and of the striate area, as further discussed in section 8 [4], this chapter, and in chapter XI, 8, 9.

References: See bibliography at the end of this chapter.

SEC. 7. NOTE ON THE BLOOD SUPPLY IN THE HUMAN FETUS AND IN THE MONKEYS AND APES

The understanding of the ontogenetical and phylogenetical origin of the multiple arterial supply of the foveal-areal, or "macular," portion of the striate area of the human brain is greatly facilitated by the study of the conditions found in the infrahuman species. This reveals that the pattern of a double or multiple blood supply of the occipital lobe is laid down far back in the ontogenesis and phylogenesis of the Primate Order.

In the human embryo, aged approximately six and one-half menstrual months (Fig. 375, upper sketches), the terminal branches of the middle cerebral artery (*mca*), spreading over the lateral face of the brain, closely approach the occipital pole. Here they meet the terminal branches of the posterior cerebral artery (*pca*) coming from the medial face and turning around the occipital pole. The meeting zone of the two arterial territories is, accordingly, on the lateral face of the occipital lobe, just in front of the occipital pole.

In a more advanced human fetus, where the conditions are more readily examined, it is found that the two territories, that of the middle and that of the posterior cerebral arteries, are in fact in this locality directly continuous (same figure, lower sketches). The connection is maintained by fair-sized anastomotical stems, producing, in the aggregate, a loose pial network. The meshes of this network in turn are filled in by a more delicate network of smaller arteries and capillaries, which together form a continuous pial netting. This arrangement indicates the possibility of an easy exchange of the blood in any direction.

The condition found in the adult human brain suggests, then, a condensation of this original pial network into definite larger and smaller stems, relatively little interconnected by the remaining anastomoses of the size of arterioles and larger (*cf.* Duret 1910).

In the Rhesus Macaque an arterial pattern is found in the posterior portion of the cerebral hemisphere which greatly resembles that of the younger human fetus mentioned. Here, too, the posterior branches of the middle cerebral arterial tree swing backward, dipping in and out of the first temporal and simian sulci, until the terminal twigs emerge over the anterior margin of the occipital operculum. The branches of the posterior cerebral artery in turn, after emerging from the deep calcarine sulcus, circle around the original "occipital pole" (which in Man becomes the posterior cuneolingual gyrus; *see* chap. VIII, 3). They spread onto the lateral face of the occipital operculum closer to the occipital pole. The zone where the two arterial territories meet runs a few millimeters behind and parallel to the simian sulcus.

In this way the anterior segment of the striate cortex along the simian sulcus (which in Man becomes the most posterior) falls within the middle cerebral arterial territory, and the segment next to the simian pole (which in Man forms the posterior cuneolingual gyrus) falls within the posterior cerebral, both being interconnected by a fine arterial network.

A double arterial supply of the foveal-areal portion of the striate area (stippled) is particularly conspicuous in the Anthropomorphous Apes. In the Chimpanzee, for example, a considerable portion of the striate area spreads over the posterolateral surface of the occipital lobe, extending almost to the lunate sulcus (*l*, in Fig. 376; *see also* Fig. 284). The branches of the middle cerebral artery, after emerging from the lunate sulcus, spread over the adjacent zone of the occipital operculum. Here they divide into smaller branches and finally into capillaries. From the medial face of the hemisphere arrive branches of the posterior cerebral artery by turning around the occipital pole. These also subdivide into smaller branches, which spread over the territory contiguous with the one supplied by the middle cerebral artery. A number

of small arterial anastomoses of a size large enough to be noticed with the unaided eye bridge over from the territory of the middle to that of the posterior cerebral artery. Such direct anastomotic links in the Chimpanzee have not been seen by Shellshear (1931). In our opinion, however, it is fairly certain that in this Ape, as one or the other of the two principal arteries becomes obstructed.

A double or multiple arterial supply of the occipital operculum, with a rich anastomotical arterial network, with the extreme lateral or "posterior" segment of the striate cortex falling within the territory of the middle (*mca*) and

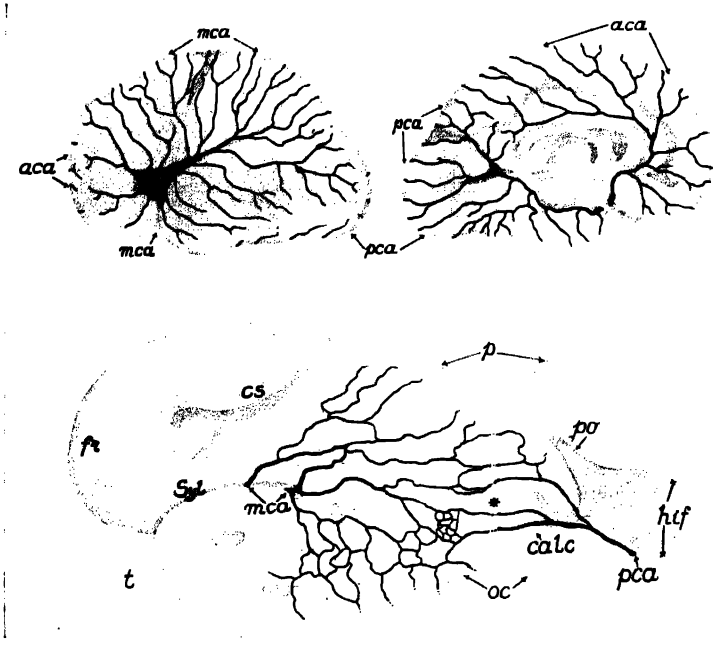

FIG. 375.—*Upper figures:* lateral and medial aspects of the left cerebral hemisphere of a human fetus of an estimated age of six and one-half menstrual months, showing the distribution of three principal arteries of the brain. *Lower figure:* left cerebral hemisphere of a human fetus of an approximate age of eight menstrual months, showing the lateral aspect and the posterior portion of the medial aspect, to demonstrate the anastomotical network by which the territories of the middle and posterior cerebral arteries are directly continuous. At this developmental stage of the complete vascular network of the pial membrane, only the larger vessels in the posterior region of the hemisphere, forming a loose meshwork, are present. One of the large meshes is filled in completely, to show the density of anastomotical connections, which in reality form a vast, continuous network, imbedded in the pial membrane, the larger vessels representing merely thicker ribs in it. *Labeling: aca*, anterior cerebral artery; *calc*, calcarine fissure; *fr*, frontal lobe; *hif*, hippocampal fissure; *mca*, middle cerebral artery; *oc*, occipital lobe; *p*, parietal lobe; *pca*, posterior cerebral artery; *po*, parieto-occipital sulcus; *Syl*, lateral or Sylvian fissure; *t*, temporal lobe; *, occipital pole of cerebral hemisphere.

in Man, both sufficient precapillary and capillary connections and direct anastomotical links exist between the middle and the posterior arterial territories to establish a collateral circulation in the foveal or "macular" cortex if either with the posterior segment of the same area around the occipital pole, marked by asterisks (*), falling within the territory of the posterior cerebral artery (*poca*), is also present in the Gorilla (Fig. 286).

In the human brain an extensive anastomotical network of smaller venous branches is also present over the entire occipital operculum, duplicating a similar vascular network found in all other regions of the cerebral cortex.

The function of the anastomotical arterial network spreading over the occipital pole may be compared to that attributed to the arterial circle of Willis. This is to assure at all times an equal amount of blood delivered at the same pressure and speed to the foveal-areal or "macular" segment of the striate area, the anatomical substratum of the all-important epicritic vision. (*See* chap. VIII, 2, 3, for further information concerning the calcarine fissure and striate area.)

SEC. 8. PHYSIOLOGICAL AND PATHOPHYSIOLOGIC IMPLICATIONS OF THE BLOOD SUPPLY OF THE VISUAL SYSTEM

1. GENERAL REMARKS.—The character of the cerebral blood supply in general and of the visual system in particular, described in the foregoing sections, lends itself to an important interpretation concerning both the normal conditions and the pathophysiological consequences in disease.

The salient feature of the arterial supply of parts of the brain concerned with the visual function is a gradual division of the principal arteries into smaller branches, which eventually terminate in arterioles and capillaries that are visible only with the aid of a magnifying apparatus. Above the level of the arterial circle of Willis at the base of the brain, where all arteries are linked together before they are distributed to the brain, there are normally, in an adult human brain, no channels of considerable size which would link the individual arteries and branches spreading over the surface of the cerebral hemispheres or those that penetrate into their core (Fig. 362).

However, numerous minor arterial anastomoses are present, through which the territories or systems of the adjoining vessels are directly connected. Such connections are of great value in localities of great functional importance, as, for example, the posterior segment of the striate area, where the two hemifoveae are represented.

The other point of special interest is a multiple arterial supply found precisely in the foveal portion of the striate area. In many other parts of the brain—for example, over Broca's motor speech region, over the auditory center in the temporal gyri of Heschl, and elsewhere—similar arrangements may be present. This subject, however, has not yet been adequately investigated.

In the region of the central foveal cortex, as

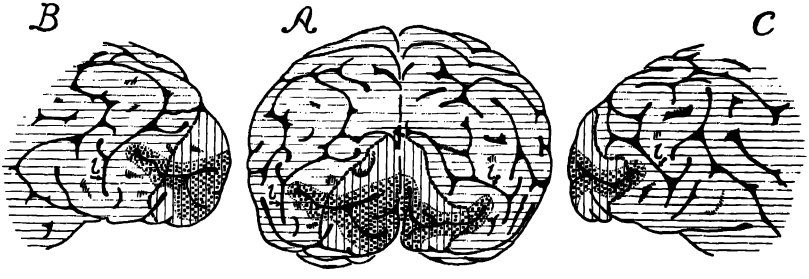

FIG. 376.—Blood supply of the occipital lobe in a newborn Chimpanzee and its relation to the striate area. *Labeling:* *A*, posterior aspect; *B*, lateral view of left, *C*, lateral view of right occipital lobe. Territories of middle cerebral arteries (*shaded horizontally*) are separated from territories of the posterior cerebral arteries (*shaded vertically*) by broken lines. Striate areae stippled. In both lobes the most lateral posterior portion of areae close to the lunate sulcus (*l*) falls within the middle cerebral territory, the larger portion remaining in the posterior cerebral territory. (*Cf.* Figs. 286, 369, 370, 372, 373, 374.)

is evident from the preceding section, a safe and abundant blood supply of that functionally important cortical locality is safeguarded, first, by a convergence of several arterial stems originating from different sources and, second, by linking the terminal twigs of these several arteries into a common terminal network.

This arrangement, on speculative grounds, not only permits at all times a uniform distribution of the amount of blood in the foveal area of the cortex but also provides for a certain amount of substitution by other arteries when one or another is shut off.

In the light of these facts and considerations it appears that all large and medium arteries of the brain, except those that make up the circle of Willis, physiologically and pathophysiologically act as "terminal arteries" in Cohnheim's sense. When any one of them is obstructed by a vascular event, such as an embolism, thrombosis, atheromatous narrowing of the arterial passage, or compression caused by an expanding pathological process (tumor, abscess, hemorrhage), its own territory receives a reduced amount of nutrient fluid—the blood—with complete stoppage if the obstruction becomes complete.

The specific tissue—the nervous parenchyma—thus deprived of the indispensable nutritive material, necessarily dies off or degenerates and is carried away. The capillary and precapillary and other slender anastomotical connections along the margins of the blocked-off territory are capable only of reducing the size of the damage in the marginal zones but can hardly prevent it entirely. This may be true of the shutting-off of the larger stems only, the small defects possibly being completely compensated for by a vicarious collateral circulation. Such may especially be the case in the processes affecting the foveal-areal cortex in the posterior segment of the striate area when a multiple anastomotical interlinkage is present. Minute transient, homonymous hemianopic scotomas close to the fixation points may be interpreted in this way (*see* chap. XI, 7).

Interference with free circulation in any artery of considerable size, accordingly, results in events identical with those which would occur if the artery were truly a "terminal artery" but of smaller territorial distribution than it theoretically has. The tissue loss in such cases is sharply defined, and the functional defect, if determinable—for example, a scotoma—is likewise well localized.

Contrasting with this are diffuse pathological processes, such as the effusion of blood within the brain tissue, compressing or directly destroying parts of the visual pathways and centers, and the hematomas and tumors exerting pressure upon parts of the system, which may possibly also be brought about by impeding the free outflow of venous blood.

Frequently the pathological process is a combination of several factors, often difficult to interpret correctly. The same is also true of the various traumas, since a localized lesion in part of the visual pathway will be complicated by an additional interference caused by the concomitant hemorrhage and stasis.

2. THE CHARACTER OF THE BLOOD SUPPLY AND THE PATHOLOGY OF THE CONSTITUENT ELEMENTS OF THE VISUAL SYSTEM.—In the following description the most important processes met with in the vascular affections of the visual system are briefly described.

An obstruction of the main stem of the *central artery* of the retina, irrespective of the agent, causes a degeneration of approximately the vitreal half of the retinal membrane, which comprises all bipolars, amacrines, and ganglion cells. The resulting complete blindness of the involved eye is not in the least alleviated by the preserved photoreceptors, which depend nutritionally upon the chorioid membrane (*see* Nicholls 1938; Tansley 1947).

If only one or a few arterioles are affected, only their particular retinal territories are eliminated, resulting in a scotoma, or partial blindness, of various shapes and locations. The layer of the photoreceptors seems to be more resistant; these, as is shown by the cases of partial detachment of the retina from the chorioid membrane, are again restored to normal or nearly normal function when they are brought into contact with that membrane.

The *optic nerve*, the most accessible part of the visual system, has been much studied, and the role that the vascular factor plays in its pathology has been fairly well represented in the literature.

The *optic chiasma*, having a multiple blood supply, possibly may not be appreciably interfered with by the clogging of any one of the several small arteries supplying it but may be affected when larger vessels, such as the anterior cerebral or internal carotid arteries, are obstructed. The same may be said of the *optic tracts*, largely depending on the anterior choroid artery, where encephalomalacic foci have been described (Henschen 1911). The insufficient experimental and histopathological study of the pertinent cases, however, leaves this important question still largely unsettled.

A little more may, perhaps, be said on the vascular pathology of the *lateral geniculate nucleus*. In a partial affection of this internode, an inferior homonymous quadrantic hemianopia is produced by a focus in the medial segment (supplied by the posterior cerebral artery) and a superior homonymous quadrantic hemianopia by damage to the lateral segment (supplied by the anterior choroid artery). The central vision represented in the intermediate segment of the nucleus is likely to remain preserved, owing to the supply of this segment by both arteries (Abbie 1933, 1938; Mackenzie, Meighan & Pollock). According to Chacko (1952), gross central visual defect results from the occlusion of the posterior cerebral artery, and an extracentral concentric contraction is caused if the anterior choroid artery is blocked.

Since the blood supply of the *visual radiation* is also insufficiently known, few valid conclusions may be drawn concerning the vascular factor responsible in the pathology of each particular segment of this long fiber system. What the symptoms of vascular interference with the anterior portion of the visual radiation are, is not clear (Abbie 1938). It is possible that the superior homonymous quadrantic hemianopia caused by an obstruction of the anterior choroid artery is, in reality, the result of damage to the lateral segment of the lateral geniculate nucleus. The possibility must be considered, however, that the same functional impairment may also be brought about by a compression or occlusion of the posterior temporo-occipital artery (*poteocca*) in the inferior temporal or in the collateral sulci, a branch of the posterior cerebral artery upon which depends the supply of the inferior segment of the sagittal fiber strata through the whole length of the temporo-occipital lobes (Figs. 374, 377). Conversely, it is fair to expect a contralateral inferior homonymous quadrantic hemianopia when the main stem, or one of the posterior branches of the middle cerebral, especially the superior temporo-occipital Sylvian artery (*Syteoccsua*), is closed (*see* chap. XII, 6, case MUNSON).

The obstruction of the main stem of the calcarine artery (*ca*), which supplies most of the *striate area*, unavoidably produces a contralateral homonymous hemianopia. However, since the most posterior portion of the striate area, in which the homonymous halves of two hemifoveae are represented, is frequently supplied either by a circuitous route from the posterior cerebral stem other than the calcarine artery or by the middle cerebral artery via the superior temporo-occipital Sylvian artery, that portion of the striate cortex remains preserved to an individually varying extent when the calcarine artery proper becomes deficient.

Conversely, the posterior or foveal-macular portion of the striate cortex becomes affected, manifesting itself in a central scotoma, in the pathology of those individual cases where that portion depends upon a circuitous blood supply, if that supply is interfered with. This is more likely to happen if, as is probable, the intermediate foveal-macular segment of the visual radiation is damaged, in addition to a direct involvement of the foveal-macular cortex or that segment alone.

Ordinarily, however, it appears that such an event may be averted when the pathological process is confined to the territory of the principal calcarine (*pca*), the calcarine (*ca*), or even to the entire posterior cerebral artery (*pocea*), provided that the foveal-macular portion of the striate cortex receives its blood supply from the middle cerebral artery via the superior temporo-occipital Sylvian branch (*Syteoccsua*), the result being the preservation of the central portions of the fields of view. (*Cf.* Fig. 374; *see also* chap. XI, 9, esp. [3].)

To what extent central vision remains spared or may be restored may also depend upon the efficiency of the arterial anastomoses between the several arterial territories mentioned. Such vicarious vascular substitution is limited by the size and condition of the connecting links and

by the condition of the terminal arterioles by which the blood passes to the nervous parenchyma. When the ultimate arterioles and capillaries have suffered from disease and a free passage of blood is mechanically obstructed or inhibited, no use or only inadequate use is made of the existing anastomotical links, even if these are present and are passable. The result is a relative or absolute ischemia, followed by encephalomalacia or degenerative softening of the brain tissue and an impairment of function or a permanent functional loss, depending on the degree of interference with circulation. Just how much the vicarious blood supply of the cortex is capable of restoring a function temporarily lost or impaired remains a problem to be dealt with by future investigation. (*See also* par. 4, this section.)

3. THE BLOOD SUPPLY OF THE STRIATE AREA AND THE SCINTILLATING SCOTOMA.—The peculiar character of the blood supply of the visual cortical centers may also be drawn upon to explain certain symptoms of visual pathology manifestly caused by a vascular factor. Such is the transient homonymous hemianopia frequently associated with migraine and with a subjective experience of scintillation, as in scintillating scotoma or scintillating blindness (for an excellent presentation, *see* Roger & Reboul-Lachaux 1921; Niessl von Mayendorf 1931, 1936; Rønne 1936; Lashley 1941; Donahue 1950; Patrikios 1950; Behrman 1951; Lieberman 1951; Somya; Weeks; *cf. also* chap. XII, 10).

In this phenomenon, in addition to the functional factors, such as the causative irritant followed by a spasm of part or all of the vascular tree of the calcarine artery, a purely anatomical factor plays an essential role (*cf.* Fig. 372). A spasm may begin with the circumpolar terminals and gradually spread along the larger branches and the trunk of the principal calcarine artery. The constriction automatically and effectively eliminates the utilization of the existing arterial anastomoses with the other related arteries (middle cerebral, for example). This interpretation harmonizes with the beginning of a subjective experience of photism at the fixation points and a gradual shifting of the "luminous scotoma" toward the periphery of the fields of view, the initial central photoma gradually being replaced by a "shiny amblyopia," as the blood stream decreases in the arterial tree.

While in most cases this is apparently a transient process, permanent impairment may follow in consequence of irreparable damage to the nervous tissue in the territory of one of the calcarine arteries, resulting in variously shaped and located scotomas. The underlying causative pathology, too, may in each case be better understood if the topography of the retinal representation in the striate area and the distribution of the blood vessels supplying it are taken into consideration.

A contrary process, an inordinate dilatation of the calcarine vascular system and its engorgement, owing to an inhibition and slowing-down of circulation because of either mechanical obstacles or paresis of the vasoconstrictors, caused, for example, by abuse of such drugs as nitroglycerin or theocalcium, may conceivably bring about a similar subjective phenomenon of amblyopic scintillation and a temporary or even permanent decrease in, or destruction of, normal function in the homonymous fields.

Understanding the pertinent anatomical and physiological factors responsible for scintillating blindness is of great practical importance, since such phenomena may be the premonitory signs preceding a thrombotic or similar impairment or destruction of a part of the central visual apparatus, resulting in permanent functional field defect, unless immediate effective steps are taken to check the basic pathological process (atheromatosis, high blood pressure, etc.). (*See* chap. XI, 8, 9, for further discussion of the problem of "central sparing," especially in cases of complete unilateral destruction of the striate area or the interruption of one visual radiation; *see* chap. XII for the clinical and pathoanatomical analysis of cases; *see* especially the following paragraph.)

4. THE CEREBRAL BLOOD SUPPLY AND THE SPARING OF CENTRAL VISION IN HEMIANOPIA.—The problem of the "central sparing" or preservation of the foveal-areal-macular portions of the fields of view frequently observed in cases of incomplete homonymous hemianopia has been touched upon in sections 6 (3), 7, and 8 (2, 3) in

this chapter and is further discussed in chapter XI, 8 and 9. In view of the great practical importance of this phenomenon, an attempt is made here to link the relevant facts of the anatomy of the supranuclear division of the visual system with those of its blood supply, in order to find a plausible material basis of that phenomenon.

The supranuclear division of the visual system in each hemisphere of the brain is essentially made up of the fibers of the visual radiation (Fig. 377, *VR*), which conduct impulses, and the striate area of the cortex (given in solid black) lining the calcarine fissure of the occipital lobe, which is the terminal station (marked by an asterisk * in Fig. 377). As is shown by the sketches of the serial sections through the parietotemporo-occipital lobe in the same figure, different constituents of the central visual mechanism are supplied from different arterial sources at various levels.

At the occipital pole (Fig. 377, sketch *A*) the entire bulk of the hemisphere, including the striate cortex and the subcortical fiber substance, falls within the territory of the posterior cerebral artery (vertical shading). This extreme condition, however, must be qualified because in numerous cases the most posterior portion of the striate area may be supplied by the middle cerebral artery (as discussed in the preceding sections).

On the levels approximately corresponding to the tip of the posterior horn of the lateral ventricle (Fig. 377, *B*) the situation begins to change. Here the territory of the middle cerebral artery (horizontally shaded) not only has taken most of the lateral face (right side of the sketch) but has invaded the core of the hemisphere, spreading in the manner of a wedge as far as the posterior horn of the lateral ventricle (small oval).

On the next anterior level (*C*), the middle arterial territory spreads over the entire lateral face from the upper to the lower margin of the hemisphere. In the core it further expands along the lateral ventricle, where it includes the intermediate branch of the visual radiation (*VR*). The upper and lower margins of the radiation, including fibers that pass over to the upper and lower lips of the calcarine fissure, together with the entire striate area and its subcortical fibers and the entire medial and inferior faces of the hemisphere, remain within the territory of the posterior cerebral artery.

On further anterior levels (*D*, *E*) the situation remains substantially the same, except for a relatively small displacement of the boundary line between the two arterial territories along the upper and lower margins of the hemisphere.

As the level of the splenium of corpus callosum (*CC*) is attained, the greater part of the visual radiation (*VR*) or, more correctly, of the sagittal fiber layers falls within the territory of the middle cerebral artery, the inferior segment of the same layers still being supplied by the posterior cerebral artery (sketches *F*, *G*).

Taking the above-described relationship as a basis, the following deductions seem permissible. When the pole of the occipital lobe is directly affected (*A*), it is probable that the central vision will be affected, since either the foveal-areal-macular fibers of the radiation close to their termination or the corresponding portion of the striate area, or both, are interfered with. The remainder of the fields of view may remain entirely free, provided that no damage has been done to any other part of the brain. The size, shape, and other features of the scotomatous defect will depend upon the size, shape, location, and kind of lesion.

If the lesion is located farther anteriorly from the occipital pole—for example, at the level of sketch *E*—an entirely different situation will arise. Assuming a massive elimination of the entire posterior cerebral territory, including parts of the striate cortex (black) and fibers of the radiation which depend entirely on the posterior cerebral artery, that is, the bundles streaming above and below the lateral ventricle (*V*), a functional defect will comprise the extra-areal-foveal periphery of the homonymous fields of view whose centers will be spared. The necessary condition for this is that the intermediate or axial segment of the radiation and the posterior or polar portion of the striate area, both related to the central fovea and area of both retinae, remain outside the pathological process. Such separation is possible, considering the territorial separation of the posterior and middle cerebral arteries at this level. The separation is further enhanced by the presence of the lateral ventricle, precisely in the line of

separation, which serves as a vascular barrier.

The elimination of the extrafoveal-areal periphery by a pathological process in approximately the middle and anterior portions of the calcarine fissure is possible on anatomical grounds, with the sparing of the foveal-macular portion of the striate area at the occipital pole, provided that the foveal-macular fibers in the intermediate segment of the visual radiation also remain unaffected. How much of the periphery is eliminated and how much of the centers of the fields are spared will depend entirely on the location and extent of the lesion in the calcarine fissure. (*Cf.* case HOLT in chap. XII, 7.)

The final and least weighty argument

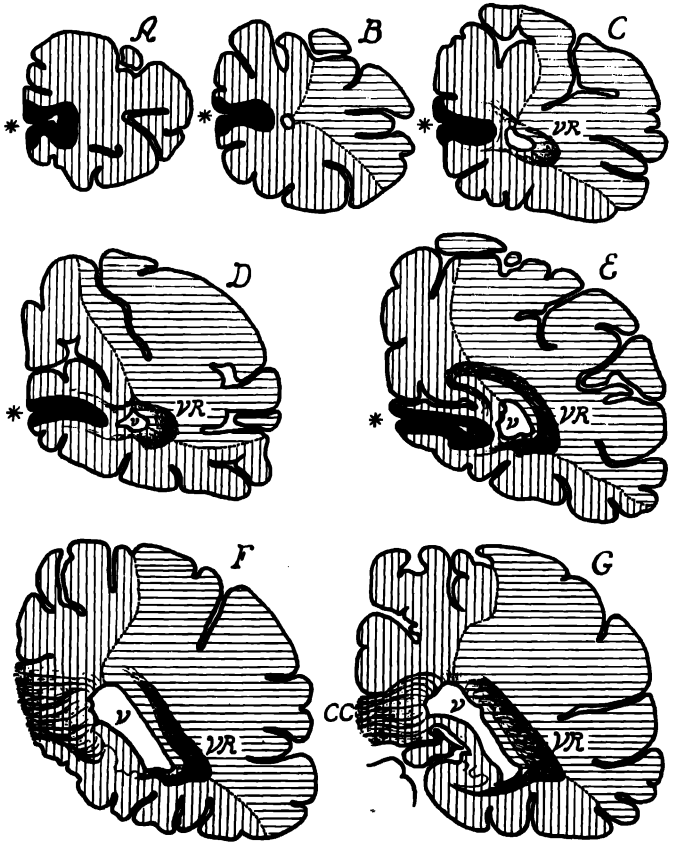

FIG. 377.—Coronal sections through human occipital lobe, beginning with the pole (*A*) and as far as the splenium of the corpus callosum (*G*), to show the variation of blood supply on different levels. The territory of the middle cerebral artery is shaded horizontally, that of the posterior cerebral artery is shaded vertically. Note the striate area (*solid black*), falling entirely in the posterior cerebral territory on all levels, whereas the bulk of the visual radiation (*VR*), in particular its intermediate branch, belongs to the middle cerebral territory, except at the pole (sketch *A*). In other cases the polar portion of the striate area is also supplied, partly or entirely, by the middle cerebral artery (*see* Figs. 373, 374). *Labeling: A*, caudal, *G*, oral levels through occipital lobe; *CC*, corpus callosum; *V*, posterior horn of lateral ventricle; *VR*, sagittal fiber layers containing visual radiation; *, calcarine fissure. (*Cf.* Figs. 231–33.)

brought in favor of the various speculations on the causes of central sparing are the minute central remnants recorded in cases where an entire striate area was removed, e.g., in occipital lobectomies. These central sparings are invariably very small, falling within the limits of error of the plotting technique, and are of no particular theoretical or practical significance.

SEC. 9. SUMMARY OF THE BLOOD SUPPLY OF THE VISUAL SYSTEM

1. SOURCES.—The blood supply of both the cerebral and the extracerebral parts of the visual system derives from the same sources as those which supply the brain—the two internal carotids and the two vertebral arteries, four in all.

2. THE EYEBALL, RETINA, AND OPTIC NERVE.—The eyeball receives its supply practically exclusively through the ophthalmic artery, which branches off from the upper end of the internal carotid.

The supply of the retina is twofold: through the central artery via the optic nerve, which provides the inner layers vitrealad to the outer plexiform layer, and osmotically from the choroid membrane, which supplies the outer retinal layers, principally represented by the photoreceptors. The venous blood is carried away principally through the vorticose veins, which empty into the ophthalmic vein. The central artery is likewise the principal supplier of the optic nerve as far as its entry into the cranial cavity, the intracranial portion probably being supplied by the anterior cerebral artery.

3. CHIASMA.—The arterial supply of the optic chiasma is from several sources, principally from the anterior cerebral artery (anterior, superior, and lateral aspects). A few delicate branches of the anterior communicating artery may spread over the posterior and inferior aspects of the chiasma. Whether the internal carotid, middle cerebral, and anterior choroid arteries also contribute to the anastomotical network in the pial sheath that envelops the chiasma remains to be investigated.

4. THE OPTIC TRACT.—The optic tract also has a multiple arterial supply: the anterior cerebral artery (initial portion), the anterior choroid artery (middle and posterior portions), and, according to Abbie (1938), also the internal carotid, posterior communicating, and middle and posterior cerebral arteries.

5. THE LATERAL GENICULATE NUCLEUS.—The lateral geniculate nucleus, according to Abbie (1938), is supplied by the anterior and posterior choroid and by the posterior cerebral arteries. The anterior choroid supplies principally the anterolateral aspect; the posterior cerebral artery supplies the posteromedial aspect; and both arteries supply the hilum of the nucleus. Some terminal twigs spread principally in the individual cell laminae, others pass through the nucleus to the initial portion of the visual radiation.

According to Alexander & Putnam (1938), the most abundant blood supply of all structures of the brain is found in the lateral geniculate nucleus, with the largest proportion of vessels of the fourth order, with a diameter measuring from 34 to 51 microns, and possessing the densest capillary network.

6. THE VISUAL RADIATION AND THE STRIATE AREA.—The blood supply of the supranuclear division of the visual system is intimately related to the blood supply of the cerebral hemisphere, particularly of the parietal, temporal, and occipital lobes, of which it is a part. Conversely, the blood supply of this division is largely independent of that of the infranuclear division of the visual system.

The visual radiation and the related cell and fiber systems receive their arteries from two sources, which, in addition, vary from level to level. The most anterior portion of the radiation, according to Abbie (1937, 1938), is supplied by the deep optic branch of the middle cerebral artery, which enters through the anterior perforate substance in association with the lateral striate arteries.

The arterial supply of the much larger pos-

terior portion of the radiation in the parietotemporal and occipital lobes is as follows (*see* Fig. 377). At the level of the splenium of the corpus callosum (*F*, *G*) a portion of the radiation (*VR*), principally its lower segment, as well as the corresponding segment of the tapetum, splenium, and the entire interhemispheric and cerebellar surfaces of the cortex, with their sulci and the subjacent white substance, is supplied by the posterior cerebral artery (Fig. 377, vertical shading). A portion of the sagittal fiber strata, corresponding to the intermediate segment of the visual radiation, however, belongs to the middle cerebral artery (horizontal shading). The upper segment of the external and internal sagittal strata is a boundary zone, where the territories of the posterior and the middle cerebral arteries meet.

From the level immediately behind the callosal splenium (*E*) to as far back as the posterior extremity of the posterior horn of the lateral ventricle (*B*), the vertical segment of all three sagittal fiber layers down to the ventricle (*V*) is completely taken over by the middle cerebral artery. The posterior cerebral artery here supplies the upper and the lower horizontal segments of the fiber layers, as well as the interhemispheric and cerebellar surfaces of the occipital lobe.

In approximately the middle of the occipital lobe the relative extent of the middle cerebral territory becomes larger, approaching, or even extending over, the superior and inferior temporal margins of the hemisphere. Behind the posterior horn of the lateral ventricle (*A*), most of the fiber mass immediately subjacent to the striate area (solid black) is again taken over by the posterior cerebral artery.

The striate area, the fibers of the visual radiation streaming from the upper and lower segments of the external stratum toward both lips of the calcarine fissure, and the fiber layer of the calcar avis, along their entire anteroposterior extent, are supplied by the posterior cerebral artery (*C*, *D*, *E*). The only exception is the tip or pole of the occipital lobe, where the middle and posterior cerebral arterial territories meet.

PART III

Pathology of the Retina and of the Visual Pathways and Centers of the Brain

Chapter XI

Disturbances of Vision and the Anatomical Organization of the Visual System

SEC. 1. INTRODUCTION

1. General remarks concerning the pathophysiology of the visual pathways and centers.—The disturbances of visual function caused by interference with the visual system are manifested in a great variety of symptoms. This is to be expected, since the visual pathway, from its beginning in the retinae of the eyes to its termination in the cortical visual centers in the occipital lobes, extends along the longer axis of the cranium, hence is either close to other important structures such as the cranial nerves or is, in fact, a constituent element of the brain itself during a part of its course.

The second and principal factor responsible for the variety of clinical symptoms, however, is the inherent elaborate organization of the visual system and of its blood supply, both of which vary at different levels. The third determining factor is the nature of the pathological agent, the locality where the pathological process applies, and the mode of its application.

The impairment of visual function depends, accordingly, upon several partly innate and partly accidental factors, such as the anatomical organization, the character of the blood supply, and the locality and nature of the pathogenic process. The latter, in turn, may differ greatly: a stationary or an expanding neoplasm or tumor, a slow or a sudden hemorrhage, an ischemic or encephalomalacic focus caused by an occlusion of a blood vessel by a spasm, embolism, thrombosis, or atheromatous constriction, an infectious focus, and, finally, a direct or indirect traumatic or mechanical injury of various kinds.

2. Fields of view and their relation to the retinal surface.—When either the retina or any portion of the visual pathway anywhere along its course is damaged or interrupted, a corresponding loss of the visual function occurs. Since the area seen by an eye, that is, a retina, called the *visual field* or *field of view*, may be subdivided by meridians or straight lines radiating from the points of fixation (*f*) into quadrants and sectors, and by concentric circles into belts or zones (Fig. 381), functional loss or blindness may be determined quantitatively by perimetric plotting.

Each field of view is customarily divided into four quadrants—an upper and a lower nasal and an upper and a lower temporal. The vertical dividing line coinciding with the vertical meridian and passing exactly through the point of fixation, or a point corresponding to the visual axis of the eye and thus corresponding with the center of the central fovea, divides each field into two unequal halves placed vertically. The larger temporal half of the field corresponds to the larger nasal half of the retinal surface; the smaller nasal half of the field corresponds to the smaller temporal half of the retina.

The reversed position of the homonymous retinal halves and of the four quadrants of the fields of view relative to their retinal halves and quadrants is a consequence of the "dark-chamber effect" and of the action of the dioptrical media of the eye. Because of this, the right retinal halves see the left halves of the fields of view, and the left retinal halves see the right ones (*cf.* chap. I, 5, and Fig. 33). The same principle holds for the upper and lower retinal halves, separated by the horizontal meridians, so that the former see the lower halves of the fields of view, and the latter see the upper.

3. Types of visual field defects.—The loss of visual function, a subjective defect, may

be either total or partial. It may range all the way from a slight impairment, subjectively barely or not at all noticeable, to complete blindness to all visual stimuli (Figs. 382, 383).

Total loss is manifested in blindness of one whole field of view or of both, or of half of each of the two fields. In a partial field defect a portion or portions of one or of both fields of view are affected.

Blindness may be complete when it concerns the entire range of the visual perceptions, including simple light perception, together with perception of color and form (amaurosis); blindness may be only relative either when light perception is preserved without perception of color and form (amblyopia) or when loss concerns perception of color alone, leaving perception of light and form more or less intact (achromatopia).

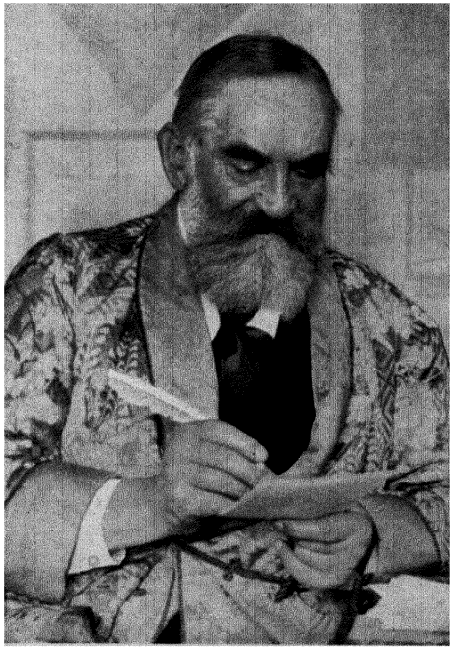

FIG. 378.—Jean Cruveillier (1791–1874), distinguished professor of pathological anatomy in Paris. His fame rests upon a systematic correlation of clinical symptoms with post mortem examination of organic pathological changes, especially in the nervous system. A lithograph by François-Séraphin Delpech from a portrait by Maurin. (*See*, for biography, Haymaker & Baer, *The Founders of Neurology*, 1953.)

4. DEFECTS OF THE FIELDS OF VIEW AND THE ANATOMICAL ORGANIZATION OF THE VISUAL SYSTEM.—The most important single factor on which the character of a visual field defect depends is the anatomical organization of the visual pathways and centers. Next in importance is the blood supply of the parts of the nervous system concerned in vision. The third factor is the locality of the lesion affecting the visual pathways and centers. The last, but not the least, important factor is the causative agency, its nature, mode of spreading, and extent. The character of a functional visual disturbance, in turn, helps us to learn about the anatomical and functional organization of the central visual mechanisms. Using the character of the visual field defects as an indicator, it is possible to make a probable regional or topographical diagnosis, that is, to draw conclusions concerning the seat, extent, and nature of the lesion or process responsible for a functional visual disturbance.

According to the location, shape, size, and other features of the affected portion or portions

of the fields of view, a number of types of field disturbance are distinguished in clinical ophthalmology and neurology (Figs. 382, 383). In the present chapter the principal types of disturbance are described, and their pathophysiological significance discussed. In the following chapter, as an illustration, a number of representative pathological cases is described, in the majority of which an attempt was made to correlate the gross and microscopic findings with the functional defects observed during life.

The value of human material as a source of information about the intrinsic organization of the visual system varies. The cases of brain tumors, because of their diffuse and expanding character, with pressure exerted upon more or less distant structures not directly affected, are least suitable for detailed analysis (e.g., cases AMES and STRAUSS). More useful are cases with multiple foci of softening, provided that each focus is well outlined and separated from the other foci (cases HOLT, HOFFMANN). Of exceptional value, equaling or even surpassing the best animal experiments, are cases where there was only a single, well-outlined lesion (cases MUNSON, MALLORY). These cases may be a welcome addition to the well-analyzed cases, still too few, reported by Pötzl (1918, 1928),

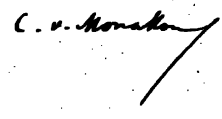

FIG. 379.—Constantin von Monakow (1853-1930), encyclopedic investigator of the brain, in advanced age *see* Fig. 118).

Putnam (1926), Balado, Adrogue & Franke (1928), Brouwer (1930), R. A. Pfeifer (1930), G. Holmes (1931, 1934), Hoff & Pötzl (1934), and others. In contrast, the many purely clinical cases without anatomical control reported in the literature, especially since World War I, are of only auxiliary value (*see* terminal Bibliography).

The investigation of clinical manifestations of functional disturbances of vision and of the underlying pathology was and still remains the principal way to disclose the intrinsic organization of the visual system and its workings under normal and pathological conditions. It is an indispensable addition to the investigations carried out upon simian and other animal material, both being of material assistance in the clarification of the mechanisms serving the sense of sight. The review of this subject presented in this and in the following chapter considers chiefly the anatomical angle, physiology and pathology serving as the indispensable tools for

FIG. 380.—Otto Pötzl (1877), professor of psychiatry at the University of Vienna, Austria. A distinguished investigator of the pathology of vision. Few men penetrated as he did into the essential pathoanatomical and pathophysiological conditions and factors responsible for the manifestations of disturbed vision in cerebral disease.

the understanding of the organization of the visual mechanisms and their working under normal conditions.

5. PRACTICAL IMPORTANCE OF TESTING THE FIELDS OF VIEW.—The importance of testing the fields of view, since its introduction into clinical practice almost a century ago by A. von Graefe and R. Förster, has been attested by its adoption as routine clinical practice. Clinical perimetry is now an indispensable method in the pathology of the eyes, optic nerves, and the ties and professional ophthalmologists to regulate and supervise the means of modern communication and the working conditions of innumerable offices and factories.

Isn't it true that the sight of the millions of drivers, using high-speed modern automobiles, is under no control or under only the most perfunctory kind? What is known of the frequency of field defects, such as smaller and larger, absolute and relative, central, paracentral, and peripheral scotomas, or perhaps of the temporary reduction of perception among the driving pub-

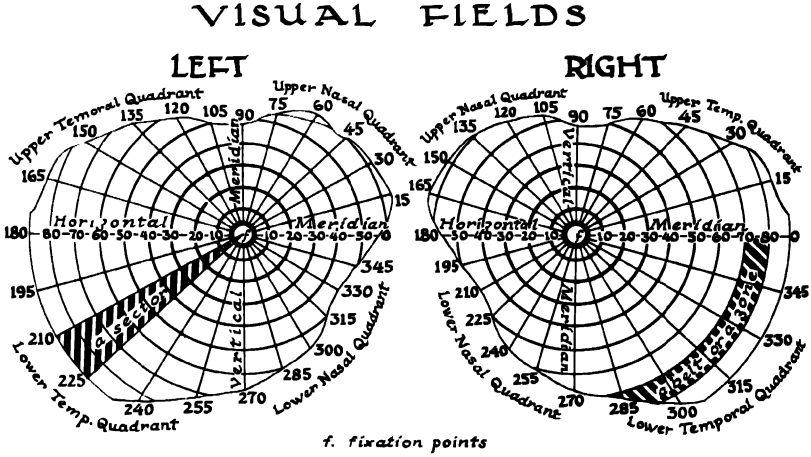

FIG. 381.—Fields of view and their landmarks. Each field represents a space seen by one eye, a left and a right visual field. Each field may be subdivided by a vertical meridian into a larger temporal half and a smaller nasal half, corresponding to the larger nasal and smaller temporal halves of the retina. The two halves of each field, in turn, may be subdivided into two quadrants, an upper and a lower, together making four quadrants in each field of view. Again, each quadrant may be subdivided into wedge-shaped sectors of different sizes, their pointed ends meeting at the fixation point. The circles inclosing beltlike zones are complete closer to the center and incomplete in the periphery. In the normal visual act the two single monocular fields largely overlap, with the fixation points coinciding, altogether forming a common binocular stereoscopic field of view. (*Cf.* Figs. 361, 401, 439.)

remainder of the visual pathways and centers, affected by the numerous diseases or by injuries, both in peacetime practice and in war. Great improvements have been made since its inception, and the theory is sound and well understood.

In contrast with this is the problem of a large-scale testing of the fields of view and of visual functions in general. In the conditions of modern life, vision is a prime factor, far surpassing the demand of the primitive conditions of the past. However, it is questionable whether enough is being done by the responsible authorilic, if it is not caused by an obvious defect, such as, e.g., hemianopia, large scotoma, or a reduction of central acuity? What effort, if any, is made to disclose the defects of which the drivers themselves under daylight conditions or good illumination may be entirely unaware or only dimly aware, but which, with decreasing illumination, increasing fatigue, or under the influence of tobacco and alcohol, may multiply many times the already great hazards of night driving, resulting in frightful slaughter along modern highways?

A more universally applied testing of the

fields of view by well-trained specialists for the actual or potential blind areas, including peripheral parts of the fields, seems the only means to use present knowledge and to increase it, for the prevention of accidents—a menacing cloud which threatens modern civilization.

SEC. 2. DISTURBANCES OF VISION CAUSED BY PATHOLOGY OF THE RETINA, OPTIC NERVES, AND CHIASMA

1. Visual field defects caused by retinal lesions.—Interference with the function of vision caused by pathological processes localized in the eyeball, which includes the retina, is extremely varied. This subject is dealt with in detail in the numerous treatises of ophthalmology and neuro-ophthalmology. The following account is, therefore, limited to those defects of the fields of view which are directly related to the anatomical arrangement of the optic nerve fibers in the retina.

A lesion of the optic nerve fibers in the eye, like that of the optic nerve between the eye and the chiasma, is generally unilateral. A disturbance of vision in such cases is confined to the respective field of view (Fig. 382, sketches *1, 2*). Or, if there are two field defects, one in each monocular field, each caused by a unilateral lesion, these defects most often differ in size, shape, and location (sketches *15, 18*). This difference is termed "incongruity." In those cases where the field defects of both sides are equal or almost equal, as is often the case in axial retrobulbar tobacco and alcohol neuritis of the optic nerves, an ophthalmoscopically found partial atrophy of the optic papillae or disks makes possible a correct diagnosis (sketch *3*).

An exception to the rule that unilateral field defects are indicative of an infrachiasmal lesion is the unilateral affection of the monocular portion of the field of view, or "temporal crescent" (Fig. 383, sketches *12, 13*). Such defect may be produced by a single, appropriately situated lesion anywhere in the visual pathways and centers, most readily in the occipital lobes. Other rare possibilities have been mentioned by Lutz (1923).

Partial damage to the retina of one eye causes an impairment of vision in the corresponding field commensurate with the size, shape, and location of the lesion or lesions. However, since the optic nerve fibers converge from all points of the retinal surface upon the papilla or disk, which is their exit (Fig. 162), retinal injuries of equal size and shape, if they involve the layer of optic nerve fibers, produce different results, depending upon their location, specifically their distance from the papilla.

If situated anywhere in the far periphery, close to the ora serrata, the field defect is likely to correspond more or less exactly to the extent, location, and size of the lesion. The closer the lesion is to the optic papilla, other factors being equal, the greater the number of fibers damaged, hence the larger the field defect. In the vicinity of the papilla, even small lesions may

interrupt numerous bundles of optic nerve fibers arising from an extensive retinal territory. A small lesion situated in the immediate vicinity of the papillar margin may eliminate a large sector, possibly a quadrant or more, of one field of vision.

Still another local factor—the peculiar arrangement of the bundles of optic nerve fibers in the temporal half of the simian and human retina—must be considered. As described earlier (Fig. 162), the temporal bundles in the primate eye, on account of the formation of the central fovea, are not arranged radially, as they are in the nasal half (*see* chap. V, 10 [2], and chap. VI, 2 [2, 3, 4]). In order to avoid the foveal depression, the bundles circle above and below the foveal region.
